The Chairman said the use of bromides was a subject which had long engaged his attention, and some time before it had received much consideration from the photographic world he had come to some definite conclusions on the subject. It was necessary to preserve the different aspects of the subject quite distinct, and consider each part of it under its own most favourable conditions. In speaking then of the respective advantages of simply iodized, or of bromo-iodized collodion, it was necessary to have reference to the developer; and the question which arose was whether simply iodized collodion with pyrogallic acid development, or bromo-iodized collodion with iron development presented the greatest advantages. He thought experiment generally, and his own experience certainly, was in favour of the latter. Another point which had not, he thought, received sufficient attention, was the different effects produced by different bromides. His own conviction was, that a bromide with an alkaline base was much more efficient than the bromide of cadmium; a small proportion of the bromide of potassium, for instance, much more readily reduced over-intensity, and gave softness and half tone than a larger proportion of bromide of cadmium. The character of the pyroxyline was another important element in the consideration. Where a bromide was used he preferred a pyroxyline which tended to give an intense image when the collodion was simply iodized; the addition then of a small portion of bromide gave the maximum of advantages, in rapidity, cleanness, and delicacy, and in reducing the density which would be present when an iodide alone was used. The bromide of cadmium he had not found so efficient in this respect, and larger quantity was necessary. Another element to be considered was the character of the lens to be employed. The use of a lens of long focus reduced the intensity of the light, and had a tendency in like ratio to reduce the intensity of the resulting picture; whilst if a compound lens of short focus were used, the image was very brilliant and intense. It was clear that some modification in the collodion was necessary in these two cases, and the collodion which gave a sufficiently dense picture with a lens of long focus, would probably give a picture too intense with a lens of short focus, and this over-intensity might be reduced by the addition of a bromide. It must not be forgotten, however, that some samples of pyroxyline were of a character unsuited to the use of bromides, and that in such cases the best results were obtained by their omission. He mentioned these points to remind members that the question was one which required considering in all its aspects. The use of a bromide, for instance, was not always an advantage if pyrogallic acid development were used. When they came to iron development, however, the advantages of a bromide were beyond a question, both in sensitiveness and cleanness. The point at issue, however, seemed to be whether greater sensitiveness was obtained with a simply iodized collodion and pyrogallic acid development, or with a bromo-iodized collodion and iron development. He had no doubt himself that with a bromo-iodized collodion and iron development, more sensibility could be obtained than with the most rapid simple iodide and pyro. Still there were interesting points to settle, and as he understood Mr. Blanchard, he was not satisfied that as yet he had given the iodides alone a fair test.

Mr. Blanchard: precisely.

The Chairman, continued, the iodized collodion which gave fog was probably too newly iodized. It should have been iodized at least 24 hours to secure its best conditions.

Mr. Blanchard said his newest sample had been iodized that length of time; but he thought probably a longer time might be better.

The Chairman said that each should be tried under its own best conditions of bath as well as developer.

Mr. Wharton Simpson said he understood that the bath Mr. Blanchard had used in the majority of the experiments was one in the most sensitive working condition, such as he would use in his practical, instantaneous operations, and such, therefore, as should give fair play to any collodion. Mr. Blanchard had referred to some recent experiments made by Mr. Sutton, which it might be interesting to state. Most of the members knew that Mr. Sutton was an authority on the manufacture of collodion, and photographic matters generally, worthy of much respect, although in the matter of bromides, he held some views which his (Mr. Simpson's) experience did not confirm. Mr. Sutton had recently detailed a series of experiments for testing the value of bromides, in which, however, they were used alone, and not in conjunction with an iodide. He stated, that a plate coated with collodion containing five grains of bromide when immersed in the bath, and withdrawn in the usual time, presented a thin blue film, and that it required some hours' immersion before it became creamy, and hence he argued, that when a large quantity of a bromide was used in conjunction with an iodide, and the plate only left the usual time, a large portion of the bromide remained unconverted into bromide of silver. If this were so, it was unquestionably an important consideration. His (Mr. Simpson's) experience did not entirely confirm this. A bromized plate left the usual time —say two or three minutes—in the bath, certainly gave a thin blue film, but on leaving it double that time it was much more dense, and he had no reason to believe from its appearance that the whole of the bromide was not converted into bromide of silver. Still, that the change was slower seemed evident, and the subject was worthy of further attention. Mr. Sutton's convictions were very strong in the matter, he even regarded bromides as retarders—useful to hang on to the wheels of the iodide as a drag, when it was running too fast. The whole of Mr. Blanchard's experiments tended to prove an opposite conclusion. He (Mr. Simpson) had tried similar experiments scores, he might say hundreds of times, and always with similar results. The use of a bromide alone, unquestionably, gave slower results than the use of an iodide, but the combination of the two he had always found most rapid, most clean, and most satisfactory. Mr Blanchard had referred to the universal reduction, in one experiment, with iodide alone, as possibly indicating a very high and almost unmanageable state of sensitiveness. If it were so, some trace of an image would have been found, however buried in fog; it only appeared to indicate over-readiness to reduction or decomposition, under the influence of a developer, and would probably have been found the same without the action of light at all. He might mention, in conclusion, as interesting, that Mr. England, whose instantaneous pictures everyone was familiar with, had recently told him, that after many months of the most careful experiment, he had come to the conclusion that bromo-iodized collodion, with iron development, was three times as sensitive as simply iodized collodion with pyrogallic acid development.

Mr. Wall suggested that the universal use of bromides by the best photographers, was a strong argument in their favour.

Mr. Harmer and Mr. Lane had both noticed the fact that a bromo-iodized collodion required a somewhat longer immersion in the silver bath, and that if it did not receive that, it looked creamier after coming from the camera, than when taken from the bath, showing that the reaction had been going forward with the free silver on the plate.

The Chairman thought the fact mentioned by Mr. Sutton as to the slower reaction between a bromide and the silver bath, worthy of further attention, as any unconverted bromide in the film would probably act as retarder, and referred to a practice which once obtained, of pouring a solution of a bromide over the plate, to prevent the further action of light.

After some further conversation on the subject,

Mr. Fry, in answer to the Chairman, said he had not a shadow of a doubt as to a bromo-iodized collodion being the best possible for rapid results, giving the highest possible degree of sensitiveness, and the maximum of delicacy and cleanness. He could scarcely understand how the matter could be brought into discussion, the thing seemed so palpable. He regarded bromo-iodized collodion, as one of the photographer's greatest boons. Whereas, at one time, a certain sample must be kept for landscape, another for portraits, another for copying, another for dry plates; he now found that one good bromo-iodized collodion was, with slight modification in the treatment, available for all purposes. It seemed to combine all the advantages which had before belonged to several.

After some further remarks, the thanks of the meeting were given to Mr. Blanchard, who was requested to continue his experiments.

The Chairman showed a dry plate, prepared with albumen and glucose, developed with pyrogallic acid, without any acetic acid, and a single drop of silver solution. The result was a good negative, with a much shorter exposure than usual.

Mr. Simpson showed an experimental negative taken with honey and tannin, in seven seconds, lens six inches focus, and half-inch stop.

The presentation print, Robinson's exquisite vignetted landscape, "Early Spring," was delivered to members.

After some further routine proceedings, and the election of Messrs. Brookes, Clifton, and Cornish, as members of the society, the proceedings terminated.

---

### Amateur Photographic Association.

A meeting of the Committee of the Amateur Photographic Association was held on Monday, the 28th April, at 26, Haymarket, Mr. G. Shadbolt, in the chair. The minutes of the last meeting having been read and confirmed, the Secretary laid before the meeting the printed catalogue of the Association pictures, with which the committee expressed their decided approval. A question having been raised by the Secretary relative to the price which should be charged to members and subscribers for the prize pictures (now the property of the publishers), it was decided, with their consent, that each member and subscriber should be entitled to select one copy of each of the prize pictures at the same rate as the other Association prints, but that for any further copies it should be left to the publishers to regulate the prices to be charged.

The subject of a Photographic Art Union, in connection with the Association, was again discussed and adjourned.

The Secretary, having pointed out to the meeting the unavoidable delay which had occurred in obtaining the first year's negatives, and consequently in the award of the prizes, the preparation of the catalogue, and the distribution of the prints, it was decided that the Association year shall henceforth commence the 1st of June, instead of the 1st of May, and that subscriptions for the ensuing year will, therefore, not be due until the 1st of June next. It was also decided in reference to the selection of prints by members and subscribers, that they may select them from any of the Association negatives, which the publishers may have in hand, irrespective of the year in which they may have been received; and further, that upon payment of the subscription, members and subscribers may at once select their two or one guinea's worth of prints, as the case may be.

The proceedings of the meeting then terminated.

---

## Correspondence.

### FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

*Paris*, *14th May*, 1862.

Positive printing with nitrate of uranium has still its advocates. M. Hermann Krône states that the best and quickest papers, which give the most brilliant results under good negatives, are those which are first well impregnated with the solution of nitrate of uranium (1 part nitrate to 7 parts of water), quickly dried, and then again floated for a minute only on the same nitrate solution. Paper thus prepared retains its good qualities a very long time, if kept in a dry dark place. After the lapse of a year, they lose in great part their sensitiveness; they then yield proofs of less vigour with a yellow ground, which in a diffused light becomes of a brownish red in the course of a few days. These proofs cannot be fixed by the usual washings, like those taken upon paper recently prepared. In order to obtain the most vigorous and beautiful proofs, we prolong the exposure in the sun, under a negative, and develop with a solution of nitrate of silver, of the strength of half per cent., slightly acidulated with nitric acid, and alcoholized with ten per cent. Wash the proofs in distilled water, and tone in a bath of chloride of platinum, one per thousandth of water; the proof to remain in this bath only a few seconds, and as soon as it becomes darkened and of sufficient vigour, it must be immediately removed and washed in abundance of water. By this method, the greater portion of the picture is retained on the surface of the paper. The vigour of the proof may be augmented by drying it very rapidly, and varnishing it with wax.

On the preparation of positive paper, M. Davanne makes the following remarks:—

"Among those who prepare albumenized paper, some are accustomed to add acetic acid to the albumen, or soluble acetates, or perhaps in certain fermentations of albumen, acetic acid is spontaneously evolved; in any case the presence of acetic acid in the paper must have a prejudicial influence from giving rise in the silver bath to the formation of needle-like crystals of acetate of silver, which remain either on the surface of the proofs, or on the surface of the negatives, and thus cause the loss of one or both.

"This result has frequently occurred to me under circumstances which I think it will be useful to describe in order to guard photographers from similar annoyance. For several days I made use of a paper charged with a soluble acetate; the acetate of silver formed remained either on the paper or dissolved in the bath, when the latter becoming weak, it was filtered into a dish, and before sensitizing any paper on it, it was sufficiently strengthened by a concentrated solution. Some sheets of paper were sensitized on this bath in the feeble light of the laboratory, and all the negatives and the positives taken from them during the day were covered with fine, needle-like crystals, which became blackened in the light, and would have caused me to lose all my negatives if I had not prevented it by quickly washing them. Analysis showed that I had to deal with acetate of silver; the acetic compounds could be derived only from the preparation of the paper. But the question arose, how could they be formed so suddenly in such abundance, while the temperature had not varied perceptibly, when the bath gave none the day previous, and only on the next day when I had added to the bath a fresh quantity of solution? The reason is, simply that, contrary to what happens with most of the other salts of silver, the solubility of acetate of silver is much less when the nitrate of silver is more concentrated, and that at the moment when in a positive bath almost saturated with acetate of silver, but not yet crystallized, a concentrated solution of nitrate is added, there is an immediate general formation of acetate crystals, which are afterwards deposited upon the proofs. By observing this fact we find a ready means of remedying this accident:—We must, when we desire to restore the bath to its original strength and volume, first add the necessary quantity of dry nitrate of silver. After it is dissolved in the bath, it is left in the cold night air; next day we begin by filtering the bath, to separate the crystals which have formed, and not till then the necessary quantity of water. In this manner we first make a very concentrated bath, which allows of the greater portion of the acetate of silver to be deposited, and when it is subsequently diluted there is nothing to fear from crystallization.

With regard to the keeping of sensitized positive paper, M. Krône remarks:—Our practical experiments on this subject fully prove that sensitized papers are not perfectly preserved in boxes by drying alone, but that it is indispensably necessary to continually maintain a small quantity of gaseous chlorine, which converts the molecules of silver recently reduced into chloride of silver. This is why we have never been able to preserve our strongly albumenized paper when sensitized in boxes with chloride of calcium only, while in boxes supplied with chloride of lime we have obtained very satisfactory results. A mixture of these two substances—

| | |
|---|---|
| Chloride of calcium ... ... ... | 3 parts |
| Chloride of lime ... ... ... | 1 part |

will enable us to preserve both sensitized paper and unfixed positives during a much longer time than is usually required, for, of these two substances, the latter constantly exhales chlorine gas; the first keeps it constantly dry. It must not be omitted to state that too much gaseous chlorine deprives the paper of all its sizing, and also diminishes the sensitiveness of the chloride of silver, that is, brings it to the state of pure chloride of silver, without excess of nitrate. The paper thus preserved tones much more readily, and assumes much richer hues in the chloride of gold. The traces of nitric acid, which are disengaged during the preservation of the paper, seem to us, without any remarkable inconvenience to the paper, provided these are well washed before toning, for the proofs preserved in this manner remained pure and white, without the slightest yellow tint. We cannot say the same for those preserved with chloride of lime alone; for these proofs always assume, after a time, a yellow line in the white portions, especially when the chloride of lime has, in consequence of long service, become moist or aqueous.

The more the paper is impregnated with salted albumen, or the more the albumen holding salt converted, by sensitizing into chloride of silver, the more difficult the preservation of the paper becomes, and the more chloride of lime must be added to the calcium in the boxes: the thinner and more superficial the albumen is, the whiter the paper remains, even without artificial preservation, when merely kept in a press. A paper, with the albumen coagulated before sensitizing, always keeps better than one not coagulated; for the albumen, like all organic substances, decomposes the salts of silver into metallic silver more slowly when the albumen is coagulated than when it is in a soluble state.

## HOT DEVELOPMENT FOR DRY PLATES.

Dear Sir,—The present rage for hot developement is calculated to do more harm than good to the novice in photography.

I have for some time past used heat in developing collodio-albumen plates, but only when the exposure has been short, and the plates newly prepared.

Extreme care must be employed in the manipulation, otherwise, foggy pictures will unquestionably be the result. My plan is to apply first a *plain* strong pyro solution, and if the image does not soon appear, to flood the plate with hot water, and go on again with the pyro, until *all* the details are well out, when citric acid and silver must be added to the developer, and the hot water discontinued.

The mistake often made, is a too liberal use of the hot element, irrespective of the exposure, and the continuance of it, after the silver has been added to the developing solution.

I enclose a stereograph from a negative taken last Monday at six o clock in the evening. There was a good light, and my intention was to give about 3 minutes exposure, but in order to illustrate my method to a friend, I exposed only 45 seconds, and produced a fair negative. Now, if I had continued the exposure to 3 minutes as originally intended, and proceeded to employ hot water in the development, I should have ruined my negative at once.

When the exposure has been *moderate* (say about two-thirds the time a dry plate usually requires), then mix the pyro with *warm* water, and proceed very cautiously to work.

Hot water is very excellent to fall back upon in case the picture develops tardily, but great discretion must be used in its employment

Perhaps these hints may be useful to some of your readers.—I am, yours very truly, John H. Underwood.

*Beech Cottage, Sale Green, Cheshire, May 13th*, 1862.

[The stereograph enclosed is a very fine one, and evidently from a good negative. The tone of the print is very charming. We should be glad to know something of the paper, printing and toning employed. Ed]

## Talk in the Studio.

PHOTOGRAPHY IN THE EXHIBITION.—We observe with pleasure that, notwithstanding the inferior position accorded to photography by Her Majesty's Commissioners, the "leading journal" regards it as worthy of repeated and prominent notice in its criticisms on the contents. Of the British department it recently remarks:—"We mentioned yesterday, with the praise they deserved, the very fine collection of French photographs in the south gallery, though we now learn that some of the very best in this display are by English artists resident in France. Some remarkably good ones are sent by Mr. Maxwell Lyte, an amateur, whose pictures may be at once known by the words, 'Lux fecit'—a true photographer's pun on his name and art. Mr. Bingham, too, one of the best of the Paris professionals, sends some fine specimens, which go far to keep up the general excellence of the French show. There is a special class devoted to English photography in the building, which contains some of the finest specimens of the photographic art ever brought together. There was no class devoted to photography in 1851, and there was near being no exhibition of the art on this occasion, in consequence of the most unfavourable place assigned to it. As it is, the London Photographic Society have refused to exhibit, and, but for the efforts made by the most eminent photographers, the art, as regards England, would have been unrepresented altogether. The photographic collection is placed along with the class devoted to educational appliances, in a large room in the upper floor of the tower, between the English and foreign picture galleries—about the most inaccessible and unfavourable spot to which it could be banished, but to which we feel now justified in calling the attention of visitors, as containing a collection which will repay a long visit. Here are collected the finest portraits of Williams, Claudet, Watkins, and Mayall, Caldezi's copies of miniatures and cartoons, the exquisite views of Bedford, Fenton, Cundall, Downes, and White, and the fancy pieces of Robinson. Frith also sends specimens of three great views in the East, which were taken for Negretti and Zambra. Some of the best exhibitors in this class are to be found among the amateurs, of whom there are many, such as Colonel Sir Henry James, the Earl of Caithness, Lady Jocelyn, Colonel Verschoyle, Colonel Stuart Wortley, Sir A. Macdonald, &c. The educational appliances in this department of the Exhibition likewise deserve an attentive visit." The error made as to the Photographic Society having refused to exhibit, will be understood by photographers as a misconception as to the nature of the steps taken some months ago."

THE PHOTOGRAPHIC CONTRACT AT THE EXHIBITION.—We intimated a conviction a few weeks ago, that the impossible conditions attached to the photographic tender, for the privilege of photographing in the Exhibition Building, had a definite purpose, and was part of a little scheme of jobbery. An advertisement which appears in the official catalogue, affords a striking illustration of this idea. A certain firm who have *not* obtained the contract, had made such arrangements and received such assurances, it would appear, that the contract was already regarded as secured. Accordingly, in the advertisement in question, the firm to whom we allude, announces the publication of a series of views of the interior and contents, taken by Mr. Francis Bedford! Rumour tells other curious tales on this subject, which we forbear, however, to chronicle. We may mention one incident we have heard related, however, which throws some light on the source of the scurvy treatment photography, generally, has received in this international undertaking. A few days ago Mr. England was engaged in photographing a piece of machinery in the annexo, and had placed an attendant in such a position, as to show relative size, &c., when one of the commissioners passing, immediately denounced this as a breach of contract, styling the operation as taking "shilling portraits," and obtaining a sight of Mr. England's pass or warrant unhesitatingly appropriated and put it in his pocket! A telegraphic message brought Mr. Nottage, who took prompt measures to have the pass restored, and his staff put on a proper position, safe from further indignities. Without mentioning this commissioner's name, we may state that it was the same gentleman, who, some time ago in certain evidence before the House of Commons, denounced "photographic professors" as "pests!" We then said photographers were obliged by his good opinion. They may now guess how much more they have to thank him for.

## To Correspondents.

B. B. L.—It is impossible to give a simple and decided answer to your question, as to which is the best method of intensifying There are several methods, all good, and each best under certain circumstances. The most skilful operators are masters of all, and apply each to the purpose for which it is best suited. Experience alone is a certain guide in this respect. The most commonly used and most generally useful is effected by the application of pyrogallic acid and silver after washing away the iron developer, and before fixing. When a slight amount only of additional intensity is required to give decision to a picture full of detail, the same process may be applied after fixing. Dr. Diamond obtains a good effect by leaving a thin negative for a few hours in a bath of old hypo, until the image is sulphuretted. One of the best methods we know of obtaining intensity and retaining delicacy, is that effected by means of bichloride of mercury and iodide of potassium; but requires careful management. When once mastered, it is a very efficient method. Avoid overloading the negative with intensity, or you will certainly bury detail. It is better as a general rule to varnish negatives.

M. A. not having sent us his address, leaves us only this method of thanking him, and acknowledging the receipt of a very fine salmon, which arrived just after going to press last week. On submitting it to the usual processes of qualitative analysis, such as cooking and eating, it proved pre-eminently satisfactory.

S. S.—Your question is a somewhat indefinite one. "Will one of ———'s No. 1 B lenses work more rapidly than other lenses, if both are stopped down to equal apertures?" "Other lenses" constitute an exceedingly indefinite standard of comparison. We presume you probably mean other lenses of the same focal length. This will depend entirely on the construction and diameter of the lenses. In regard to the lens of which you speak, it will work more rapidly and perfectly with the same aperture than common lenses of the same focus.

J. H. S.—It is probable that thin blue glazed calico will answer your purpose better than the stout calico you describe. But we fear the defect of limited size, and too little glass is a radical one, and can only be palliated, not cured. If you can move the house, the best remedy would be found in so placing it that the sitter should face the north; you would then be free from the troubles of direct sunlight, and of imperfect illumination, when that direct light is shut off.

J. A. SLATER.—When we state a process as described by another person, we are not responsible for any want of clearness or detail in the statements. We have pleasure in giving any information or assistance, but our correspondent must work out the matter for himself. 2. In dissolving gum, time is required, a few hours at least; if you boil and burn it, as you describe, you alter its character. 3. In the process referred to, use throughout a saturated solution of borax, which will be at the rate of about one ounce in a pint of water. Borax is soluble in 20 parts of cold water. 4. When a small quantity of spirits of wine is recommended to be added to a solution, we should judge it to mean about half a drachm to the ounce. Such phrases are used when the operation has been done by guess, precise proportions being unimportant.

J. H. JONES.—Bury's Rolling Presses are the best and cheapest of which we have any practical knowledge. We use one of their large ones and find it extremely efficient and satisfactory. For prices, see advertisement. We shall be glad to hear from you.

W.—We are glad you have found the method described practically useful, and are obliged by your good opinion. We have no intention of noticing such matters as those to which you refer. They are too small for attention, and our space is demanded for more important matter. We don't care to deal in counter-imputations, however easy to establish. It is unnecessary to disprove what nobody regards or believes. You will see the propriety, therefore, of not inserting your letter.

NEGATIVE.—The proportions of pyroxyline altogether depend upon its quality; hence you will see the propriety of saying in the formula to which you refer, "soluble cotton, *quant. suff.*" We have in hand at present samples of cotton, one of which gives a thin film with eight grains to the ounce of solvents, and another which gives a thicker film with three grains to the ounce. Both yield good collodion, but we prefer the former for its physical qualities; it is much finer, and a more manageable film. 2. Negatives for enlargement should be produced with a collodion of the former quality, as a collodion made with cotton like the latter shows a great deal of structure, which when magnified is very injurious. As a general rule, equal proportions of ether and alcohol will be found most useful.

PHOTOS.—We prefer albumenized prints to be prepared for colouring in oil by means of gelatine or isinglass. We cannot give you the exact proportions, as we have always mixed it by rule of thumb. We should say as much isinglass as will lay on a penny in a couple of ounces of water, dissolve by heat, and then add a little spirits of wine. It is better to use it too thin than too thick, for in the latter case it will crack off; but if it be too thin, a second or third coat will make the print all right. A little practice will enable you to hit the happy medium between having the paper in the condition to absorb the medium, and having the paper so thick that it will crack off. Bear in mind that oil colours dry very slowly, especially in damp cold weather: the pictures should be kept, if possible, in a room at a temperature of about 60° whilst painting. A little of some "drier," sugar of lead, for instance, may be added to colours which dry slowly, but this must be done sparingly. Try the mode of sizing we have indicated, and let us know how you get on. 2. We should think that enlarging on to iodized paper with a good north light, by means of the lens you mention, and a moderate sized stop, would require an exposure of at least half an hour, probably more. A bromide in the salting preparation would give increased sensitiveness. 3. We should prefer the production of an enlarged negative on glass and then printing from that, as described in our ALMANAC for this year, and also by Mr. Heath at a recent meeting of the Photographic Society.

C. M. SMARTT.—We are glad to find that you have been successful in preparing a non-actinic transparent silk. From the print enclosed, it appears to be entirely satisfactory. We shall be glad to call the attention of our readers to it when we see a sample.

W. H. WARNER.—We are glad to hear that you are working the enlarging process so successfully, and are kept so fully employed. The other matters shall receive attention. We shall have pleasure in receiving the paper.

Several letters and articles in print, and answers to correspondents, are compelled to stand over until our next.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 194.—May 23, 1862.

## SOUTH LONDON PHOTOGRAPHIC EXHIBITION.

From a recent inspection of the pictures now in course of hanging at the Crystal Palace, contributed to the Exhibition of the South London Photographic Society, we have every reason to believe that the display will be eminently satisfactory. Many excellent photographers, whose works we have always examined with interest at other exhibitions, and who are entirely unrepresented at the International Exhibition, have some very superior pictures here. Amongst these we may mention the name of Mr. Annan, of Glasgow, whose fine large, and artistic landscapes, with natural skies, both by the wet and dry processes, will command universal admiration. Mr. Earl, also, contributes a series of the largest landscapes we have seen on one sheet of paper, which are very excellent. Messrs. Jackson Brothers, of Jumbo, near Manchester, contribute a series of artistic gems, in the shape of landscapes with figures. Without entering in detail here, however, we may simply repeat that we find, with pleasure, that this exhibition has afforded opportunity for the display of many very excellent photographs, both in landscape and portraiture, which in the South Kensington Gallery have found no place.

As regards position and publicity, the advantages of the South London exhibitors are out of all proportion superior to those in the garret of the International Building. At the Crystal Palace, the pictures are in an accessible gallery in the most attractive part of the building, within sight and tempting reach of all the hundreds of thousands of visitors who will be present during the summer. The gallery is well ventilated and comfortable, an awning having been erected in this part to shut out the heat of the sun's vertical rays. The screens are conveniently arranged and neatly decorated, the main colour being maroon flatting, bordered with black and Etruscan yellow. The ample space placed at the disposal of the society permits them to restrict the position of all pictures to within a foot or two of the eye line, so that nothing will need to be "skyed," nor will the visitor break his back by stooping to examine meritorious pictures. The whole of the very large collection of photographs contributed, will, we understand, be hung so that none shall be at a height greater than six or seven feet, or lower than within two feet or eighteen inches of the ground, whilst an effect of the utmost value to individual pictures, as well as to the *ensemble*, will be gained by leaving a space of two or three inches between all the frames. Some attempt at classification will also be made. Portraiture will occupy one department, landscapes another, and reproductions a third; and these, again, will be divided into sections, consisting of different processes. If the contemplated arrangement can be well carried out in this respect, there can be no doubt of the great value it will possess.

A difficulty will be found here, we fear, arising out of the tardy arrival of some of the promised contributions, the space for which cannot possibly be calculated in their absence. The work of hanging is, however, now going rapidly forward, and contributions arriving late must, we apprehend, be placed as best they may, without strict regard to arrangement.

It was originally contemplated, we believe, to open in the middle of May, but owing to the causes to which we have referred this was found impracticable. It is now definitely determined, we understand, to invite members, exhibitors, &c., to the private view on Saturday, the 31st, when we anticipate the pleasure of examining a very highly satisfactory exposition of photographs.

## THE EFFECT OF BROMIDES IN COLLODION.

Mr. Sutton resumes his remarks on this subject in the last number of the *Notes*, and in order to do justice alike to the subject and readers, by placing his statement of the matter fully before them, we make some further extracts. It will be seen that he admits that bromides are useful in counteracting the effect of impure chemicals; but enforces his conviction that no advantage is gained by their use when pure chemicals are employed. In this case, even, we conceive, photographers will continue to avail themselves of their aid, as it is with the commercial standard of purity photographers have to deal. Our own experiments, from which we derive our conviction of the value of bromides, have been conducted with the purest chemicals we could obtain, and with a nitrate bath, &c., in the best possible condition. Nevertheless, we have often stated that it is possible to obtain conditions in which a simply iodized collodion and pyrogallic acid development will produce results as good and rapid as bromo-iodized collodion and iron development; but that these conditions are difficult to secure, and impossible to maintain. Mr. Sutton says:—

"The effects of bromide are widely different, according as the chemicals used are pure or impure.

"With pure collodion and nitrate of silver, which are working well with the pyrogallic developer, and giving rich creamy negatives, with red intensity and blooming surface, the addition of bromide to the collodion renders the process *slower*, and after a time, affects the nitrate bath so that it will not again give the same kind of negative as before, but a thin grey negative, difficult to intensify. It is, however, difficult to work out-of-doors in a very strong light with simply iodized collodion, on account of its tendency to give red solarization in the over-exposed parts, and under these circumstances, the addition of a bromide to the collodion reduces the redness and brings the process more under control. There is, however, another and a better remedy for solarization, which consists in soaking the pyroxyline for half-an-hour in water containing carbonate of soda, so as to neutralize all the acidity which pyroxyline invariably shows, and which no amount of mere washing will entirely remove. Red solarization appears due, in great measure, to the acid contained in the pyroxyline, and it is most marked with cadmium collodion, which contains no base capable of liberating the iodine and neutralizing the acid. Negatives taken with cadmium collodion are generally the reddest, and the most given to solarization. The most rapid known wet process, which is at present practicable, is that in which pure chemicals are used, and no bromide; and in this process it matters not greatly whether the developer be iron or pyrogallic acid, for in neither case does the negative require intensifying with silver, and in both cases the time of exposure is about the same.

"With collodion simply iodized, the details in the shadows may be brought out with so much vigour and intensity as to destroy the effect of shadow altogether, but with a bromide in the collodion it is more difficult to give intensity to the details of objects in shadow, and therefore it may happen, in such cases, that a more truthful representation of objects in strong contrasts of light and shade can be produced.

"Such are the effects of bromide in collodion when pure chemicals are used, and it is then only useful when the light is too strong, and the contrasts too violent for the iodide alone. But these statements do not agree with the general experience of photographers, because pure chemicals are not commonly used by them.

"With common chemicals—that is to say, with collodion made with methylated ether, and nitrate of silver which has not been recrystallized and is acid to litmus paper—the effects of a bromide are different from what has been described before.

In this case, with iodide alone, the negative is thin and poor, and devoid of detail, requiring an enormous exposure, and difficult to intensify, so that things do not work well at all; but when a bromide is added, a thin picture can be got with a fair exposure, with a good deal of detail, which can be intensified into a printing negative by treatment with pyro and silver, after the details have been first brought out with the iron developer.

"We now see why the common opinion has gained ground that bromide is an accelerator in the collodion process. It is so when the chemicals are bad, but not so when the chemicals are pure.

"When the chemicals are bad they contain an acid or highly oxydized principle which interferes with obtaining a dense negative in the ordinary way; and we have now to endeavour to explain how the addition of bromide to the collodion counteracts that effect.

"In the preceding article on this subject it was stated that the film of bromide of silver is very slowly formed in the nitrate bath, requiring sometimes as much as a couple of hours to convert the whole of the bromide of cadmium into bromide of silver. But the film of iodide of silver is fully formed after the plate has been immersed a few minutes in the bath. If, then, a plate is removed from the bath after it has only remained in it a few minutes, some undecomposed bromide of cadmium will remain in the film, and this will no doubt render it less sensitive. But we are now speaking of a pure neutral nitrate bath. Suppose the bath or the film to contain traces of a strong acid, such as nitric or oxalic, it is then easy to see that this will attack the cadmium, and liberate the bromine, allowing it at once and promptly to combine with the silver and form bromide of silver in the film. The proof of this is, that if you add nitric acid to a solution of bromide of cadmium, you at once liberate bromine and form nitrate of cadmium in the solution. It appears, therefore, that a strong acid in the film (produced by free iodine or oxalic acid in the collodion, or nitric acid in the bath), assists the rapid formation of the bromide of silver, and thus renders the bromo-iodized collodion more sensitive."

Some very interesting remarks on the value of bromides in the dry processes follow, from which it will be seen that Mr. Sutton's views on this subject have undergone considerable modification:—

"We have next to determine, by careful experiment, the effects of bromide in the dry processes, and here some remarkable results are obtained, so remarkable that we must defer for a time the completion of this article, until we are able to speak more confidently on the subject. Those only who have experimented much in photographic processes can form an idea of the difficulty of arriving at a constant result and safe conclusion, and of the time these experiments take, and the multiplicity of little accidents which throw you out, however well arranged your system may be, and however carefully you may perform the manipulations. It appears, however, to be nearly certain that bromide *is* an accelerator in some of the dry processes, giving, with a wonderfully short exposure, details to which the preservative seems to impart greater power of acquiring density. When a bromo-iodized collodion film is exposed in its wet state it is not highly sensitive, probably, as we have shown, from its containing free unconverted bromide of cadmium; but when this film has been washed nearly free from that bromide and also from the free nitrate, and then allowed to get dry, the small quantity of free nitrate which remains entangled with the pyroxyline and preservative, becomes concentrated by parting with its water, and the dry film then acquires exquisite sensitiveness. In order, however, to produce this state of things, certain proportions must be observed among the various substances used, and when these are properly determined, a highly sensitive dry plate may be produced —as sensitive, in fact, as the best wet collodion, or possibly even more so."

To this we may add that in all the most rapid dry processes of which we have any knowledge, a collodion containing a large proportion of bromide is used. Mr. England, who contemplates competing for the Marseilles prize for an instantaneous dry process, uses four parts of bromide to three of iodide. From a conversation we had with Dr. Hill Norris, we glean that a bromo-iodized collodion was used in his rapid dry plates; and in our own experiments dry plates with bromo-iodized collodion have been at least two or three times as sensitive as those with iodide only.

## REMARKS UPON SOME OF THE APPARATUS EMPLOYED IN PHOTOGRAPHY.*

BY F. R. WINDOW.

### Trays and Dishes.

Trays and dishes may be separated into two classes, according to the use for which they are required. 1st. Those which are intended for developing paper or glass negatives. 2nd. Those which are intended for washing, sensitizing, or any other purposes.

Trays intended to be used for developing pictures with any reducing agent and nitrate of silver, must be made in glass or porcelain; because the vitreous surface of these materials affords a greater facility of ensuring that absolute cleanliness which is indispensable in this operation. The most minute particle of organic matter, or metallic deposit, adhering to the bottom of the tray, will, under the action of the developing agent, and in the presence of free nitrate of silver, prove the cause of a reduction of metallic silver upon the surface of the dish, which will speedily spread itself, first in isolated patches, and gradually over all that portion of the dish which is covered with the solution. This action is of course produced at the the expense of the picture which is at the moment being developed in the dish, and upon which alone the reduction of silver should take place; but in addition to this loss, the picture is more frequently than not spoiled by contamination with the irregular deposit, and by detached particles of this latter floating in the liquid and settling upon the face of the picture.

To the beginner these remarks may appear to be hypercritical, as it will seem to him an easy matter to wash a dish of any material perfectly clean. He must remember, however, that not only ordinary and apparent cleanliness is necessary, but that a vessel in which a reducing agent and free nitrate of silver are to sojourn together must be absolutely and chemically clean. The following experiment, will go far to convince him of the truth of this. Clean a porcelain tray thoroughly with whiting and cyanide of potassium, and having washed and dried it, develop in it a collodion plate of any kind—say a collodio-albumen with gallic acid. If the proper quantity of free silver only be added, it will be found that the liquid will remain to the end of the operation quite clear and nearly white, and the dish will remain perfectly clean. When the picture is finished encourage a deposit of silver upon the dish by placing it with the refuse developing liquid still in it in the day light.

The bottom of the tray will soon be blackened. When it is in this state pour off the liquid, and let the deposit dry on the dish, still under the influence of light, for a few days. Then wash the dish with a piece of rag and water *only*, until it appears perfectly clean, and after wiping it, proceed to develop in it another plate similar to the first, with a like solution. It will be found, in all probability, that the developing liquid will soon become turbid, and that the bottom of the tray will be covered in patches with reduced silver, which will gradually spread over its surface to the detriment of the picture. These effects are produced by some *chemical* impurities which the simple washing was unable to remove, and that the eye could not detect.

A glass or porcelain tray can always be rendered chemically clean by rubbing them with whiting, or some such substance, and cyanide of potassium. But the porous granulated surface of such materials as gutta-percha, india-rubber, ebonite, &c., renders it impossible to apply mechanical friction to every part of their surfaces, and unfits them consequently for the purposes of development.

For sensitizing positive paper, for washing, dipping, or

---

* Continued from page 232.

any such uses, trays made of other materials, such as gutta-percha, ebonite, or wood well coated with rosin cement can be employed.

Many of the remarks made concerning the various kinds of baths will also apply respecting trays of the same material. Thus the glass trays are the least well made of all so far as workmanship goes, and from the amount of material used owing to their enormous thickness they are extremely expensive. Some glass trays, however, are much better made than others, having tolerably flat bottoms, parallel sides, and being provided with a lip; but the greater number are clumsy, inconvenient, and ill-made utensils, by no means up to the mark, or as good as we have a right to expect for the price charged.

Porcelain dishes are generally well made and suited to the work for which they are intended. They are constructed with a lip, and can be had of every size and shape.

The same remarks apply equally to trays of gutta-percha, which, when made of the pure gum may be safely used for all purposes except developing. They are mostly very well made. These trays are especially useful for washing plates in, for those processes in which such an operation is necessary: as the soft nature of gutta-percha permits the operator to shake about the plate roughly, which is the most efficient way to wash it, without danger of injuring it. It is indispensible to procure these trays as well as all other apparatus constructed of gutta-percha from a house where it is known that only articles manufactured of the pure gum are supplied, otherwise disappointment will inevitably ensue. Utensils made of adulterated specimens of gutta-percha not only act in an injurious manner upon the various chemicals that the photographer is in the habit of using, but they will stand little wear and tear, and in a short time crack to pieces, proving the false economy of buying cheap trumpery. These observations are necessary, as there is a great deal of rubbish in the market. There are several respectable firms who are known to manufacture all articles for the use of photographers out of perfectly pure gutta-percha, and the purchaser will do well to supply himself from such a shop, even if the prices be a trifle dearer: though it is worthy of remark that the most worthless adulteration of gutta-percha is generally charged for at the same rate as the pure article.

Ebonite trays have been lately introduced. Ebonite does not appear to possess any advantages over gutta-percha for photographic dishes; and it is nearly three times as costly, its use, therefore, is not likely to become very general. The articles of this material are generally very well made.

Trays for sensitizing positive paper, and washing, can be made of wood, as described for baths. They must be securely fastened with screws, and properly coated with rosin cement. With perfect efficiency they combine the advantage of extreme cheapness, and the photographer can make them himself. These dishes are probably the most convenient kind to employ for washing paper prints after fixing, as they can be made large at little expense, and are not liable to fracture.

(*To be continued.*)

## PHOTOGRAPHIC CHEMICALS:

### Their Manufacture, Adulterations, and Analysis.

In giving an account of the principal chemical compounds which are of interest to photographers, we have been obliged to follow a certain order, which, whilst it has been very convenient in grouping together bodies of like action, and presenting similar substances to our readers in juxtaposition, has rendered it necessary for us to separate other compounds from those with which they have many points in common. We have conveniently classified the chemicals with which it was our task to deal according to the acids which they contained, and under these headings—hydro chloric acid, nitric acid, sulphuric, &c., have given their most important saline compounds. We have necessarily been obliged to exclude much valuable matter referring to the equally important group of bases, and it is our intention now to glance at the chemistry of these bodies, so far as they are likely to be of interest to our readers, and have not been before referred to.

We have already noticed several salts of *potash* under the headings of the respective acids, we will now speak of the few remaining compounds of that base which are of photographic interest.

Hydrate of potash, or caustic potash, as it is more frequently called, is the oxide of the metal potassium in combination with water: it is the type of the *alkali* class of bodies, being a highly caustic and energetic body, uniting with great violence to acids forming very stable salts. It is prepared commercially from the carbonate by mixing slaked lime with its hot solution. Carbonate of lime is formed, and the solution, which must be allowed to become clear by standing, is decanted off and rapily concentrated by boiling down in silver vessels. If the liquid be filtered it is liable to be contaminated with organic matter, as the strong caustic alkali has a powerful solvent action upon organic bodies. Filtering also gives the solution of caustic potash an opportunity of absorbing carbonic acid, which it does very greedily, from the air. Caustic potash is liable to contain many impurities. The following is a list of the principal ones, with their means of detection:—*Carbonate of lime*, this is owing to the liquid not having been clear when decanted from the precipitated carbonate of lime. *Oxide of iron* may also be present from the evaporation being conducted in an iron instead of a silver dish. Both the carbonate of lime and the oxide of iron, together with other insoluble substances accidentally present, remain behind when the potash is dissolved in water. When the evaporation is conducted in the air, *peroxide of potassium* is formed in small quantity towards the end of the operation. It is owing to the presence of this substance that the hydrate of potash gives off oxygen gas when dissolved in water. The ordinary caustic potash in sticks, which is used in surgery as a caustic, and which is prepared by evaporation in iron vessels, evolves a considerable quantity of oxygen upon solution. Graham and Davy state that the amount of oxygen evolved appears to be in direct ratio with the oxide of iron left behind when the potash is dissolved in water. According to Watts this connection between the oxide of iron and evolved potash suggests the supposition that ferrate of potash is formed. If the solution of carbonate of potash has not had sufficient lime added to it for the purpose of rendering it caustic, or if the mixture has not been sufficiently boiled, *carbonate of potash* will remain in the solution; this may be detected by adding an acid in excess to the diluted solution; an effervescence will show the presence of carbonic acid. It may be removed by cautious addition of lime-water, and subsequent filtration and decantation. *Sulphate of potash* is also a very frequent contamination, owing to the presence of this impurity in the crude pearl-ash which is generally used for converting into caustic; it may be detected by supersaturating with hydrochloric acid and then adding chloride of barium; a white insoluble precipitate proves the presence of sulphuric acid. *Chloride of potassium* may likewise be present; it is readily detected by adding nitric acid in excess and then nitrate of silver; the well-known white precipitate of chloride of silver is produced if the slightest trace of chlorine be present in the solution. *Nitrate of potash* is an impurity which is sometimes present; it may be detected by testing the solution for nitric acid according to the plan given in a previous number under the head of nitrates. Besides the above-mentioned impurities certain metallic oxides may be present. *Alumina*, which is a very common as well as a very annoying impurity in caustic potash, may be detected by adding an excess of hydrochloric acid, and then an excess of ammonia, and boiling, a translucent white precipitate shows the presence of alumina. Other metallic oxides may be detected by supersaturating with acetic acid, and then precipitating them with ammonia and sulphide of ammonium, a white, brown, or black precipitate shows the presence of a metallic impurity. For photographic purposes caustic potash is generally required pure, and when used for the preparation of oxide of silver, by precipitating nitrate of silver with it, the presence of many of the above impurities would be very injurious, as the oxide of silver is usually wanted absolutely pure for neutralizing minute traces of nitric acid, or other delicate reactions. We will, therefore, give a process by which impure caustic potash may be purified, and also another by which a perfectly pure article may be prepared *ab initio*, in case the photographer has no crude caustic potash to purify.

The caustic solution, after evaporation to a syrupy consistency, is mixed with about one-third of its volume of alcohol, and well shaken together in a close vessel, it is then left to settle. Three strata are formed, the bottom one consisting of a precipitate which may contain lime, oxide of iron, and sulphate of potash; over this is an aqueous solution of chloride of potassium, carbonate of potash, and sulphate of potash, together with a portion of caustic alkali; on this floats the upper stratum, consisting of an alcoholic solution of caustic potash. This is to be poured off, and the spirit separated by distillation or evaporation in a silver vessel, until the hydrate begins to sublime. A resinous matter will be formed by the decomposition of the alcohol; this will be found swimming on the surface, it must be removed, and the hydrate of potash poured out on plates. The only impurities which this alcoholic potash is likely to contain are chloride of potassium, together with traces of carbonate and acetate of potash.

The next method of preparation to which we alluded is more expensive, but yields a very pure substance. Sulphate of potash, which is readily obtained in a state of perfect purity, is powdered finely, and then boiled in a strong solution of caustic baryta, until a small portion of the liquid filtered off from the precipitate gives a turbidity upon supersaturation with hydrochloric acid, and addition of chloride of barium. This proves that the sulphate of potash is present in excess. This is now decomposed by careful addition of baryta water in slight excess, and the decanted solution is evaporated, the small excess of baryta being precipitated during evaporation by the carbonic acid in the air.

Solid caustic potash must be preserved in very well stoppered glass bottles. Both in the case of the solid and solution of potash it is advisable that the stopper of the bottle should be rubbed over with solid paraffin, in order to prevent the adhesion of the stopper to the bottle, which almost always takes place after a certain time when this precaution is not taken. It should also be preserved in hard German glass bottles, in preference to the lead glass in general use in England, as the latter communicates silica, lead, and other impurities to the potash.

The solid hydrate is white, hard, brittle, and very deliquescent. Below redness it melts to a clear oily liquid. It requires but half its weight of cold water to dissolve it, the solution being attended with considerable rise of temperature. In more dilute solution it forms the liquor potassæ of the druggists. In this state it is a clear, colourless, inodorous solution, possessing intense alkaline properties, shown by the perfect manner in which it neutralises the most powerful acids; the strong blue colour which it communicates to reddened litmus paper, the brown colour which it imparts to turmeric paper; the decomposing power which it exerts on most, if not all metallic salts, withdrawing their acid and setting free their oxide; and finally by the strong power which it possesses of disorganizing the skin, communicating to the fingers, for instance, a greasy feeling, owing to its having dissolved the epidermis, and converted it into a kind of soap.

## CELESTIAL PHOTOGRAPHY.

Mr. Warren De la Rue has presented to the *Académie des Sciences*, a collection of astronomical photographs and engravings, upon which M. Faye reports that he has carefully examined them, and will endeavour to make their importance in a scientific point of view, fully appreciated. He says—The total eclipse of the year 1860, is too familiar to you to render it necessary for me to detail the great enterprises it occasioned. On the other side of the channel, Mr. De la Rue was charged with the photographic department, and here we have the results of this portion of the English expedition into Spain, placed before our eyes. The original proofs have been enlarged by well known methods, in order that the details of the mysterious phenomena may be better appreciated. Among these photographs, some faithfully represent the first impressions with all their defects, occasioned by accidental jarring: others have been retouched to remove these defects of which the origin is known: all are deserving of the lively interest you have shown in them. It is in fact a real triumph of modern science to be able in this manner to transmit to the remotest posterity, the brilliant but transient phenomena of a total eclipse. It would be useless to repeat in this place the results that may be derived from these remarkable designs for the solution of the problem which astronomers have pursued since the eclipse of 1842: the *Académie* has received ample details upon this subject, from Padre Secchi, who, in the south of Spain, has also succeeded in obtaining photographs of this same eclipse. I shall limit myself to remarking that the fact of the impression of the protuberances does not prove that these appearances are real objects floating in the supposed atmosphere of the sun. Simple flashes of light would show just as well upon the plates, on the sole condition of having the same intensity. To speak decidedly on this particular, we should find a much more significant argument in the correspondence established by Padre Secchi between the proofs obtained by Mr. De la Rue and his own, obtained at intervals of a few minutes at stations separated by the entire width of the Spanish territory.

Whatever it may be, the success of my honourable colleague of the Royal Astronomical Society of London, is a great step in a new and fertile field of observation. It will be desirable that the *Académie*, in thanking Mr. De la Rue for his present, should enquire of him the details of the method he has pursued, and particularly respecting the improvements which his recent experience in Spain may have suggested to him for future operations.

But while rendering full justice to these beautiful works, it must not be supposed that we remain strangers, or are indifferent to the progress which is based upon a French discovery. I will remind you, therefore, that in the year 1858, there were presented to the *Académie* at its sitting on Monday the 15th of March, some beautiful large proofs of the principal phases of this phenomenon, proofs which were susceptible of exact measurements and obtained direct without the intermediate operation of enlarging.* Upon the first glance at these proofs we may distinguish the smallest spots, and even the very curious and complicated undulations of the marginal faculæ; and on this same occasion you were reminded how useful to science it would be to collect, on the same scale, day by day, and with the same fidelity, a continuous history of the solar disc.

Let us for a moment suppose the *Académie* to be in possession of such designs, continued perseveringly for many years; what problems connected with the consitution of the sun should we not be permitted to solve? Who at the present time can tell, by an attentive but excessively special study of the spots in the sun, that the appearance of these spots is a periodical phenomenon. It is even suspected that the appearance of these spots is connected with the variations of terrestial magnetism. In taking the remarks of one of our members on the motions peculiar to these spots as a starting point, a learned German has, by the aid of long-continued observations determined the direction and velocity of the currents of the photosphere.

* It must not be forgotten that Mr. De la Rue's photographs relate to the phenomena of *totality*, and that the photographic impression of this phase presents much greater difficulties than that of a partial eclipse.

Again, the continuous study of the solar disc presents to us one of the best means of verifying the hypothesis of a group of asteroids in the region of Mercury, which that enigmatical planet which M. Lescarbault's observations led us for a time to hope would soon be in our possession. Now the proper means of attacking the questions I now raise, and all those reserved for the future, is photography. With photography we do not incur the risk of losing our time in the pursuit of a false idea, for we register all the pheuomena at once, those which interest the science of the present day, and those which the scieuce of the future may hereafter claim for observation. Well executed photographs taken on a large scale, and susceptible of exact measurement, are complete and uuimpeachable witnesses, which may be as profitably consulted a century hence as now. We cannot, therefore, receive with too much favour the recent progress accomplished by Mr. De la Rue in this direction, in which he has for some time past acquired a pre-eminent and indisputable authority; but, at the same time, that this direction be not neglected by us, we must not cease to point it out to persons occupied with photography scientifically, and to show ourselves disposed to welcome the results of their efforts.

I now pass to designs of another kind, which Mr. De la Rue has also presented to us. These designs are based upon minute micrometric measure, executed with the aid of a Newtonian telescope of 13 inches aperture. We first remark several representations of the great comets of 1858 and 1861. These cometary desigus are very beautiful. Yet we find the contours too marked, too hard, the details too forcible. I fear that these defects will prevent astronomers from consulting them, if not with benefit, at least with entire confidence. In spite of their merit and perfect execution by the engraver, these plates please me less than those of the comet of Donati by Mr. Bond, and those of Padre Secchi of the last great comet.

We have next the designs of the plauets Mars, Jupiter, and Saturn. Those of Mars are admirable. I judge of them by memory, for it is a long time since I observed this planet; but I had the good fortune to study it at the Paris Observatory with M. Lerebour's great lens, at a time when this lens had undergone no alteration, and no design has ever recalled my impressions of that period iu so striking a manner as these of Mr. De la Rue.

But what removes these designs from the category of ordinary representations of the celestial bodies, and which will especially excite the attention of the *Académie* is the putting in practice of an idea at the same time original and profound.

The distance of these planets is such, that their images always appear, even in the largest telescopes like flat figures, without relief, as on maps. It would be physically impossible to apply the method of the stereoscope in such cases; for no two places on the surface of the earth would be sufficiently distant to give the necessary visual angle. Mr. De la Rue has wished, nevertheless, to make the planets be seen stereoscopically, and he has succeeded. Instead of varying the point of sight, which is impossible, he has varied the moment of observation by some hours, or by some years, according to circumstances. Two images of Mars, obtained at an interval of two hours, correspond for this planet, to an angular rotation of thirty degrees. It is as if the artist had turned so much around the planet to procure a pair of images of it. Placed in the stereoscope, these beautiful engravings must produce a grand effect. With Saturn, of which all the superficial changes assume a figure of revolution about the axis of rotation, the same method leads to no result; but two images of Saturn, taken at an interval of three years and a half, give, in respect to the ring of that planet, the same stereoscopic effect, aud exhibit the motion of translation around the sun. I venture to beg of the *Académie* to have constructed a stereoscope of suitable dimensions, so that we may all enjoy the pleasure of this singular planetary relief, which so naturally represents an unnatural effect, but one not beyond our comprehension. Already a learned Russian has taken advantage of analogous images of the moon, to study certain very delicate points in the confirmation of our satellite.

In conclusion, the photographic proofs and eugraviugs of Mr. Warren De la Rue possess great scientific value; they merit our approbation.

I have the honour to propose to the *Académie* that it communicates our testimony of their value and importance to the learned secretary of the Royal Astronomical Society of London.

---

## ON THE EXPENDITURE OF SILVER USED IN PHOTOGRAPHIC OPERATIONS, AND ON THE SAVING THAT MAY BE EFFECTED.

BY WILLIAM TUDOR MABLEY.*

In the early days of photography but little was thought of the expenditure of salts of silver: we were only too happy if we gained satisfactory results, irrespective of expense. As the art advauced, it was observed that but a very small portion of the silver employed entered into the composition of the picture; and those who practised it largely began to turn their attention to the saving of that which had been allowed to flow away from the sink.

At present professional photographers, for the most part, economise their expenditure of silver solutions, but the great bulk of those who practise the art as amateurs do to this day throw away a considerable quautity, which may be easily saved: there are, indeed, some amoug professional photographers who still do so.

The purpose of my observations this evening will be to show what quantity of nitrate of silver is taken up by floating paper for printiug purposes, how much of that quantity may be recovered, and what savings may be effected from other sources of waste.

It has been asserted that only five per cent. of the silver employed in sensitizing paper goes to form the picture. This may be; but what I propose now to do, is to state the amount that can, in ordinary manipulation, be recovered with very little trouble, and without any great aptitude for chemical operations. It must be understood, therefore, that larger quantities than those I shall mention may be obtained if the processes be followed out with chemical accuracy. I may state that the results I shall bring before you are reliable, they having been arrived at by workiug with considerable quantities, and having been verified by repetitions.

To carry out the first point, viz., the expenditure of silver —I floated fifteen whole sheets of paper; and this I did the one after the other, so as to avoid any error which would arise from allowing the solution to remain any length of time in the dish, or from the pouring of it backward and forward. These fifteeu sheets were floated upon a bath of nitrate of silver, containing fifty-six ounces, at seventy grains to the ounce. Immediately this was done, the solution was again measured, aud was found to have lost seven and a-half ounces; but, at the same time, it had decreased in strength down to sixty-two grains to the ounce. The original bath, therefore, contained 3920 grains of nitrate of silver, and the bath, after the floating of the paper, 3007 graius—showing a diminution of 913 grains, and an appropriation by each sheet of sixty grains, or one drachm, which, with nitrate of silver at four shillings the ounce, is just sixpence in money value. It must, however, be remarked that the result will somewhat vary accordingly as the paper has more or less albumen, more or less chloride, or is thick or thin. The paper that I used was of an average quality of albumenized paper, and the result may fairly be taken as an example.

I now proceed to state how much of this may be recovered. The first thing is to save the drippings. The most conveuieut method of doing this, to my miud, is to suspend

* Read at a meeting of the Manchester Photographic Society, April 2nd, 1862, and reported in the Society's organ.

the paper from a cord, which is placed in an inclined direction over a board, or anything that will carry a cup to receive the drippings; the remaining moisture may be drawn off by a piece of bibulous paper. In this manner I saved from fifteen sheets of paper one and a-half ounce of solution, containing eighty grains of nitrate of silver.

The next point is the recovery from the washing of the prints before toning. This operation of freeing the prints from nitrate of silver is not so easily accomplished as might be expected. It adheres to the paper very strongly, and the bulk of it can only be removed by at least three changes of water. The prints should soak in the first water for fifteen minutes, and be afterwards moved about: the operation is greatly expedited if hot water be at hand. Prints washed in this manner gave for the fifteen sheets of paper a solution which yielded 350 grains of chloride of silver.

I now come to the hyposulphite fixing bath, which is thrown away more frequently than the water used for washing prints. This, for the fifteen sheets of paper upon which landscapes had been printed, yielded 180 grains of metallic silver. The methods adopted for precipitating silver from the washings and fixing baths are to be found in all books on photography. I may, however, mention that it will be found desirable to keep two stock jars—one for the washings, and one for the fixing baths. From the former of these chloride of silver may be precipitated by the addition of common salt; but such a proceeding cannot be adopted in the latter, as chloride of silver is soluble in hyposulphite of soda. Another course must, therefore, be adopted, and the most simple is to add sulphide of potassium, and thus precipitate the silver as a sulphuret.

My reason for recommending the use of two jars is, that when chloride of silver can be precipitated, it is of a known value; the sulphuret, however, arising from the use of sulphide of potassium is a variable compound, and the quantity of silver it contains can only be ascertained by trial. Sulphide of potassium has, however, a very disagreeable odour, and the operation should, therefore, be conducted out of doors. There are other methods which do not involve this inconvenience, and for which I refer to Hardwich's *Photographic Chemistry*, &c.; but the plan I have mentioned is the most simple, as the precipitation may be done in the old way, and may be continuous.

If an excess of chloride in the one case, and sulphide in the other, be kept in the jars, the operation goes on, and it is easily ascertained whether they be exhausted, by removing a small portion of the clear liquid, and testing it with a fresh solution of chloride or sulphide. As the latter substance, however, is sometimes slow to act in the case of weak solutions, a small quantity of sulphuretted hydrogen gas may be used; but a better method is one which I have adopted at the suggestion of Mr. Caro, an ingenious chemist in the establishment of Messrs. Roberts and Dale. It is simply this:—Take a test tube, and partly fill it with some of the clear solution; in this place a small quantity of caustic soda, so as to make the solution caustic, drop in a fragment of grape sugar, and heat the whole over a spirit lamp or gas-burner: if there be a trace of silver present, it is immediately precipitated in the metallic state.* This method is indeed the best that can be adopted for dealing with the bulk of the solution, if the trouble of heating it be not regarded.

So far the savings treated of have reference to the printing process; but there are other sources of loss to the photographer. For instance, it is a common practice to wash out vessels which have contained nitrate of silver at the sink. I find that a dish for floating a whole sheet of paper, and which is 24 inches by 20, retains upon its surface a quantity of solution, at sixty grains to the ounce, which after close draining yields 25 grains of chloride of silver; and when we consider how often this operation of washing dishes, measures, bottles, and other utensils takes place, it will be seen that a great loss is sustained.

* Mr. Mabley illustrated this experiment.

Again: it is a very common practice to throw away filter papers. I find that such a piece as this, and which is eight inches in diameter, retains 15 grains of nitrate of silver, the solution used being 60 grains to the ounce.

In preparing dry plates, which have to be washed after leaving the silver bath, there is much to be saved. In washing a series which gave a combined area on one side of 480 inches, and which were sensitized in a 30-grain bath, the washings afforded 35 grains of chloride of silver.

There is also a continual waste by spilling solutions, and these may be recovered simply by keeping blotting-paper at hand to absorb the fluid.

In developing collodio-albumen plates, a large quantity of silver is often required to get up the intensity, and a very small quantity of this goes to the picture; as it is renewed when it becomes dirty a great sacrifice is made. This refuse may be added to the stock jar containing the hypo baths.

## PHOTOGRAPHY IN THE TROPICS.

BY WM. FITZGIBBON.*

For some months past I have been promising myself to write you, but the multiplicity of my engagements, and my business occupations, added to no small share of laziness, have prevented me; at last, however, I have made an effort, and I give you its result.

First, I enclose you a few stereoscopic views, and shall occasionally send others, provided you like them. By the first friend I find going home I shall forward some negatives for your Photographic Society; of course I do not know whether you are forming a collection of views from different parts of the world, but if not, I would suggest it; and I am pretty sure if other brethren of the photographic art feel as I do, they will not refuse a little labour to add their mite to the collection.

I have read so much about processes, toning and fixing, &c., by this method and by that, during the last five years, that I have become thoroughly bewildered; you will probably laugh when I tell you that I have scarcely ever seen a toning or fixing process published that I have not tried; some would work, others failed, as to the results stated, in my hands, and others were worthless; as I never made but a few ounces of each, the loss could not be great, and everything was worth a trial. Instead of throwing them away, I put them all together in a glass jar, holding about three gallons, and to these I added occasionally an old hypo bath. Imagine to yourself what a toning and fixing bath it is, a mixture of nearly everything used by anyone; and, as to proportions, well, the less said about that the better. A few weeks ago it came into my head to *try the mess*, and the stereoscopic views numbers one, two, and three are the result. The albumen paper I prepared myself, fifteen grains of chloride of ammonia to the ounce of albumen, floated for three minutes, the albumen four days old before using, and Saxe paper: silver bath, eighty grains to the ounce, and one drop saturated solution of citric acid to three ounces; floated for five minutes. This I have worked for the last twelve months, and always with excellent results. I overprint a little, and instead of washing in water I wash in a solution of chloride of sodium, two ounces, to eighty ounces of water; in this the print changes rapidly, first bronzing, and finally to a dirty red or brick colour; I now wash in several waters until the saline taste is removed, and then pass to the mixture above, and leave it until I get the tone I like, say from twenty to forty minutes, afterwards work as usual. Now, whether these prints will fade or not is a question; so far I have been very fortunate, and it rarely happens that any of my proofs fade. I may here remark that some two years and a-half ago, I toned some albumen prints as follows, and out of over one hundred not one has faded, and I work it now in preference to any other, except

* From the *American Journal of Photography*.

the mixture. Nos. 4, 5, and 6 are done so, and are two years old.

On taking from the printing-frame, wash in chloride of sodium, as above, then in water, and tone in—

| | |
|---|---|
| Chloride of gold ... ... ... | 8 grains |
| Distilled water ... ... ... | 16 ounces |

Shake well, and add—

| | |
|---|---|
| Acetate of soda ... ... ... | 1 drachm. |

This quantity will tone the proportion of thirty-two prints whole-size.

After washing thoroughly, fix in hypo bath, one ounce to five ounce of water. All my work is done in yellow light, and an abundance of it. In the toning bath the proof needs close watching for the first few proofs, afterwards it works slower.

I believe that the principal cause of fading (of course there are several others, such as bad paper, bad toning, and bad fixing, and want of proper care in handling the proofs), is our bad system of washing. The plan of hanging a print up to dry I have never approved of, because I do not believe that any amount of soaking or washing will remove all the effect of the toning and fixing ingredients from the paper; they must be forced out. In a number of your Journal of 1860 you allude to a good plan, that of passing the proofs through a patent clothes-wriuger: I have tried it, but the pressure is not enough, as I understand it. I therefore set to work and got a machine that answers a double purpose, and I firmly believe will be found of great utility, not only in removing the water from the proofs, but afterwards in mounting them on pasteboard, and for which a lithographic press is recommended.

I enclose you a sketch (made for me by Mr. Thompson, an American chemist residing here, and who estimates the expense of getting them up, in New York, at from sixteen to twenty-five dollars) and description, to which I refer you; I have now a bungling wooden one, but wish for a proper one, if it can be made at about the price above stated. Please give me your opinion about its utility.

I have lately noticed that an effort is being made to introduce some new articles into collodion, with a view of obtaining sufficient intensity without resorting to redeveloping agents. With this object before me I now send you a sample of cotton known here as "Ixcaco," which, I think, would be worth the while of making gun-cotton of it, and testing it. The colour is very suitable, and I have an impression it may help. My own experience is, that any collodion of a deep yellowish colour will produce negative pictures of greater intensity than a clear one, provided the colour is not caused by the liberation of iodine from the sensitizing agents used. The cotton in question will produce the effect. It will require picking out and cleaning, as I send it in its rough state. Try it, and if it suits let me know, and I will send you a quantity; I cannot get the right quality of acids here for a fair test, so that some trials I made were failures, the cotton not dissolving.

A root grows here, and is known as *camotillo*, that produces the effect of turmeric, described in the Xantho-Collodion; I have tried it with good success; but what I have found answer equally well is the following developer :—

| | |
|---|---|
| Protosulphate of iron ... ... | 2 ounces |
| Distilled water ... ... ... | 20 „ |
| Acetic acid ... ... ... | 2 „ |
| Sulphuric acid ... ... ... | ½ drachm |
| Refined loaf sugar ... ... | 10 grains |
| Alcohol ... ... ... ... | 1½ ounces. |

I have obtained negatives with this developer as intense as needs be, though not at all times, for instance, when the exposure has not been right, For positives I use a modification of the developer: half the quantity of acetic acid, and substitute nitric for sulphuric; the result is a clear, bold white and black picture, with well-defined half-tones, and but very slightly metallic. My object in adding the sugar to the developer is, that I find it has a tendency to rot the collodion when added to it; this effect is not observable when used in the developer, yet a like intensity is produced. These facts I learned as far back as 1854, when experimenting with different articles as developers.

You will probably recollect sending me, some time since, a few articles, among which was some iodide of cadmium: on its reaching me, one ounce of it, from some cause or other, was nearly black. I made no use of it, until a few days ago, on running short of the article, I opened the bottle, and found it in a black wet mass. I sensitized a few ounces of collodion with it, and unfortunately threw the balance away; I say unfortunately, because, on trying a picture, on the collodion, settling very bright purple and green colours appeared (and for which I am unable to account), which still retain all their original brightness; they are not well seen without slightly turning the picture on one side. The editor of one of our newspapers was with me at the time, and has since published a uotice of it. I tried a second, and a third, in fact several, and in every instance obtained the same result: in some instances the collodion peeled off on drying, in others it did uot. One of these pictures I shall send you for examination, probably you can explain the cause, ou seeing it; it has evidently been caused by some peculiar state of the iodide of cadmium used, as nothing of the kind has been produced by the other bottles of iodide.

I trust that you will not find my letter a bore, if you do, throw it away; if not, make such use of it as you think it may deserve. I shall write again, in all probability, about June, or July, as by that time I trust I shall be enabled to give you the results of some experiments in which I am now engaged.

I regret to say that, owing to a large number of operators traversing the country, the photographic business is pretty well ruined, as to a fair price or an amount of work. This city, which will hardly support one establishment, has four; and apart from this there are some three of four young men who have learned the business (with a vengeance!), and are now working hard to break it up entirely.

At the present time I am preparing to take advantage of the dry weather for a trip up towards the Mexican frontier, to add to my collection of views and Indiau costumes.

A good, simple, dry process would be of great service to me, but as yet I have met with none that gives me the desired results, without being too complicated to work with in a country like this, where an artist has a thousand difficulties to encounter, that are not dreamed of by our friends at home.

*Guatemala, March 6th*, 1862.

## THE NITRATE OF URANIUM BATH.

THIS toning bath is the best, but like all alkaline baths requires great care in the manipulation. It will produce those tones of black and white, so desirable in the *cartes de visite*.

Float the albumen paper in a solution of 90 grains of silver to each ounce of water, having previously added a few drops of strong aqua-ammonia, to neutralize the acid in the nitrate of silver. Let it settle a few minutes, and filter. Prepare three solutions as follows:—

| | |
|---|---|
| No. I.—Chloride of gold ... ... | 15 grains |
| Or, one bottle of the ordinary chloride of gold. | |
| Water ... ... ... | 2 ounces. |

Neutralize with bicarbonate of soda.

| | |
|---|---|
| No. 2.—Acetate of soda ... ... | 100 grains |
| Water ... ... | I quart, or 32 ounces. |

| | |
|---|---|
| No. 3.—Nitrate of uranium... ... | 15 grains |
| Water ... ... ... | 2 ounces. |

Bicarbonate of soda sufficient to neutralize the acid, which may be known by test paper.

Mix Nos. 1 and 2 by pouring the gold into the soda. Then add the nitrate of uranium, and filter. This will tone nearly 200 prints, when a new bath can be prepared, to which this old one may be added, and the tone in most cases improved; but should there be any mealiness, lay aside the whole bath, and prepare a new one, reserving it for future use, and it may be added gradually to the new baths. Always wash the prints well, as in other alkaline baths, and immerse in the above the usual time. On removal from the toning bath, wash carefully, and fix in a solution of hyposulphite.

The foregoing method of toning is now adopted in the most extensive establishments in New York. On trial, it will prove the most practicable, and there is not so much waste of chemicals.

The use of aqua-ammonia in all the silver solutions for the albumen paper, is recommended.

Difficulties will occur in the use of all baths, and slight variations in the proportions of the chemicals of each of the toning baths, as laid down in this book, may be adopted.

Great attention should be paid to the quality of the paper, and to the negatives, which must possess all the requisites for a good print. Wash carefully through all the various stages, until the final mounting of the picture.—*American Journal of Photography.*

## VARNISHING PHOTOGRAPHS.

The practice of varnishing photographs has always, in our own opinion, issued in spoiling them. As, however, it meets the taste of some photographers, and is much practised on the Continent for large developed prints, we subjoin a couple of letters on the subject from American journals. The first is signed J. Longwell, and is as follows:—

"Take a clean glass the size of the picture, warm it sufficiently to melt bees' wax, which is to be rubbed over one side. With a piece of Canton flannel rub the superfluous bees' wax off, leaving only a thin even film on the glass. It should present no uneven ridges or markings caused by rubbing; they would show afterwards in the picture. Set the plate aside.

"*Enamelling Solution.*

| | | |
|---|---|---|
| Patent gelatine | ... | $1\frac{1}{2}$ ounces |
| Alcohol | ... | $2\frac{1}{2}$ " |
| Water | ... | $7\frac{1}{2}$ " |

"Put altogether in a bottle, and melt in a water bath. When dissolved, filter into a flat dish. A moderate heat should be kept under the dish, so that the solution may be kept fluid, and not allowed to cool. Float the picture for three minutes, picture side down, carefully expelling all air bubbles, the same as albumenizing paper. Raise it up, and let it drip a moment. Have on hand a pail of clean water. Hold the picture by the upper edge in the right hand, and take the glass previously waxed in the left hand. Let them both descend (a few inches apart) perpendicularly into the pail of water, which should be deep enough to cover them. Bring the upper edge of the picture even with the upper edge of the waxed side of the glass. Hold the two firmly together, and gradually raise them out of the water. The picture now adheres very nicely to the glass. Should there be any air bubbles, they must be worked out. The glass can now be laid flat, a piece of blotting paper laid over the picture, a glass on top of that, and a moderate weight on top of all for a few hours. Then place the picture and glass where they will thoroughly dry, when the picture will come off with a beautiful enamelled surface."

The next letter is from Mr. Sinclair, as follows:—

"Many good operators oppose the use of any varnish, or sizing of any kind, after the photograph is mounted, and tell us that it destroys the artistic effect: that an engraving is always injured by varnishing; that photographs should resemble engravings as much as possible, and therefore should not be varnished, and much more to the same effect. It is not my intention to dispute these statements, notwithstanding my non-concurrence in them, but merely to state my opinion and the reasons I have for it.

"Those who follow photography as an amusement are at perfect liberty to varnish their pictures or leave them plain, and nobody has any right to find fault, but with those who follow it as a business the case is very different, nine out of ten of our customers want their pictures varnished; 'They look so much better;' under these circumstances we have the strongest reason in Dollardom in behalf of our practice; but I hold that a properly varnished photograph is more lasting than one not so protected. I have some photographs that have been exposed to the fumes of coal-gas until the unvarnished cardboard upon which they are mounted has become quite yellow, yet the photograph is unharmed, while others left plain are considerably faded, and this I think conclusive evidence that varnishing is not only no injury, but a positive benefit to the photograph; and as I have no patent process to sell, I think it will do no harm to let your readers know what I use, and perhaps save me the trouble of sending it to some of them as I have had frequent applications for my process.

"I take fine picked gum arabic and make a solution about as thick as collodion, and spread one coat over the photograph with a clean brush and set it aside to dry: when dry I take the 'Artist's Picture Varnish' (to be had of all colormen and dealers in artist's materials), and having diluted it with twice its bulk of spirits of turpentine, I give the pictute a thin coat, which finishes the operation.

"If the gum is too thick it will crack, and the picture will be spoiled; if too thin, the varnish will strike through, and produce transparent spots, but if the gum and varnish are of the proper consistency and neatly laid on, the surface will be almost as fine as heavy albumenized paper."

## RAPID DRY PROCESSES.

The great problem of an instantaneous dry process is not yet completely solved. Dr. Henry Draper's process is only a step in that direction, although it has been demonstrated to be a genuine discovery of real and great utility, yet leaves much still to be desired and to be accomplished.

The dry plates wanted are such as can be used in the ordinary work of the practical photographer—portraiture. When such plates are found, Humidus' occupation will be gone, he will needs go drown himself. Who would dabble about a silver bath in a dark room at the top of a house reeking with fumes of drugs and heat, when he could buy his plates all prepared at a cheaper rate, or if he could prepare them himself in the cool of the evening or morning, or prepare a store for the whole summer in the bracing winter atmosphere?

Depend upon it, photographers, the time is coming when you will abandon your silver bath and collodion, and when you will have no more risk of staining your carpets and patrons with silver solutious than the Emperor of China. Here is work for the experimenters; let them bend themselves to it, for it must be done. We sincerely believe that the next great sensation which shall send a thrill through the photographic world is a *genuine* instantaneous dry process.

While the ink on the above is still wet, the *Photographic Notes*, of April 15th, reaches us, and we find that Mr. Sutton therein tells his readers that he has "succeeded in preparing rapid dry plates as sensitive as the best wet collodion; that these plates yield excellent printing negatives," &c., and we begin to think the great time has surely come. But further on he tells us that the principle on which these plates "consists in using a suitable iodized collodion, in washing the excited film thoroughly from the silver bath, in order to prevent stains, and in restoring the sensitiveness by means of fresh silver added to a suitable preservative, which never becomes absolutely dry and hard." So we have our doubts; a film containing free nitrate cannot be kept for ever; a preservative which requires a certain amount of moisture in it will not yield steady results. Yet many thanks to Mr. Sutton; he is a worker, and his zeal is in the right direction.—*American Journal of Photography.*

## PHOTOGRAPHING FROM BALLOONS IN MILITARY RECONNOISANCES.

Last summer, when Professor Lowe first commenced his ascensions in his balloon, for the purpose of observing the positions of the enemy, the Photographical Society of this city made a communication to the War Department, through their president, Professor Draper, pointing out the great advantage that might be derived from taking photographs of the enemy's camps from the balloon, and offering their services to aid in carrying the suggestion into effect. The *American Journal of Photography* suggested that the photographs thus taken might be examined under the microscope, and thus the most minute details might be studied at leisure.

Secretary Cameron, in the multiplicity of his public and private affairs, never found time to reply to the communication, and the matter was dropped.

We see that Professor Lowe has just commenced his ascensions, and we suggest to General M'Clellan, or any other officer who may chance to see these remarks, the propriety of calling upon the Photographical Society for the services which they offered last year. Professor Draper, the president, is a man of European reputation. Professor Joy is vice-president. Many of the leading members are men of position in the world of science, and the high character of the society is sufficient warrant that its suggestions are worthy of consideration. Let our military art accept the wonderful aid tendered to it by the most subtle department of science.—*Scientific American.*

## Correspondence.

### FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

*Paris*, 21*st May*, 1862.

The prize of 2,000 francs, offered by the Duc de Luynes, for a perfect carbon-printing process, has been awarded by our Photographic Society to M. Poitevin. The committee were anxious also to mark their sense of the great improvement effected, both in the mode of operating and in the resulting proofs, by M. Fargier, and suggested that a medal of the value of 600 francs should be given to this gentleman. Upon putting this proposition to the members of the society, it was so far modified as to be awarded in money, instead of a medal; the sum to be taken from the funds of the Photographic Society.

M. Ad. Martin recommends that the free sulphuric acid of the iron developing solution be completely removed, because the presence of this acid favours the deposit of large crystals of silver, which increase in size in proportion to the quantity of acid present. He proposes the following formula for a developing solution:—

| | |
|---|---|
| Water ... ... ... ... | 500 parts |
| Sulphate of iron ... ... ... | 100 „ |

After filtering, add 25 parts of a very limpid solution of acetate of lead, of the strength of 10 per cent.; the object of this is, by forming an insoluble sulphate of lead by double decomposition, to replace the free sulphuric acid and a portion of the sulphate of iron by acetic acid and acetate of protoxide of iron.

We then filter the liquid again, and add 25 parts of acetic acid, and 450 parts of water, with 5 parts of acetic ether (which, by retarding the coming of the image a little, avoids stains), and 5 parts of alcoholised nitrous ether. Negatives developed with this solution possess vigorous black tones, similar to those obtained by pyrogallic acid, and very different from the usual gray tones given by sulphate of iron employed in the ordinary way.

M. Davanne, referring to a process for obtaining very superior tones in proofs upon albumenized paper, recently published in *Humphrey's Journal*, remarks, that this preparation, which evidently has an alkaline reaction, owes it to the well-known property possessed by nitrate of ammonia of dissolving a large proportion of oxide of silver. This may, possibly, be an excellent photographic preparation, but it is a mixture of nitrate of silver, and of nitrate of ammonia holding oxide of silver in solution; hence the name of *ammonio nitrate* bestowed upon it can only give a false notion of its composition. It may be useful to remark, that the solution of oxide of silver in pure ammonia forms, not a mixture like the preceding, but rather a definite compound, very detonating, and extremely dangerous to handle when dry.

Most of the salts of silver, which are either insoluble, or only slightly soluble in water, are more or less soluble in nitrate of silver; thus the chloride, and iodide of silver, dissolve in much larger quantities when the solution of nitrate of silver is more concentrated. Acetate of silver, however, forms an exception, and is, on the contrary, less soluble in proportion to the greater strength of the nitrate of silver; this peculiarity of acetate of silver is sometimes the cause of failures in photography, which it becomes easy to avoid, when the fact is known.

It sometimes happens that the preparations of albumen, and also of collodion, contain small quantities of soluble acetates, introduced accidently, or purposely; when these preparations are immersed in the silver bath a little acetate of silver is formed, which remains in solution, and as the bath becomes weaker by use the solubility of the acetate of silver increases in proportion, and makes no deposit; but if we strengthen the bath, the conditions of solubility become altered, and a crystallization of acetate of silver, in the form of fine, needle-like crystals, takes place, either upon the collodion plates or upon the positive proofs. When we know a bath to be in these conditions, we must add an excess of nitrate of silver, leave the solution in a cool place for a night to filter, then add the proportion of distilled water necessary to restore the too concentrated bath to its normal strength.

M. Robinet has communicated some interesting remarks upon the spontaneous purification of natural waters by freezing. The fact that water loses all its calcareous salts when converted into ice, is, since the beautiful researches of M. Dufour, of Lausanne, no longer a matter of surprise. The experiments were conducted by the hydrotimetrical process, which consists in adding to the water to be assayed sufficient of the test liquor to cause the soap lather to appear. The first experiments were made upon water from the lake in the *Bois du Bologne*: before congelation it marked 29° of the hydrotimeter, after congelation and melting it marked 0°. M. Robinet has frequently seen the hydrotimetric degree of water descend, after congelation, from 30° to 0°; from 29° to 2°, from 19° to 3·5°, from 29° to 2°, from 33° to 4°, from 11° to 1°, from 18° to 1°, &c., &c.

M. Van Walderen remarks upon the dry collodion process, that all the methods practised give results more or less satisfactory, with an exposure varying from 25 to 50 seconds, but he thinks that the question of *rapid dry collodion* is still unsolved. He adopted the Rev. J. Lawson Sisson's process, and obtained by it negatives in much less time than by any other process he had previously employed. He considered that this extra sensitiveness was due to the alkaline state of the borate of silver employed, and in order to satisfy himself on this point he dissolved 0·1 grain of caustic soda in 100 grains of water, and covered with it some plates which had been sensitized in the ordinary silver bath, and well washed. These plates, several days after this operation, and consequently quite dry, were found to be at least as sensitive as those prepared by Mr. Sisson's process, for stereoscopic views were obtained upon them in three seconds, while with the most sensitive collodions previously employed, they required at least 30 seconds exposure with the same objective. With the same collodion in a humid state the result was scarcely less prompt.

Mr. Sisson, by his discovery, undoubtedly made a great step towards obtaining an instantaneous dry collodion, but I think that his process might be rendered much simpler, either by covering the sensitized and well washed plates with a solution of dextrine in water, simply saturated with borax, or rather with a very weak aqueous solution of caustic soda. It is very probable that some other alkaline salts will give as good or even better results. I have tried phosphate of soda, but the results it gave were less satisfactory with respect to rapidity, than with soda or borax, for it required no less than 4 or 5 seconds exposure to obtain a good negative. There is an advantage in using borax which deserves mention, this salt, but slightly soluble in water, admits of its saturated solution being employed without the fear of seeing the film blacken immediately under the developer, an accident that frequently occurs when we employ a too concentrated alkaline solution. Other alkaline salts will therefore require to be carefully weighed.

The science of all sciences, Anthropology, the "science of man," is one of those which receives most valuable aid from the art of photography. Our photographic society has recently received a series of proofs, taken by M. Gavet, a missionary, representing various types of the natives of Nova Zembla, taken under the most difficult circumstances The artist remarks that photography, by its marvellous results, has, in the hands of the missionaries, become one of the most powerful agents in converting the untutored natives to Christianity. M. Hammerschmitz, of Cairo, has also made a similar contribution of a number of proofs, representing various Egyptian types of the human family.

A method of photographic engraving, invented by M. Fontaine, of Marseilles, is thus described:—"Having a photographic negative of the object which it is desired to engrave upon copper, I expose it in a pressure frame to the light in contact with a plate of that metal, covered with a solution composed of pure gelatine, bichromate of potassa, and fish glue. After exposure to the light, I immerse the plate in a dish containing lukewarm water, the bichromate of the soluble portion of the gelatined plate being dissolved, I obtain the design from the negative *en creux* (intaglio); then I pour upon it some pyrogallic acid to harden the gelatine and fix it, so that the minute details should not disappear upon its drying. When dried, I pour upon the plate a solution of pure gutta-percha in sulphide of carbon, and afterwards I take a piece of gutta-percha of the same size as the plate, and warm it on one side. I then put it in contact with the side of the plate, which I had covered with the solution of gutta-percha, and put in a press. Next removing the whole from the press, I remove the gutta-percha from the gelatined plate, which is perfectly united with the purified gutta-percha, and I have then obtained in relief in great purity the design of the negative which I desire to engrave. After black-leading it, I place it in an electrotype bath, and thus obtain an engraved plate."

M. Mathieu Plessy communicates the following, upon the use of a bath of acetate of soda for washing positive proofs, by immersing them, upon removal from the pressure frame, in a solution of that salt, of the strength of two per cent., for ten minutes. The proofs tone much better, more quickly, and of very superior vigour and intensity. In this particular, M. Plessy's experience exhibits a remarkable coincidence with that of Mr. Fry in England.

M. Aimé Girard, upon presenting to our photographic society some stereoscopic proofs, obtained from negatives taken by Mr. Warren de la Rue, remarked, "We know that the planets, in consequence of their remoteness from the earth, appear like plane surfaces, even in the most powerful instruments. Mr. De la Rue conceived the ingenious idea of producing proofs of those stars in relief, by placing different views of them in the stereoscope. But as it would be impossible to find on the surface of the earth stations sufficiently wide apart, he obtained the desired result by executing two views of the same star taken at different times, when its aspect had become sufficiently modified. Such views, when placed in the stereoscope, furnish an image of the star in relief.

In connection with the important question of dry collodion plates, M. Aimé Girard remarks that it would be well for photographers to direct their attention to the qualities primarily attributed to the Taupenot process by its inventor, who had, in fact, presented his method as capable of furnishing instantaneous pictures. M. Girard exhibited to the photographic society an album, the proofs in which had been obtained, if not absolutely instantaneous, at least with remarkable rapidity. Beside, the Taupenot process seems very apt to furnish good results, in consequence of the almost indefinite resistance it offers to the developing solutions. M. Ferrier added that he had tried the Taupenot process, but had hitherto found it too slow in his hands, as it always required at least an exposure of a second under the most favourable conditions; but he had every reason to hope that with more experience, it would eventually accomplish all that could be desired in an instantaneous dry process.

## THE NITRATE OF MORPHINE DRY PROCESS.

Sir,—I am surprised that we see nothing in the pages of the News, to indicate that this very important process has been deemed even worthy of a trial by any of your readers. Had Mr. Bartholomew's experiments been published, even by an anonymous writer, and had his communication betrayed any evidence of his ignorance of chemical changes, one would have thought that, at all events, some of your many readers, even if for the purpose only of placing others on their guard, in common fairness to your correspondent, have done him the justice to test his good faith, and would have given others the benefit of their report. But when you prefaced the insertion of your correspondent's letters with a notice of the valuable hints which his former experiments in photography had suggested in the pages of your journal, the silence, on which I beg to remark, seems the more unaccountable. The reason, perhaps, is not hard to divine. The introduction of organic matter into the nitrate bath is one of those things which photographers are most anxious to eschew. It seems, with reckless hand, to assail one of the very axioms of our art—to soil with known impurity that which we have been taught to keep with such scrupulous care intact from all contamination. Theory, and that not hastily formed; practice, too, long acquired, seem with united voice to say, "Beware of such nostrums!" and "don't run the risk of spoiling your bath;" "place this process in the category of crude notions which ought to have no quarter with any photographer who knows what he is about." Prejudice would be, perhaps, too harsh a name to affix to such conclusions; and yet, if they form a hindrance to that investigation, which may tend to give us a deeper insight into those mysterious molecular changes, which are brought into play in the production of a picture, I know not whether this twin-sister of ignorance has not had something to do with such contempt prior to examination. Now, in the absence of any other communication on the subject by abler hands than mine, I venture to hope that the following account of some very interesting, and, I may add (eventually), successful experiments, which I have recently undertaken, may prove not unwelcome, nor unprofitable, to some of your readers, who may, perchance, employ photography in the pursuit of *knowledge*, as well as of pleasure or profit:—

1. I added about 3 grains of muriate of morphine (pre-

viously dissolved in a little distilled water) to about 40 ounces of an old 40-grain negative bath. This, of course, led to the precipitation of chloride of silver, produced by the combination of the silver with the muriatic acid united with the morphine, which, in its turn, joined affinity with the morphine. The bath now consisted of nitric acid, in combination with silver and morphine, and, *so far as any organic substance can approach to stability in such a union*, we may, I think, assume that we have it here. I use the term, "*approach to stability*" advisedly, because it is absurd to expect that, under such circumstances, the bath is not exposed to the taint of change and decomposition, at least, to a certain extent. Whether this contamination is fatal to success, and accompanied with the ruin of the bath, or whether it is unworthy of notice, compared with the advantages it now offers, remains to be seen.

2. The bath thus prepared is passed through a filter to free it from the chloride deposit. In this condition it is highly sensitive, and if made of fused nitrate, it is, without the addition of acid, very liable to produce foggy pictures. The question is, what kind of acid should it be treated with to remedy this tendency? The condition of the bath in the course of a week or ten days points to *nitric* acid as the curative agent required. For, if the dipper be examined, it will be found covered with an exceedingly thin deposit of silver, the formation of which the nitric acid will have a tendency to prevent, just in proportion to its excess.

3. I added a weak solution of this acid in distilled water, until blue test paper showed a very decided and immediate change of colour. In this state the bath is still capable of imparting a high degree of sensibility to the collodion film, which is retained after unlimited washing and drying.

4. The exposure need be little more than half of that required in the Fothergill process.

5. I develop with the usual 1-grain pyro developer, first moistening the plate with distilled water.

6. The result is the same with different kinds of collodion, but films which are tough and contractile, are apt to leave the plate after fixing. A previous coating of thin albumenous solution would be advisable. I have had some correspondence with Mr. Bartholomew on the subject, and found him very communicative and obliging, and my own experiments lead me to the conclusion that the report of his discovery, published in your pages a month or two ago, is thoroughly reliable, and the discovery itself is *in the highest degree important*.

All that the bath requires is occasionally filtering, and replenishing with fresh nitrate; it would, undoubtedly, be better to make it in the first instance of *unfused* nitrate.—I remain, dear sir, faithfully yours, William Law.

*Marston Rectory, Rugby, May 16th*, 1862.

## Photographic Notes and Queries.

### Failure in the Dry Processes.

Sir,—I have been trying to realise the great advantages which must result from the method of preparing dry plates, as proposed by Mr. Bartholomew, strictly according to his directions, so far as I know, but so entirely without success, that I cannot help thinking there must be some fallacy I am unable to discover in my mode of operation. I will, therefore, with your leave, detail my method of proceeding as briefly as possible, and beg your advice and aid in detecting my error.

1. I carefully cleansed, coated, and sensitised the plates. Collodion, Perry's, of Sheffield, bromo-iodized, and works well by the wet method; bath 40 grains to the ounce, neutral, which also works well.

2. Immediately on removal from the bath I washed the plates in three waters, by placing each plate in three successive dishes of boiled rain-water, and causing the water to flow over it by a rocking, undulating motion for several minutes.

3. On finishing this operation, I coated them with a solution of gelatine, in the proportion of 1 drachm to 10 ounces of water rain-water—boiled and filtered—the gelatine was dissolved in this water by raising it to the boiling point in a clean, new pipkin.

4. This done, I left the plates to dry spontaneously, and when quite dry, I left them for a minute or so in a solution of the best sub-carbonate of soda of commerce, and dried them spontaneously by leaning them against the wall of the room, the prepared side outwards. All the operations took place in the dark room.

After exposure, I developed with iron (20 grains to the oz.) and acetic acid. Not a trace of a picture appeared. I afterwards exposed one of the plates to sunlight for about two minutes, and applied developer, with scarcely the smallest darkening of the film. Again I prepared a plate in the same way, by using in all the operations rain-water boiled and filtered. I proceeded as far as the gelatine, coated as before, and then applied the alkaline solution only on half the plate; neither side was at all affected by the exposure of 5 to 10 seconds.

Finally, I exposed a plate after washing only, with precisely the same result—a perfectly white and unsullied film.

I should tell you that the rain-water is not such as answers perfectly well for solutions. I tested it with nitrate silver without producing any evidence of impurity.

I am particularly desirous of mastering this process, and shall be much obliged by any assistance you can give me.—Yours obediently, Quæsitor.

*May 4th*, 1862.

[Our correspondent describes every step in his operations as having been apparently conducted with legitimate care, and at the first glance it would appear impossible that failure should have occurred. On a more second examination of the operations we think the source of failure becomes clear: our correspondent developed with a solution of iron and acetic acid, but without any nitrate of silver. In such case, he would not be likely to obtain an image with even much longer exposure. With pyrogallic acid, without acetic acid, an image may be obtained in a dry plate if it contain any salt of silver capable of reduction; but in his operations, as described, a few drops of silver should be added to the developer.—Ed.]

### Keeping Fothergill Plates after Exposure.

Dear Sir,—Your correspondent, "G. S. Penny," on page 226, if he wishes a dry-plate process that will keep after exposure should work the Fothergill, as plates prepared that way will keep any reasonable time between exposure and development. I have developed Fothergill plates on the thirtieth day after exposure; this I did last October; they were only kept in tin-plate boxes, of course, light-tight, no extra precautions; two I kept for that same time in the mahogany dark slide, only to try, and they all developed as quickly, and as cleanly and free from fog as if they had been exposed and developed the same day. I am, sir, yours truly,

*London, May 18th*, 1862. W. L.

### Bromo-Iodized Collodion.

Dear Sir,—I find in last week's News, an enquiry whether my collodion contains any bromide, as a similar question has been asked on two or three occasions previously, I would state for the information of your readers that it is a bromo-iodized collodion. These remarks apply to my dry process collodion. My new wet process collodion, as will be seen on reference to your advertizing columns, is sent out cadmium iodized, cadmium bromo-iodized, and extra bromo-iodized, according to the purposes for which it is required. The bromo-iodized being for general use.—Yours, &c., Alfred Keene.

*Leamington, May* 14th, 1862.

Photographic Literature.—M. Disderi, the celebrated French photographer, has just issued an illustrated volume, entitled "The Art of Photography," with an introduction by Lafon de Camarsac. We notice, also, that Major Russell's excellent little work on the tannin process has been translated into French by M. Aimé Gerard.

## Talk in the Studio.

AMMONIA NITRATE FOR ALBUMENIZED PAPER.—Mr. G. R. P. Frazer, of New Glasgow, Nova Scotia, sends us the following formula for ammonia-nitrate of silver, to be used with albumenized paper. Some fine-toned prints are enclosed as illustrations of the operation of the process:—Dissolve an ounce of pure nitrate of silver in eight ounces of water, pour off one-third of the solution into another bottle, and add aqua ammonia until the precipitate first caused is redissolved. Then add to this the remaining two-thirds, and add to the whole one drop of nitric acid to each ounce of solution. The paper should not be floated on this solution for more than a quarter of a minute. The tones are rich and brilliant, and the process considered by those who use it a decided improvement on the usual method.

THE JURORS IN THE PHOTOGRAPHIC DEPARTMENT OF THE EXHIBITION.—We learn from the *Photographic Journal* that Dr. Tyndal is acting as deputy chairman, and Dr. Diamond as secretary or reporter to the jury in the photographic department. The jury have been requested to take under their adjudication all photographic apparatus, and chemicals designed for photographic use, whether in their own or other classes. The jurors are proceeding actively in their labours, and are summoning, where it is deemed necessary, exhibitors to explain the details and claims of their contributions. The awards are to be made before the 15th of June. The following selections from the "Instructions to Jurors," explain the arrangements in regard to medals:—*Medals to be awarded without reference to Nationality:* The medals will be awarded for excellence only, without reference to countries, the Exhibition, so far as regards the juries, being considered as a whole, and not as consisting of a mere juxtaposition of separate displays by different nations. *Number of Medals:* The number of medals required by each class cannot be determined with precision before the examination of the objects. Guided by the experience of former exhibitions, Her Majesty's Commissioners have authorized the special commissioner to place a definite number of medals at the disposal of each jury, but have reserved the right of the council of chairmen to increase this number, if individual juries give reasons which are considered satisfactory by the council. *All Medals of one kind:* There are no gradations of medals, all being the same. The medals are to be awarded for merit, without any distinction of degree, and without reference to competition between producers. It is not the best manufacturer, in any particular branch of industry, who should alone be rewarded by a medal, but all producers who shall show by their exhibits, that their products are excellent in their kind. No exhibitor, however, can receive more than one medal from one jury. *General Instructions for the giving of Medals:* The council of chairmen do not deem it advisable to issue formal and positive instructions as to the conditions under which medals should be awarded, but think it expedient to offer the following suggestions to the juries, trusting in their ability to make rules for their separate guidance. The jury for Class XIII., Philosophical Instruments, will reward novelty of inventions, or novelty in the whole or part of the instruments exhibited, ingenuity of construction, new application of old principles, application of new priciples, improvements in beauty of form, increased durability, extended applications, excellence and precision in workmanship, economy of production. The jury for Class XIV., Photography and Photographic Apparatus, will reward the instruments of photography on the same considerations as are attached to the class of philosophical instruments. In regard to photographic impressions, they will reward novelties in the mode of production, durability, excellence in the results obtained, and artistic merit. With reference to photographic materials, novelty or new applications, increased sensitiveness, or powers of retention, and facilities of operating should be favourably considered.

## To Correspondents.

J. JEFFERSON.—So far as we know the authorities of the South Kensington Museum still publish their photographs. Their catalogue can be obtained at the Museum at the cost of a few pence.

J. R. P. FRAZER.—We are obliged by your letter and enclosures. As regards an instantaneous collodion, we cannot advise you to do better than follow the formula of Mr. England, given in our pages.

W. W. B.—It is somewhat difficult to speak of the character of a lens from the specimens of its work sent; as whether the lens be a good or a bad one, better results might have been obtained with it. The negative is as you state considerably under-exposed, and the model is not well lighted. The image is not perfectly sharp or well defined at any part. The lens may be a good one, and from the maker you name most probably is so, but it has a curved field, which accounts for the middle of a standing figure being out of focus when the head and feet are in. If a lens cover imperfectly, the falling off will of course show at the edges, but as regards curvature of field, it entirely depends upon the focussing as to where the defect is most apparent. If you focus for the edges the centre will be out. Probably this may be an excellent lens for some purposes, but scarcely well suited for card portraits with standing figures. A smaller aperture will reduce the evil.

A. B.—Prints may be placed in the acetate of soda bath previous to toning, direct from the printing frame.

CANTUAR.—We have never tried the addition of bromide to the collodion you name. It is possible that for some purposes, and with iron development, it might improve it. It is not certain that it does not already contain some. The best mode of adding bromide would be to make a solution of bromide of ammonia in alcohol, say 8 grains to the ounce, and then add half a drachm of the solution to an ounce of collodion, which would be at the rate of half a grain of bromide to the ounce of collodion. 2. The varnish in which you attempted to dissolve wax and failed, was probably a spirit varnish. Wax is very sparingly soluble in alcohol. You should use a benzine varnish, commonly sold as a "crystal varnish." Wax is freely soluble in benzine or in essential oils. Spirit varnish without wax, applied cold, so as to chill, may sometimes be used instead of ground glass with transparencies. A thin solution of starch may also be used. Leaving the unaltered iodide of silver would not answer well, as it would be too opaque, and would probably eventually darken somewhat.

M. A. O.—We have not answered your letter until we had opportunity of making some enquiry. From what we learn, the prints which were decided to be ineligible for exchange were not the same as those of which we spoke favourably. You will readily perceive that the referees can have no motive in the decisions at which they arrive, but a wish to do justice to all, and to elevate the art as much as possible; and you must remember that in order to make their unremunerated labours tolerable, or even possible, the rules arrange that their decisions shall be final, and not subject to question. We would recommend you, when one lot of prints is rejected, to resolve to improve and send some better next time. We feel assured that the referees, whether we are present at their deliberations or not, will gladly give a favorable consideration to all contributions, and that to a lady they would rather err on the side of lenient judgment than otherwise.

TROUBLESOME.—The alkaline gold toning bath with acetate of soda is largely and successfully used. It is well, if the chloride of gold contain free acid, to add just sufficient carbonate of soda to neutralize it. 2. Filter out the cyanide of silver precipitated in the silver bath, to which the cyanide was added by mistake. If there be any quantity, add more silver to the bath to restore its strength. The bath will not be injured if the cyanide were pure, except so far as its strength is reduced by the loss of silver. 3. We have not found acetic acid cause pinholes in the negative. 4. You have probably given your tannin plates too little exposure. You say that with honey and tannin you got a picture, but it required five minutes' exposure. It entirely depends on the state of the light, and the focus and aperture of your lens, whether that was a long or short exposure. It might be a very short one.

R. C. H.—Your lens would probably answer very well for enlarging. The size of the stop to be used will somewhat depend on the amount of definition given, the state of the light, &c. Probably about ⅜ths of an inch aperture would be found to answer. 2. It is desirable in enlarging to reverse the position of the lens. We are glad your glass house proves satisfactory.

J. G. B., Huddersfield.—All the accounts we bear confirm the conviction that honey is a decided advantage in the tannin process. We have not used gelatine with plates so prepared; but we see no reason to believe that a two-grain solution would retard at all. Probably with honey you will not need the gelatine coating. The experiments we described were with collodion made by ourselves; but we apprehend that any good bromo-iodized sample would answer. In cases where you wish to follow some formula, without the trouble of making collodion, you will find it a convenient plan to buy a good plain collodion, and then add such iodides and bromides as may be necessary. This is a better plan, and involves less trouble, than purchasing pyroxyline. The negative from which the enclosed print was taken appears to be very good; but three quarters of an hour is a frightfully long exposure for an open-air picture.

J. W. R.—We cannot tell in what point you have failed, but the process as described in the work to which you refer is successfully practised by manufacturers in gelatinizing the covers of fancy boxes, &c. Remember that it is necessary that the glass should be prepared with ox gall, or a trace of oil or grease, so that the gelatine shall not adhere firmly. A little practice, carefully observing all the instructions, will probably issue in success.

J. G. L.—The "black stuff" enclosed, which had been scraped out of the corners of ebonite dishes, appears to be simply some kind of india-rubber varnish. You will rarely find articles of this kind sent out by manufacturers chemically clean; photographers should always take the precaution to thoroughly cleanse new vessels. 2. The formula for a bromo-iodizing solution would depend somewhat on the character of the pyroxyline, and the purpose for which the collodion is to be used. You can add a little more bromide, using either the bromide of cadmium or of ammonium, to a bromo-iodized collodion, if it tends to over-intensity or hardness; or you may procure plain collodion, and iodize it yourself with iodide of sodium, 4 grains, and bromide of cadmium, from half a grain to a grain and a half, according to the quality of the pyroxyline and use of the collodion. Or, with iodide of ammonium or potassium, 2 grains; iodide of cadmium, 2 grains; and bromide of cadmium in the same proportion as above. 3. We think you will find the tannin and honey preferable to the tannin alone.

R. ALBURY.—We are obliged by your letter. We will make use of some of its suggestions shortly.

B.—The exposure necessary for the interior of a church will vary very much with circumstances, such as the number, size, and aspect of the windows, and whether they are of plain or coloured glass, &c. Your own judgment and experience must guide you. The interiors of St. Etienne, in Paris, by Mr. England, received exposures of five or six minutes. Use a bromo-iodized collodion and iron development.

Several correspondents in our next.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 195.—May 30, 1862.

## COPYRIGHT IN PHOTOGRAPHS.

On another page we give at some length the discussion which arose at the second reading in the House of Lords, of the "Copyright (Works of Art) Bill," in which protection from piracy is provided for photographs. We do so in order to impress on those concerned the fact that the Bill and their recognition in it, is by no means safe yet. We know there are, at the present moment, many photographers who are reserving, at temporary inconvenience and loss, with hopes of permanent gain, works ready for publication, until the Bill shall pass into law. It is important, therefore, that any influence which can be brought to bear shall not be neglected or relaxed.

We do not intend here to discuss the principle or the wording of the Bill; we believe both are capable of some amendment. But we accept the fact, with thankfulness, that a method is provided by which an artist or photographer may secure his property in the results of his own skill and labour, and that on the sale of such works means are provided for vesting the copyright in either vendor or vendee, as may be arranged and agreed.

We are concerned, however, to see the steady persistence with which apparently feasible, but really foolish and ignorant objections, are brought against the right of photography to be included in the protection of the intended Act. Earl Stanhope, whilst defending the Bill generally, and showing the groundlessness of the forebodings and vaticinations of objectors, stops short when he approaches photography. In defending the object of the Bill he cannot be gainsaid. "If," he observes, "it were once admitted that a man should profit by the fruits of his own genius, no person could fairly say that, having given a copyright to another, Parliament should refuse it to the artist. There was no difference in theory between a poem and a picture, and the producers of both had an equal right to protection." Why, in the name of common sense, the insertion of the word "photographic" before the words "artist" and "picture" in the above sentence, should alter the whole case, we cannot conceive. But he suddenly qualifies his arguments, and admits he feels some difficulty on one part of the Bill. "For example, he could not see how the principle of copyright could be carried out in the case of photographs. One person might make a copy of a photograph of the Coliseum, originally produced by another; but who could say that the copy was not an original photograph? How could any one assert that the person who published it did not go to the Coliseum, take his stand upon the same spot of ground as the other photographer, and commence his operations at the same hour? So, too, with respect to photographic portraits of living persons. He should be glad if some noble and learned lord could show how the proposed law was to be enforced in the case of photographs."

If the noble earl had understood anything of his subject, had known anything of photography or photographs, he would not have needed to ask how it was possible to distinguish between the works of different photographers. He would have understood that in photography it was as possible for the artist to stamp his individuality upon his productions, and be distinguished by his "manner," as in painting. If he will walk with us, or any one familiar with photography and photographers, through any public exhibition of photographs, we will undertake, unhesitatingly, to point him out at once, without reference to catalogue, the works of Bedford, Heath, Mudd, Wilson, or any other artist of standing, in landscape; or of Williams, Claudet, Mayall, and others, in portraiture. But another argument might have suggested itself to the noble earl. If photographs were so lacking in individuality as he seems to conceive; if photographs of the same place and person were necessarily as much "alike as two peas," a large element in the photographer's desire for protection would be removed. If all photographs were alike, the value of property in any of them would be at least much diminished. But one part of the injury done to photographs by piracy derives its force solely from this individuality. The pirated copies possess the style and manner of the artist who is plundered, but the work is bad, flat, mealy, and fading. Thus the original artist is not only robbed, but his works are travestied, and his reputation damaged.

Again, in the case of portraiture, there could rarely be any difficulty in enforcing the law or proving its infringement, because it would be very easy to prove, in the majority of instances, that the original of any pirated portrait never sat to the pirate for the picture in question, and that he could only have obtained a negative by reproducing it from an original print. The piracy would in such case be placed beyond a doubt.

But we can put a stronger case than this, in reference to many subjects, and one in which the wroug is still more patent. We have not, moreover, to suppose a case; there is one before us actually in point. The London Stereoscopic Company have just paid a heavy sum to Her Majesty's Commissioners for the right of photographing inside the Exhibition Building. Fifteen hundred guineas have been paid down, and an engagement entered into for the prospective payment, under certain conditions, of sums which may amount to twice the amount already expended. The Company have undertaken these heavy payments for the *sole* right of photographing in the building, and doubtless with the view to reaping the sole profit of such undertaking; and, if we are not mistaken, they are at present delaying the publication of the pictures until the passiug of this Bill shall give them protection. Without such protection the moment they publish their views, the sole right to obtain which has cost them some thousands of pounds, they are at the mercy of all who are sufficiently unscrupulous to profit by pirating the property of others. Now in such a case there could not be the shadow of a doubt as to the piracy; there could not be the slightest difficulty in proving it; for no other photographer could by any possibility get a negative of the building except by piracy, or other dishonest means.

That cases may be supposed in which some difficulty to prove piracy might exist may be granted. The Earl has supposed one case: two photographers may take negatives of the same subject, from exactly the same spot, with exactly similar lenses, on the same sized plates, and under like conditions of light and atmosphere. All this is possible, although not very likely. But even then it would be very easy to prove all this, and we venture to assert that it is next to impossible for two different photographers to produce two negatives, under whatever conditions, so exactly similar, that an expert could not readily distinguish whether one was a reproduction, or both were original negatives. Moreover, these things, which are easy for any photographer to produce, afford no temptation to piracy. If a photographer can easily get an original, he will not pirate for the mere pleasure of selling piracies. It is only where certain difficulties exist, where an amount of capital in skill or money, not possessed by the pirate, require to be expended in obtaining an original, that copying is resorted to. In portraiture the likeness of a distinguished person only accessible through the agency of position, ability, or influence, all of which constitute capital. In landscape, architecture, &c., places and scenes only accessible by privilege, or the expenditure of money. In subject pictures, where the genius in conceiving, and skill in working out, good ideas, not possessed by the incompetent. It is in regard to these, and such other things costing effort, skill, and money, and in which the property in an original is easily proved, that piracies are most usually practised, and not upon common-place subjects easily obtainable by all, and originality in which is not easy to dispute, nor worth the denial, that cases of piracy causing difficulty in enforcing the act would arise.

But the truth is, these and other frivolous objections raised, originate with those who have a material interest in the continuance of photographic piracy. These gentlemen have been more active we fear in opposing the protection of the Bill, than photographers generally have been in seeking for it. The Solicitor General informed the Lord Chief Baron, President of the Photographic Society, that he had received various communications purporting to come from photographers, stating that photographers did not wish for such protection! We have good reason to believe that Mr. Harvey Lewis, who opposed the protection of photographs when the Bill was in the Commons, was, as we then suggested, "coached" on the subject; but we did not then suppose that it was, as we have since been informed, by those interested in the maintenance of piracy. We have heard something of the arguments used against the Bill. It will cause endless litigation, it is stated. That can only happen if the pirates resolve on continuing their work; litigation can only arise out of infringement of the law; and in such case, all laws for the protection of society might be said to cause litigation. It will be a great hardship, it is urged, upon the multitude of small shopkeepers of various kinds. who now sell pirated reproductions of album portraits, &c., who knowing nothing about the art or the difference between reproductions and originals, will become quite innocently amenable to the law and its penalties. To this we may reply in the first place, that however ignorant some of these dealers may be of photography, they are not so entirely ignorant of the difference between copies and originals as might be supposed. They generally know how it effects the price. We have repeatedly lately inquired in such establishments, the prices of photographs, and asked why such a one was so much more than another. We have promptly received the answer, "This is from life, and that is a copy from another picture." If, however, this were not the case it in no wise affects the justice of the case. It is the duty of all persons engaging in any especial trade, to acquaint themselves with the laws which affect it. Moreover it would rarely occur we apprehend that the mere vendor transgressing the law in ignorance, would be called upon for penalties without warning, or except in the case of persistent delinquency. The law will not, unfortunately, be retrospective, and these dealers can continue the sale of the mass of rubbish which now disgraces the art, until the public taste is sufficiently educated to reject such things.

A variety of equally frivolous and more irrelevant arguments against the inclusion of photography in this Bill have been brought before us, and, we fear, before members of the legislature. It is quite possible that, even at this stage, unless every effort be made, that photographers will find themselves unrecognized by law, and without any protection against piracy.

## CARD PORTRAITS.

WE are in the habit of receiving from time to time, amongst other specimens of photography, various examples of card portraiture. As this class of portraiture is of very great interest to photographers at the present time, and involves some especial conditions, whenever we meet with unusual excellence, we endeavour to ascertain the precise formula used. We have noticed from time to time the artistic qualities of the late Mr. Lacy's, and Mr. H. P. Robinson's—a recent group by the latter gentleman, consisting of two lovely girls standing in front of a rustic arbour is the finest card picture we have seen, and was recently pronounced by a friend, one of the first landscape painters in water colours of the day, to whom we had shown a copy, to be the best photograph he had ever seen. We have noticed the portraits of Mr. Hawke as especially excelling in delicacy, roundness, and vigour. We have recently received some specimens from Mr. McNab, of Glasgow, which, besides many excellences of arrangement, accessory, &c., are unquestionable the most brilliant and vigorous, without being hard or wanting in delicacy, we have yet seen. The negatives from which they are produced are evidently of the very best class: sufficiently dense in the highest lights to preserve intact the purity of the white paper; but these high lights are most sparingly used, consisting of little more than mere points; there are no patches of white without drawing or detail. From these minute high lights, descending by the most delicate gradations of half-tone to the deepest shadows, in which, although still cautiously used, we have points of black, evidently bare glass in the negative. On an examination of such pictures, we see how sparingly either pure black or white may be used in obtaining brilliancy. It is in the infinite gradation and variety of tones, and not in crude harshly-contrasted masses of black and white, that this quality consists. It is necessary, however, in order to secure the widest scale of tones, to begin with the lowest. A brilliant negative must be clean and free from fog, commencing from bare glass. Mr. McNab's pictures eminently illustrate this; and as regards brilliancy and gradation of tone, they are perfect. Some very quiet inobtrusive scenic backgrounds are introduced with good effect. The definition towards the edges is not in all cases quite satisfactory, probably from the use of a lens of short focus, but the principal parts are very sharp and well defined.

Mr. McNab supplies us with a few particulars of his working, but, as will be seen, it is the old story; there is no secret to tell, merely careful application of well-known principles. It will be seen that he does not swear by any formula or process, but uses his judgment as to the method which will best suit the circumstances. He says:—

"It affords me the greatest pleasure to comply with your request in furnishing the formulæ (if such they may be called) in use by me. In the first place, the collodion is mostly of my own making, after Hardwich's formulæ: paper or cotton is prepared with weak acids at a high temperature to ensure intensity in the collodion; but sometimes I find it of advantage to mix it with that of other makers. The silver bath is prepared in the usual way, from recrystallized nitrate of silver, 35 grains to the ounce of water. If on using it for the first time, it shows a tendency to fog, it is slightly acidified with nitric acid. I develop with iron, 15 grains to the ounce of water when the light is good; but in cold weather, and weak indifferent light, it is increased to 20 grains. I sometimes find it of advantage to use the following:—

| | |
|---|---|
| Iron ... ... ... ... | 4 drachms |
| Acetate of soda ... ... ... | 1 ,, |
| Water ... ... ... ... | 17 ounces |
| Pyroligneous acid ... ... | 2 ,, |
| Alcohol ... ... ... ... | 1 ,, |

"The plates are developed and well washed, and put aside in a rack to dry, until we find it convenient to clean them. When they are dry, a line of varnish is put round the edges to prevent the film from being removed in the following operations of cleaning and intensifying. I find this saves much valuable time in the busy part of the day, while engaged in taking sittings. The plates are wetted again, previous to clearing them with cyanide of potassium.

"Discrimination and caution have now to be exercised in the selection of the treatment suitable for the various conditions of the deposit formed in the first development.

"Sometimes when the light has been good, the negatives are nearly dense enough, and but slight intensifying is required. In this case, pyrogallic acid, $1\frac{1}{2}$ grains to the ounce of water, and one or two drops of silver from a 30-grain solution is floated over the plate, until it has attained the required density. When the negatives, as first produced, are feeble, with slight deposit of silver, they are treated to a weak solution of iodine, which is floated upon the plates for a short time; they are afterwards copiously washed previous to applying the pyro and silver. At other times I find it better to intensify by pouring on a saturated solution of bichloride of mercury until the film is of a grey colour, after which it is washed, and a solution of iodide of potassium, of 1 grain to the ounce of water, is applied until a greenish yellow tint is produced, in which state I consider it best for printing. If carried too far, hardness is the result; if stopped somewhat soon, any amount of softness can be obtained. The length of exposure, and density of the negatives determines the course to be adopted.

"In printing I prefer *Rive* paper for soft negatives, and *Saxe* paper for hard ones. The sensitizing bath contains 90 grains of silver to the ounce; the paper is floated upon it from three to five minutes, according to temperature. I tone with Maxwell Lyte's formula."

We may remark, in conclusion, that Mr. McNab does not tone his portraits beyond a warm purple brown, which tint in our estimation gives the utmost effect of brilliancy and transparency obtainable in photography.

## THE WEATHER DURING THE COMING SUMMER.

A correspondent forwarded to us, some little time ago, a copy of a provincial paper, the *Kent Pioneer*, containing a series of observations, from which were deduced the conviction that the weather during the coming summer will be fine and dry. As photographers are pre-eminently interested in the question, we make a condensation of the remarks, for the benefit of our readers, who may take them *quantum valeat.*

The conclusions arrived at are based upon certain observations by the late Dr. Kirwan, who says:

"1. When there has been no *particular* storm about the time of the Spring Equinox (March 21), if a storm arise from the east on or before that day; or if a storm from any point of the compass arise nearly a week after the Equinox, then, in either of these cases, the following summer is generally dry, four times in five.

"2. But if a storm arise from the S.W., or W.S.W., on, or just before that Equinox, then the following summer is generally wet, five times in six."

The writer of the remarks to which we refer, has found the truth of those observations strikingly verified, and especially instances the last two years, of which he takes a retrospect, showing the conformity of the results with Dr. Kirwan's theory. Applying the same observations to the present year, he predicts a dry summer, and observes:

"Having just shown, as we trust to the satisfaction of our readers, that these observations of Dr. Kirwan are not undeserving of notice, we propose to apply them in our anticipations for the ensuing summer. In the first place, there was no particular storm, such as a hurricane, nor even a brisk gale, about the 21st of this month. But for nearly a week previous the wind was in, and near to, the N.E. On the 20th a great quantity of rain fell, the wind still in the N.E., and on the 21st we had a snow storm from that direction. None of the phenomena indicating wet have occurred; but on the contrary, those only that promise a dry summer. The weather itself during the past fortnight would by no means lead one to speculate from that, on the likelihood of a dry summer; but from observations of twenty years, we have no hesitation in saying that our belief is that the summer of 1862 will most probably be a dry one."

Photographers generally will be heartily glad if these predictions be verified.

# The International Exhibition.

## THE BRITISH PHOTOGRAPHIC GALLERY.

The photographic visitor to the International Exhibition, will, doubtless, be tempted, as we have been, to flit from one part of the building to another, examining, now the fine pictures of Notman, of Canada, then of Angerer, in Vienna, next, those of Ghemar, of Brussels, next those of Albert, of Munich, then, perhaps, those of Hansen, of Copenhagen, or Wothly of Aachen; and next, perhaps, those of Disderi, or Warnod, or Alophe, or Lyte, or Bingham in the French Department. He will, from time to time, visit these and others because they are new to him, and because they are well worth seeing, and above all—no light matter in a building of such extent and such attractions—they are easy of access. Until within the last few days, the British Department has not been in a state approaching completion or permitting criticism. Now, however, it is a little more in order; the awnings are erected, and some ventilation established; the covers are removed from apparatus—we wish we could say as much for the coating of dust on the pictures—and the place is presumed to be nearly complete, it may be more profitable to our readers if we endeavour to go through the contributions in something like consecutive order.

Before proceeding further, however, we must say a word or two more on the shortcomings of the place; not for the purpose of grumbling—we are tired of that—but in the way of warning some of the contributors of a danger which it may be they have not contemplated. Some of the contributors of apparatus have already found to their cost the trying alternations of temperature in the room. French polish has been cracked; collodion bottles have exploded; dark tents and boxes of pine have warped and twisted in all ways; cameras have been stuck together in their sliding bodies by the size with which the lamp-black was mixed to black the inside, melting; and a variety of similar evils have, we may say, been already discovered. Contributors of pictures, however, especially those living at a distance, may not anticipate, nor by personal inspection be able to ascertain, that their pictures are hung against damp walls. In the picture galleries this has already been found to act disastrously on some of the paintings; and steps are being taken, by lining the backs with American cloth, to put a stop to the evil. But no such care need be anticipated in regard to photographs. Already we are startled by the yellow cheesy effect of some specimens, which but a little time ago were pure and white. In water-coloured specimens the effect is still more disastrous. Many beautiful prints, carefully tinted in water colours, represent fair faces as covered with leprous and livid blotches, the effect of some of the pigments changing under the combined action of damp and gases exhaled from the materials of the newly made walls. We hope those contributors who have opportunity will, for their own sakes, look to this so far as may be possible. We may suggest that, in addition to other precautions, or where no other can be taken, a piece of cork, placed at the back corner of each frame, is known by experts in the management of pictures to afford a good protection against damp walls, by preventing immediate contact, and by being a non-conductor.

We have also one word to say about the hanging. Much fault has, we know, been found with this and the general arrangement. It is objected, indeed, that no arrangement of any kind seems to have been made, and that the various contributions of the same contributors are hung about the room at random. To this we may reply that it is an easy matter to find fault with what has been done; but it would not have been found so easy to have done differently. We can speak from personal observation of the industry and effort of the gentlemen to whom the thankless task of superintending this duty was committed. Two of the gentlemen forming the Committee, and the superintendent were, we know, constant in their attendance and indefatigable in their labours. The third gentleman of the Committee, whose name, we presume, was added to supply the inevitable aristocratic element, without which such affairs are supposed to be incomplete, is, we believe, guiltless of praise or blame iu this matter, except so far as either may be due for non-attendance. But in regard to the hauging, we repeat, we do not see how it was possible to do much better. The task was worse than making bricks without straw. Beset on every side with applications, the Committee granted allotments for every inch of space on the walls, and then failed to satisfy all applicants. The mass of contributions sent in were to hang somewhere, not one-fourth of them could be hung on the line, or in reasonably accessible positions. As for keeping the contributions of each photographer together, that would simply have been making the matter worse. A. for instauce, sends in half-a-dozen or a dozen frames, and because one of them is of sufficient excellence to occupy a central position on the best wall or screen, the remaining eleven indifferent frames are to be hung in the same place to the exclusion of the good frames belonging to B, C, D, and E, respectively. Where space permits nothing is more desirable than careful arrangement and classification, as adding to the convenience and satisfaction of visitors as well as photographers; but where mauy pictures have to be hung in limited space, the only attempt at justice can consist in giving, as far as possible, the best positions to the most worthy pictures, and where many contributions are sent by one person, iu aiming that at least some portion of such contributious shall, if worthy, be hung well, even if the remainder be skyed or cornered. But whatever attempt at selection might thus be made, one consideration was imperative: the pictures must be hung in such arrangement as they would best fit, and thus economise space. The result is, there is no denying it, very ugly; very bewildering; but the Committee deserve something better than unreasoning blame for their unrequited labours, aud we feel it only due to them to say, that, however unsatisfactory may be some parts, or the whole, of the Department, it arises from causes for which they are in no respect responsible.

A distinct catalogue, and a distinct system of numbering in accordance with this catalogue, has now been adopted. In some instances the process by which the pictures have been produced is appeuded, but not in all; nor are we furnished in every instance with the name of the subject. With such facilities, however, as we can command we shall proceed in our next to give some consecutive account of the contributions, which the length to which our preliminary remarks have exteuded, preclude us froni commencing this week.

## REMARKS UPON SOME OF THE APPARATUS EMPLOYED IN PHOTOGRAPHY.*

BY F. R. WINDOW.

### Plate Boxes.

Before considering whether the boxes sold for stowing photographic plates, are made in the best form that could be devised, it is necessary to examine the several uses to which they are intended to be applied, and to study the differeut requirements of each of them.

Plate boxes are used for stowing clean plates ready for immediate use; for preserving sensitized dry plates, or in some cases partially prepared plates which have to undergo another process before being ready for the camera; and for packing away negatives. I think it will appear that the plate boxes offered to us by manufacturers, are not entirely suited to any of these purposes, though at the same time I believe it may be shown that there is no difficulty in designing one, to fulfil the necessary conditions.

It is not usual or prudent to pack away plates cleaned and ready to use for any considerable time before they are required, as it is rare that the polished surface of the glass will retain for long that absolute dryness and cleanliness, which are in such a high degree necessary to ensure the most perfect results. Still, it is frequently a conveuience, especially to the amateur, to prepare beforehand to this extent all the glasses that are likely to be needed for the day's work, in which case, a plate box is the most handy receptacle. But it is necessary that no part of the surface of the glass should come in contact with anything, as, however harmless the touch may appear to be, it *may* have the effect of producing a stain upon the negative; and the direct contact with wood, especially those woods which have much essential oil in their composition, should be avoided. It is well known that if a piece of perfectly clean filtering paper (a cleaner thing than which it is difficult to imagine), be placed for some time between two polished glasses larger than itself, an impression of it can be seen upon each of them by breathing upon them, and this impression would probably be visible in negatives taken upon those glasses.

Now the grooves in the present plate boxes are merely rough cuts, as the tool left them, with parallel sides, and the surfaces of the glasses placed in them not only can touch the wooden divisions but *must* of necessity remaiu in direct contact with them so long as the plate continues in the box. It is true that, as the contact is only with the extreme edges of the surface of the glasses, probably little harm would result from this if the plate box were kept specially for this purpose; but if it have served previously for stowing negatives or uncleaned plates, foreign matter may have got deposited in the grooves, and the glasses will be stained. The simple remedy for this is to make the sides of the grooves V shaped, instead of parallel, when it will be impossible for any portion of the surface of the plate to come in contact with them.

For the permanent stowing away of negatives the plate-box is both cumbersome and costly if their number be at all considerable. Professional photographers in this country, mostly have cupboards with grooved shelves, suitable to each size of plate they employ. The number of the negative is scratched upon the plate itself with a diamond, and is writteu again upon a strip of paper laid along the edge of the shelf: so that reference to any particular negative is easy, and at the end of the day, after being used, it is returned to its proper groove.

A simple way for amateurs, who have not generally so many negatives to pack away to which daily access is necessary, is, when they are properly varnished and numbered, to place a piece of paper betweeu each couple laid face to face, and tie them up in parcels of say ten apiece: every parcel being labelled with the numbers of the negatives it contains, and an index made descriptive of the subject of the several numbers. In this way reference to any particular negative is easy, and the method is neither expensive or cumbersome.

Negatives that have not yet been varnished; that are in daily use, or that are not iutended to be permanently kept, must be temporarily stowed in plate boxes. For the reasons given above, the present plate boxes are not well suited to this end, as the rough and parallel sides of the grooves inevitably scratch the edges. This is frequently of little importance but sometimes it damages an essential part of the picture, and as the simple expedient of making the sides of the grooves V shaped (fig. 25), is all that is required to avoid the evil, it is to be regretted that mauufacturers continue to neglect this trifliug alteration.

Fig. 25.

Boxes for the above purposes may be of the present form with the exception named, and of the cheapest material, white wood being as effective as the most expensive.

* Continued from page 243.

The only intention in their use, is to preserve the plates from mechanical injury, and from dust.

Boxes intended to hold sensitized dry plates, have other conditions to fulfil, and it will be found a wise economy to provide separate boxes, devoted specially to this particular use, rather than to employ one kind indifferently for every purpose. They need not necessarily be expensive, but they cannot be made so low in price as the simpler class for negatives.

One of the chief causes of spontaneous decomposition in a sensitized dry collodion plate, is damp; indeed I am very inclined to believe it is the only one, and I think it not improbable that a prepared plate kept in a *perfectly* dry condition, would retain its sensitiveness indefinitely. The intrusion of air, which always contains a certain amount of moisture, should therefore be scrupulously guarded against. The joints and lid must be air-tight, and the pores of the wood—if that substance be employed in its construction—must be filled up. The grooves must be so formed, that no part of the surface of the glass can touch their sides, and they must be made of some material not liable to be scratched or chipped by the sharp and hard edges of the glasses as they slide in them, because the fine particles thus separated, adhere to the plates, and cause spots in the negatives. Metal boxes with metal grooves are open to this objection, as tiny spangles of metal are ground off by the hard glass, which cause a real amount of mischief. A coating of gutta-percha or india-rubber varnish, or a solution of any neutral and not brittle gum, lessens this objection to metal grooves, but the coating must be very thick to make their use perfectly safe, and I think it will generally be found advisable to employ at once some softer substance on which the friction of the glass edges has no effect.*

The fastening should be attached to the box, and not be a loose piece which can be mislaid: probably the best kind of fastening is a spring snap as with that the mere shutting down of the lid fastens it also.

As the grooves of the boxes must be made sufficiently large for the plates to slip freely into them, they do not offer a suitable means of packing the prepared glasses for travelling, as they would run great risk of being broken with a very little jolting; and if cotton wool, paper, or any other kind of padding be placed with them to keep them firm, they may get covered with dust. The dry plate box should only be used at home, and even then not to stow the sensitive plates away for any considerable time, but only to deposit such as are intended to be used within a limited period. Therefore the element of bulk need not be considered in their design.

There is no way, I think, of packing sensitive plates, whether for travelling, or keeping at home during a long period, so good as that adopted by Dr. Hill Norris for his gelatine plates, which are sent in this manner to all parts of the world, without being injured or loosing their sensitiveness. It is extremely inexpensive, compact, and entirely efficient, and for the reasons given above, to be preferred to any kind of plate box. Two strips of stout paper, about 6 inches wide are well dried and doubled up four times, making each a four fold strip about $1\frac{1}{2}$ inches wide. These are folded backwards and forwards as many times as the package is to contain plates: from eight to ten will be found a convenient number.

In the paper grooves thus formed the plates are laid one over another, one of the paper strips being of course placed at each end. When all the grooves are full, the back of a plate being outside top and bottom, they are tied round firmly with string and enveloped in paper, making a compact parcel. This is wrapped up in a piece of thin sheet gutta-percha, or mackintosh of suitable size, also securely tied round, and the whole is buried in bran contained in a common deal box, $\frac{1}{2}$ an inch larger each way than the packet. Plates so packed are securely guarded against light, atmospheric moisture, and rough usage. They will travel safely without further

Fig. 26.

protection, or can be put in a portmanteau, or bag. At home, they can lie in a drawer or on a shelf, and in all cases can be easily got at when wanted.

The following description of a box for sensitive plates, will not be found open to any of the objections I have stated; I think it will be found generally efficient, and at the same time not expensive. Wood should be selected as the material in preference to metal, as this latter when made of moderate thickness is too flexible to be of any serviceable protection to its contents in case of a fall or blow. But, for the double purpose of excluding air, and of preventing any escape of volatile essences the wood may contain, which might produce an injurious effect upon the prepared plates, it is necessary that the pores of the wood be effectually closed. This is achieved by soaking the various pieces, after they have been properly shaped, for a few minutes in melted beeswax. The ordinary white wood generally used for plate boxes is well suited, as its soft structure readily absorbs the wax. When each piece has been thus treated, and the superfluous wax well wiped off from the surfaces, the box is to be put together with a waterproof glue and screws The lid is fastened on with strong hinges in the usual way, and closed with a spring snap. Upon the edges of both the box and the lid, are fastened bands of vulcanized india-rubber, previously boiled in potash to extract all the free sulphur, which, when the lid is closed, press firmly on each other, like the human lips, and form a perfectly air-tight joint all round. The grooves for the glasses are of the section shown in fig. 25, stamped out of stout sheet gutta-percha, and fastened into the box with a waterproof glue or other cement. The gutta-percha extends to the bottom of the box, but the grooves finish about $\frac{1}{4}$ of an inch from the bottom, so that the plates may be kept from contact with the wood.

It will be seen that such a box may be kept in any climate or atmosphere, or even under water, without the sensitive plates contained in it being in any way injuriously affected.

(*To be continued.*)

* Since writing the above I have seen a very excellent plate box, intended specially for stowing sensitive plates, manufactured by a well-known photographer, in which gutta-percha, grooves, nearly similar to those described, are used. These plate boxes are very well suited for the use for which they are made, and can be obtained of all sizes at a reasonable price.

## Scientific Gossip.

Fusion of Two Hundredweight of Platinum—Nitrate of Silver—Rock Salt and Aniline Purple in the Exhibition—Examination of Glass in the Spectroscope.

At the time that M. St. Clair Deville's experiments were known to very few in Paris even, and totally unknown in England, we published the first descriptions of his wonderful results which appeared in this country. Great was the astonishment and incredulity with which the account was received. It is true that platinum had often been melted by the oxyhydrogen blowpipe in small masses, and scientific men were not unprepared to hear that lumps of some ounces in weight had been reduced by this means to a liquid form; but when we inform them that 20, 30, and even 40 lbs. of it had been liquified at one operation, the figures were thought by many to have been a misprint. A few months, however, showed that we were perfectly correct in our statements, and long after philosophers were thrown into a state of scientific amazement by the full publication of Deville's wonderful metallurgical processes. Athough devised by a French *savant*, the process has, we believe, met with the most extended application in England. Messrs. Johnson and Matthey, the well-known metallurgists of Hatton Garden, having immediately seen the importance of the process, and made arrangements with the inventor for employing it in in their works. The crowning feat of all has just now been performed. In the presence of the inventor, aud a goodly collection of English and Foreign *savans*, this firm accomplished an operation hitherto unparalleled in the science of metallurgy. In their lime crucibles and furnaces, and by the calorific action of ignited jets of mixed oxygen and hydrogen, they reduced to a perfect fluid state, and then run into a mould, a mass of platinum of the astounding weight of 2 cwts.

This magnificent ingot, of the value of £3,840, is now one of the most striking ornaments in the Metallurgical Department of the Internatioual Exhibition. In order to show the extreme fluidity of the melted metal, the lump is purposely left in the state in which it came from the roughly constructed mould; the metal has ruu into every minute crevice, between the blocks of which it was built, and illustrates in a striking manner the great adaptability of this metal for castings. The still more highly refractory metal, iridium, has also succumbed to the enormous temperature at their disposal, and is present in the same case, in the form of a perfectly fused lump, weighing 27¾ ounces. The manufactured metals exhibited by this firm are also of the highest interest; they show an enormous platinum boiler, capable of rectifying three tons of oil of vitriol of full strength in twenty-four hours. This is worth £465. Coming to articles of more special interest to the photographer, we find some beautiful specimens of gold, both in the metallic form, and also in the form of neutral chloride of gold, prepared especially for photographic purposes. There is likewise upwards of £80 worth of silver in different forms, viz., a lump of chemically pure silver, weighing 41 ounces, a bar of the same metal, melted by the combined gases, weighing 377 ounces; nitrate of silver commercial, and fused into sticks; and finally some beautiful specimens of fused and recrystallized, nitrate of silver, prepared especially for photographic purposes, and hermetically sealed in glass tubes for exportation.

Passing on to the Chemical Department of the Exhibition, after braving the difficulties of the subterranean passage, and with difficulty, and after much enquiry, finding our way through the ponderous iron forgings and mineral products into the Eastern Annexe, as it has become the fashion to designate this remarkably ugly and ricketty shed, we find ourselves amongst a collection of scientific products the inspection of which amply repays us for the difficulties and dangers encountered in our voyage of discovery. One of the first objects which meets the eye is the pillar of rock salt supported upon large square blocks of the same material. This is shown in the same state in which it was dug from the mine, and is of some photographic interest, inasmuch, as it illustrates, in a striking manner, a fact which we have taken several opportunities of impressing upon our readers. Pure chloride of sodium does not, as our readers well know, absorb moisture from the atmosphere, but the presence of small quantities of certain mineral impurities communicates to it deliquescent properties. The mass of salt in question affords a fine illustration of this fact. Close examination shows it to be always covered with a film of water collected here and there into drops, whilst the floor upon which it rests is soaking wet with brine for some distance round it. It is growing small by degrees and beautifully less, and before many weeks are over the boards in that department will only require sprinkling with nitrate of silver solution to render them in a high state of photographic sensitiveness. The Stereoscopic Company, who will require positives printed by the acre, would do well to avail themselves of this interesting phenomenon. The natural tendency of this salt to absorb from the atmosphere is not diminished by the leakages in the roof. It is a great pity that this beautiful specimen of the product of our English mines is not better protected, it far more deserves a glass case than many substances prettier, perhaps, to look at, but of considerably less commercial importance. From mineral salt to mineral coal is an easy transition, and the latter naturally leads us to the magnificent products derived from its destructive distillation. The best known of these, coal-gas, we shall not mention, but the splendid array of coal-tar colouring matters, is too important to be passed by. One of the first things that strikes the eye upon entering the department is the gorgeous display of Messrs. Perkin aud Sou, as the originators of a branch of industry entirely new since 1851. These gentlemen certainly deserve prominent notice. They here show us a collection illustrating their manufacture of mauve or aniline purple from the rough coal-tar to the pure dye; a lump of the latter, upwards of a cubic foot in bulk, the product of 2,000 tons of coal, occupying one corner of the case, whilst the centre is filled up with dyed specimens of all kinds in skeins aud fabrics with the various mordants used in fixing the colour. The completeness of the collection will give it an interest to all intelligent visitors beyond the beauty of the display, and will make them readily appreciate the happy intelligence which succeeded in extracting "a thing of beauty" from the vilest refuse, aud the skill which has adapted it to the most agreeable forms of decoration.

Two specimens of yellow glass have been sent us by a correspondent for examination in the spectroscope; they are, both to the naked eye and in the instrument, of the same quality—a rather light orange yellow. A spectrum examination shows that they are but ill-adapted for photographic purposes, as they allow considerable quantities of green and blue rays to pass through. Placing one over the other effects some improvement, but even then some chemically acting rays filter through. When perfectly good glass is easily obtained for illuminating purposes, we do not counsel the employment of an inferior variety.

## SENSITIVE DRY PROCESSES.

BY H. COOPER, JUN.

During the last four months, I have been making experiments to ascertain which is the simplest, most sensitive, and surest of the dry processes. The processes I took to experiment upon were the tannin, Mr. England's modification of ditto, the morphine, alkaline gelatine, alkaline resin, plain washed collodion, and morphine resin. The collodion was a mixture of Ponting's, and one iodized with iodide of potassium and cadmium, and bromide of cadmium. The bath, 35 grains of nitrate of silver, and $\frac{1}{10}$ of a minim of acetic acid to the oz. I prepared six plates by each of the above methods; I will give a short epitome of my method of preparing them, so that a more definite conclusion may be drawn between the conflicting merits of each:—

1. *The Tannin.*—Coated and sensitized a perfectly clean plate, washed thoroughly, and coated with solution of tannin 15 grains to the oz. I ran a brush-full of varnish, prepared as follows, round all the plates to prevent slipping of the film:—The varnish: 1 drachm of shellac and 1 drachm of fused gum benzoine to enough alcohol to form a solution about double as thick as Sœhnée varnish. The advantage of this solution is, that it adheres firmly to the glass, but can be easily removed by alcohol, to which a little nitric acid has been added.

2. *Mr. England's Modification of the Tannin.*—Proceeded as before, but coated with—

| | |
|---|---|
| Tannin ... ... ... ... | 15 grains |
| Pure honey ... ... ... | 16 ,, |

to the oz. of water.

3. *The Morphine.*—Took a good working negative bath strongly acid, and added ¼ grain of nitrate of morphine, previously dissolved in a little distilled water, and filtered out the black deposit. Coated and sensitized the plates; thoroughly washed and dried.

4. *Alkaline Gelatine.*—Coated and sensitized a plate in the ordinary bath, washed and coated with a warm solution of gelatine, 15 grains to the oz. I forgot to say, that before coating with gelatine I added 5 grains of carbonate of soda to the salt bath used for soaking the plates in.

5. *Alkaline Resin.*—Added 1 grain of gum guaiucum to each oz. of collodion, coated and sensitized the plates in the ordinary bath, washed, soaked in the alkaline and salt bath used for the last plates, for five minutes washed, and dried.

6. *Plain Washed Collodion.*—Simply washed a sensitive plate in an unlimited quantity of water, and dried.

7. *Morphine and Resin.*—Sensitized a plate coated with the collodion containing the gum guaiucum, in the morphized bath. Being determined to give them a fair trial, I kept them all for three weeks. Then I took, as my standard of sensitiveness, Ponting's collodion, and a nearly neutral bath, with which I have taken negatives in ½ of a second. Exposed each kind on same day, on same subject, &c. The results were as follows:—The tannin developed with pyrogallic acid, after being wetted with cold water, required *twenty* times as long as the wet plate. One wetted with water at 160° required twice as long as the wet plate; but the film required *great* care to prevent its slipping. I lost the first plate I tried by this method, by *dipping* in the fixing bath (hypo); for on washing it very carefully, to my great astonishment, the film which had appeared perfectly firm, slipped off, so that I saw the picture slowly float down the sink.

2. Mr. England's modification required, with cold water, twice as long as the wet, and with water at 120°, half as long again; so that it will be seen that the hot water did not exert the same accelerating effect as in the tannin prepared by Major Russell's method.

3. *The Morphine* I found to be about equal in sensitiveness to Mr. England's tannin, but yielding a much softer negative, and being, also, more free from stains, &c.; so that, on the whole, I prefer the morphine, for which every photographer ought to thank Mr. Bartholomew.

4. On proceeding with my experiments on the alkaline gelatine, I was much disappointed in this process, as I had hoped, at first, great things from it. With cold water it required three times the exposure of the standard wet plate; with hot it took about the same time as the wet, but the picture was covered with a fog, which could not be rubbed off. Some might fancy that this fog was produced by over exposure, but to test it I exposed a plate for a much less time, when only the high lights appeared, but the same annoying fog appeared in full vigour. Great care is also necessary in the preparation of the plates, to prevent a net-work formation covering the bottom of the negative. It is produced if the soda be mixed with the gelatine, or if the soda be not thoroughly removed by washing, if applied before or after the gelatine.

5. The alkaline resin I found to be less sensitive than the preceding, but easier to work.

6. With the plain washed collodion I have had some very curious results. Some two months ago, I prepared a batch of plates by this process. After spoiling a good many, I succeeded in the following way:—Expose for same time as wet collodion, soak for two minutes in distilled water, then just *dip* in the bath, wipe the back, and develop with—

| | |
|---|---|
| Sulphate of iron ... ... ... | 15 grains |
| Sulphate of copper ... ... | 10 ,, |
| Acetate of soda ... ... ... | 1 [illegible] |
| Citric acid ... ... ... | 1 ,, |
| Acetic acid ... ... ... | 15 minims |
| Water ... ... ... ... | 1 ounce |

The negatives developed in this manner were very fine, all that could be wished, soft and brilliant.

On exposing and developing one of the six prepared with the others for these experiments I was astonished to find not even the trace of an image after prolonged development. In the last week's NEWS a correspondent writes to say that he has met with something very similar; but it appears he used no silver in developing, which would easily account for it; but mine was dipped in the bath. I then exposed one for five minutes with no better result. Thinking that something might be wrong with the developer I exposed one and developed it in a totally different way with fresh chemicals, as also the remaining three plates, each in a different way, but the film remained perfectly white and clear, no kind of stain of any kind, or any trace of an image appearing. I have not had time since to prepare any fresh plates, but I soon hope to do so, when perhaps I may find some solution of this strange behaviour of the film.

7. *The Morphine Resin* I found to be very clean, bearing a good deal of rough usage, and being nearly as sensitive as the plain washed *morphine.*

Having heard a good deal of Dr. Norris's plates being developed satisfactorily with hot water after a very short exposure, I procured some of those plates, and the results were quite sufficient to justify the praise which they have received. I am afraid that this paper has exceeded the ordinary limits, but those who have had to write on subjects in which every detail is important, know how difficult it is to express oneself clearly, and so that no one may be misled, in a short space. Pleading this as my excuse, I will only ask those who have time to make carefully some such experiments as I have endeavoured to explain, so that we may soon reach the "consummation devoutly to be wished," an instantaneous dry process.

## COPYRIGHT (WORKS OF ART) BILL.

House of Lords, Thursday, May 22nd.

EARL GRANVILLE, in moving the second reading of this Bill, observed, that under the present state of the law, artists and engravers were entirely without protection for works of art. The purchaser of such works was also liable to have them pirated, and inferior works of art might be passed off as the productions of masters. Besides, some change was required in our law, in order to enable us to avail ourselves of the provisions of international treaties, with reference to this subject. Under this Bill the artist was to have the copyright of a picture or other work or art during life; but, as between the artist and purchaser, it was necessary that there should be a written agreement. After that agreement was made it was to be registered in the same manner as a literary work. There was a provision to the effect, that copyright should not in the slightest degree interfere with the reproduction of any scene or object. Protection was only given to the work of art as it stood. He would not on that occasion go into the details of the Bill, which were matters of procedure. He should be glad, in committee, to receive suggestions from any noble lord; but, as it was desirable to confer with others on the subject, he hoped notice would be given of them before going into committee.

Lord OVERSTONE had great doubts as to the propriety of their lordships reading this Bill a seconding time. It was an artists' Bill, for protecting the interests of artists, and without any reference to the interests of the general purchasers of pictures, the interests of purchasers of pictures by commission, and the interests of the public at large. It was always understood that the fundamental principle of patent rights was, that there should be some invention, something new, creative, on the part of the individual seeking their protection. In consideration of granting that exclusive protection, it was also understood that at the end of a certain period there should be an effectual dedication of the invention to the public interest. Neither of these objects was provided for by this Bill. His main objection to the Bill was, that it did not discriminate as to the character, position, and interests, as well as the reasonable rights, of the various parties concerned. If a person ordered a portrait to be painted of himself or of any member of his family, or if he commissioned an artist to produce a picture upon a given subject, surely common sense required that the copyright, if there was to be a copyright, should at once be vested in him rather than in the artist. Such was the law in France, such was the law that reason and justice would dictate, but such was not the law that this Bill contemplated. Again, the Bill provided that copyright might be reserved at the time the picture was produced, but the registration of it was not necessary for a twelvemonth. The consequence would be, that there would exist a patent right unknown to the public for the whole period of one year. It was obvious that, if a copyright was to be granted, the registration of it should accompany, if not precede, the first production of the work, otherwise copies made and sold in good faith would be liable at any moment to be seized and suppressed. Even the language of some of the clauses was calculated to give rise to a great deal of doubt, and he believed that much litigation would result from the passing of the Bill, particularly that portion of it which related to the fraudulent imitation of works. The Bill, if pressed forward, would require very careful consideration, and he thought it should be withdrawn and a different measure introduced in another session.

Earl Stanhope did not think the noble lord had stated any valid objection against the principle of the Bill. The noble lord had spoken as if the Bill were retrospective in its character. No doubt that idea was in the minds of several persons when the Bill was before the other House, and he knew that some great publishing houses were afraid that their property in illustrated works would be destroyed; but if their lordships would look at the Bill, they would see, especially from the commencement of the first clause, that it was entirely prospective. Moreover, though the Bill were to be passed to-morrow, it would still be in the power of a purchaser to make a bargain with the artist whom he employed that the copyright should be vested in him. When, many years ago, he had charge of the Literary Copyright Bill in the House of Commons, he was opposed by some persons who anticipated all kinds of disastrous consequences from the passing of the measure. Those anticipations had been entirely belied by the result, and the same would be the case in the present instance. If it were once admitted that a man should profit by the fruits of his own genius, no person could fairly say that, having given a copyright to another, Parliament should refuse it to the artist. There was no difference in theory between a poem and a picture, and the producers of both had an equal right to protection. He admitted, however, that there were one or two points in the Bill on which he felt some difficulty. For example, he could not see how the principle of copyright could be carried out in the case of photographs. One person might make a copy of a photograph of the Coliseum, originally produced by another; but who could say that the copy was not an original photograph? How could any one assert that the person who published it did not go to the Coliseum, take his stand upon the same spot of ground as the other photographer, and commence his operations at the same hour? So, too, with respect to photographic portraits of living persons. He should be glad if some noble and learned lord could show how the proposed law was to be enforced in the case of photographs.

Lord Taunton entertained great doubts as to whether the true interest of art or artists would be promoted by the operation of the Bill. A good picture should, he thought, be its own protection against the art of the copyist; and he, for one, had no sympathy with the man who purchased a picture and laid it up in his gallery for the purpose of boasting that he possessed something which nobody else could procure. The Bill, moreover was, he was afraid, calculated to give rise to litigation, and on these grounds he was not disposed to look upon it with favour. It might benefit the dealer in pictures, but he did not believe it would operate for the advantage of the artist or the public at large.

The Lord Chancellor was surprised to find that while a man was allowed a property in that which was, in the ordinary way, the work of his hands, it should be gravely contended that in those productions which were the creations of the mind no such right should be admitted. For his own part, he was entirely of the opinion which was expressed by the great Lord Mansfield, to the effect, that in all works of the mind and of genius the common law of this country ought to be held as giving an absolute property. After great exertion, the imperfect state of the law, so far as literature was concerned, was amended to meet the requirements of the case, but the fine arts were still left without an adequate protection—the painter, in point of fact, without any at all. As an illustration of the justice of that view, he might mention a case in which a celebrated artist sold a picture for a considerable sum, of which some time after, a copy was produced, with the name of the artist attached to it. The person by whom it was so attached was indicted for fraud and forgery, but it was held he was not amenable to the law. A state of things such as that, surely stood in need of alteration nor was it due merely to our country, but to foreign nations, that some step should be taken in the matter. As far as the artist was concerned, there was no possible ground why he should not receive the same protection as the poet and historian. The purchaser of a work of art would also obtain benefit from the passing of the Bill, as the measure would tend to prevent inferior repetitions of works of art from being improperly hawked about. In these respects the Bill proceeded not only on the principle of justice, but of great expediency; and, as regarded the public, its operation would be most advantageous, because in proportion as protection was given to works of genius, and the remuneration of the artist thereby enhanced, would productions of beauty and talent be increased in the country. Some observations had been made in reference to the provision which related to alterations made in a work of art; but that provision had been introduced in consequence of it being known that many pictures, in respect to which alterations had been made, were sold again as the works of the original painters. As an illustration of this, he might mention that in a picture painted by Mr. Charles Landseer there were introduced the figures of two dogs, which received some touches from his brother, Sir E. Landseer. The picture got into the hands of a dealer, who cut out the figures of the dogs, and sold them as the work of Sir E. Landseer, and having repaired the hole in the original picture, and got it painted over by some inferior artist, he then sold it as the work of Mr. Charles Landseer. These were some of the frauds committed on artists, and, without being actuated by petty feelings, they might naturally manifest some sensitiveness on the score of their reputation at being so treated. A point had been raised respecting the difficulty of proving in some cases that photographs were copied, but he thought it possible that the copy of a photograph might be sufficiently detected, as it would be hardly possible for two persons to produce representations of the same object under exactly the same conditions of light, position, and other circumstances. He did not deny that there were many provisions in the Bill which would require careful consideration in committee; but the great principle of the measure, which recognized property in works of art, and the adoption of which had been too long delayed, was in accordance with a natural feeling of justice.

The Bill was then read a second time.

Friday was appointed for the consideration of this Bill in committee. It was announced, however, that it would be postponed till the Tuesday following.

Lord Overstone trusted that the postponement of the Bill might be taken as an indication that the Government was alive to the full force of the objections which had recently been urged against it. It was not his intention to propose any amendments in committee; but, nevertheless, he might throw out one or two suggestions for the consideration of the Government. In the first place, he thought it was reasonable and proper that the words, "new and original," should be introduced before the word "picture," in the first clause. Secondly, he thought that if Parliament were prepared to grant a copyright, it ought at once and absolutely, without any necessity for negotiation and arrangement between the parties, to vest that right in the employer, and not in the artist. Such was the law in France, and in the discussion upon the Bill the other night the Lord Chancellor rested his argument upon the expediency and necessity of making our law correspond with that of our neighbours on the Continent. His third suggestion had reference to the question of registration. Not a single word had yet been said in explanation of that extraordinary clause in the Bill which provided that copyright was to be obtained without the necessity of registration, except after the lapse of a twelvemonth. An arrangement more inexpedient, more impolitic, and more inconsistent with justice, could not well have been devised. He trusted the objections which had been raised against the Bill would lead his noble friend, the President of the Council, more carefully to consider its provisions, and introduce into it those modifications of which it stood in need.

Lord Taunton observed, that under the operation of the Bill, as it stood, an artist in Australia who happened to make a copy of a work sent out to the colony might do so without knowing that the work had been registered in this country, and might, in consequence, unwittingly be subjected to all the inconvenience which the penal operation of the Bill would entail.

Lord Chelmsford suggested that the further consideration of the Bill should be postponed to Friday.

The suggestion was adopted.

## Proceedings of Societies.

### North London Photographic Association.

The last meeting of this association, before the summer recess, was held in Myddelton Hall, Islington, on the evening of Wednesday, May 21st, Mr. G. Shadbolt in the chair.

The minutes having been read and confirmed, the following gentlemen were elected members of the association:—Messrs. J. Turner, Wm. Cornish, and J. Sinclair.

Mr. Hill presented two fine photographs from metagelatine negatives to the Society's portfolio.

Mr. G. Dawson, Lecturer on Photography, at King's College, then read a paper on the practical working with the panoramic lens, in the course of which he exhibited the apparatus, and gave practical illustrations of some of the manipulations, and also exhibited a series of prints he had taken to show the class of subjects to which the lens was peculiarly adapted, and those which should be avoided.

Mr. Dawson, having coated a curved glass to illustrate the best mode of manipulation, a conversation on the subject followed, as to the influence on the collodion film of supporting the plate on the tips of warm fingers, some gentlemen suggesting, that the use of india-rubber finger stalls would be an advantage from their non-conducting quality. Mr. Dawson responded with an adage, having reference to a "cat in pattens," and said, he found the simplest plan was to change the position of his fingers, thus avoiding continued contact with one part of the plate.

A conversation on the use of spirit levels followed. Mr. Dawson had pointed out that the camera was furnished with two, to show the slightest inclination in either direction, which was important in all cameras, but especially so in the panoramic.

Mr. Hill did not see any possible advantage in having two spirit levels of the cylinder form, over one of the circular shape, which would show the inclination in any direction.

Mr. Shave had not either of much use, as he had seen a camera placed considerably out of truth without the spirit level showing it.

Mr. Martin suggested that the level had not been properly adjusted in the first instance. In order that a spirit level on a camera might be of any service, it was important that all the surfaces, that of the top glass, the brass, and the wood on which it rested, should be quite parallel to each other; and, also, that the mixture of spirit and water should be in right quantity. If these things were attended to it could not fail to be useful.

A conversation on the dilute form of developer, recommended by Mr. Dawson ensued. He was in the habit, when using pyrogallic acid, of diluting the ordinary one-grain solution with five of water, in order to cover the curved glass without stains.

Mr. Wharton Simpson referred to the method described some time ago by Mr. Vernon Heath, of first covering the plate with distilled water, and then adding that water to the developing solution, by which means he avoided stains and secured slow development, and consequent softness.

The Chairman thought it would be difficult to make the distilled water flow readily over the curved glass, without causing stains.

Mr. Simpson said, of course the freedom in flowing would depend somewhat on the condition of the bath; in a new bath it would flow easily enough; in an old one, containing much either and alcohol, it would be repellant at first, but that would not cause stains, as there would be no chemical action.

A member suggested that the use of citric acid would retard the action of the developer sufficiently to allow the curved plate to be covered without causing stains.

Mr. Dawson said he generally found the use of citric acid rendered longer exposure necessary.

A conversation on the use of dilute iron developers followed, in which Mr. Hill said, he thought that too little attention was given to the importance of increasing the quantity of acid in iron developing solutions in hot weather.

A conversation on economy of water in the field, cleaning glasses, &c., followed.

Mr. Hill said he used only one cloth in cleaning glasses, and that had been in use for months. The glasses, after being roughly washed, were dried with this cloth, and then a little collodion poured on the plate, and rubbed with one piece of cotton wool, and the plate polished with another piece. This old cloth, and two pieces of cotton wool had been in use a long time, and were his complete equipment for cleaning glasses.

A member suggested, "and a wash-leather;" to which Mr. Mill replied, "No;" and

The Chairman remarked that considerable difference of opinion prevailed as to the use of wash-leather for polishing glasses. For his own part, he considered it a most fertile source of dirty plates.

Messrs. Hill and Moens both agreed in this opinion.

Mr. Dawson said, Mr. Hill's method reminded him of that of the peripatetic photographer, who moistened the plate by a very summary process, and wiped it on his sleeve (with a pantomimic illustration).

Mr. Shave asked Mr. Dawson, if he were going out again on a photographic tour, which camera and lens he would prefer to use, the panoramic or the ordinary form?

Mr. Dawson said it would depend on the class of subjects he was going to take. For some subjects the panoramic lens was pre-eminently well adapted; but for ordinary work the other was better. He was not advocating the universal use of the panoramic lens. It was a special lens, for special work.

Mr. Moens suggested, that in all panoramic views where several plates were now used, the lens would be valuable. He wished to know the price of the curved glasses?

Mr. Simpson believed they were eighteen shillings a dozen.

Mr. Dawson regretted Mr. Ross was not present to answer questions of detail, which he did not remember; but he had in his pocket a letter of apology from Mr. Ross, who was prevented from indisposition from being present. The chief difficulty he had met with was, the glasses not being quite true, or all of the same curve. If they could be bent perfectly to a certain guage it would be a great improvement.

Mr. Simpson believed it was originally intended to do so; possibly, when they were more used, that would be done.

A conversation on the difficulty of getting the glasses perfectly clean followed, in which it was suggested, that as they formed sections of a blown cylinder, if the plates were rubbed crosswise, which would be in the direction of the length of the cylinder, they would be cleaned more easily, as the fine lines formed in blowing would be in that direction.

Mr. Foxlee asked how often the lens required refilling with water?

Mr. Dawson said he had only worked with it for two or three days. The first day, as he had explained, he used common water, and was troubled by the fixed air forming bubbles on the inside of the glass; after using distilled water, he had no further occasion to change the water.

Mr. Moens asked if spirit would not keep better, if the lens were filled with it?

Mr. Simpson said, spirit would have a different density to water.

The Chairman said the calculations were for distilled water; spirit, having a different density, would have a different refractive power. Referring to the shape of the bath, he might remark, that if the inner curve were the arc of a circle, in the slightest degree larger than the outer one, there would be no danger of injuring the film; it might then, also, have as little depth from from front to back as might be desired. The front and back might, in fact, join at the edges, and form a crescent.

A conversation arose on the manufacture of the curved baths in glass. Mr. Dawson, having expressed a conviction that gutta-percha injured the bath,

Mr. Simpson said he believed that if the gutta-percha were pure, no such injury would occur. He had left a bath for four years in one gutta-percha bath, without the slightest injury.

Mr. Hill had met with similar experience. He had his bath of Burgess and Key, and believed all their's were made of pure material.

Mr. Martin suggested that, probably, the baths referred to were purchased many years ago, before gutta-percha was so largely adulterated. Manufacturers of photographic vessels of gutta-percha were dependent upon the purity of the sheet gutta-percha they bought for the purpose.

Mr. Simpson said, the purity of sheet gutta-percha was chiefly a matter of price. Manufacturers of photographic vessels would, doubtless, be able to obtain a pure article if they would pay the price. Pure sheet gutta-percha, of a thickness suitable for photographic vessels, was, he believed, worth about four shillings per pound, whilst an article of similar substance and appearance, but not pure, could be bought for eighteen pence a pound. The latter, he feared, was too often made into photographic baths by some makers.

Mr. Dawson said he had long held the opinion that gutta-percha might be used with impunity, but a careful examination of the matter had convinced him that he was wrong. He had made ten ounces of bath solution, and put half of it into a gutta-percha bath for a short time; he then applied Barber's test for organic matter, making the solution slightly alkaline, and exposing it to the light. That which had been in the gutta-percha turned black and turbid, whilst the other was unchanged.

Mr. Simpson had some years ago given a good deal of attention to the subject, and he then applied a test of a similar character, but, he thought, even more severe. He made a new neutral bath of nitrate of silver, and placed it in a bottle; he then cut up some very pure gutta-percha into fine shreds or shavings, and put a large quantity into the solution, so as to secure as large a portion of acting surface as possible. The bottle was then placed in the light for a few days, without any blackening or change taking place.

Mr. Dawson asked if the solution was made alkaline?

Mr. Simpson said it was nearly neutral, just in fact, in good working condition. A picture was taken with it before this treatment, and another after, without the slightest apparent change in the condition.

A conversation on the subject followed, in which Mr. Sang's suggestion of varnishing the interior of gutta-percha vessels with shellac was referred to.

Mr. Bingham said that the shellac in such cases was apt to crack.

Mr. Moens asked what was the best method of preventing the india-rubber lining of the top from sticking to gutta-percha baths, with watertight tops.

Mr. Simpson suggested the use of vegetable parchment over the india-rubber.

Some further conversation followed on the use of gutta-percha dippers with iron supports, &c., after which the subject dropped.

Mr. Barber exhibited a bottle of a collodion, which was usually known to be quite colourless, and was thought to be a cadmium collodion. This was, however, quite red. He showed this to illustrate the uncertainty of organic chemistry, and the difficulty of making in collodion a perfectly uniform article. After some conversation on the subject,

Mr. Seely showed some negatives recently taken on tannin plates. After some conversation on the subject,

The Chairman asked if any one had tried honey and tannin, as suggested by Mr. England?

Mr. Seely had tried it, but could not get such clean negatives as without the honey.

Mr. Simpson had tried about a dozen experimental plates with honey and tannin, and was highly gratified by the results. The plates were extremely sensitive, and the quality of the negatives was excellent. The manipulation was extremely simple, less than usual care being required apparently in the preparation of the plates.

Mr. Barber could fully bear out Mr. Simpson's remarks. He had added a little methylated finish (methylated spirit with shellac, about an ounce to the gallon added) to the solution of honey and tannin to make it keep better, and he thought the quality of the negative was better for the addition. He had tried a solution of sulphate of quinine, instead of tannin; the results were very similar. He had tried the iodide of quinine without perceiving any advantage.

Mr. Simpson asked the Chairman if his experience in the honey process had led him to the conviction that it exercised a chemical influence on the preserved plate, or merely a mechanical action. It certainly seemed to accelerate materially in the tannin process.

The Chairman said his conviction was that the effect was decidedly chemical as well as mechanical. He had known plates, when kept some little time after exposure, show a developed picture, which proved that the honey had a reducing action.

Mr. Simpson exhibited a print from a negative taken by Mr. Underwood to illustrate the influence of a hot developer. The negative was collodio-albumen, exposed for 45 seconds at six o'clock in the evening, a few weeks previous.

The result was regarded as very satisfactory. A conversation on hot development followed, in which a general conviction was expressed that the term warm development was more safe and correct than hot, as the temperature should not generally exceed 100° Fah.

Mr. Simpson exhibited an iron print on albumenized paper, toned with pyrogallic acid, which he had received from Herr Liesegang. The print very much resembled a silver print with gold toning. He also exhibited a print from a negative by Mr. Penny, to show the injury of delaying the development of tannin plates long after exposure.

The Chairman called attention to a portfolio, containing some very excellent prints by the members of the Amateur Photographic Society.

Mr. King presented some prints to the portfolio of the Society. The proceedings then terminated.

## Correspondence.

### NITRATE OF MORPHINE DRY PROCESS.

Sir,—The solutions used by the Rev. Mr. Law in the Morphine Process are, I think, unfavourable for the attainment of the maximum sensitiveness; he has used an old negative bath, with (it appears) strong nitric acid reaction, and a weak pyrogallic developer. If nitric acid is used in the bath, it should be a very small excess, and the developer a 3-grain one, applied first without silver or acid, to make the image visible, and then with silver and acid to intensify; then, I think, the sensitiveness is considerably more than twice that of Fothergill's. There need be no fear of contaminating the bath for the usual wet process; I have used the same one for some months, and a few days since I precipitated about ½ drachm of carbonate of silver in it, filtered, and took several negatives clear, dense, and with remarkably short exposures; this exactly parallels Mr. Blanchard's experiments. Hardwich says, carbonate of silver is soluble in water, sufficiently to react on litmus—can it be so in the silver solution? Carbonic acid cannot neutralize it, if it were soluble, itself producing an alkaline salt. It has long appeared to me that the higher atomic weight the iodizer and bromizer possesses, the more sensitive is the resulting collodion, and so if a still greater atomic weight than lithium or cadmium could be used, we might reasonably expect greater sensitiveness.

May I suggest the use of Mr. England's tannin and honey solution on the morphine plates; for if the sensitiveness is increased by it *pro rata*, as in the plain tannin process, the exposure would be reduced to instantaneity; they would be eligible for the hot water as well, either plain morphine plates, or tannin and honey combined with the morphine process.

I recommend "Quæsitor" to dissolve the gelatine 3 to 5 grains per ounce, and put the subcarbonate of soda into it, 1 or 2 grains per ounce, and apply at one operation to the plate. Of course, no image will develop on them without the addition of silver to the developer, unless a solution of pyrogallic acid is applied first without acid or silver. Feeling I have taxed your space more than I ought, I am, sir, yours respectfully, Wm. Bartholomew.

*Alum Bay, May 24th*, 1862.

P.S. Whilst writing, I will mention that it occurred to me that possibly a little gallic acid added to the tannin solution would get over Mr. Penny's difficulty in keeping exposed and non-developed tannin plates.

## NITRATE OF MORPHINE DRY PROCESS.

Dear Sir,—There are one or two errors apparent in my letter of the 16th inst., due, I fear, to the illegibility of my writing, which I beg leave to correct in your next number. After "*guard*" insert "*would*," in the ninth line from the commencement; and instead of "*morphine*" in the sixth line of the following page, read "*liberated nitric acid*."

I may add that in making my experiments I employed three different kinds of collodion—Keene's, for the Fothergill process; Thomas's "portrait," diluted with washed ether and absolute alcohol; and some made by myself with mixed acid at a high temperature. The little difference, if any, in the results, pointed to the superiority of Keene's—which, in my hands has always proved immeasurably the best for the Fothergill (my favourite) process, and equal to any that I have ever tried for dry processes generally.

Since my last communication, I have tried other experiments with a nitrate of morphine bath, freshly prepared with pure unfused nitrate of silver; and I am happy to inform you that my opinion as to the *high importance* of Mr. Bartholomew's discovery is fully confirmed by all that I have accomplished.

For printing transparencies on glass, this process answers admirably.—I am, sir, faithfully yours. William Law.

*Marston Rectory, Rugby, May* 24, 1862.

---

Sir,—Acting upon the suggestion of Mr. Bartholomew, I took an ounce of bromo-iodized collodion, added thereto a ¼ of a grain of muriate of morphine, and prepared a couple of experimental plates for the dry process.

I exposed one of these dry plates for 30 seconds (view lens 11 inches focus), against a sun-lighted view, at 6 o'clock in the evening, and obtained a very fair negative, the dense foliage, however, being rather under-exposed. The second plate I kept 10 days, and then exposed for *one* minute to the same view, at 1 o'clock, the sun shining brilliantly. Upon development I obtained only the tops of some trees.

As these plates were prepared under precisely similar conditions it would appear that some great loss of sensitiveness must have taken place.

I know that Mr. B. *prefers* the addition of the morphine to the bath, but Mr. Law truly observes, "the introduction of organic matter into the nitrate bath is one of those things which photographers are most anxious to eschew."—I am, sir, your obedient servant, F. M. Y.

*London, May* 26, 1862.

---

## PRINTING AND TONING.

Dear Sir,—In compliance with your request, I have great pleasure in forwarding you the details of my printing process, but must first remark that I have really no *secret* to divulge.

The great "*secret of success*" is extreme care in all the operations, and to this I attribute the tones I produce in my prints.

In the first place, I never allow the strength of my silver to get below 80 grains. The prints are *well washed* in several changes of water, for at least half an hour. (In cold weather I use warm water). The toning bath contains, to 8 ounces of water, 1 grain of gold, and 5 grains carbonate of soda. Wash thoroughly, and fix in fresh hypo, 1 ounce to 5 of water.

I have some hundreds of prints, and assure you I cannot find one mealy, or showing the least symptoms of "yellow fever."

I may add, that unless great care is taken in the first washing, the resulting proofs are certain to dry a dingy brown colour.—I remain, dear sir, yours very truly,

John H. Underwood.

*Beech Cottage, Sale Green, Cheshire, May* 20*th*. 1862.

[Our correspondent's prints, as we have recently had occasion to remark, are amongst the richest and most perfect in tone we have seen. Although, as he states, he has no secret to communicate, we always think it of interest to put upon record the process by which the best results are obtained, and especially so in regard to subjects on which troubles are common, and opinions diversified.—Ed.]

---

## INSTANTANEOUS DRY PLATES.

Dear Sir,—Being on an extensive photographic tour, far away from the smoke and soot of busy Manchester, obtaining views in England, Scotland, and Ireland, for the purpose of illustrating a new work, I had occasion, when at Glasgow, to go down the river for a view of old Dumbarton Rocks and Castle; whilst operating there I had the pleasure of meeting Mr. Charles L. Floyd, of Birmingham, who, to my great surprise, was taking instantaneous views on dry plates, with Dallmeyer's triple lens. I have had a very large experience in dry plates, but with every system I have used a tedious exposure was necessary. Mr. Floyd was kind enough to send me a print from one of his negatives, which gave the curl on the water, and a steam-boat sailing beautifully. Now, as he appears to be very obliging and gentlemanly, perhaps, if he is asked courteously through your columns, he may be kind enough to give his *modus operandi* to the profession, by whom, I am sure, it would be considered a great boon, and by none more so than—Your most obedient,

John H. Taylor.

*Belfast, May* 26*th*.

[It is scarcely necessary for us to say that we shall receive and publish with pleasure any communication from Mr. Floyd on this interesting and important subject. Dry plates which give instantaneous effects with a lens of long focus and small aperture, like the triple, must unquestionably be as rapid as wet collodion in its most sensitive condition. We shall feel anxious to learn more on the subject.—Ed.]

---

Keeping Solutions of Tannin.—Tannin solution sometimes becomes mouldy if kept, particularly when the alcohol has been nearly removed by evaporation from frequent use. A drop of oil of cloves in each bottle entirely prevents this tendency, and does not seem to produce any injurious effect, unless undissolved globules of the oil are poured upon the film. All chance of such globules may be avoided by allowing the oil to remain at the bottom of the bottle, which is never to be quite emptied, and by taking care not to apply the solution to the sensitive surface without previous filtration. Undissolved globules of oil, if poured on with the solution, will adhere to the film, and produce transparent spots of insensitiveness. A quantity of strong solution of tannin, which became very mouldy about four years ago, and to which oil of cloves was then added, settled quite clear, and has remained in the same state ever since, and, although dark in colour, gives as good results as the freshly prepared solution.—*Major Russell's Tannin Process.*

Photographic Society.—At the meeting of the Photographic Society, to be held on Tuesday evening next, Mr. Claudett will read communications on the following subjects:—1. Enlargement of photographs by tracing the image of a negative on any surface upon which it may be thrown, in the camera, by the sunlight, or artificial light. 2. Rule for finding at once the degree of amplification produced by any distance of image, and also, from the size of the negative, having determined how much its image is to be enlarged, to know the distance at which both the negative and the screen must be placed on each side of the object-glass. 3. New mechanical diaphragm, permanently fixed between the two lenses of a double achromatic combination, which, by a rapid expansion and contraction, being capable of opening and shutting the whole aperture, can produce any degree of aperture required, even while the operation is going on.

## Talk in the Studio.

MR. VERNON HEATH'S STUDIO.—Mr. Vernon Heath, who, as our readers know, has recently devoted himself entirely to photography, portraiture as well as landscape, issued cards to the press and a select circle for a private view—on Friday and Saturday last—of his specimens, his fine gallery having just been completed. In addition to his fine series of Scottish views taken last autumn—which, in their entirety, have not, we believe, before been exhibited—and other landscapes, a variety of examples of fine portraiture were shown, amongst which the features of especial interest were various portraits of His Royal Highness the late Prince Consort, the last portraits for which he sat. Two or three specimens of the same portraits enlarged were exhibited, the delicacy and softness of which were much admired.

CARD PICTURES IN AMERICA.—Mr. Coleman Sellers, writing to our Liverpool contemporary, says:—"The card pictures have become so important a branch of the photographic art, that we find several of our leading papers publishing two-column articles on the subject. The *Philadelphia Press* had a very interesting article on the subject, showing the commercial value of these pictures; for, as an article of manufacture and trade, I dare say we shall soon see General M'Clellan, President Lincoln, and so forth, quoted in the price-current lists, as follows:—'Card pictures rather uppish: some slight advance on former rates. Note the sale of 2,000 portraits of *Mrs. Lincoln, in ball dress*, to one *party* at two dollars per dozen. Considerable inquiry for proofs from the suppressed plates, but owners refuse to sell.' I cannot but notice that the name, "*cartes de visite*," is being rather dropped, and the plain English card-picture used instead. Our language is quite capable of expressing all our wants, and there is little need of our befogging ourselves with the belief that card-pictures are not visiting cards, but are *cartes de visite*."

CLEANING GLASSES.—The gentleman above quoted says in the same letter:—"As there is no doubt clean plates conduce to clear solutions, it is of the utmost importance to have a good method of cleaning glass. What seems to be most in favour in New York just now is a solution consisting of equal parts of commercial nitric acid and water, to which a quarter of an ounce of mercury per pint of acid is added, making an acid nitrate of mercury. This solution can be kept in an open vessel in the room, and the plates, whether varnished or not, can be thrown in, and should remain there for some days until needed: they can finally be washed under a stream of running water, and stood up to drain. They may then be used without polishing. There is claimed for plates so cleaned an entire immunity from all metallic irridescence under the films in the clear shadows."

PHOTOGRAPHIC RECORDS OF A STORM.—Mr. E. J. Lowe recently communicated to the *Times* an account of a severe storm, near Newark, of which a photographic record was taken. He says:—"About 3.30 p.m. mutterings of thunder: from 4 to 4.30, heat oppressive; about 4.45 and till 5, exceedingly large and curious hail-stones fell, and the air became chilly. About 5.3, looking out of a window facing the east, our attention was attracted by seeing a small pony, closely followed by sheep and cattle, rushing in terror and at great speed from the S.S.E., opposite the house. The pony stopped and looked back, and then started off at still greater speed, as if pursued. On looking in the direction from which the cattle came, we saw the sky quite obscured by a strange dark wall of cloud, which was approaching us. Then a large quantity of hay and straw, which seemed to fill the air, followed by clouds of the blossom of the horse-chestnut and small twigs; then at once, with a roar that is indescribable, came a furious blast, which seemed as if it would sweep the land of all that stood on it. Great trees went down before it, torn up by the roots, levelled as if by a sudden blow. Our impression was that the house must be swept away. This continued rather more than a minute, and was accompanied by gleams of lightning so frequent as to seem continuous. When it passed, there was a torrent of rain, with extremely vivid lightning. The Rev. W. H. Fox and myself took a number of photographs in illustration of the ravages of this great hurricane; so that I think we shall have preserved, very satisfactorily, a record of one of the most destructive storms that has ever visited this island.'

## To Correspondents.

TO ADVERTISERS.—We have to crave the indulgence of some of our advertising friends this week, whose announcements, from the pressure on our pages, we are compelled on this occasion to omit.

EGAORO YEVRAH.—The cracking or reticulation in your film is caused by the presence of too much water in the collodion, *i. e.*, the solvents have been too weak. The same collodion may not, however, under other treatment, produce the same result; as two or three causes may be in operation to produce it. If the plate be immersed before the film be properly set, a similar effect is produced on it to that arising from water in the collodion. Intensifying with bichloride of mercury will sometimes cause reticulation if there be the slightest tendency to it in the collodion. We shall be glad to see a description of your developing box.

M. A. C.—We have not time to submit your samples of paper hangings to a proper analysis; but from the hasty test to which we have had time to submit them, we have very little doubt of the presence of arsenic. The bright green tint is probably produced by Scheele's green (arsenite of copper). This is very soluble in ammonia, on contact with which it at once turns blue. This occurs, you will find, in both your papers, in the light green ground of No. 1, and the pattern of similar tint on No. 2. If your children suffer from the symptoms you describe, it is very probably the result of arsenic; and we should counsel the removal of the papers at once. In future either avoid papers of the doubtful tint, or before using them forward samples to an analytical chemist for his opinion and advice.

BERMONDSEY TANNER.—We do not counsel placing the print in salt and water immediately on taking it from the pressure frame. If salt and water be used at all, the print should be well washed first. We prefer the bath of acetate of soda to that of chloride of sodium.

A CONSTANT READER AND SUBSCRIBER.—It necessarily follows that in two pictures taken from the same position, on the same sized plates, with a lens of short focus and another of longer focus, the picture by the lens of longer focus must delineate objects on a longer scale, and include a less amount of subject. Of the two lenses by the maker you name, that with the longer focus will unquestionably answer your purpose best if you wish to take card portraits. It also answers admirably for stereoscopic pictures as well; and where you wish to secure more subject and objects on a smaller scale, you can do so by retiring to a greater distance with the camera. You can also secure more rapidity, as the stereo plate will be covered when a large aperture is used. For stereoscopic purposes only, however, the stereo lenses are admirable. 2. The formation of a thick edge of collodion may be to some extent prevented by skilful manipulation; but it is probable your collodion is not sufficiently thin and fluid.

J. N. A.—The most striking defect in your specimens of card portraiture is the cracked, creased condition of the background: it would spoil the effect of the best photography. A little more control over the lighting would be an advantage; this you might secure to some extent by using a white reflecting screen to throw a little light on the shadowed side of the sitter. A little more care in securing perfect focus on the face, and in arrangement generally, may be used with advantage. The photography is promising, and for an amateur of little practice is very creditable.

SIGMA.—There are, of course, a large number of dealers in photographic materials in the United States; we may mention, however, two or three of the principal: Anthony, 501, Broadway, New York; the Scovil Company, 141, Nassau Street, New York; and Holmes, Booth, and Haydens, 81, Chambers Street, New York. We do not at this moment remember the address of any photographic dealer in Holland; but the Industrial Catalogue of the International Exhibition will help you to the address of some photographers there.

X.—See the communications on the subject from the Rev. W. Law in last week's number and the present.

W.—If the practical result of the operation proved correct and satisfactory, it is not necessary to discuss anybody's crochets on the subject. We saw the allusions in the article to which you refer, but they do not come before us in a form to call for specific notice. We may remark, however, that two of the statements made by the writer are incorrect. We said nothing at all about single lenses, but spoke of compound lenses only; and the writer has not "shown" that the equivalent focus of a compound lens could not be obtained in the way described; that still remains to be done. His third charge is correct; we were not quite accurate in stating that an angle of 60° is covered when the diameter of the circle of definition equals the focus of the lens. We were speaking approximately, without exact calculation, and stated the amount too high. We have not tried the lenses in question; but have heard good accounts of them as single view lenses. It does not necessarily follow that a dogmatic writer is incompetent practically.

A CONSTANT SUBSCRIBER.—If your glass positive of a cavalry troop be perfect and sharp, we see no reason why you should not get a good enlarged negative from it. For successful enlargement, it should be well defined all over, and quite clean; as, of course, every defect becomes magnified, and that which may scarcely be noticed in a small picture, might become a glaring defect in the enlargement. We cannot recommend any especial person to undertake the commission; but a reference to our advertisement pages will help you.

E. E.—The faults of your card pictures chiefly belong to the printing, and these probably less of formula than of manipulation. You are probably not sufficiently careful throughout. You will see two or three communications in the present number, which have reference to printing. Be careful to use a strong silver bath: sensitize, print, tone, and fix, all in one day if possible; or, in any case, with as little delay between each operation as possible. Be careful never to touch the print at any stage before fixing, with fingers which have been in contact with hypo. We regret that our engagements do not permit of our fulfilling such a commission as that you ask.

C. W. SMART.—We will take an early opportunity of testing and noticing the sample of silk sent.

F. B.—It is wise in portraiture always, and especially with card pictures, to use a glass a little larger than the picture, so as to allow imperfect margins to be cut away. The thickness of the card for mounting is purely a matter of taste; for album portraits we should say a five sheet board was too thick, a good three or four sheet board would be sufficient.

Several correspondents in our next.

# THE PHOTOGRAPHIC NEWS.

VOL. VI. No. 196.—June 6, 1862.

## WHO SHOULD RECEIVE THE MEDALS—ARTISTS OR EXHIBITORS?

"*Palman qui meruit ferat.*"

As the period approaches when the awards of jurors in the Exhibition will be made; a question of considerable interest arises, which is, however, one of not less difficulty. On examination of the pictures, and reference to the catalogue, it will be seen that the contributor and the artist are not always comprised in one and the same person. A correspondent, whose letter will be found in another column, calls attention to the anomaly which may very easily be perpetrated in the award of medals in such cases, by placing the laurels on brows which have not won them, awarding an honour to the publisher, who exhibits, which unquestionably should belong to the artist who has produced.

We think that it would be unhesitatingly admitted, that it is the skill and ability which produce meritorious works which should be recognized in any award of honours. It is the capitalist who generally gets the largest share of pudding: the skilled hand and conceptive brain might at least have the praise. But we are aware of the difficulties which at once beset this position. In the glorious and vast treasures of industrial art now collected in the Exhibition building, it would be found difficult, we imagine, in the majority of instances, to select any object and say, this is due to the skill of one man. Take the Western Annexe, for example, and examine with renewed wonder and admiration the various machines which seem to do everything but think, and on enquiry it will be found that there is scarcely one which is not the joint product of many brains. It is possible, indeed, that the first master conception may, in many instances, have emanated from one mind, but in so crude a form that without the more practical executive skill of others, it could never have had a material existence. Take again examples where the industrial more nearly approaches the fine arts, such as the exquisite ceramic productions of Minton or Copeland. In some of these it is the form or design, in some the colour or painting, in others the material in which the object is produced, and in many the combination of all these which win admiration, and deserve the recognition of the public as well as the jurors. To single out the especial artist would be impossible. The exquisite design of a vase may be due to one, the skilful selection and combination of the materials to another, the manipulation to a third, the painting to a fourth, the enammelling and burning to a fifth, and so on. There can be but one course for the jurors in such cases. It is the skill, the judgment, and the enterprise which directs capital into such channels which the jury must recognize. This enterprise it is, as much as the labour of skilled workmen, which, in a commercial country, raises the standard of its manufactures, and gives its products pre-eminence in the world; and this it is which will always command pre-eminence and win renown.

We submit that the case is different, however, as regards photography. There is no difficulty in deciding to whom the palm belongs. Whatever advantages he may have derived from the purest of chemicals and the best of apparatus, these matters will receive recognition in their proper quarter. Whatever wide-spread publicity his productions may have received through the efforts of an enterprising publisher or employer, there no is room for doubt at any time that the results of the skilful photographer are due to himself alone, and that he alone should receive recognition in an award to merit. Francis Bedford is at this moment in the employment of the Prince of Wales: his pictures are announced for publication by Messrs. Day and Son; but no one will for a moment dream of crediting either his Royal Highness, or the publishing house we have named, with the merit of Mr. Bedford's pictures. As a general rule, moreover, there is no obscurity or doubt existing about these matters. Skilled photographers are well-known and recognised; their productions being more familiar evidence than their sign-manual.

There is, or may be, however, another difficulty. We have said *may* be with a reason: we wish in our brief remarks on this subject to discuss it purely as an abstract question, without regard to individual cases; and since the matter has come under our attention we have avoided examination as to whom it might concern. There may be, however, we have said, another difficulty. The jurors, we apprehend, will be presumed to have no official knowledge of either artists or exhibitors, except that which comes officially before them in the official records. If then in the consideration of a meritorious picture by a well-known artist, the only name before them in connection with it is that of a publisher or exhibitor, they will not, we fear, have any choice or discretion as to whom they shall recognize in making the award. Injustice in such cases is, we regret to say, not a new or uncommon thing. We remember a case in which an amateur, of high repute, received and accepted an award in a French Exhibition for an astronomical photograph, which had been produced and given to him by a friend who was not less distinguished as a photographer. In such a case the jurors would never dream that the exhibitor was not the photographer also. In the International Exhibition we fear that even where they may know it, they cannot act upon the knowledge.

The difficulties may in some cases be still more complicated. In one of the cases quoted by our correspondent, they are so. Mr. Blanchard's instantaneous photographs are published by Elliott, but they are exhibited by the photographic firm of which Mr. Blanchard was a partner, and in the first edition of the Catalogue appeared as the contributions of "Smyth and Blanchard." Since then Mr. Blanchard has, we understand, seceded from the firm; and in the new and corrected edition of the Catalogue, we find Mr. Blanchard's pictures catalogued with the name of "S. Smyth," from which we conclude that the negatives remain the property of his late partner, whose name in case of an award would, we presume from the Catalogue, be the only one before the jurors.

In the Fine Arts Department, where the contributor and the artist are so frequently distinct persons, this difficulty is avoided by discarding medals altogether. In many of the industrial departments we hear loud complaints of the unsatisfactory management in the juridical examinations; in the photographic department we hope and believe things are better managed, and notwithstanding that three of the jurors are exhibitors also—Dr. Tindall having resigned, and his place being filled, we understand, by Mons. E. Delessert, who is an exhibitor in the French Department—we hope for a satisfactory result. In any case, we commend to the attention of the jury the anomaly which may so easily creep into their adjudication, and suggest the importance of exercising, if possible, a discretion which may avoid it.

## THE INFLUENCE OF BROMIDES IN COLLODION.

BY ALFRED KEENE.

THE experiments both of Mr. Sutton and Mr. Blanchard, given in the NEWS of the 16th ult., for elucidating this subject, appear to me open to objections; those by the former gentleman, as you correctly observe, from being performed with a collodion containing a bromide only, instead of the combined salts—iodide and bromide; also, probably from Mr. Sutton being so strong an advocate for excess of alcohol; the normal collodion he used was of that character, and if so it may account, not only for the length of time he has found necessary for the decomposition of the bromide in the collodion, and its conversion into bromide of silver, but also in some measure for other opposite peculiarities in his experience. Paradoxical as it may appear, collodion containing a large excess of alcohol is *less* quickly acted upon by the bath than one containing excess, or equal portions of ether, which may be explained by the fact that alcohol, though having great affinity for water, makes a film of a very homogeneous nature, that sets more like albumen or gelatine, and therefore offers little facility for the bath to penetrate, and produce the chemical change. Ether, on the other hand, though possessing little affinity for water, gives more porosity to the film, which allows the bath to penetrate freely, and come in contact with a very much larger quantity of the bromide, and consequently quickly decompose it.

Again, during investigations on the character of alcoholic collodion, I have noticed that the excess of alcohol modifies it in some respect similar to what a bromide does ordinary iodized collodion, for instance, a collodion simply iodized, made with *three or four parts of alcohol to one of ether*, will bear a stronger iron developer, and also its being kept on longer without producing fog or stain, than one made with *three* to *five*, or equal parts of ether. If, therefore, Mr. Sutton has used an alcoholic collodion, and those who differ from him the, I think, far preferable kind, made with say equal portions of ether, *some* of their opposite results may be thus explained.

Mr. Blanchard's experiments appear at first sight satisfactory, and to promise definite results, simply iodized and bromo-iodized collodions being compared with the use of the same bath, same developers, and exposure for each respective set; but the very care devoted to insure uniformity of treatment has defeated his object. All who have experimented largely will have observed that not only must the bath, developer, and collodion bear certain relative proportions—a strong bath or strong developer fogs a weak collodion, *i. e.*, one containing a small comparative quantity of iodide—but also that bromides enable a collodion to bear, and, I may say, cause it to require, a stronger developer, and of its being kept on longer than a simply iodized collodion, the latter fogging all over almost immediately, under the action of a developer suitable for the former, which will account for all the simply iodized collodion plates treated in Mr. Blanchard's experiments fogging, and the bromo-iodized remaining clear and clean, without deciding the respective merits of each. The developer used chiefly being a 30-grain iron one, and the iodized collodion only of the strength of from 3½ to 4½ grains, according to the salt used per ounce, for which a 10 or 15 grain developer would have been more suited; whereas the bromo-iodizer contained from one grain of bromide upwards in addition, and in some instances also *extra iodide*. To arrive at correct conclusions respecting their comparative sensitiveness, we must prepare and *use* the collodions under circumstances best adapted for each.

As regards the respective *merits* of iodized and bromo-iodized collodions, nothing, I think, can be more conclusive in favour of the latter, than the universal preference shown for it when the two salts are judiciously combined with a suitable pyroxyline, in proportions that bring out fully the peculiar advantages of each; but on the other hand there are undoubtedly circumstances, even though they may be rare, under which the former gives the best results. I think, therefore, it cannot be advisable exclusively to advance or condemn either, which is taking too narrow a view of the subject, but consider it desirable instead to ascertain which is best adapted for general use; whether either possesses peculiar characteristics, or offers peculiar advantages under particular circumstances over the other, and if so, what? Having devoted, during the early part of the year, considerable time and attention to the subject, I submit a *summary* of the conclusions arrived at as the result of them. The separate results, amounting to probably several hundreds, were very varied, as might be expected when I explain that collodions made with almost every variety of pyroxyline, and prepared with ether and alcohol, ranging in proportions of from *five* to *three* to *one* to *five*, and containing iodides and bromides in various proportions and quantities, and iodides of various quantities were used; also developers weak and strong, and light varying from the dullest to most brilliant.

*Iodized collodion, characteristics*—Simply iodized collodion, when developers of suitable strength were used, as compared with bromo-iodized with the *same developers*, proved rather more sensitive, developed in less than half the time, and in very dull weather or a badly-lighted room—with light well diffused—*when but little contrast of light and shade*, gave a more brilliant picture—picture with better contrast, but will not bear a developer *half* the strength, or continued on half the time without fogging; is more liable to stains and marks, more quickly solarizes, and very liable to be deficient in half tone, excepting under the circumstances mentioned as favourable for it.

*Bromo-iodized collodion*, as compared with simply iodized, requires rather longer exposure when a developer suitable for the latter is used, but as *short or even shorter* exposure when a strong developer is employed, works cleaner, is not liable to solarize, gives more half tone, softer and more pleasing results, particularly when the light is brilliant, decidedly preferable for general use, and may be considered essential for *cartes de visite* and view purposes. The ordinary bromo-iodized collodion, containing a small portion of bromide, which works quick, clean, and brilliant, I find most suited for all ordinary requirements, but there are circumstances, more especially in view photography, and at times for portraiture, where there are extreme contrasts of colour, or light and shade, or any other cause, rendering the use of a very strong developer, and comparative long continued action of it desirable, without producing fog or loss of definition in the high lights, when a collodion containing as much as equivalent proportions of each salt answers best, or a mixture of it with the weaker bromo-iodized. The larger the quantity of bromide, the stronger may be the developer. I have used with a collodion, containing equivalents of each salt, as much as 80 grains of iron, and 15 minims glacial acetic acid to the ounce, with very good effect, without producing fog, and the negative requiring little after intensifying with pyro and silver.

## ON THE EFFECTS OF AFFINITY IN PHOTOGRAPHY.

BY DR. SCHNAUSS.*

IF gold be separated from its solution by silver, the latter enters into the combination in place of the gold, and, as in photography gold is employed under the form of chloride of gold, or hyposulphite of gold, it is evident that it will form analogous combinations of chloride, and of hyposulphite of silver. It is identical with the chemical process by which the *Tree of Diana* is produced, by immersing a piece of zinc in a solution of acetate of lead. The lead, a very feeble electro-positive metal, is precipitated upon the zinc in the form of a delicate moss.

* Continued from p. 29.

The same thing occurs to silver when we immerse a less noble metal (that is to say, a metal which is more strongly electro-positive, and which, consequently, has more affinity for oxygen than the silver has), in a solution of silver, the nitrate for example. A pin falling accidentally into a nitrate bath must have demonstrated this fact to most photographers, who will, in consequence, have been taught not to place the less noble metals in contact with solutions of silver, such as *mercury*, copper, iron, zinc, tin, lead, &c.; but which may be done with metals more noble than silver, such as gold, and platinum.

*What takes place with paper positives in the gold toning solution?*—The question of ascertaining in what state the silver exists in finished positives taken on chloride of silver, often presents itself to chemists, as well as photographers. In chemical treatises, we find it stated ordinarily, that chloride of silver becomes blackened in solar light, meanwhile, chlorine being liberated, it forms some sub-chloride of silver in a humid state: these treatises say that hydrochloric acid is formed, with disengagement of oxygen gas. As regards the products of decomposition, this latter is correct, but the state in which the reduced chloride of silver exists, depends solely on the intensity of the light. The chemist operates upon compact masses of chloride of silver, and if they be divided ever so much, and if they be suspended and diffused in water, this does not suffice for their complete reduction by light, as the thinnest layer of blackened chloride of silver completely protects the parts it covers from the action of light.

On this point I made the following experiment:—After precipitating some chloride of silver in a liquid containing nitrate of silver, I exposed it in this argentiferous liquid to a very strong solar light, stirring it frequently. Some days subsequently, the liquid smelt of chlorine, but the colour of the exposed chloride of silver remained chocolate brown, without becoming darker. I washed the chloride with distilled water to remove every other substance than the darkened chloride. After exposing the chloride to the solar light for eight days, I treated it with ammonia; this liquid dissolved nearly the entire mass, leaving at the bottom of the flask only some black particles, which dissolved in nitric acid. We perceive that the chloride of silver is decomposed by light only in very small quantities. The decomposition of this body is much more complete in photographic processes. If we float a piece of paper upon a dilute solution of chloride of sodium, and afterwards upon a solution of nitrate of silver, also diluted, this paper presents, in comparison with the extent of surface, only a very minute quantity of chloride of silver; and this latter is not only reduced in the state of sub-chloride, but it is perfectly reduced as *metallic silver*, as my experiments abundantly prove. Only the *metallic* silver may, through the effects of affinity, separate the gold from these solutions; no chloride of silver can do that. A polished silver wire immersed in an alkaline gold bath—

| | | |
|---|---|---|
| Chloride of gold | ... ... | 1 part |
| Carbonate of soda | ... ... | 4 to 5 parts |
| Water ... ... | ... ... | 1000 parts |

will be covered with a thin film of metallic gold in 15 or 20 minutes. We know that the alkaline gold bath decomposes spontaneously in a few hours; the gold separates in red flocks; this decomposition is effected in a few minutes if the bath be warmed. The addition of an ethereal oil does not appear to accelerate the decomposition, nor does a mirror of gold form upon the sides or bottom of the flask. Metallic silver in a finely divided state (such as the precipitate formed by adding sulphate of iron to a solution of nitrate of silver), decomposes the alkaline gold bath rapidly: a corresponding quantity of chloride of silver is formed, and silver containing gold in mixture: the gold may be readily found by treating the precipitate with ammonia to dissolve the chloride of silver, washing it, and dissolving the metallic silver in nitric acid; a brown residue remains, which dissolves in *aqua regia*, and gives the reactions of gold.

To obtain a correct idea of the decomposition of chloride of silver paper by light, and of the gilding (toning) of the proofs, I proceed as follows:—

I expose paper prepared with chloride of silver for a long time to light, until it has acquired a uniform bronze colour, and changes no further. By washing this paper thoroughly in *distilled* water, I remove all the nitrate, and other soluble salt of silver. After drying the paper, I replace it for half an hour in the ordinary alkaline gold bath. At the expiration of this time, the bronze colour is changed into a deep bluish black.

Freed by thorough washing from the adherent gold solution, the paper was immersed in a concentrated solution of hyposulphite of soda, in order to remove all the chloride of silver. There now only remains the last decisive proof to be made: if the silver were perfectly reduced, by the light, to the metallic state, it should, by the long action of the gold bath, be completely replaced by metallic gold, while all the salts of silver should be removed by the washing, on the one hand, and by the hyposulphite of soda solution on the other.

If these suppositions were correct, no silver should be found in the paper, but only gold. I dry the paper, after having *thoroughly* washed it, and burn it in a platinum crucible, and treat the ashes with nitric acid. Very little is dissolved with slight effervescence; the addition of hydrochloric acid to the solution causes only a slight opacity, proving that there is no silver present. The brown-red residue dissolves immediately in *aqua regia*; the yellow solution, which contains some white gelatinous flocks, gives, with chloride of tin, a blue violet tint (purple of cassius), and a black precipitate with sulphate of iron.

The *presence of gold* in the toned and fixed positive paper, also surely proves the *absence of silver*. The same conclusion is applicable to every proof which is toned with chloride of gold, or in an alkaline gold bath, always supposing that the exposure to light has been sufficiently long, and that the toning, fixing, and washing, have been completely and carefully performed. A paper exposed to light for a long time, and gilt in this manner, resists for some time the action of the nitric acid, notwithstanding the extreme tenuity of the film of gold; while silvered paper which has not been toned with gold, is immediately deprived of its colour by nitric acid, and even by the acid nitrates, such as the nitrate of copper. Chloride of copper, and other metallic chlorides, also deprive the silvered paper of colour, by forming chloride of silver, which blackens if subsequently exposed to light.

## The International Exhibition.

### BRITISH PHOTOGRAPHIC DEPARTMENT.

WITHIN the last few days a corrected and more complete catalogue of the photographs exhibited in this department has been issued. An introductory chapter, or preface, glances at the progress of photography since the Exhibition of 1851, and briefly summarises its present position, as illustrated in the present Exhibition. Referring to the position of photography eleven years ago, the writer remarks:—

"In the Great Exhibition of 1851, Photography had not sufficiently advanced to be placed in a separate Class,—Photographs, and the apparatus used in producing them, were included among Philosophical Instruments. It has now a class of itself (XIV). The art was, in 1851, represented by a large number of Daguerreotypes, some Talbotypes, or Sun Pictures, as they were then frequently termed, and by a few specimens of the albumen process on glass. The collodion process, to which is due the enormous development which has taken place since 1851, was not known previously to the opening of the Exhibition in that year. Photographers were anxiously looking for some material which should be free from the defects of the paper on which the Talbotype negatives were taken.

Albumen on glass had been tried with some success. Archer turned his attention to the use of a film of collodion, and was experimenting on it previous to the opening of the Exhibition; and Dr. Diamond, in company with him, took a portrait with some collodion given him by that gentleman, as early as September, 1850. A collodion portrait, taken by Mr. Archer, assisted by Messrs. Fry and Horne, early in May, 1851, and what is termed a positive picture,* was placed in Messrs. Horne and Thornthwaite's case in the Exhibition, with their Daguerreotype and Talbottype apparatus. Towards the end of June in that year, Mr. Rippingham, by permission, placed in this case some prints from negative collodion plates, the collodion for the purpose having been given him by Mr. Archer. The description of the process was published by Archer, in March, 1851, when it appeared in *The Chemist*. In the Jury report no other notice is taken of these pictures than that 'Rippingham has exhibited several Talbotypes, being a series of untouched positives from collodion negatives on plate-glass.' No medal was given—indeed no one could have then foreseen the influence which these experiments were to exercise on the Photographic Art—and the Jury may well be pardoned for passing them over. In a short time, however, the simplicity of the process and the beauty of the results caused its almost universal adoption, though numerous improvements had, in the mean time, been made in the negative paper processes, more especially that known as the wax paper process, invented by Le Gray."

Commencing with the first number in the catalogue, we find a valuable application of photography, but possessing no pictorial interest, as it is simply an enlarged copy of a map by Mr. G. Downes. It is from several negatives, printed separately and joined: so far as we can see, is sharp all over and free from distortion or curvature of lines. A frame of *genre studies*, by Rejlander, come next: most of these, we have seen, and noticed before; but we may again call attention to the wonderful truth and pathos of "A Night in London." The subject is a half-clothed outcast boy, seated in "looped and windowed raggedness" on the step of a doorway, his head stooped to his knees, and buried in the folded arms, which grasp the knees. The face is hid, but the picture is still eloquent with expression, and tells unerringly its sad tale: desolation and wretchedness are more forcibly told by the position and the hidden face than they would have been by the most woe-begone countenance. The management of light and shadow, and tone, all contribute admirably to the effect, and place unmistakeably the subject of the sketch amongst the class to which Victor Hugo is just devoting his great work, "Les Miserables."

The next pictures which attract our attention, less by their beauty than by our interest in the process, are some views exhibited by Cramb Brothers. These are views of Palestine, on dry albumen plates. The subjects have an interest of their own; the pictures are clean and sharp, and in many respects are good as photography, with the exception of being generally somewhat under-exposed.

Dollomore and Bullock exhibit a variety of landscape and architectural photographs, amongst which we may mention a view of Christ Church, Oxford, as an exceedingly fine, harmonious, and atmospheric picture. No. 16, by Mr. J. Sands, is a view of St. Paul's, from the Thames, of unusually large size, the plate being about 20 by 16. The negative is, we understand, by the collodio-albumen process, and the result is, in our estimation, decidedly successful, especially when the conditions of atmosphere usually surrounding St. Paul's is remembered.

Dr. Wright exhibits a frame of pictures as illustrations of what may be produced in his field box or tent, of which we shall have subsequently to speak. These pictures are exceedingly good, and indicate that no manipulatory difficulties are experienced in working in the tent referred to.

No. 24 is a frame of photographs executed by Mr. Herbert Watkins, of various sections of the brain of a chimpanzee, dissected by Mr. J. Marshall, F.R.S. These possess an especial interest, as affording the basis for comparative examination and estimate of the difference between man and this travesty of humanity.

Cundall and Downes, amongst other excellent contributions, send one possessing unusual interest—a copy of the original manuscript of "Gray's Elegy." Also, reproductions of some fine pen-and-ink sketches entitled, "Waifs and Strays," by E. V. B. Ross and Thompson, of Edinburgh, have a good frame of portraits of children, in which the feeling reminds us considerably of Rejlander; from under-exposure in some, however, and heaviness of accessories in others, there is a general sombre effect which would have been better absent.

Paul Pretsch contributes largely of his specimens of photographic engraving, both from blocks in relief and intaglio. Some of these are reproductions of drawings, some of engravings, and some are photographed from nature; some of the plates have been retouched by the engraver, and some are untouched. All possess many excellent qualities, but we do not notice any especial progress during the last year or two. There is some ground for regret, that the descriptions attached are not always sufficiently explicit. Some of the prints which are marked as from untouched plates, leave us in doubt as to whether they are exhibited as photographs from nature or from engravings of photographs. We may mention the print of the "Venus Callipyge," which, whilst marked untouched, has the appearance of possessing an acquatint ground or grain. It would have been desirable, in relation to the specimens of a process so interesting, that the descriptive particulars should be fuller. The specimen, which strikes us as best of those exhibited by Herr Pretsch, is No. 162, a large sized copy of the "Venus de Milo." The picture is hung somewhat high, and is, therefore, beyond the reach of minute criticism, but seen from this distance it leaves nothing to be desired.

The various specimens of Col. Sir Henry James are at present perhaps the most interesting and perfect produced by any adaptation of photography, to the ordinary methods of printing by means of ink and press. The process has the merit of being perfect in its kind; all that it aims at or makes claim for, it accomplishes. Its object is to reproduce by photographic agency a printing surface from anything delineated in lines or dots. The specimens sent in by Col. James show at once how extensive the range of application is, and how perfect the results. Its value in the reproduction of old, scarce, and valuable engravings, is shown by copies of Hogarth's "Canvassing for Voters;" "Antique Vases," drawn by Piranesi; and some panels in the Vatican, painted by Raffaelle, and engraved by Volpato, in 1776. Its value in the reproduction of maps on any scale is now familiar to every one; the specimen here exhibited is a plan of Edinburgh Castle and its environs. No process ever before discovered could in any degree rival this for the production of fac-similes of old documents, such as the Domesday Book. What other method of reproduction could yield anything possessing the interest and value which one of the first editions of Shakespeare so rendered would have, and which the two specimen pages of an edition of 1623, here exhibited actually possess. The exact value as reproductions of some of the specimens, is here exhibited by the display, side by side, of the originals, of prints from collodion negatives, and prints by the zincographic process; and increased interest is given to the contributions by the exhibition of different stages of the process, such as the transfer, the completed zinc plate, &c. Here also are some specimens of the process which Col. James has named photopapyrography, by which copies of documents, of which not more than two or three are required, rendering the process of transferring to stone or zinc undesirable, can be produced in printing ink, thus securing the most indisputable permanency. The *modus operandi* of photopapyrography is not described, but any one familiar with photolithographic processes will readily understand how the image obtained on paper, in gelatine and bichromate, may be used to obtain copies in printers' ink.

* Very few pictures of this character are shown in the present Exhibition, though the process is that by which the cheap portraits, so common now-a-days, are taken. Some may be seen in frame No. 43.

Mr. Field exhibits some very excellent specimens of photolithography, but they are unfortunately hung so high as to render critical examination impossible. In this case the image, it is stated, is impressed on the stone by photography, and not by means of a transfer as in Col. James's process. From the preface we learn that Mr. Field's process is based on the special action of light on a surface of bitumen of Judea covering the stone, which was one of the first photographic processes which received attention from early investigators. Mr Contencin exhibits some photo-lithographs, regarding which we have no particulars, except that the image is impressed on the stone, and not transferred. Mr. Ramage also contributes some of his very fine copies of engraving by photolithography. His image is also, we understand, produced from the negative direct on the stone.

Mr. Pouncey exhibits some specimens of his carbon printing, which will not enhance its reputation. In fact we see nothing in carbon printing by means of light, in our own gallery, which will at all compare with the specimens in the French department.

Many of the specimens executed in printing ink by the aid of photography, leave, however, little to be desired. This, in an economic point, is one of the most important and interesting applications of the art. Here the images are depicted in carbon, one of the forms of matter least changeable under the influence of moisture, light, or atmosphere, in fine particles, which are enveloped in a resinous coating, manifestly one of the least alterable conditions of this permanent substance. If photography had done nothing more than produce and perfect such processes as the known processes of photolithography and protozincography, it would have been entitled to higher consideration from Her Majesty's Commissioners than it has received in this Exhibition.

## REMARKS UPON SOME OF THE APPARATUS EMPLOYED IN PHOTOGRAPHY.*

BY F. R. WINDOW.

### Plate Holders, Developing Stands, &c.

Plateholders are required for holding the glasses while the collodion is being poured on to them, and during the process of development.

For the first-named use, or coating the plate, many photographers, especially professional men, prefer using the hand alone, the plate being held by a corner between the forefinger and the thumb of one hand, while the collodion is poured on with the other, the small portion which is in contact with the hand being left bare. Although it is desirable that the photographer should be familiar with, and practised in this way of coating a plate with collodion, so that he may not be awkwardly inconvenienced if the usual appliances be not at hand, still I do not think that, as a rule, the bare hand is the proper or best thing to use for this purpose. There are other reasons against it, besides the chance of absolutely dirty fingers. A very large proportion of photographs are taken in summer, during the hot months of the year, when the hands are liable to be moist; and, besides this, at all seasons, the fingers have a certain amount of natural greasiness, which, when they are laid on highly-polished surfaces, leaves a mark. I think these considerations are sufficient to advise the use of a plateholder when it is possible, in order to avoid the chance of soiling and staining the glass.

In the early days of collodion, a piece of heated gutta percha, or india rubber, was mostly used to hold the glasses while they were coated with collodion, and the plate stuck on, or fell off, as the case might be; the chances were about equal. For a long time past the pneumatic holder has been almost exclusively employed for this purpose, for which it is admirably adapted. There are several modifications of it in the market, all of which, as far as efficiency in principle is concerned, are equally good: though I must add, I think it to be regretted, that at least a portion of them are not made a little better than they are, as regards workmanship. Their solidity is sacrificed to cheapness, and most of them soon go to pieces if they are much used, while, if they were properly made, they would bear very rough handling for a long period without getting out of order. Many, I think most, photographers would prefer to spend an extra shilling or so for a more substantial article, if they had the option.

The special requirements for a holder to be used for developing the picture upon vary considerably from those for coating with collodion. The operator must be able to hold the plate firmly in any position, horizontal or vertical, and, at the same time, it is absolutely necessary that he should be able to look through the plate, and examine every part of the picture by transmitted light. The ordinary pneumatic holder evidently does not admit of this, as its bulk obstructs the view through the part to which it is made to adhere; which being, for the sake of safety, generally about the middle of the glass, contains frequently the most important points of the picture. This is of less consequence if the plates are stereoscopic, as a portion of each, or, by placing the holder a little out of the centre, one whole picture can be seen; also, if the plates are of considerable dimensions, the examination of one proportionately small part in the middle may be of diminished importance, but, unfortunately, as the size and weight of the plates increase the security of the pneumatic holder to sustain them during development is less to be depended on; and as nothing can be more annoying than to lose a picture by breakage at this late stage, it is well not to trust large plates too confidently on the pneumatic holders for so long a time, and to such active movement, as the proper development generally demands.

The prepared plate being wet during the process of development, and constantly covered with fluid, the *clean* hand will not have any deleterious effect upon it, and as it is found to be the most efficient holder without any additional apparatus, it is the most generally adopted, the plate being held, as for pouring on the collodion, by a corner between the fore finger and the thumb. It may safely be said, that of all the appliances suggested up to the present time, for the purpose of developing collodion plates the bare hand is the very best, and the "tripod developing stand" is the very worst.

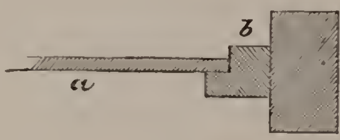
The tripod developing, or levelling stand, is a useful and serviceable apparatus for developing albumen or collodion plates with gallic acid, or for any operation which requires time for its fulfilment, and does not need constant attention or movement. But the case is very different with collodion plates developed with pyrogallic acid or iron solution, in which the changing effects must be noted from moment to moment, and the reaction stopped exactly when the best results are obtained, which requires to be kept in continual movement, and never to be left an instant alone. Here the developing stand is evidently unsuited to the work, and to supply its deficiencies the operator has constantly to lift up the plate in his fingers, both to keep the liquid in movement and to examine the progress of the development, and then to put it on the stand again, until he thinks he had better look again. It is needless to remark, that he would be able to observe much more minutely if he never laid the glass down at all on the stand, and the constant and repeated handling of the plate is more likely to injure it, and more *certain* to stain the fingers, than if it were grasped once for all in one place, and not set down till the operation was over.

Although clean fingers have no injurious effect upon a plate when it is being developed, the said plate, unfortunately, does not reciprocate the compliment, for it has a very marked and unpleasant effect upon clean fingers. This is doubly inconvenient, for it necessitates abundant use of cyanide of potassium to remove the stains, and this poisonous substance is never applied to the skin without some being absorbed, which has a deleterious effect on the

* Continued from page 257.

health; also, it is very unsightly to have the fingers in mourning while engaged in posing sitters, especially ladies, who are not always convinced by the assurance that "it will not come off." And yet developing is the very part of the process that a photographer who really cares to excel cannot trust to an assistant; in witness of which it may be remarked, that all those gentlemen who most illustrate their profession by their photographic gems are in the habit of developing every picture they take with their own hands. It is evident, therefore, that any apparatus that could efficiently replace the hand for sustaining the plate during development, would be a great boon to all grades of photographers, both professional and amateur. But, although several holders have been brought forward from time to time with this object, in the construction of which considerable ingenuity is evinced, they are not up to the mark sufficiently to induce their adoption in preference to the hand, for which not one of them is an effective substitute. One of the main objections to their use is, that—I think in all cases—the instrument is made to grasp the glass plate at several points by means of certain parts upon which it rests, and which are also kept pressed against its edges by means of springs or other appliances. These parts, which vary in form in different holders, may be generalized by fig. 27; the plass plate ($a$)

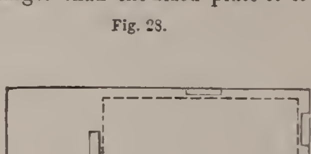
Fig. 27.



being held in pads of glass or gutta percha, or other neutral material ($b$). These pads being of a material not affecting silver solutions, are without any chemical influence during the process of development; but they act mischievously by serving as conductors to lead the liquid off the surface of the plate, which is soon left nearly dry, unless more than ordinary caution is used. This vice would be corrected if the shoulder of the pad pressing against the edge of the plate were made of less thickness than the thinnest plates used, but in such a case it would have only a very insecure hold upon the glass, and one evil would probably only be exchanged for another. Besides this common fault, most of the holders have other objectionable features peculiar to their several instances, which need not be noticed here.

I have used considerably a very simple holder for developing plates up to whole-plate size, withing soiling the fingers, which, although much inferior to the unassisted hand, has proved, in my experience, more practical than several others which I have bought and tried. It has the advantage of cheapness and simplicity; anyone can make one for himself. It has not, necessarily, the disadvantage named above, as common to nearly all holders, but it has others, from which some are free. It consists simply of a piece of glass larger than the sized plate it is intended to

Fig. 28.



hold, with one of the corners cut off. Upon this glass plate are fixed with cement four very thin slips of glass, as shown in fig. 28, to serve as pads for the plate to rest against, ample space being provided, so that the glass cannot touch both sides or ends at one time. In use, the plate to be developed is laid on the glass between the pads, the holder is held by the further end, and the developing liquid is poured off and on at the corner which projects over the cut off portion. It can be held safely at an angle of about 80° to examine the progress of development, which can be seen through the glass holder. It is needless to remark, that this holder, like every other, must be scrupulously washed after every plate that is developed upon it.

The principal disadvantages of this holder are, that each one is only suited to one sized plate, consequently several are necessary for those operators who work with different sizes. Also, sometimes a portion of the developing solution will get between the holder and the plate, and if it be discoloured, or if any deposit be formed betwixt the glasses, it hinders to some extent the examination of the progress of the development. A little care will generally prevent this from occurring.

(*To be continued.*)

## PHOTOGRAPHIC CHEMICALS:

### Their Manufacture, Adulterations, and Analysis.

*Potash salts* (continued).—Of all bases potash possesses the strongest affinity for the greatest number of acids, and neutralizes their effects in the most perfect manner. Its alkaline characters are so intense that when the acid is weak it is unable to mask the alkaline reaction of the base, unless several equivalents are taken. All potash salts are colourless, except when the acid is coloured. In the absence of soda they communicate a violet colour to the blow-pipe, or spirit flame, but this reaction cannot be observed, if the slightest trace of soda is present. All potash salts are soluble in water, except when they are united with a great excess of silicic, titanic, or other insoluble acid. Some of its salts are, however, sufficiently sparingly soluble to admit of their being employed as tests for the presence of this element, when it is not in too small proportions; thus perchloric acid, tartaric acid, carbazotic acid, sulphate of alumina, hydro-fluosilicic acid, and chloride of polatinum, form precipitates when a moderate quantity of potash is present, the precipitant being added in concentrated solution. Potash has a great tendency to form double salts, its combinations of this class, with many metallic oxides, forming crystals of extreme beauty and permanence. Potash is obtained commercially almost solely by means of the vegetable kingdom, it is present in small quantity, as far as percentages are concerned, but in enormous quantity, when the mass is considered, in felspar, granite, and many other rocks which, by the disintegrating action of the atmosphere and weather, constitute the great bulk of earthy soils. Plants and vegetables growing in this *débris* of the primitive rocks have the property of absorbing and concentrating the potash from it, and it is from the ashes of these that potash is almost universally extracted on the large scale. Another source of potash is from tartar, this is a deposit consisting of the alkali combined with tartaric acid, and is deposited in enormous quantities from grape juice during the manufacture of wine, the source of this being, of course, the same as in the preceding instance.

From the crude ashes of inland plants the potash is obtained by soaking in tubs of water; the alkaline solution thus obtained is boiled down in iron pans until it solidifies on cooling. It now forms a brown mass, which is placed in a reverberatory furnace, and the flame allowed to play over it with constant stirring with an iron rod, until the organic matter is entirely consumed; in this state, it forms what is called burnt or calcined potash. To purify it, it is dissolved in two parts of boiling water and the solution after being filtered through white blotting paper, or bleached linen, is evaporated in an iron pot to the proper degree of concentration: it is then allowed to stand for some days, when the sulphate of potash crystallizes out, and may be strained off.

Upon boiling the clear solution down to the density of about 1·43, most of the carbonate of potash will crystallize out on cooling and stirring. The crystals of carbonate are lastly washed with a small quantity of cold water, and then rendered anhydrous by ignition in a cast-iron, silver, or platinum vessel.

When prepared from crude tartar this is to be purified by one or two crystallizations, and then heated to low redness in a covered iron crucible, the mass is then extracted with hot water. After filtration the liquid must stand for some days in order to allow the carbonate of lime to settle, and the clear solution is then evaporated to dryness in a vessel of either cast-iron, silver, or platinum. (As a rule we may observe that whenever alkaline substances are to be evaporated down, or to be ignited, the operation should always be performed in vessels made of one of these three metals, silver being the best.) The dry residue is covered with three times its weight of cold water, and allowed to stand for three days, and the solution is then filtered or decanted from the insoluble matter and evaporated to dryness. It is necessary to purify the crude tartar before employing it for this operation, as otherwise the carbonate of potash would be contaminated with cyanide of potassium formed from the nitrogenous matter which it always contains.

What is known as *black flux*, a substance of considerable use in reducing photographic residues to the metallic state, is a very impure mixture of carbonate of potash and charcoal; it may be readily prepared by mixing together two parts of crude tartar and one part of nitre. The mixture is then to be thrown into a red-hot iron crucible. Upon cooling it will form a black mass which may be powdered and kept for subsequent use. It thus forms a mixture which, from the presence of carbon (from the decomposition of the acid of the tartar) and cyanide of potassium, has eminent reducing properties. The *white flux*, which is a constant accompaniment of the former mixture in chemical laboratories is formed in a similar way, but with an increase in the quantity of nitre, equal weights being taken. In this way all the carbon is burnt. It is used as a flux when no reducing action is desired.

The impurities found in commercial carbonate of potash are very numerous, and as a knowledge of the means of detecting them is of some consequence, we will proceed to notice them in detail.

*Sulphate of potash* is detected by adding an excess of hydrochloric acid, and then chloride of barium; the formation of a white insoluble precipitate is a conclusive proof of the presence of this substance. For many purposes it is important that it be got rid of; this is effected without much difficulty by dissolving in water and evaporating once or twice to a syrupy consistency. The sulphate of potash, being much less soluble than the carbonate, crystallizes out and may be strained off.

*Chloride of potassium.*—This impurity is detected by adding an excess of nitric acid, and then a drop of nitrate of silver; it may be removed in a similar way to the sulphate of potash.

*Phosphate of potash* may be detected by adding an excess of hydrochloric acid, and boiling for some time until all the carbonic acid is expelled, and then adding an excess of ammonia and a little solution of chloride of calcium. A flocculent precipitate indicates the presence of phosphoric acid.

*Nitrate of potash* is detected by dissolving the salt in excess of sulphuric acid, and then adding a crystal of sulphate of iron; the well-known reddish halo will be produced round the crystal if the slightest trace of nitric acid be present.

*Nitrite of potash* may be detected in the same way.

*Cyanide of potassium.*—To detect this add excess of hydrochloric acid, and then a little sulphate of iron which has become partially per-oxidized by exposure to the air. (Positive developing solution will answer the purpose very well.) If the smallest trace of cyanide of potassium be present, a precipitate of prussian blue will be formed.

*Soda.*—This is a very common, but not a very important impurity; it may be detected by heating a little of the dry salt on platinum wire in the flame of a spirit-lamp; if soda be present the colour of the flame will be a pure yellow: the separation of soda from potash would be attended with too many difficulties for an amateur to attempt to perform.

*Carbonate of lime* is also sometimes present. The solution in this case deposits crystals of carbonate of lime when allowed to stand for some time; if it be neutralized with acetic acid, and then a drop of oxalic acid added, a white precipitate of oxalate of lime will be produced. Silica is a very common impurity in commercial carbonate of potash. When it is present in large quantities the solution yields a gelatinous precipitate of silica when an excess of hydrochloric acid is added, especially on boiling. Smaller quantities may be detected by evaporating the acid solution to dryness and gently heating, the silica will be left behind upon redissolving in water.

*Oxide of copper*, which is sometimes present, is detected by adding an excess of hydrochloric acid and then an excess of ammonia. A blue colour will show the presence of copper, which may be verified by adding to the solution a drop of ferro-cyanide of potassium, a brown precipitate will in that case be produced.

Pure carbonate of potash forms a white solid mass, fusible at a bright red heat. Being only united to one equivalent of carbonic acid, it has a strong alkaline reaction both to the taste and litmus paper. It rapidly deliquesces in the air, forming an oily liquid. If this liquid is allowed to stand in a dry atmosphere for some time, it forms crystals. Carbonate of potash is capable of absorbing another atom of carbonic acid, forming a bicarbonate. This salt is much less soluble in water than the mono-carbonate, and therefore may be precipitated from a strong solution of the latter by passing carbonic acid through it, or better still by only conducting it to the surface of this solution. The absorption takes place completely, although slowly, sometimes not being finished by the end of a week. The crystals are washed in a little cold water, and then drained on blotting paper. They form large oblique prisms, transparent, of a saline and slightly alkaline taste, but no longer caustic. Its reaction is still slightly alkaline to test paper. When dry, the crystals remain unaltered in the air; but when heated strongly, they lose half the carbonic acid, and then return to the condition of mono-carbonate.

## ON THE PRACTICAL WORKING OF THE PANORAMIC LENS.

BY GEORGE DAWSON,*

*Lecturer on Photography at King's College, London.*

This paper is meant to be thoroughly practical. I do not, therefore, intend to discuss the scientific principles on which the panoramic lens has been constructed; nor, indeed, is this course necessary, inasmuch as Mr. Sutton, the inventor (to whose papers I refer you), has on several occasions fully entered into that portion of the subject, and explained the circumstances which compel the use of a curved glass for the reception of the negative. For my own part, I confess that the extraordinary appearance of the whole apparatus, so different to the traditions and ordinary requirements for the practice of photography, prejudiced me strongly against the estimation of it for practical utility. The difficulties attending the coating with collodion and evenly developing curved surfaces seemed to me almost insurmountable, and it was with strong misgivings as to the result that I determined to spend a few days of my holiday in trying the capabilities of the lens, and how far the difficulties above indicated could be overcome. I have succeeded beyond my expectations, and can now truly say that there is no pleasure greater than that of agreeable disappointment. The specimens before you, good, bad, and indifferent, are my first attempts. Some of them, the architectural for instance—in

* Read on the evening of Wednesday, May 21, at the North London Photographic Association.

subject and treatment are far from artistic, and evidently unfitted for the panoramic lens; others again, such as the general landscapes (deducting for faults of inexperience), have a breadth of effect and completeness totally unobtainable by aid of any other form of lens. I was well aware before commencing operations of its unfitness for rendering pure architecture; but I wished to satisfy myself, by experiment, of the extent of error and distortion arising from the necessary curvation of the glass. On examining the specimens you will observe that, except in cases were a straight row of houses runs across the plate, the horizontal curvature is quite inappreciable by the eye, and I can vouch for it that for ordinary landscapes the effect is apparently perfectly natural.

I now proceed to the principal object of this paper, viz., the practical details. My short experience of a few days will not warrant me in saying that my mode of procedure may not be considerably modified by future practice and improvement in the apparatus. On the latter point I have some suggestions to make, which will fall in their proper place at the close of this paper. It would have been more satisfactory to myself, and probably to you, could I have been able to lay before you a larger number of specimens; but it was impossible for me to get together more than eleven plates, on all of which I took pictures once, and some twice. Failures are awkward things to deal with in any way. I shall not detail mine; but if the instructions and precautions about to be given seem in some respects too minute, you may be assured they are for the purpose of avoiding failures experienced by myself.

*The Camera and Lens.*—The camera having two spirit levels fixed at right angles on its upper surface—a plan, by-the-bye, I should like to see introduced into all cameras—is readily adjusted to the level. The lens when unscrewed in the middle should be filled with distilled or boiled spring water. If ordinary water be used the consequence will be that, in the course of an hour or so, the air contained in the water agglomerating into a multitude of little bubbles will adhere most obstinately to the inside surface of the lens, and cause irregular refraction and confusion in the image. Care also should be taken that the stop inside the lens—an ingenious contrivance called, I think, the "*butterfly stop*," from its not bearing the most distant resemblance to that insect—be adjusted with its longer axis quite horizontal: this is in the direction of the greater length of the plate.

*Cleaning the Plates.*—The plates should be ground or roughed on the surface all round, to the distance of about $\frac{1}{10}$ inch from the edge. This may readily and quickly be done by tiling a rectangular notch in a piece of copper—an old penny piece will do very well—and rubbing along the edge with some rather coarse emery powder and water. The collodion will hold on to this rough part with great tenacity, and prevent, what is otherwise most inevitable, the total destruction of the film during some part of the after process. The thorough cleaning of the surface, is a much more difficult operation than with plate-glass, arising probably from it being originally unpolished. Nevertheless, the fact is certain, and recourse must often be had to strong solution of soda, and afterwards nitric or sulphuric acid, to remove the last traces of dirt. In all cases, when the plate has once been varnished, strong acid will be required to remove impurities from the rough edge of the glass. A padded cushion for the purpose of polishing is sold along with the apparatus; but I have found it more convenient to dispense with this, and in one hand, covered with chamois skin, to hold the plate and polish with the other.

*Coating the Plate.*—The collodion should possess no glutinous or contractile properties, and still contain a large proportion of alcohol to allow the film to set slowly, and thus give more time for coveringly the plate evenly. The operation will scarcely be intelligible from a mere description. I hold the plate in the left hand balanced on the tips of the fingers and steadied by the thumb of the same hand resting with gentle pressure against the corner. Pour on that end a body of collodion sufficient (but not in great excess) to cover the whole: then with a tremulous motion of the hand, which prevents streaks, and by gradually tilting the held end, direct the wave of collodion evenly and slowly till it reaches the other end. At the moment of its arrival there, pour off the excess from the corner into the bottle; but this must be done very quickly, and the plate turned back into its original vertical position, otherwise ridges will be formed diagonally across, and will be very conspicuous in the finished negative. Excite in the usual way.

The time of exposure seems to me to be rather less than that required for Ross's 4½-inch single lens. The longest exposure, under a rather dull leaden sky, was 20″, and the shortest, under more favourable circumstances, 2″ or less—in fact, as fast as I could open and close the shutter. Still you will observe in the latter cases very considerable detail in the dark green foreground, and the driving clouds in the distance show their outline and shading very distinctly.

*The Development.*—First, with pyrogallic acid.—Dilute a one-grain-to-the-ounce-of-water solution of pyrogallic acid with four or five times its bulk of water, which pour over the plate in the same manner as the collodion was applied. Tilt it backwards and forwards till the picture has begun to develop evenly all over. A stronger solution, with a few drops of nitrate of silver solution added, may then be applied without danger of streaks and uneven development, until the requisite intensity has been obtained.

Second development, with iron.—In some of my preliminary experiments I developed with pyrogallic acid, and would have continued to do so from choice had not my collodion contained a pretty strong proportion of bromide, which I find contributes much to slowness and thinness of negative with that developer. I had no alternative, then, but to use an iron salt; and as, under any circumstances, it is rather difficult to cover even a flat plate always evenly with that solution, the difficulty is much increased in the case of a curved surface. I have, therefore, devised and constructed, very roughly as you see, a kind of rocking dish of gutta percha, the bottom having the same curve as the plates. Two ounces of about a fifteen-grain iron solution poured into this was amply sufficient for one negative. The plate, gently dropped in and quickly rolled about, will develop very evenly. The iron solution thus used need not be thrown away, but with the addition of another ounce or so will serve over and over again without any seeming bad effects. The negative may now be washed gently; intensified to the proper degree with pyrogallic acid and silver; fixed in the usual way, by pouring on and off a saturated solution of hypo; and, finally, well washed.

It was occasionally inconvenient for me to intensify immediately after the iron development, on account of scarcity of water, and for other reasons. Under such circumstances I fixed with hypo, after the application of the iron developer, partly washed, and then stowed the plates away in the box for future treatment at home when more at leisure. I am not sure but this mode of re-development gives a more vigorous picture than the other, provided the iron developer has acted long enough to bring out all the details; it is, at all events, more convenient for field-work. It requires great care and some precautions, but may be safely done in the following manner:—

After drying and slightly warming the plate by the fire, apply with a camel's-hair brush Sœhnée or other varnish all round the edge to the depth of one-eighth inch or thereabout, taking care to fasten in the same way the edges of all incipient cracks or rents in the film. This prevents water, &c., from finding its way underneath the collodion, and renders it so strong and adhesive that the plate may now be washed without danger and intensified to any extent with pyrogallic acid and silver.

Having thus detailed, I hope clearly enough to be understood, the manipulations I have found to be the best for insuring good negatives, I would now suggest some improvements in the apparatus which will make this object more easily attainable.

With respect to the lens and camera nothing better fitted for their purpose could possibly be devised. They are perfect. The former, being only rather over five inches focus, gives exquisite definition to the very edge of a rectangular field 9¼+4¼ inches, comprehending an angle of about 105 degrees; and the camera is in every way well fitted for giving effect to this enormous angle. In one of the specimens on the table—"Pulteney Bridge"—I had the curiosity to measure the angle included after trimming the print for mounting. It was rather over 97° and is of course pretty nearly the same in all other cases.

On the other hand the material of the bath—gutta-percha—is apt to contaminate the nitrate of silver (especially in warm weather) with organic matter. I do not see any formidable difficulty in constructing receptacles of glass covered only externally with gutta-percha; or, indeed, what prevents them from being cast in sold glass? I object also to its shape. The sides, as you may observe, are arcs of two concentric circles of nearly the same radius as the curve of the glass. The practical effect of such an arrangement is, that during the act of immersion or removal of the plate, unless extraordinary caution be used, the film is liable to come in contact with the inner surface, and suffer injury. I propose that the side against which the plate leans should be of the same curve as, or rather larger, than the glass, and the opposite side an arc of a much larger circle, or indeed quite straight. We can thereby prevent the least chance of any part of sensitized surface from becoming injured by coming in contact with the sides. A larger quantity of silver solution will necessarily be required; but that I consider not only no disadvantage, but an actual gain, inasmuch as the bath will keep in good working condition for comparatively a much longer period.

*Plates, Defects in.*—If I call your attention now more closely to the specimens on the table, you will see that some of them are sharp and well defined up to the very edge of one side of the plate, but less so towards the other end. This arises from no defect in the lens—which, as I have said before, seems perfect—but from some slight variation in the curve of the plates. A variation of less than $\frac{1}{12}$ inch in the curvature will throw the image considerably out of focus, when working with a lens of which the range of focus from near to distant objects is very limited. I feel certain our glass manufacturers can easily get over this difficulty, so I need say no more about it. In all other respects a limited range of focus is advantageous, for, the point of best definition having been once ascertained and marked, no more focussing is required.

Allied to the previous defect, and partly dependent on it, is the difficulty of obtaining an even pressure on the printing-frame. No matter how many folds of flannel or felt may be interposed between the prepared paper and the pressure-board, there will still be some part of the proof not so well defined as the sharpness of the negative would lead us to expect. An air-cushion of Macintosh cloth, or other air-tight material, and covered on one side with thin felt or fine flannel, seems to me a simple and certain remedy.

In conclusion, I trust Messrs. Sutton and Ross will receive these suggestions of mine in the same spirit in which they are offered, viz., a desire to improve and extend the use of a lens and camera which have proved highly satisfactory in my short practice, and which in subjects of a particular class will, I believe, exercise no small influence on the future of photography.

## Correspondence.

### FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

*Paris, 4th June*, 1862.

"Blessed among modern inventions be photography. It has no rival on earth except the printing-press, but it works a thousand times quicker; it sheds a light upon all mysteries; it rules over darkness as a sovereign power, and brings to light, by light, an inexhaustible quantity of hidden treasures which mankind would, without its aid, have remained ignorant of for ever."

Such is the eloquent apostrophe to photography written by the eminent publisher, L. Curmer, in his prospectus of a magnificent edition of *Les Evangiles*, he is now publishing. Remarkable as are all the productions of this enthusiast, especially his *Imitation de Jesus Christ*, his *Heures de la reine Anne de Bretagne*, this new edition of the Evangelists surpasses them all, and this excellence is due entirely to photography. A short description of this bibliographical curiosity may be not without interest. The work consists of 400 pages of text, each surrounded with the richest ornamental borders, beside 100 miniatures from coloured photographs, copies of rare manuscripts executed by Jean Fouquet, Hans Memling, Albert Durer, Julio Clovis, Angelico da Fiesole, Atavante, Lorenzo Monaco, and others, and preserved in the libraries of Paris, London, Oxford, Brussels, Munich, Turin, Milan, Venice, Bologna, Florence, Rome, Naples, St. Gall, Rouen, Lyons, Grenoble, &c.

M. Curmer speaks with gratitude of the readiness with which the precious manuscripts contained in the hidden recesses of various libraries were placed at his disposal. He has good reason to be grateful to photography. In the library of Brera he copied forty magnificent pages of the rare *Antiphonaries* preserved there. At Venice he found himself in the presence of that miracle of art, the *Breviary* of Cardinal Grimani, with its eight hundred leaves of vellum radiant with the genius of Memling, Gerard d'Anvers, and Lieven of Ghent. At Florence he copied the six-and-twenty precious *Antiphonaries* of the Duomo, representing the miracles and sufferings of Christ. At Rome he obtained an audience with Cardinal Antonelli, in order to procure admission to the manuscripts of the Vatican. Permission to *view* these treasures was readily accorded, but, in obedience to inviolable rules, photography was strictly prohibited. The Cardinal himself could not exceed his powers. What was to be done? An audience with His Holiness the Pope was sought and obtained. An offering of the publisher's previous publications so won upon his Holinesses admiration and sympathy, that he wished a gold medal bearing his effigy to be presented to the favoured publisher, as a mark of his esteem. Now was the critical moment! Could his Holiness permit any obstruction to impede the publisher's project of an unique edition of the Evangelists? Certainly not. The necessary permission to photograph the MS. of the Vatican was graciously accorded, and the *Bible* of Matthias Corvin, *The Bible and History* of the Dukes of Urbino, and the *Dante* of Julio Clovis contribute some of the most beautiful pages to the Evangelists.

Should any of your rising young artists ever find themselves at a loss for a subject for a cartoon I think this little episode, suggestive of a scene representing *the Pope interceding for Photography*, well worthy their attention.

In Italy M. Curmer was fortunate in meeting with artists who could colour his photographic copies in a style equal to that of the originals. These, again, are reproduced in facsimile by chromolithography, and the result is truly wonderful. The cost of such a work must necessarily be high; this, when completed, will amount to twenty-five pounds sterling; but its publication in parts renders it accessible to persons of very modest income.

You may expect to see shortly some truly mammoth specimens of photography, being copies of some of Kaulbach's cartoons, the figures as large as the original drawings. The specimens measure some six feet by three feet. Your Great Exhibition contains photographs of Kaulbach's drawings to illustrate Göethe's Heroines, and it is not unlikely that these colossal specimens will soon form an addition.

### CARBONATE OF SILVER IN THE NITRATE BATH, &c.

Sir,—You were good enough some few weeks ago to insert a short communication of mine on some "Experiments with a Nitrate Bath." I find in the last number of the *Photographic Notes*, Mr. Sutton has done me the honour to reprint it; but, as in doing so, he has introduced some additional comments which, I think, not altogether warrantable, I shall be glad if you will give me a corner in your journal for some remarks thereon.

Mr. Sutton thus comments upon my communication:—

"Mr. Blanchard says, 'before adding acid to neutralize the alkalinity,' &c. This is an error. A nitrate bath, to which carbonate of soda has been added, may be rendered neutral, but never alkaline. The carbonate of soda continues to throw down carbonate of silver, as long as any silver remains in the solution, and this does not render the bath alkaline," &c.

Now, the Editor of the *Notes*, in his comments, has overlooked the important fact of the case, viz., that carbonate of silver *is* soluble to a very considerable extent in the bath, under certain conditions.

When salts of ammonia are employed in the collodion, nitrate of ammonia is formed in the bath. Now, it will be found, that carbonate of silver is soluble in a solution of nitrate of ammonia.

You will possibly remember that my experiments were performed upon an old bath that had been some time in use, which will account for the peculiar condition brought about.

Mr. Sutton goes on to say : "The iron developed negatives to which Mr. Blanchard alludes, and which appear to be a novelty to him, are no novelty to us. We have frequently told our readers in this journal of negatives developed with iron, which required no after-intensifying, and came out very quickly in the development. We strongly advise Mr. Blanchard to use purer chemicals than he has evidently been in the habit of using, and he will find quite a new field open to him in photographic chemistry. In particular, we recommend him to try the use of pure iodized collodion, containing no bromide—a pure nitrate bath, without any doctoring—and the common proto-sulphite of iron developer, strength from only 5 to 10 grains to the ounce, and no after intensifying. He will find that process twice as sensitive as that by which he usually works, and more suitable for taking instantaneous views in diffused light. In a strong glare bromide in the collodion is certainly an advantage."

Now, I consider these remarks entirely without warrant. I commenced to use iron for development at a time when *not* a single photographer of my acquaintance employed it, and have used it constantly ever since. It is now about six years since I took several portraits of you, which, as you may remember, yielded good prints, with no intensification whatever. I have a high regard for Mr. Sutton's attainments as a practical photographer and good optician, and think very highly of many of his ingenious inventions, but am sorry that there is not sufficient *lead* to counterpoise the *mercury* that enters so largely into his chemical composition, and causes him to jump so hastily to rash conclusions. The nine years I have spent in wading through the *slough of despond* in my desire to reach the portals of success in photography would have been sadly mis-spent if I had now to learn, for the first time, the importance of pure chemicals. I think the name of Hopkin and Williams sufficiently well known among photographers, and that I may therefore sleep contentedly, without any fear of the visitations of any impure *spirits*, methylated, ethereal, or otherwise.

I have now been engaged some years in the manufacture of collodion, and have had, consequently, to make at least some few experiments, but if Mr. Sutton will, some time, when in town, find leisure to produce an instantaneous negative of any crowded thoroughfare in London, with simply iodized collodion developed with iron, 5 to 10 grains to the ounce, and with no after intensifications, I shall then think that I have spent two years in working hard in the wrong direction, but not until then.

Valentine Blanchard.

## COLLODIO-ALBUMEN PROCESS: SHORT EXPOSURES.

Dear Sir,—Much has been said and written about the *long* exposures necessary to produce good negatives by the collodio-albumen process. Now I wish to prove that when *short* exposures are required, pictures of average merit may be obtained. The stereos enclosed are intended to illustrate what I wish to convey in this letter. No. 1 was taken on a dull day, and exposed half-a-minute. The plate was excited in the morning, and developed in the evening of the same day.

Knowing the conditions of my plate, I commenced the development by pouring over the film a few ounces of boiling water, then immediately applying a warm pyro solution, when the image began gradually to appear. I continued the plain pyro until the details were out, and then strengthened cautiously. The negative is very clean, and has no appearance of fog, or anything to indicate the harsh treatment employed to produce a picture. If the light had been good, and the subject a more *open* one, I should have given a only a few seconds.

The other two stereos are to illustrate what may be done in the development of a plate. No. 2 was exposed one minute, and No. 3 three minutes, both in a moderate light. The first was treated with hot water, and the second developed in the usual way; yet, you see the resulting prints are very similar.

I *always* give long exposures when I can, but if I am compelled to shorten the time, I feel no anxiety about my negative; for if care and *thought* be employed in the various operations, a *fair* picture is sure to be the result.—I remain, yours truly, John H. Underwood.

*Beech Cottage, Sale Green, Cheshire, June 3rd, 1862.*

[Our correspondent's specimens are valuable illustrations of the latitude which an intelligent photographer may possess in the exposure of dry plates, if due care be taken to use the resources which heat and plain pyro give him in development. There is no trace of fog in these pictures, and, photographically speaking, the plate which received one minute's exposure, is better than that which received three; although, artistically, the latter is a charming bit. —Ed.]

## WHO SHOULD HAVE THE EXHIBITION MEDALS.

Sir,—As the time for awarding the medals to those photographers who have distingushed themselves is now drawing near, it is most desirable that no anomaly should be added to the already long catalogue of official blundering, or any opening made for such severe strictures as those elicited by the course pursued in Edinburgh. Perhaps a word of caution may not be out of place. I know not whether the medals will be few or numerous, but it has been observed that many of the photographs, &c., are exhibited by publishers and others. In some cases, such as those of Heath, Mudd, and others, the photographer is also the publisher. Due care must be exercised in distinguishing the *picture* from the *picture-dealer*, or the jurors will fall into an error such as that—to take a parallel case—of bestowing the honours due to Frith's last celebrated painting upon M. Flatow.

Of course, in some of the best known cases there can be little fear of error; such as those of G. W. Wilson—Marion and Co., Regent Street; W. England—London Stereoscopic Company; Blanchard—Elliott and Co., Aldermanbury; W. Russell Sedgfield—A. W. Bennett, 5, Bishopsgate.—I am, Sir, your obedient servant, X.

# Proceedings of Societies.

### London Photographic Society.

The usual monthly meeting, being the last of the summer recess, was held in King's College on the evening of Tuesday, June 3, C. B. Vignoles, Esq., F.R.S. in the chair.

The minutes of a former meeting having been read and confirmed, the following gentlemen were elected members of the Society: Messrs. Lenthall, Roberts, Fenn, and McLean.

The Secretary said he had received a letter from Mr. Foster, who presided at the last meeting, saying that he on that occasion had remarked that certain pictures sent to the International Exhibition by Mr. Warner were not from enlarged negatives. From the pressure on his attention at the time, and the excellence of the pictures, he had overlooked the intimation attached to the pictures, which explained that they were from enlarged negatives, and he now wished to correct his former mistake.

Mr. Dallmeyer exhibited a new form of Instantaneous Shutter. He said the shutter was not his own invention, but that of Mr. Mann, of Bruce Castle, Tottenham. Its claim to attention was that it would give the maximum of exposure in a minimum of time. It opened from the centre on pulling a string, on releasing which it closed at once. There was another modification of it with a trigger movement. He believed it one of the best shutters for the purpose which had yet been produced; and as instantaneous photography seemed to be receiving increased attention, such a shutter was a decided advantage to photography.

The Chairman called attention to some fine reproductions from Turner's paintings, by Mr. Thurston Thompson; to a large view of St. Paul's, by Mr. Sand, exhibited by Horne and Thornthwaite; to some views in Australia, by Mr. Haigh; to some portraits of the Japanese Ambassadors, by Caldesi, exhibited by Mr. Kater; to some views of Genoa, by Messrs. Fothergill and Branfill; to a photograph of the Cripple's Home, by Mr. Greenish; and to a large number of fine stereoscopic views of the International Exhibition and its contents by Mr. England.

M. Claudet then proceeded to read his communications on the subject of enlargement, which will appear in our next. The papers were illustrated by the production of the apparatus used. Various images were projected on to a screen by means of the solar camera, the light obtained from a gas jet and a bull's eye condenser, in addition to the solar camera condenser being used. The object of the various images was to show the effect produced by various degrees of enlargement, to illustrate the working of his system of ascertaining the respective distances at which the negative and the screen required to be placed, and finally to illustrate how a drawing in outline of an image thus thrown on the canvas might be traced by anyone without a knowledge of drawing, from which, by the aid of a photograph printed from the small negative, the painter might easily produce a large coloured portrait. M. Claudet pointed to a fine large portrait of Professor Faraday, and to some others which had been produced in this manner.

In the course of his experiments, M. Claudet explained and illustrated a very simple process, which he stated he had found very efficient as a remedy in cases where the film or varnish had cracked. Few photographers but were familiar with this evil, which rendered a negative quite worthless for printing. He had found a very simple remedy, which rendered the cracks invisible, and restored the printing powers of the negative. It consisted in taking a piece of cotton wool, and applying charcoal in a very fine powder to the face of the negative; this seemed to fill up the cracks, without showing or in any way affecting the perfect printing qualities of the negative. M. Claudet then took some negatives quite honey-combed with cracks, and after applying the charcoal, passed them round for examination; it was found that the cracks were in most cases rendered quite invisible. In answer to questions as to whether this improvement would not soon wear off in printing, M. Claudet said he had not observed it, but if it did it was easily renewed.

M. Claudet now referred to Mr. Heath's challenge at the last meeting, and called attention to the prints he had produced from Mr. Heath's negative, and also to those from his own negative, which had been handed to Mr. Heath to produce an enlargement from. He now asked if Mr. Heath had brought his specimens with him.

After a few words from the Chairman,

Mr. Heath produced his prints from his own and M. Claudet's negatives, enlarged four times. He said he could not help feeling that he could not possibly have found a better advocate for the method he had described than M. Claudet had proved during the evening. He had listened with great attention and interest, and he hoped with profit, to the able communication of M. Claudet; but he had been struck by the difficulties to which he had referred, as to the question of sun-light. If he remembered rightly he said he had despaired of getting the sun to help him. Now he (Mr. Heath) would undertake to produce results, by the process he had described, at any time, winter or summer, sun or no sun, at any time when ordinary photographic operations could be conducted. In regard to the results of the friendly rivalry which had resulted in a challenge at the last meeting, he would now submit them for examination, and he felt no hesitation, whatever in soliciting a comparison of the definition as compared with the results of the solar camera. He felt the less hesitation because, as he had before said, he claimed nothing for himself in the matter, beyond an attempt to improve the manipulation. All he had done was to take a well-known method of enlarging, and by some careful experiments endeavour to fix more definitely the conditions yielding the best results. As regarded the character of positive, he thought he had entirely succeeded, and he invited attention to those on the table. He now just wished to say one word on the question of focussing. He had described at the last meeting that having been supplied by Mr. Dallmeyer with the exact equivalent focus of his lens, he simply measured the distances required by means of the scale he had attached to his camera. The best proof of the correctness of the calculations upon which this operation was based, was the fact that by measurement merely, without focussing at all, he obtained definition such as might be seen in the transparent positives on the table, in which he would venture to say every hair was most perfectly defined. He would now leave the specimens in their hands.

Mr. Mayall, having been engaged and interested in enlarging for a number of years, wished to make one or two observations. He thought there could be no doubt about one thing, namely, that the solar camera properly constructed was the best enlarging instrument in existence, because it effected its work without distortion. He was aware that Mr. Shadbolt dissented from this view, but he thought it was because he had not seen the instrument in operation to any extent. He was not aware whether M. Claudet had mentioned the fact, but it was important to know that in the solar camera distortion was avoided by the rays being made cross on the front of the enlarging lens at a mere point; every other part of the lens might be cut off without affecting the result. There was, consequently, no distortion, even if they magnified an image to twenty-five feet high. He thought the method used by Mr. Heath was a round-about method of producing what might be obtained at one operation. As regarded the novelty of the solar camera, he had a word or two to say. Two years ago, when Mr. Woodward was in this country, he offended some people by saying that the solar camera was not a novelty. Fifteen years ago Mr. Willatt made such an instrument for Dr. Carpenter, the aim being to enlarge microscopic objects for illustrating his work on physiology.

M. Claudet enquired if it were arranged for focussing the image of the sun upon the front lens?

Mr. Mayall said it was. Mr. Willatt then came to consult him upon the subject, and he told him that it would be quite possible to produce a combination which would enlarge without distorting. He now held in his hand the identical instrument which was then made, and as its value, historically, was greater perhaps than intrinsically, he thought it should be in the possession of the society rather than of an individual. He begged, therefore, to present it to the society. Regarding the solar camera, has advice was to use albumenized paper, and print entirely without development, and he believed very fine results could be obtained. It was, he thought, going backwards to attempt to revive the old method of enlarging at two operations, as Mr. Heath did; and the results were certainly not to be compared with the images produced by the solar camera. He believed, with good light and sensitive paper, direct prints might be obtained in from an hour to an hour and a half. He would say, in conclusion, that great praise was due to Mr. Atkinson for the effort he had made in perfecting and adapting the solar camera to the requirements of the country.

Mr. Warner said as his name had been referred to at the last meeting he might be allowed to remark, that whilst M. Claudet had been waiting months for the sun, his own (Mr. Warner's) enlarged pictures in the Exhibition had been commenced in the month of February in the pouring rain. He found that nothing short of fog stopped his operations.

Mr. Heath wished distinctly to remind the meeting that he had not introduced the question of the solar camera at all. It was not a question of his method *versus* the solar camera method, but simply thus: he desired to enlarge small pictures up to 12 by 10, and he described a method by which he could effect it with better results than he had seen by other methods. He had said nothing whatever in depreciation of the solar camera except that it required the light of the sun, which in this country could not always be obtained.

The Chairman said it must not be forgotten that there were other countries besides England, where sunlight was plentiful and powerful. Referring to M. Claudet's method of focussing, he offered his opinion as a mathematician, that it was mathematically correct.

Mr. Dallmeyer referring to an expanding and collapsing diaphragm which M. Claudet had shown and described, said that

M. Dafft had some time ago invented a similar diaphragm for a similar purpose, which worked a little more perfectly he thought than that of M. Claudet.

Various specimens of enlarging were shown by Mr. Warner and Mr. Gilling.

After some further conversation, and votes of thanks to M. Claudet and others, the proceedings terminated.

## Talk in the Studio.

South London Photographic Society.—The South London Photographic Exhibition, at the Crystal Palace, was opened to the public on Monday last. The display, both as regards numbers, quality, and arrangement, is, as we anticipated, exceedingly good, the general effect far exceeding that at the International Exhibition. The number of frames contributed is between four and five hundred, which include excellent specimens of every process in use. We shall notice the pictures in detail in our next.

New Industries.—Mr. Hawes, in a recent lecture on the International Exhibition and the Society of Arts, makes the following remarks on photography as a "new industry" since 1851:—"Then, as regards new industries, or those which, from the change that has taken place in the mode of manufacture, have become almost new industries: first, we will call attention to photography, that now branch of fine art still in its infancy, but employing many thousand persons, and which is most admirably represented by English and foreign artists. It is not for me to say which country exhibits the finest specimens. French, Austrian, and English artists have all produced pictures showing great taste and most skilful manipulation. So great has been the progress in every branch of this art since 1851, that we may fairly expect, with the aid of chemical science, to see still greater advances in the next ten years. The apparatus and appliances exhibited for working in and out of doors are of much interest. One striking fact conveys a clearer view of the value of this art as an industry than any description. M. Voigtlander, a manufacturer of the most expensive lenses only, has just celebrated with his workmen the completion of his 10,000th lens; this gives some idea of the immense demand for apparatus of this character that has been created in the last few years."

The Copyright (Works of Art) Bill.—This Bill has been submitted to a select committee of the House of Lords for revision. The *Athenæum*, whilst recognizing the importance of such an Act, objects entirely to the framing of the present Bill. It says:—"This great principle, of the right of property of an artist in his works, being admitted, it only remains to carry it out by such an equitable measure as will equally protect *all* parties interested under it. These parties are the artists, the purchasers of their works, either when commissioned or otherwise, and the public. Does the Bill, as it is now framed, accomplish all these objects? We submit that it entirely fails to do so, and that Lord Overstone is perfectly accurate in denouncing the measure as being inequitable; as being simply an artists' Bill for protecting their interests, and without any reference to the interests of the general purchasers of pictures, or of the public. The Lord Chancellor advocated the general principle of the measure, and carefully avoided committing himself to its details. Indeed, both he and Lord Granville, as we have shown, invited suggestions for its amendment. Now, Lord Overstone had pointed out three vital defects in the Bill. For the first time in the history of our legislation upon copyright, it proposes to give that right without limiting it to new works: secondly, it ignores the principle established by all the statutes upon copyright, that when the author of a work is employed to execute it, the copyright shall vest in the employer, and not in the author; and, thirdly, that the registration proposed by the Bill is useless for protecting the public. It is contrary to common sense that it should do so when the contract for the preservation of the copyright may be registered at any time within twelve months after its date, and then only a short written description of the nature and subject of the work is to be registered. How is it possible to identify any work of art by a written description?"

## To Correspondents.

V. B.—The addition of water to collodion has a tendency to make the film more porous, but it requires adding with care and judgment, as too much will cause reticulation in the film. The best method of making horny collodion powdery for use in dry processes is to add a little bicarbonate of soda, and shake it well up with the collodion. This will entirely remove the horny texture of the film.

J. H. Meays.—The mottled appearance of your mounted prints is caused by the material with which you state they are mounted. Gum, when thin, is very apt to sink in through the paper, giving the dirty mottled effect of which you complain. In some of them it seems to have caused fading or discolouration as well, which if it were acid, and the prints not well washed, it would be very apt to do. Starch paste newly made, or good glue or gelatine, are best for mounting.

Amateur.—Crapy diagonal lines occurring at the corner of the plate where the collodion is poured off, arise from the plate being immersed in the silver bath before the film is well set. The corner where the collodion is poured off is, of course, least set of any part, and there the lines and reticulation occur.

A New Subscriber.—The Latimer Clark stereoscopic camera and lens which you describe will be well fitted for all the purposes you mention. For copying engravings, &c., you will probably require some means of lengthening the body of the camera; that is, if you wish to copy objects of the same or nearly the same size as the originals. We should scarcely recommend you to use the calotype process for anything so small as stereoscopic pictures.

M. J., Berlin.—The letter has been forwarded.

A. B. C.—The print appears imperfectly fixed. Probably your hypo has been too weak, or too much used. 2. The time required for toning will depend on the temperature and on the quality of the paper. The appearance of the prints is the proper guide; they should be a little blacker than they are required to be in the finished print. A grain of gold is generally calculated to tone a whole sheet of paper, but with care, and a good sample of paper, it will tone considerably more.

Lens.—Entirely a fallacy to believe that in such a case "Jack is as good as his master." It is not the merely mechanical process of grinding which affects the question. Do not rely upon such a fallacy at all. We will answer you more fully in our next than we have time to do just now. 2. It is very difficult to eliminate acetic acid from a silver bath. On adding carbonate of soda to neutralize it, acetate of silver is formed. To get rid of this when the bath is supersaturated place the bath in a cool place, when needle-like crystals will form, which may be filtered out. Acetate of silver is stated to be less soluble in a strong solution than a weak one; therefore by strengthening the solution you will more easily get rid of it.

James Dale.—The sole cause of the poor brown tone of your pictures is the thinness of the negative, which manifestly does not possess anything like sufficient vigour. In order to get a rich, deep tone, no matter of what tint, you must have a sufficient depth of reduced silver. If your negatives have not enough vigour you are obliged to stop the printing before this depth of reduced silver is obtained, and thus you fail to get good tones. If you tone lightly you get poor browns, if deeply you get weak, slaty, greys. The appearance of a print from a weak negative before toning, is often very deceiving, as its want of depth is not then very apparent.

Oxygen.—The method referred to is that used by the Lime Light Company. It is not adapted to operations on a small scale.

W. Matthews.—We had replied to your first letter privately before receiving your second, and answered your present queries.

Ancient Photo.—The new work of M. Disderi on Photography can doubtless be obtained through any foreign bookseller in London, such as Dulau, Trubner, and others. The price, if we remember rightly, in Paris, is ten francs.

J. A.—Your negatives appear to be too weak, and you do not print nearly deep enough. See answer to James Dale.

C. Smartt.—A notice in our next. 2. The advantages claimed for formic acid in the developer, are great detail, delicacy, and gradation of tone. The formula given by Lieut.-Col. Stuart Wortley, who has produced some of the finest pictures we have seen, and attributes great virtue to formic acid, stands thus:

| | |
|---|---|
| Water ... ... ... | ... 18 ounces |
| Sulphate of iron ... ... | ... 200 grains |
| Formic acid ... ... ... | ... 3 drachms |
| Acetic acid ... ... ... | ... 4 ,, |

Negatives developed with solutions containing formic acid are said by some to continue blackening under the influence of light.

Photos.—A piece of glass half an inch or an inch square is sufficiently large for a spectroscopic examination. 2. The cotton wool seems in every way well suited for the manufacture of pyroxyline. If your acids are somewhat weaker than the formula, you may, as you mention, increase the quantity of sulphuric acid; but the difference between yours and those of the proper strength appears so little that you may with propriety try them as they are in equal quantities first. If the cotton dissolve in the acids, or when made give a collodion too powdery, then add more sulphuric acid next time. Please notice in your copy of the Almanac whether the quantities of acids are stated in drachms or ounces. Some copies went out with drachms of acids, which for the cotton stated should have been ounces. 3. In our practice, we have rarely used more than a grain of bromide to an ounce of collodion, and we have generally found that proportion work well. Much depends upon the character of the pyroxyline and other circumstances, which can be best ascertained by experiment. Bromides generally serve a treble purpose: they increase the sensibility, they reduce over intensity, and go far to ensure clean pictures. The proportion in which they are required depends much upon the tendency to the opposite evils present. It is probable that you will find from a grain to a grain and a half sufficient for your purpose. We prefer the collodion a few weeks iodized, and we have some equally good at the end of two years, iodized by the formula we give in the Almanac.

All Letters, Works for Review, and other Communications for the Editor, should be addressed to 32, Paternoster-Row.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 197.—*June* 13, 1862.

## THE SOUTH LONDON PHOTOGRAPHIC EXHIBITION.

We cannot help coming to the conclusion that the Crystal Palace at Sydenham possesses, for a Photographic Exhibition, many advantages over the building, which is no palace, at South Kensington; and we fancy that those least disposed to admit this some months ago, will now, in view of the absolute fact, be quite prepared to agree with us. We admit the occasional distraction of music and "frivolous amusements;" but the music is not perpetual; and even the agile Blondin cannot risk his neck for more than an hour a day; whilst the minor claims on attention, such as distant music of the organ or pianos, the plashing of water from fountains, the murmur of a happy multitude in the magnificent grounds, &c., add, we think, to the pleasure—rather than cause any distraction—of examining the photographs. These, and the ready access to the department, the ample space afforded, the good array of pictures, and the excellent arrangement, will all contribute, we think, to make the South London Society's first Exhibition a successful one.

The first feature which strikes us is a very fine display of reproductions exhibited by Mr. Hering. These consist chiefly of what, perhaps, present the fewest photographic difficulties—reproductions of engravings. It is somewhat singular, however, how very rarely this kind of work is well done; if the copies are soft, they are dingy; if brilliant, they are crude, hard masses of black and white, with the most delicate touches of the graver entirely omitted. The specimens here exhibited are admirable examples of good judgment and manipulative skill, combining to give the best results; the softness and delicacy, as well as the vigour of the originals, being well preserved. Another point appears to have received attention here, which is too often neglected: good copies of the engravings have been selected, as the basis of the reproduction; the difference between the photographic reproduction from a proof impression of an engraving, and one from a feeble, worn-out print or lithograph, is even more striking than in the originals, because, in the photograph of the latter, in the attempt to get vigour, it is almost impossible to avoid hardness. The majority of these reproductions are from the works of the best masters, and few things are more calculated to cultivate the art taste of the young photographer than a careful examination of such pictures. Here is Guido's "Cenci," for instance; it is but a bust, but look at the winning grace in the turn of the head; or, as an example of dignity, in a standing position, take the figure of Christ in Signol's "Qui sine peccata," &c., and mark, also, the value, in completing the composition, of the unobtrusive column in the background. We might multiply examples; but we counsel photographers, who have the opportunity, to make a collection of photographic reproductions from the best masters, and study them carefully as one of the best means of art culture which they can adopt.

There are some other interesting and valuable reproductions besides those of Mr. Hering, of which we have just been speaking. Here are copies of the grand etchings of Albert Durer, exhibited by Mr. Jeffrey, who also exhibits a reproduction from Turner's well-known "Windsor Castle, from Eton;" and a frame containing three views of the same head, right and left profile, and full face; the subject is a bust of William Fairbairn, by Woolner. Mr. Dodd also exhibits some copies from Durer's etchings.

The display of portraiture is very good. The most noticeable picture in this department is the colossal group by Mr. A. Brothers, of Manchester. The size of the picture is 48 inches by 21 inches: it consists of between forty and fifty figures, all, or nearly all, of which, if we remember rightly, were on separate negatives. The design and general arrangement of grouping must, of course, have been conceived beforehand. The grouping and composition are so skilfully managed that the art critic of the *Athenæum*, when noticing the picture, could not conceive that this was due to the photographer, but attributed it to a happy fortuitous arrangement, remarking that:—"with the felicity that sometimes attends chromatic combinations in the kaleidoscope, they are perfectly grouped in simple masses." As regards the photographic merits of the picture, the negatives have manifestly been for the most part excellent; there is perhaps a slight tint of yellow in the whites of the picture, but when it is remembered that it was produced by not less than forty-five different printings, and that the paper was fifteen days in hand before the printing was completed, the marvel will be that the colour of the whites is so good. It is, of course, touched, but with care and judgment.

Mr. C. T. Newcombe exhibits some very large portraits taken direct, which are very good; but we must confess that we think that for portraiture of this size, enlargements, from small negatives, permit scope for better results. Mr. Newcombe also exhibits a frame of card portraits, in which the feeling and manipulation are alike good.

Messrs. Maull and Polyblank exhibit some whole-plate pictures as well as card portraits, of which the former are much the best; of the latter we cannot say much. They also exhibit some whole-plate pictures with the general characteristics, as regards proportion and accessory, of card portraits: the result is decidedly successful, and we think worth the attention of photographers generally.

A frame of portraits is exhibited by M. J. de Mouxy. One of these is a photograph on ivory: it is very exquisitely coloured in water colours; from the purity of colour exhibited by the ivory, of which, as the portrait is vignetted, a good deal is seen, it may be fairly assumed that the printing—the chief difficulty on ivory—was successful. In the same frame is a vignetted print executed in a style which is worthy of attention: the general background, instead of being, as is customary in vignetted prints, white, is of a middle tint, into which the image is graduated. This, of course, gives greater force to the lights, and is pleasing in general effect. In this instance the result is, in our estimation, spoiled by very elaborate "touching."

A frame of portraits, exhibited by Francisco Sargent has very considerable merit; a vignetted group in the centre is exceedingly good.

Mr. Macandrew, of Regent Street, contributes a large number of portraits of public characters, chiefly large busts, the heads being from two to three inches long. Those who have seen the large heads of Pierre Petit, in Paris, will be familiar with the fine effect attainable in photographs in this style. The majority of Mr. Macandrew's are very excellent indeed, vigorous, delicate, round, and well modelled; No. 67, a portrait of a lady, is especially fine.

Mr. H. P. Robinson's "Lady of Shalott," "Holiday in the Woods," "Elaine," &c., our readers are already familiar with. Mr. Noel Fitch's portrait of a sleeping child is a decided gem. Mr. A. H. Wall exhibits a frame in which the central vignette, and some vignetted card pictures are very pleasing.

Passing from the portraiture, we come to a screen covered with the well-known pictures of Francis Bedford. Most of these are very familiar; but from their real excellence they always seem to possess the charm of freshness. The interiors have unquestionably never been surpassed. Mr. E. C. Buxton contributes a frame containing shipping, genre studies, &c. "The Pickle" yacht, on one of the Scottish lochs, is a very good picture. Messrs. Jackson, Brothers, of Jumbo, near Manchester, contribute a series of their charming studies of rustic grouping and scenery. We have more than once on former occasions referred to these pictures, which are, of their kind, amongst the very finest which have been produced by our art. The subjects are for the most part familiar and accessible to every one; but by careful and judicious selection of position and lighting, we have pictures such as would have delighted Gainsborough. We especially commend these pictures to the attention of those visiting the Exhibition.

Four fine instantaneous pictures, two of which are glass positives, are contributed by Mr. Kibble, of Glasgow. They are chiefly studies of clouds, with sufficient of foreground and water to give force and effect to the compositions. The bank of clouds in one of the glass positives is wonderfully beautiful, and will repay careful examination. Two frames of Mr. Blanchard's instantaneous stereographs, consisting of marine subjects and London street scenes, are contributed by Smyth and Blanchard; we have before noticed the beauties of many of these slides. Mr. Lennie, of Edinburgh, contributes a frame of similar pictures to those of Mr. Blanchard, some of which possess merit.

Mr. Lyndon Smith contributes some specimens, which are unworthy of his powers. Mr. S. Thompson contributes some of his series published as "Cabinet Photographs," which we have noticed before. His "Tomb of Edward the Black Prince" is, perhaps, the best exhibited, and is a really fine picture, free from the flatness and imperfect lighting which characterises some of his photographs. Mr. Morgan, of Bristol, exhibits some very fine landscapes, at once forcible and delicate. Mr. Ernest Edwards sends some exceedingly fine pictures, of which we may mention one of King's College Cambridge, and another of Netley Abbey, as especially fine and worthy of attention.

We shall resume our notice next week.

## HOT DEVELOPMENT FOR TANNIN PLATES.

We have recently received a letter from Lieut.-Col. Stuart Wortley, in which he details his experience as to the great advantage of heat in development. It will be seen from the extracts which follow that not only is the exposure less, but in some cases the negative is of a better character than could have been obtained even by a prolonged exposure. Colonel Wortley says :—

"I have found in one of the last numbers of the News that you have taken sufficient interest in the hot development of tannin plates to induce you to devote a leading article to the subject. As I have worked the process through the past winter on 12 by 10 plates, my experience may perhaps be of some use to yourself or your readers. I was first led to use warm water (80°) by finding that the use of cold water to wet the plates previous to development, unless continued for an inconvenient length of time, had a tendency to leave the tannin solution not evenly dissolved on the plate, producing marks on the sky during development. When Dr. Draper's process appeared I increased the heat of the water, with the decided advantage not only of shortening the exposure, but of obtaining a detail and intensity in the case of very dark shadows and insufficiently lighted objects, and which, working with lenses covering my plates properly, I had before found the tannin process inadequate to, even with a prolonged exposure.

"I have seen several letters and remarks in the different journals on hot water development, but with few exceptions no allusions to the temperature of the water. In my opinion the value of the process lies entirely in the adaptation of the heat of the water to the amount of exposure given to the plate. I find by repeated experiment that if I expose one plate six minutes and another twelve minutes, by heating the former with water at 180° and the latter with water at 100°, I obtain as nearly as possible the same negative, but I should be inclined to give a slight preference to the former. According to my subject, and to the exposure that I have given, I vary the temperature of the water from 80° up to 200°, beyond which heat I have never yet gone.

"I use no preliminary coating under the collodion, yet out of sixteen plates, 12 by 10, brought home and developed after an excursion some short time since, not one of the films showed any tendency to leave the plate under the influence of the hot water, and I only lost one of the number, which, being an interior, and requiring a very long development, cracked across the plate during the final application of pyrogallic and silver; and, as I have frequently noticed this effect on films during a prolonged pyro development, this loss cannot be laid to the charge of the hot water.

"The one thing to be avoided in working this process is over exposure and too hot water together. In a case of this kind the picture appears rapidly, very red and weak, all detail coming out at once, and the silver added deposits itself at once on the shadows as much as on the lights, and the result is a negative deficient in contrast, though full of detail in even the darkest shadows. I have seen complaints of fog and stains on negatives developed by this process, the first I believe to arise solely from the want of sufficient acid in the bath or developer, and the second from insufficient washing after removal from the nitrate bath.

"In my own practice, I have found that with a bath made of pure neutral (or, indeed, slightly alkaline) nitrate of silver, $1\frac{1}{2}$ minim of pure nitric acid to the ounce of solution has not been too much to secure clear plates. And in my developer, I use citric acid in the proportion of from 4 to 6 parts to 1 part of silver.

"With regard to the washing of the plate after removal from the nitrate bath, I can only say that it must be *thoroughly* done, and it is impossible to do it too much. In my own practice I have six horizontal baths full of water, and as the plates leave the nitrate bath, they go from one to the other, and then when the six are out of the bath they go one by one under the tap, and then are covered with tannin. The three first baths contain distilled water, and I invariably find, that after preparing 15 or 20 plates, there is no appreciable amount of silver in the fourth bath, and I feel sure that the soaking of the film (face downwards) in the six baths is a far more certain mode of removing the free nitrate than mere washing under a tap, which might, I should be inclined to think, leave sufficient nitrate of silver entangled in the pores of the film to produce stains in the development; and in the case of careless washing, the silver might accumulate in one of the corners, and the stain would commence from there.

"I do not use alcohol in the tannin solution, as I have found it apt to cause marks to appear in the film, as if the resinous substance in tannin did not dissolve thoroughly, remaining in undissolved lumps in various places.

"After what has been written in America, about the instantaneous results obtainable on tannin plates with hot water, I have felt surprised, that in my experience, there is still a very wide difference between the exposure required for wet collodion, and for the same collodion prepared with tannin.

"I am afraid I have made this letter prolix and uninteresting, but it appears from the letters I have seen, that the process has been so mismanaged, that I have been induced to write to you rather more fully than I should otherwise have deemed necessary. I hope on my return to show you my results, and we can discuss the subject at greater length."

On the subject of intensifying, our correspondent makes some remarks which may be found useful.

"I see in Mr. Heath's remarks before the Photographic Society, that he complains of being unable to obtain intensity in the intensification of an iron developed negative during his enlarging experiments, and invites suggestions thereon. I have obtained good printing qualities from the weakest negatives by the application, first of bichloride of platinum, and iodide of ammonium, and then, after thorough washing, bringing up both detail and intensity by the use of pyrogallic and silver. Or, after the application of the bichloride and iodide, pouring an acid solution of silver on and off the plate, and then, re-applying the bichloride and iodide as before, bichloride of mercury has answered in my hands as well as the platinum.

"I must not conclude this letter without mentioning that I feel indebted, in a great measure, for whatever successful results I have obtained, to the invariable excellence of the chemicals supplied to me by Messrs. Hopkin and Williams. I had, and still have in my experiments, myriads of failures; I never do a day's work without learning something, or noting some important fact, and it all leads to my being convinced of one fact, viz., that the purity of the nitrate of silver bath is the all important foundation of perfect photography; and that to attempt to work a delicate instantaneous process on large plates would simply be a waste of time without the use of pure silver. Many things tend to put a bath out of order, bad ether, bad distilled water, and, in fact, many causes, the discussion of which, I will not trouble you with at the end of so long a letter. But start with pure silver, and keep deteriorating causes as far as possible from the bath, and what a difference one finds between one's work, and the unhappy wearying state of things which the use of bad chemicals entails.

"I have used Messrs. Hopkin and Williams's preparation of pure nitrate of silver constantly during the last year, and have found every sample equally good, as well as all the other chemicals that I habitually use of their preparation.

"I may mention, that a sample of silver from Messrs. Bailey gave also very satisfactory results, and the collodion with which I have principally worked the process alluded to above, has been a mixture of one of Mr. Rouch's manufacture according to Mr. Hardwich's formula, and a preparation of my own. These two I mix in various proportions, according as it seems fit.

"I think I had better leave off, or I shall be induced to begin on the subject of collodion, and bore you utterly to death, so I shall beg you to believe me, very faithfully yours, STUART WORTLEY."

## PHOTO-CHEMICAL RESEARCHES UPON THE SALTS OF SILVER.

BY DR. D. VAN MONCKHOVEN.

The history of the salts of silver is one of the most curious that can engage the attention of physicist or chemist. A common property, so to speak, that of being decomposed under the influence of light, distinguishes the salts of silver, generally, from the salts of all other metals.

It must not be supposed that, beside the salts of silver now employed in photography, there are not other salts susceptible of similar application. This would be a serious error, and the object of this essay, which is a summary of elaborate researches during many years, is to show that it is more than probable that the processes now adopted will receive many important modifications.

Our desire is to aid earnest experimentalists by pointing out to them the route they should follow. They must, indeed, be thoroughly imbued with this idea, that research becomes fruitful only in proportion as the thought precedes the experiment. The following, then, is the order to be pursued in a given research.

For example. Suppose it be desired to substitute more rapid collodion processes than any of those now in use. The process to find is threefold. First, to substitute a more sensitive salt for the alkaline iodide, or rather, to compose a silver bath with a soluble salt of silver, which is more readily decomposed under the influence of sulphate of iron, or, what would be still better, to discover a new developing agent, which will permit the time of exposure in the camera to be diminished.

The experimentalist will perceive, upon reflection, that these are the only processes possible. It is not the addition of new alcohols or other substances that will give greater rapidity. There remains then the substitution of a salt of silver for the iodide of this metal. Certain considerations thereupon present themselves which it is important not to lose sight of.

The salts of silver divide themselves into two very distinct categories. The first includes the salts directly sensitive to light, that is to say, those which, when exposed to daylight, assume a violet hue after a few moments' exposure. It will be remarked that, strictly speaking, the iodide of silver is scarcely sensitive to light, while the chloride and bromide blacken very rapidly.

The second category includes those salts of silver which are easily reduced after being exposed to light, and it seems that the salts possessed of this property are very little endowed with the first. Thus, of three collodions prepared exclusively with a chloride, a bromide, and an iodide, the latter will be the most rapid, while the bromide will be slower, and the chloride much slower still—in contact with the developing agent be it understood.

Under the direct influence of light it is the bromide that becomes coloured the quickest, then the chloride. As to the iodide, it is only slowly that it assumes a light grey hue.

Among the salts of silver which may be substituted for the chloride of silver for use under the action of direct light, as in positive printing for example, we may mention the chloroacetate of silver, the cholate, the malate, &c. We shall, however, recur to these in other articles upon this subject, for the present, the better to show the importance of these researches, we shall instance a familiar example.

To whom has it not occurred, while preparing positive paper, to touch the paper with his fingers? Now persons who perspire freely stain the paper they touch. But if we experiment with the paper so touched, we shall find that it possesses greater sensitiveness to light. If we collect the perspiration with a hair-pencil, and spread it upon the surface of the sensitized paper, we shall perceive that it very rapidly augments the action of light upon the chloride of silver.

Analysis clearly demonstrates the presence of chloride of sodium in the perspiration, but this is not the cause of the acceleration of the luminous action, it is due solely to organic matter.

If space permitted, it could easily be shown, by curious examples, that we are very far from having attained perfection in our present method of printing positives; on another occasion we shall enlarge upon this subject.

With respect to the salts of silver, which are developed after a short exposure to light, a strange fatality seems to prevail, namely, that we have at first sight hit upon a salt unique in its rapidity. In fact, among the hundreds of experiments we have made, no compound, after a very short exposure, developes so well under the influence of reducing agents. From this point of view, the question becomes difficult.

Our researches have led to the discovery of salts of silver perfectly fixed in the light; that is to say, of such as do not in the least change colour after many days' exposure to the sun. Among these we may mention the cobalticyanide, and the sulphomellonate, which after exposure to the sun for several days remain perfectly white.

The most curious salt is the resinate of silver, which may be very readily prepared. This substance enjoys the very curious property of being soluble in spirits of turpentine. This solution, spread upon paper, leaves resinate of silver in the substance of the paper, and this resinate is very sensitive to light. It is the same with resinate of gold.

Another curious compound is the chloro-succinate of silver. This salt is produced in the paper by double decomposition, and is very slightly sensitive to the light of the sun; but if the paper be placed on a sheet of glass heated to 212° Fah., the action of the light becomes very active, and the salt decomposes rapidly and turns black.

Moist nitrate of silver is very sensitive, but dry, it is discoloured very slowly.

All the salts of silver are not white; some are red, green, yellow, brown, &c. The *picrimate* is of a very beautiful *red* colour, and unchanged by light; the *phloroziate* is *blue;* the *nitrophtanilate* is *orange*, &c.

We shall give hereafter a summary of the general properties under the influence of light of a great number of salts of silver, from which the experimentalists will probably derive very useful suggestions: as to the means of procuring these substances, most of them will be found in commerce.

It is evident that with regard to greater sensitiveness under the influence of *direct* light, there is little to be hoped from the substitution of new salts of silver for the iodide now employed. It is not the same, however, with regard to the substitution of soluble salts of silver for the nitrate of silver, of which negative baths are composed.

It is well ascertained at the present day, that it is not the sensitiveness to light of iodide of silver which gives rapidity in our present processes, but rather the singular property possessed by this substance of being the *motive* of the local decomposition of the nitrate of silver by the developing agent. Thus pure iodide of silver is not of itself sensitive to light, but it fixes the molecules of silver set at liberty wherever they have been struck by light. This is perhaps a physical property, and not a chemical one, of the iodide.

But according as we mix sulphate of iron or pyrogallic acid with a more or less stable salt of silver, the reduction takes place more or less quickly; it is also very probable that other salts of silver may be substituted for the nitrate now employed. Our task in this place is to give a list of these salts, such as are easily prepared and quickly reduced.

In the first place we name the *chlorate of silver*. This salt behaves exactly like the nitrate.

The *sulphoglycerate*, the *ethyl sulphate*, which is also very soluble in alcohol, the *amyl sulphate*, the *amyl citrate*, and the *lactate*, are the salts best adapted to these researches, and to which we shall recur in another article.

Such is the list of the organic salts of silver, or, at least, of such as possess properties which cannot be doubted, and upon which experimenters will, doubtless, be glad to obtain some details.

Our aim, it must not be forgotten, is not to dilate upon the researches we have accomplished in this direction, but rather to aid experimentalists by condensing the most striking properties of these organic salts of silver. The enquirer in this direction will, probably, find many useful hints; it is our intention to publish our researches upon these salts at an early date.

## Scientific Gossip.

Japanese Crystal Spheres; Danger of Fire at the International Exhibition Building—Paraffin and American Oil, their Dangers and Methods of Testing—Fusion of Platinum—Injury to M. Deville by the Fumes of Osmic Acid.

A curious accident lately happened at the International Exhibition, by which, had it not been for the promptness with which it was discovered, the building might by this time have been reduced to ashes in a very scientific manner. Among the most noteworthy objects in the Japanese court were two spheres of rock crystal, about five inches in diameter, ground and polished with mathematical accuracy. They were exhibited by Messrs. Baring Brothers, and attracted very little attention from the general visitors. One very sunny day, however, a person rushed into the superintendent's office with the alarming intelligence that "the two glass globes had caught fire." On hastening to the spot it was found that the spheres had acted the part of burning glasses, and had concentrated the rays of the sun, which was shining full upon them, on to the mahogany stand, which was then in a blaze. These globes have now been removed to the Chinese Court, where the curious visitor may see two holes in the stand large enough to insert the top of the finger. These holes are of some interest, as they are each double, showing in a very perfect manner the double refracting properties of the quartz.

A very important report on paraffin oil has just been made by Mr. Charles O'Neill. This oil is now so generally used for illuminating purposes, and on account of the purity of its light is of somewhat frequent employment for microscopic photography, that a knowledge of the properties of the multitudinous liquids sold under this name, and of the simple methods of ascertaining whether their employment would be attended with danger, cannot be too generally made known. In deciding whether a sample of oil is dangerous or not, reference must always be had to the lamp in which it is used; some of the dangerous oils might be used with safety in lamps of a different construction, and the most harmless of them would be dangerous, if used in a moderator or carcel lamp. Special lamps are now constructed for burning this oil in, and Mr. O'Neill's report must be considered as referring to the oil when burnt in these lamps. From his experiments, it results that the chances of accident from the use of these oils may be referred almost exclusively to their greater or less proneness to form an explosive mixture with the air contained in a partly-filled bottle, or lamp reservoir. Nearly all the accidents arising from the use of the new illuminating oils have been primarily caused by the ignition of the explosive mixture of combustible vapour and air, either in the bottle in which the stock of oil is kept, or in the reservoir of the lamp. Thirty-two samples of oil, from as many different establishments, were examined, chiefly with a view to ascertain whether any of the oils would form an explosive mixture with air at a mean temperature of 60° Fah.; this representing the average temperature of domestic rooms where the bottles of oil are kept. To ascertain this point, about a quarter of an ounce of the oil was put into a six-ounce stoppered bottle, the stopper inserted, and the bottle shaken and moved about, so as to facilitate the escape of vapour from the oil; in three or four minutes the stopper was taken out, and a lighted match held to the mouth of the bottle: if there was a rush of pale blue flame through the bottle, the oil was said to give off an explosive vapour at the ordinary temperature of the atmosphere, and to be highly dangerous. Only two out of the thirty-two samples exploded when tested in this way. This temperature can, however, be only considered as the lowest limit of possible danger; the actual limit of danger being the highest temperature to which, under all ordinary circumstances, the oil is likely to be exposed, either in storing or while burning in the lamp. A temperature as high as 85° to 90° may be calculated upon as often existing in the cistern of a lamp; this high temperature being produced by a long-continued burning in a warm room, and on a table near the fire. Any oil, therefore, giving off combustible vapour, and forming an explosive mixture with air at this temperature, must be looked upon as unsafe for ordinary use. Out of the remaining thirty samples, three were found which were dangerous at a temperature of 85°. With these five, therefore, it would require the constant exercise of skill and care to prevent serious accidents. The remaining oils were then successively tested at temperatures of 100°, 120°, and 150°. Four of them were dangerous at the first, three others at the second, and the remaining twenty at the highest temperature. This is, however, beyond the limits of actual danger, and these twenty may, therefore, be looked upon as a very safe oil. The classification of these oils presents several points of interest. The whole of Young's paraffin oils were found to be safe, whilst the whole of the oils which exploded at or below 120° were American, only two of the latter sort being considered safe. Another method of testing, which, although not quite so effectual as the above, may be of more use, as it is easier to employ, for our readers, is to try the liability of the various samples to inflame upon contact with a lighted body. This inflammability is in close, if not in exact, relation with the explosibility. None of the samples of Young's paraffin oil were found to take fire at 130°, whilst out of fourteen samples of American oil, eleven inflamed at this temperature, whilst three did not. It must, however, be carefully borne in mind that whenever the oils are scattered upon linen or woollen rags, at even the ordinary temperature of the air, they burst into a violent flame upon the most momentary contact with a lighted match or candle. This is the most dangerous property of the oil, and in it there is no considerable difference between the best and the worst samples of paraffin or American oils. It is generally considered that the specific gravity of an oil affords a good test of its quality, and several methods of examination founded upon this have been frequently described in newspapers; but O'Neill finds, however, that the specific gravity of the sample does not give any idea of its liability to explosion, but it forms a tolerably reliable means of distinguishing between the British paraffin oil and the American substitutions. Young's oil has an average density of ·833, whilst the American oils are generally below ·816; a sample of coal naphtha, however, which was incomparably more combustible and dangerous than either of them, had a specific gravity of ·865. The boiling point is no better guide, for, though volatility is generally in close relation to the boiling point, the vapours of many of these oils have a diffusive power sufficient to counterbalance a very high boiling point.

It is seen, therefore, that these illuminating oils are midway between the oil-lamp oils, which cannot explode in any kind of lamp, and the very volatile and inflammable liquids such as naphtha, camphine and spirit, which are liable to explode at any time. The common coal naphtha is infinitely more dangerous, more explosive, and more inflammable than any of the American or paraffin oils, and yet it is largely consumed as an illuminating material with but few accidents, because its dangerous properties are known and guarded against. The real danger to society consists in selling one species of oil for another; if paraffin were sold for sperm oil it would be very dangerous, genuine paraffin oil is perfectly safe in a paraffin lamp, but a majority of the American oils are not safe in this lamp.

In a recent number we gave an account of a wonderful metallurgical feat which had just been accomplished, the fusion and casting in a mould of upwards of 2 cwt. of platinum, by M. H. Ste. Claire Deville, in the workshops of Messrs. Johnson and Malthey; during this operation considerable quantities of fumes of osmic acid were given off, which so seriously affected M. Ste. Claire Deville, that he was obliged to return to Paris, where he has since been suffering severely. We are happy to say that he is now recovering from the ill effects of this very poisonous metallic vapour.

## ENLARGEMENT OF PHOTOGRAPHS.*

BY M. CLAUDET, F.R.S.

The possibility of enlarging small photographs is at present engrossing the attention of the photographic world; and there is no doubt that it is a considerable advantage in many respects. Small pictures are produced with the greatest facility, and with a perfection which cannot be obtained by large lenses and complicated apparatus. For taking views the operator need not encumber himself with a heavy baggage, and he may carry all his appliances packed in a moderate compass. Small glass negatives are less subject to be injured or broken in travelling, and may be contained in a light box. For taking portraits the preparation of plates is very simple and rapid, the pose is nearly instantaneous, and consequently the expression is not constrained and unnatural. Small lenses operating at a great distance from the sitter give an image without distortion and exaggeration of perspective. All is perfect in small pictures; and before an audience of experienced photographers I need not do more than mention the fact that if we enlarge such small pictures we can obtain portraits of great beauty, characteristic in countenance, and correct in forms.

The solar camera is the means by which we are able to enlarge photographs, and if we could depend upon the sun more than it is possible in our latitude and climate, nothing would be easier than this operation; but, unfortunately, the sun does not shine every day, and we may be sometimes waiting for his beneficial influence during many long weeks.

This difficulty has induced some persons to replace the light of the sun by artificial light, and the electric light has been tried with some success; but this is a very difficult and expensive process, which very few operators could practically employ.

During the months preceding the reception of photographs at the International Exhibition, wishing to prepare enlarged photographs for my contribution, I was constantly watching for the appearance of the sun; and I may say that during five months I hardly saw it more than ten or twelve days. Still I have been able to produce all the specimens which have been admitted at the International Exhibition; they are all from negatives of *cartes de visite*, enlarged seven or eight times, and I hope the result will prove what can be expected from the solar camera during the clear days of the fine season.

The enlargement of negatives, however, has some limits, when we wish to produce black photographs. I think that an enlargement of six to eight times is the greatest proportion which ought to be employed. But if you wish to enlarge *cartes de visite* to the size of nature, the small defects imperceptible in the negative are magnified to a degree so apparent that the picture requires considerable touchings up and correcting, in order to give to the picture the appearance of a perfect and clean drawing worthy of being framed. These corrections, however, can be made without altering the character of the photograph, which has all the qualities of the small *carte de visite*, preserving proportions of all the forms, and the natural expression of countenance. The result is far preferable to all the attempts made for producing at once large portraits with lenses of considerable aperture, which require a long sitting, distort the proportion of the figure, and, if the model has not moved, exhibit the forced expression of a sitting too much prolonged. Although, as photographs, many parts of the figure which may be in the right focus require very little touching up, still the greatest part is so ill-defined and so much out of proportion, that it is absolutely necessary to modify them considerably. The touchings of enlarged photographs, at all events, can be done without altering any proportions; and when these pictures are destined to be painted or coloured, they are even in a better condition for the artist than more strongly marked photographs taken direct in a large size.

Large photographic portraits are, in general, not very agreeable in effect, and, to please the public, they require colour. The more perfect the photograph is, and the more it shows all the defects of the face. It is not very desirable to exhibit all the roughness and every wrinkle of the skin in black lines. For this reason some artists, not understanding the impossibility of imparting the same degree of softness to the whole picture by it, have recommended to operate a little out of focus. Certainly, if all the parts of the picture had the same focus it would be of some advantage, for the artistic effect, to obtain an image in which every

* Read at a Meeting of the London Photographic Society, June 3, 1862.

part would be slightly out of focus to the same degree—just enough to soften the hardness of the lines; but this cannot be obtained, because if some parts which would have been in the right focus were softened by a slight alteration in focussing, this would render the other parts already in bad focus perfectly confused and indistinct.

The principal object of taking photographic portraits as large as nature is to give to the artist a ground to paint upon, containing a correct representation of all the features, forms, and draperies, which he can follow until the picture is so far advanced that a short sitting of the person is sufficient to impart the exact colour of the eyes, hair, and complexion. But it is evident that as soon as the artist has begun, and the more he advances his work, his colours cover and hide the photograph, and that it becomes very difficult for him to go on without losing the likeness if he had not always before his eyes another copy of the same photograph, to which he can constantly refer, in order to see when he is erring, and which enables him to correct any false touches of his brush. It would really seem that a skilful painter does not strictly want to paint upon the photograph; that he might as well trace the enlarged photograph upon his canvas to form the base of his painting, and to keep the photograph for his guide. In this case he might paint upon a canvas properly prepared to receive the colours, and not affected by the strong shadows produced by the nitrate of silver, upon a surface of paper which has had to undergo a quantity of washings and manipulations. While speaking of the immense difficulty of producing a photograph upon a surface of paper large enough for a portrait of natural size, the chemical substances forming the photograph are capable of affecting the durability and constitution of the colours forming the picture.

Considering all these difficulties, and while waiting in despair for the sun which was to enable me to produce enlarged photographs, it occurred to me that if I could supply the artist with a canvas upon which, while the image of the negative was thrown upon it by the light of the sun, and in its absence by the light of a gas-burner, I had traced every part of the picture with a black pencil, this would form a base even better than any photographic impression for the painter, who, being supplied with such a perfect lightly-drawn portrait, and, with a photograph for his guide, would have all which is necessary for his work.

I have tried the experiment, and it has answered beyond my expectations. In the British Department of Photography at the Industrial Exhibition may be seen several portraits as large as nature, which have been painted on canvas upon which a small negative had been enlarged by pencil-drawings. I have done it myself; and when I add that I am quite incapable of drawing, it must be acknowledged, by the inspection of the result, that it is entirely due to the help of photography, and is one of its most useful applications. The artists whom I have employed to paint these enlarged photographs have found them preferable to those produced by the chemical operation upon paper, because they have been able to lay their colours in all their brilliancy, without being impeded by the dark shadows of the ordinary photographs.

As an example of the result, I call the attention of the meeting to a portrait of a boy painted in pastel, and to another of Professor Faraday painted in oil—both of which have been completed without sitting. Those to whom the features of the eminent Professor are familiar will be able to judge of the correctness of the likeness, and to appreciate this new mode of applying photography to the production of large portraits.

I have thought that this mode of turning the base for large portraits upon canvas, the usual and most suitable surface for the work of the painter, deserved the attention of photographers, who, to satisfy the want of the public, are obliged to employ artists to produce painted portraits. If it is found that this mode of operating is capable of results entirely satisfactory, and that it can be effected at any time when wanted, without the light of the sun, surely this must be considered as a great advantage in one of the most important applications of photography, which consists in furnishing the artists with a perfect base for painting portraits—having all the truth and character of painted photographs, and so easy to be obtained.

Having been the first to practise this process, the idea of which I have no doubt must have occurred to many others, and the productions having been received in the British Department of Photography at the International Exhibition, I have considered it my duty to explain before this Society how these large portraits have been obtained, in order to prevent any misconception as regards their nature.

It is known in optics that when an image is considerably enlarged by a lens, the centre only of that image is in correct proportion, because the screen being flat and the image being curved the parts thrown on the margin of the screen have a focus nearer than the screen, and consequently being represented on the screen at a farther distance, they are out of focus and enlarged. In order to obviate that defect the negative should present, alternately, all its various parts to the centre of the lens, and at every change, horizontally and vertically, a different image should be taken. Having taken the various parts forming the whole picture, and cutting them all in order to mount them in one picture, we obtain a representation without distortion. When we wish to draw the picture by hand we have only to bring the various parts of the canvas in the place corresponding with the movements of the negatives, and we have a perfect picture of the whole.

This plan has another advantage: it enables us to enlarge a negative to a degree at which it would be impossible to light the whole picture, by the limited centre of light of the condenser. The arrangements by which I move the negative vertically and horizontally will be better understood by the inspection of the apparatus and its action.

## RULE FOR FINDING AT ONCE BOTH THE DISTANCES OF NEGATIVE AND SENSITIVE SURFACE FOR ANY DEGREE OF ENLARGEMENT, AND VICE VERSA.*

BY M. CLAUDET, F.R.S.

In a former paper, which was published in the number of the *Journal of the Photographic Society* for March, 1861, I have given a new theory for the measurement of the focal distances on one side of the lens, and the distance of the object on the other side. I have explained why both these distances must be measured, not from the surface of the lens, but from a point before it, which is the nearest distance at which an object may be placed for producing the largest image possible, and another behind which is exactly the focus for parallel rays giving an image as small as possible. The space between these points and both sides of the lens is a nonentity, being in fact nothing more than the thickness of the partition dividing the two sides of the camera-obscura without lens.

These two points are the zero of the scales of measurement for the focal distance and distance of object. When these two points have been determined, if we find two other points at which the object must be placed before the lens to produce behind it an image of the same size, these two points form the other extremity of the scale, and that scale is the unity which serves for measuring all the distances and determining exactly the proportion between the size of the object and that of the image.

To facilitate all the calculations these scales are divided in one hundred equal parts.

When we want to have an image of the same size as the object, we have only to place both the object and the screen on the 100th division of each scale. For an image double the size of the object we place the object on the half of the scale precisely on the division 50, and the screen destined

* Read at a meeting of the London Photographic Society, June 3, 1862.

to receive the image at a distance equal to two unities, or to $\frac{200}{100}$ divisions. For an image half the size of the object we reverse the proportionate distances.

If we want to enlarge the object 100 times we place it on the division 1 of the scale, and the image will be at a distance equal to 100 times the unity.

All intermediate distauces and proportions are calculated and fixed in the same manner.

Let us suppose that we have a portrait on a negative, which is twenty times smaller than the natural size, and we want to enlarge the image to its natural size. We have only to place the negative on the fifth division of the scale, and the sensitive surface for the image at a distance equal to twenty times the unity.

If we wish to enlarge the same negative only five times, we place it at once on the twentieth division of the scale, and the screen for the image exactly at a distance equal to five unities.

These few examples will be sufficient to show how all the calculations can be effected by means, firstly, of a scale marked with all its divisions fixed on the table containing the camera, and secondly, by means of a tape long enough to extend to twenty-five or thirty unities and marked all over its length with these unities and subdivisions.

The scale fixed in the camera contains opposite each of its one hundred divisious the number indicating the corresponding distance of the screen, and the tape upon which all the distances of the screen are marked indicates also the corresponding divisious of the scale fixed in the camera, so that if the the two measures have been once for all correctly constructed, it is no more necessary to examine on the screen if the image is in good focus. It must necessarily be so, and that will save an immense trouble and all possible errors.

I think that nothing is more interesting than to examine and study the law by which these scales of measures are regulated. We can see the curious progression of foci, which increases and diminishes exactly in the same proportion as the distance diminishes and increases. The two quantities, whatever they are, being multiplied one by the other, must have for product the unity forming the scale; and if that unity is divided in one hundred parts, the product must be equal to one hundred: so that, knowing any distance either of the image, or of the object, we have only to divide one hundred by the quantity known, and the quotient is the other. For example, if the distance of the image is found by the tape to be 17·67, we have only to divide 100 by 17·67, and we have 5·66 for the distance of the object.

## NEW METHOD OF EMPLOYING WAXED PAPER WHEN TRAVELLING.

BY CAPT. CHAMPLOUIS.

Waxed paper, by its lightness and the convenience of its negatives, is one of the most convenient processes for travellers. In warm countries especially, the absence of collodion gives to this process a much greater value, as the chemicals its process requires are not decomposed by the highest atmospheric temperature. The traveller, however, experiences some inconvenience from the numerous washings the preparation of dry paper requires, as well as for development and fixing in hypo-sulphite of soda.

During an expedition into Syria, Captain Champlouis, seeking to obtain photographic views by the quickest and simplest process available, finally adopted the following, by means of which he always obtained satisfactory proofs in whatever circumstances he happened to be placed.

*Preparation of the nitrate of silver bath.*—The sheet of iodized wax-paper is immersed in a nitrate bath (aceto-nitrate of the strength of 8 per cent.), and immediately afterwards it is laid, still wet, upon a glass plate intended to be placed in the slide; the paper is carefully applied to the glass by means of a piece of sponge, which, by gentle pressure, expels the air-bubbles, which if allowed to remain between the paper and the glass, would cause the silver to be reduced. Then with the same sponge a sheet of bibulous paper is applied to the sensitized wax-paper, and upon this a sheet of waxed paper, or a piece of water-proof cloth, which serves to exercise a last pressure: these two sheets must be moistened with distilled water; they form a cushion upon which a second plate of glass, of the same dimensions as the first, is placed. The whole is placed in a slide, and the paper thus prepared will serve to take a view at any time, even within ten or twelve days, perhaps even longer, as there is no reason to believe that the sensitized paper will undergo any change, as it is out of contact with the air, and cannot become dry except after a considerable lapse of time.

*Development with gallic acid.*—After exposure the negative is submitted, the same. or the next day, to the action of gallic acid, previously immersing it in the nitrate bath to restore its humidity, if it has lost it. A glass plate is covered with a thin layer of a saturated solution of gallic acid, and the picture is developed very rapidly, under the influence of the silver solution with which it is moistened. This method is preferable to immersing the proof in the developing solution.

*Temporary fixing.*—When the negative is properly developed, it may be temporarily fixed, by once washing in common water, and then immersing it for five miuutes in a solution of iodide of potassium, strength 8 per 100. A single washing in ordinary water afterwards will suffice, and the negative is then dried between blotting paper. The negatives thus treated require nothing more until the photographer returns to his operating room. Before printing positives from them, they are completely fixed in hyposulphite of soda.

*Advantage of this process.*—This method of operating offers: 1. Economy of time; 2. Economy of water. Economy of time in the preparation of the paper; as it does not require to be washed or dried before exposure, nor fixed as by the ordinary methods. Economy of water, as there is no water for washing required, but only the silver bath and a bottle of distilled water to moisten the cushions with, which is preserved after each operation; and one or two litres of distilled water, which is used in successive small quantities for thirty or sixty negatives.

The slight washing of the negative, between the gallic acid and the iodide of potassium, beiug only to maintain the purity of the iodide, requires very little water. The iodide bath lasts a very long time, and seldom requires to be renewed, and is only diminished by evaporation and the operations to which it contributes.

An experience of five months travelling in the method above described has given the most satisfactory results.

## ACARI IN THE NITRATE BATH.

Dr. Maddocks communicates to our contemporary the *British Journal* a most singular discovery in connection with his nitrate bath, in which he has found some *acari*, apparently generated and living there. We append an extract from his communication:—

In the early part of December a twenty-ounce nitrate of silver bath, forty grains to the ounce, which had been in use during 1861, and placed for a month previous in a stoppered bottle, was returned to the bath, and set aside in a cupboard partitioued off in my working-room, so as to convert it iuto a dark chamber. It remained unopened until the 12th of April. The bath is of cemented glass, covered outside with asphalte varnish, and kept in a vertical wooden case with the cover shutting down to half the depth of the bath. When the solution was returned to the bath, half a sheet of white foolscap paper was first folded down on the top, and then the cover placed over it. The bottle was a perfectly clean one kept to receive the nitrate bath when filtered, or when the sides of the bath were to be cleaned. The bath, after cleaning, was always washed out finally with boiled and filtered or simply filtered fresh-caught rain water—not out of the butt. I am thus particular in these details for reasons that will appear.

Late on the afternoon of April 12th I moved the bath from the dark cupboard to the table in the room. On removing its cover, lifting off the paper, and looking along the surface of the liquid (as is my habit) to see if any scum be visible, and remove the same by a little blotting paper wrapped round a strip of whalebone, I noticed on the surface numerous bright glistening points, the mass altogether in length about $1\frac{1}{4}$ inch and $\frac{3}{8}$ inch in width. Supposing these to be crystals, I proceeded to remove them with the blotting paper; but I could not gather them up, for they floated by and opened out on the surface. A thin piece of wood was then turned up, and with this a few of the points were lifted out. Examining these with a doublet, I found them to be insects, with beautifully-curled and long straight hairs. Sixty-six were in this way taken from the surface of the solution. Not knowing exactly what to do with them, some were placed in a spirit of wine and acetic acid, which happened to be at hand, and the rest in water in a test-tube. These were replaced in the dark cupboard; the others left to diffused daylight. On the first appearance they looked like very miniature FAT SHEEP, with eight legs, curled and straight feathers from the back, a long depending snout, which was always turned down in the liquid, and some with a very short tail or tubercle. On a slip of glass they resembled a particle of a fat of a dirty yellow colour, the snouts and legs of the parentals being darker and more defined than in the rest of the progeny. Sunday intervening, they were further examined on the Monday. Those in the acetic acid were all at the bottom of the tube. Their colour had altered to a darkish brown. Of those in the water a few were at the bottom, the rest floating on its surface. None were found in the stoppered bottle, which had also been kept in the dark, wrapped in paper.

A few were now mounted in a cell with a little alcohol and water, and placed under the compound microscope, but I could not discern their general structure. They appeared to be covered with a granular deposit. Concluding this to be some silver compound entangled at the surface, it became a question how to remove it. At first washing with water, and a fine sable pencil was tried; but the insects got so injured, and were so exceedingly tender, that this plan was set aside, and they were soaked for a short time in a solution of cyanide of potassium. This quickly cleared off the deposit, and also seemed to abrade or break up the substance of the body; for they became more tender, so that I could not keep the form at all perfect under the slightest pressure. Alcohol mixed with the cyanide solution answered no better. Others were now placed in a solution of iodine in iodide of potassium. This turned them yellow; and, on being replaced in a watch-glass with a little water, gave a well-marked precipitate of iodide of silver. They were now removed to a solution of hyposulphite of soda. By alternately treating them to these baths, and finally washing, the general structure was rendered very visible under the microscope, though still very fatty in appearance. Wishing to preserve some of the specimens, I proceeded to put them upon the usual slides—first trying washing in spirits of wine, then drying, soaking in turpentine, and setting up in Canada balsam diluted with benzole. I could not set them out in this, as the parts gave way very readily from the tenacity of the balsam, and portions were rendered too transparent. Others were first cleared of the deposit, soaked in glycerine and camphor water, and finally mounted in the glycerine and gelatine *medium*: this proved the most successful, though I found that they still so retained their fatty quality that I dared not use sufficient pressure to flatten out their rotund bodies, ere the skin gave way. They gave me considerable trouble, although long accustomed to put up objects of various kinds. Further observation led to the opinion of their being *Acari*, though not like any that I was acquainted with.

The insects are very visible to the unaided eye, being a little larger than the cheese mite. They are variable in size. The sexes are evident, the females being provided with a curious short protuberance or tubercle at the end of the abdomen, nearer the dorsal surface; and at a slight distance from it, on the under surface, when seen sideways, are two thin projecting flaps, which meet at the free edges, thus forming a sort of deep and long triangular space, sack, or groove, protected at the anterior entrance with a few short crossing hairs. Looking down on this structure, it has an elliptical form: the edge of each flap has from four to six reddish marks—query glands or hooklets of apposition. In this pouch I was fortunate enough to find a body suspended, which I considered to be an extruded ovum. Pressure in several cases, especially after the cyanide solution, forced out larger ova or ovisacs through the same groove. The ova or ovisacs in some were eight in number: in others I could only find six. The males are rather smaller than the females—no projecting tubercle, no groove nor pouch. In some I found a very curious structure, visible only from the abdominal surface, but the exact plane of which, even by the most careful focussing, I could not decide on, as it was only seen when the two surfaces were closely pressed. It was oval in shape, with a slight projecting limb from the upper part of the oval on each side. In the centre of the ellipse was a well-defined line, and, abutting against this, on each side, short, slightly-curved marks or lines, looking somewhat like the gizzard teeth of some insects; but whether it belonged to the digestive or genital system I could not satisfy myself. Many attempts were made by pressure to separate these parts, but yielded no good result, the whole breaking up into a sort of fatty sarcode. The outer surface of the skin is covered with minute granulations, which, seen edgeways, are resolved into very minute points—not *cilia*, being much shorter and stouter. The long curled hairs on the back, and the straight ones near the posterior end of the body, are finely barbed or feathered. The insects are provided with a pair of terrible, strong-looking mandibles, each composed of two claws with irregular teeth, four or five that interlock. The labia are notched at the end like a small reversed ∧ set in a larger V. The legs are furnished with sharp bristles, the ends of the foot padded, and on some of the feet I noticed a sort of short rod with a knob at the end. No eye spots were visible.

This description of the insects is very imperfect. I had purposed to have enclosed a drawing, with measurements, &c., but severe indisposition has disappointed me in the attempt. Of their life-history I know nothing, nor do I attempt to advance a theory of how they came into the bath. After the strange incidents met with by the late Mr. Cross, the celebrated electrician, of the Quantock Hills, when forming crystals by the agency of his small but numerous-celled water battery, we may well pause before the portals of creative power, without bringing to our aid equivocal or spontaneous generation, as some of the critics of his labours ventured unreasonably to apply to him. No doubt the ova were there in the exact conditions to furnish forth their dormant energy, though strange to us may seem those conditions:—the liquid a solution of a caustic salt capable of seriously injuring animal membranes, at least in ourselves; the light *nil* or non-actinic; the creatures themselves highly organised, yet not high in the scale—a genus of *Arachnidæ*. Few, I think, would look for animal life in their nitrate baths; yet these remarks may, if of no further use, now call the attention of photographers to the fact of its supporting living organisms, even to fatness, and elicit perhaps more of their history and structure.

## PRINTING, TONING, AND FIXING OF DIRECT POSITIVES ON ALBUMENIZED PAPER.

BY PROFESSOR TOWLER.*

AMMONIA-NITRATE of silver is more sensitive to light than nitrate of silver, as is also the chloride of silver produced by double decomposition with ammonio-nitrate of silver and any of the alkaline chlorides; it produces more vigorous pictures, and sensitizes the paper more quickly than the simple nitrate of this metal.

2. These are three very important qualities in photography; it has, however, its disadvantages or difficulties, which are the following:—Free ammonia easily dissolves the albumen from the surface of the paper, whereby the solution becomes discoloured, forming albuminate of silver; this deteriorates the effectiveness of the solution for future operations; the paper is reduced again to plain salted paper, and the picture is mealy, imperfect in the middle tones, and possesses but very little vigour.

3. The question therefore arises, how can the ammonio-nitrate process be modified so as to obviate these disadvantages? I have experimented with various re-agents, such as ether, hot water, acids, &c., and have selected, as success-

* From *Humphrey's Journal*.

ful in a high degree, the following method, by which the albumen surface is preserved entire, the tone is a rich purple black, all mealiness or snowiness avoided, and uniformity of action maintained.

*Silver Bath.*

4. Dissolve one ounce of nitrate of silver in six ounces of rain water; of this solution take two ounces, and add ammonia until the precipitate is dissolved; afterwards mix these with the remaining four ounces. Now add four drachms of *alcohol* and allow the oxide of silver to settle. If any particles still swim on the solution, remove them by drawing a small sheet of paper two or three times over the surface. It is not necessary—it is even injurious—to filter the solution; for the sediment is oxide of silver, which is afterwards dissolved by the addition of ammonia.

The paper, already cut and prepared according to art, is made to float on the silver for about ten seconds; all bubbles and particles that may adhere are carefully removed from its surface, and afterwards it is dried in the usual manner. Every time this bath of silver is again used fresh crystals of the nitrate are added together with a few drops of ammouia and about one drachm of *alcohol*.

*Toning.*

5. The prints are first well washed in several waters; this operation may be performed in teu minutes or a quarter of an hour; if the time is much longer the tone is impaired. They are then passed through hot water previously to their immersion in the toning solution. This solution is formed as follows:—From the stock bottle containing one part citrate of soda and six parts water, take two ounces; to this add one pint of warm water, one ounce of rain water, holding in solution one grain of chloride of gold, or more, according to the number of prints to be toned, and two drachms of *alcohol*. The toning soon commences, and is soon finished if the gold is in sufficient quantity. The temperature must be preserved at a blood heat, or about 100° Fah.; if it were greater the gold would become decomposed, and the solution blackened instead of the prints; if lower, the time of operation will be prolonged, and the operation itself tedious. The alcohol in this solution prevents all action of the alkali on the albumen, whereby the vigour of the print is preserved. I do not use the same bath twice unless immediately, and then of course with the addition of more gold. After the toning is finished, any gold that may remain is reduced by sulphate of the protoxide of iron, and collected.

*Fixing.*

6. The fixing medium consists of the ordinary solution of hyposulphite of soda. Every time I use this bath I add fresh crystals of the salt, two drachms of *alcohol* and an ounce or two of warm water, so as to raise the temperature. The prints, previous to their immersion in this bath, are again passed through warm water. The colour of the prints is not much changed when they are introduced, or if slightly changed, they soon regain their original and final tone. In two or three minutes the prints will be sufficiently acted upon by the hyposulphite, and are then removed into the water bath and thoroughly washed. The material point in these operations is the use of alcohol in each sub-division; because upon this re-agent success depends. Carbonate of soda may be used instead of citrate in the toning solution; the tone, however, is a richer purple black with the latter than with the former.

I would finally remark that unless the negative be properly and successfully taken with due contrast of light and shade, and without a universal fogginess over the whole surface, deep purples or blacks can never be obtained by any process; the silver salt has to be thoroughly acted upon by light in order to receive the desired toning.

## ANNUAL REPORT OF THE SOUTH LONDON PHOTOGRAPHIC SOCIETY.

At the conclusion of this, the third year of its existence, your Committee have much pleasure in assuring you of the satisfactory and promising aspect of the Society's affairs. At our last three or four meetings we elected sixteen new members, many of whom have already displayed the most laudable activity in forwarding the interests of the Society. At no one of our pleasant monthly meetings have we lacked either an interesting and useful paper, or the elements necessary for originating an animated discussion, and our Treasurer's account will show that—despite unusually heavy expenses, we have, for the first time, a balance in our favour. The papers read were as follows:—

| | | |
|---|---|---|
| Oct. 10. | Photography at the International Exhibition of 1862 ... ... | C. J. Hughes, *v.p.* |
| | On the Photogenic Action of Colour | Thomas Clarke. |
| Nov. 14. | On Mounting Photographs ... | G.W.Simpson, *v.p.* |
| Dec. 12. | A Prologue for the Seasou ... | V. Blanchard. |
| Jan. 9. | On Mealiness in Toning... ... | S. Fry. |
| Feb. 21. | On the Manufacture of Collodion | S. Davis, *v. p.* |
| March 13. | The Experiences of an Amateur in Portraiture ... ... ... | N. E. Fitch. |
| April 10. | On Photographic Reproductions.. | A. H. Wall, *hon. sec.* |
| May 8. | On the Use of Bromides in Collodion ... ... ... .. | V. Blanchard. |

The Committee take this opportunity of thanking the authors of the above for their generous labour in the Society's behalf. It is hoped that the useful little papers which were first introduced to our meetings by Mr. Hannaford, under the title of "Photographic Jottings," will not be entirely absent from our next year's list of papers as they are from the above.

The society has another source of gratification in the successfully organized Exhibition at the Sydenham Crystal Palace, which, it is hoped, will be the first of a series of annual exhibitions, each at least equalling it in the number of contributors and in the quality of the contributions; for it should not be forgotten that painting, sculpture, engraving, and other branches of fine art, all date their prosperity and influence from the establishment of periodical exhibitions. The present exhibition of this Society has been brought to its very satisfactory position mainly by the untiring energy of the Exhibition Sub-committee, to the members forming which, and to the Secretary of the Society who assisted them, the best thanks of the Committee are very gratefully awarded.

The Committee also desire to express their thanks to those gentlemen, friends and members of the Society, who have kindly contributed to the folio during the past year.

Special thanks are also due to Mr. Samuel Fry, Mr. C. J. Hughes, and Mr. J. J. Cole, to whose kindness the Society is indebted for the gratuitous use of apartments in which the Committee and Sub-committee have held somewhat frequent meetings.

Availing themselves of the present opportunity, the Committee also desire to thank the exhibitors whose productions are now at the Society's Exhibition.

Among the few sources of regret which have arisen during the past season have been the retirement from an active participation in the proceedings of the Society—in consequence of a change of residence—of our Vice-President, Mr. Hughes; and that of one of the most active members of the Experimental Sub-committee, Mr. Hannaford. We have another source of such feeling in the fact of our Secretary and Treasurer having tendered their resignations. The Society owes its existence primarily to the efforts of these gentlemen, and having now held office for three years, their retirement cannot but prove a source of regret to the members generally. It is part of this evening's business therefore to elect their successors.

In reviewing, as is usual, the progress of photography during the past year, we find such progress chiefly made palpable in an artistic direction. No new scientific facts of particular importance have been developed in connection with the art, no particular novelty in process or apparatus has been introduced to notice; but in every department, artistic, chemical, and optical, very rapid strides have been made in the direction of pictorial truth and beauty. Every paper read at our own meetings, and nearly every paper read before kindred associations have had their bearing more or less direct on the perfection of photographs as pictures, and in the Photographic Journals the principles of art in their applications to landscape and figure compositions have received regular and continued attention. We think this is an advancement in the right direction.

The claims of photography as a fine art have been put prominently forward since our last annual meeting, and no little controversy has arisen in all quarters from the fact of the Commissioners for the International Exhibition having classified photography under the term "mechauical." The Central Society took an active part in opposing such an arrangement, and called upon all societies devoted to the art to join them in protesting against its injustice. In reply to a circular letter from Dr. Diamond, the South London Society, while thanking and applauding the Couucil of the Central Society for tbe energy and character of its proceedings, aud fully approving the object thereof, expressed a hope that it (the Central Society) would not take snch steps as might tend to exclude British photography from competing upon equal terms with its foreign brethren and rivals. The controversy between the Commissioners and the Council of the Central Society which commenced in the May previous having terminated very unsatisfactorily in August last, and all appearances seeming to argue the entire neglect of the interests of photography, so far as regarded its conuection with this country and the Great Exhibition, the South London Society took action in the matter, and memorialized Her Majesty's Commissioners, urging the importance of making arrangements which might induce photographers to co-operate iu the production of such a result as should best serve the art, and do most honour to the country. Steps similar to those proposed in the memorial were taken by the Commissioners, and shortly after, their secretary, Mr. Sandford, politely acknowledged its receipt.

Much dissatisfaction has been pretty generally and pretty justly expressed with the position assigned to British photography in the International Exhibition. The art has been located in the smaller portion of a comparatively small apartment, situated in the most remote part of tbe building, and approached by a most nninviting entrance, with scarcely notice to indicate where it may possibly lead to, the said entrance appearing more like the opening to a ventilatiug shaft than anything of greater consequence.

Despite the insult to which photographers generally have been subjected in the catalogue classification, however, photograpby is to the full as attractive as any other portion of the great show, aud will undoubtedly carry off high honours, of which the share of this country will be by no means insignificant; for, contrary to pnblic expectation, British photography ranks proudly with the best of its foreign companions.

Tbe out door meetings, which were so pleasantly taken advantage of during onr past recesses, will be resumed during the present, only instead of meeting once a month, it is proposed that we meet once a week; and, to avoid some of the chances which led to uo little apprehension and disappointment last year, the dates and places of meeting, with the hour at which we shall assemble, will be anuounced before the close of this evening's proceedings.

The presentation print selected for the past year, in pursuance of the plan adopted by the first managing Committee, of selecting from the works of some eminent photographer a specimen illustrative of a distinct phase of the art in connection with some one distiuctive process, was selected from the works of Mr. H. P. Robinson, of Leamington, being a landscape by the wet process.

## FUSED NITRATE OF SILVER.

BY PROFESSOR E. EMERSON*.

"Commercial crystallized nitrate of silver is frequently contaminated with traces of an impurity, which is probably produced by organic matter falling into the nitric acid employed in dissolving the silver. Repeated recrystallization is required to remove this substance. If allowed to remain, it injures the sensitiveness of the film to obscure radiations, makes the negative weak and metallic, reverses the action of the light, and produces either foggings or markings of various kinds, the result of irregular reductiou of silver."—*Hardwich.*

I cau furnish an illustration of the truth of the above passage by detailing the experience of a young friend of mine, who is deeply interested in amateur photography. His silver bath was carefully made witb pure rain water, and crystallized nitrate of silver, iodized in tbe usnal manner, and was used at first at a temperature of 50° Fah. The collodion was a sample giving intense resnlts in my own practice; but in my friend's hands the resnlt, in every case, was very weak and metallic. Tbe following changes were then made, in a course of careful experiments extending through three weeks :—

1. The acidity of the bath was varied.
2. The strength of the developing solution was modified.
3. The amount of acetic acid in the developer was varied.
4. The sample of sulphate of iron was changed.
5. Alcobol and ether were gradnally added to tbe silver bath.
6. The bath was exposed to the sunlight for a day, after being made neutral.

The result in each of the foregoing cases was feeble negatives.

7. The temperature was now raised to 60° Fah.
8. The bath was boiled down, and carefully diluted again with pure pnmp water, and slightly acidified; but with no change for tbe better.
9. The developer was again varied in several ways. N improvement.
10. Care was now taken to see that the batb was fully iodized.
11. The temperature was raised to 70° Fah. for all the solutions.
12. The bath was again exposed to the sunlight for a day. Until finally, every condition had been repeatedly changed, except that of the nitrate of silver, and the uniform results were great slowness, and a weak and metallic image.
13. The nitrate of silver was now carefnlly fused, and the bath again made with pure pump water. The immediate and permanent results were rapidity and intensity with tbe same samples of collodion.

## Correspondence.

### FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

*Paris, 9th June*, 1862.

M. Becquerel, in presenting to the *Académie des Sciences*, a treatise on photolithography, and on printing photographic positives in carbon, and other indelible colonred powders, stated, that he had no hesitation in affirming that the process of carbon printing, to which the French Photographic Society lately awarded the prize offered by the Duc de Luynes, is the greatest progress realized in photography since its discovery by Daguerre.

Dr. Ozanam asserts that carbonic acid gas, when inhaled, is a most efficacious anesthesiac agent, entirely free from danger. Ether and chloroform are unquestionably anesthesiac agents, of great energy and value, but they often cause death, even under circumstances where no reason to expect a fatal issue existed; it is therefore greatly to be desired to substitute for it a succedaneum of equal efficacy, but more inoffensive. This succedaneum, Dr. Ozanam thinks will be carbonic acid. Forty experiments made upon the most

* From *Humphrey's Journal.*

delicate animals, in which sleep was prolonged from one to two hours, were followed by no ill consequences, and it was expected that the same result would follow its application to human beings: the following observation proves this to be the fact. He states—"I had to open an abscess that penetrated deeply into the inner and lower part of the thigh of a young man. It was necessary to dissect it layer by layer, to a considerable depth. The patient, dreading the pain, asked to be put to sleep; I consented, and informed him that I should cause him to inhale an hypotic gas in lieu of chloroform. A mixture of three parts carbonic acid, and one part of atmospheric air, was put into an india-rubber bag, of the capacity of about five gallons. To this was attached a long flexible tube, terminating in a mouth-piece in the form of a funnel, which could be applied to the nose and mouth of the patient. The mouth-piece was not applied hermetically, on the contrary, a small space was left, so that the patient could at the same time inhale carbonic acid and a certain quantity of atmospheric air. Sleep ensued after an inhalation of about two minutes, with accelerated respiration and abundant perspiration over the face. This latter phenomenon appears peculiar to carbonic acid, for it is even produced locally on parts submitted to douches or baths of this gas. The patient being asleep, I made an incision into the skin and subjacent tissues, without his making the slightest motion, or uttering the slightest complaint; there was complete insensibility. Just before the operation was concluded I interrupted the inhalation, and then gave the last stroke with the bistoury. Very different from the others, this stroke was felt, although bearable, and the patient immediately recovered his consciousness. I thus proved that the anesthesia produced by carbonic acid ceases immediately the inhalation is stopped, and that the awakening is almost instantaneous.

The innocuousness of carbonic acid seems evident, *à priori*, because it deprives the blood of no vital element, nor does it bring to it any toxical element, while chloroform, by becoming decomposed in the circulation, deprives the arterial blood of oxygen, and places it in contact with oxide of carbon. Therefore, I conclude that *carbonic acid is the most innocent of all anesthesiac agents;* it is the natural moderator of organic sensibility, and its employment in medicine will constitute a real progress.

M. Flourens gave to Dr. Ozanam's communication not only an impartial but a generous and warm reception. "Although it was I," he said, "who discovered the anesthesiac properties of chloroform, which has become so generally substituted for ether, although this immense surgical progress has been to me a source of renown, it is sufficient on the one hand, that the employment of chloroform has been once the cause of death, and it has often proved mortal; on the other hand, if carbonic acid proves to be as efficacious and more inoffensive, I shall sacrifice all pride, and become the apostle of this new anesthesiac agent."

A cement for uniting wood to metal, glass, stone, and other materials, is prepared by Dr. Elsner in the following manner. Carpenter's glue is dissolved in water and boiled to the usual consistence for joining pieces of wood together. Then add sufficient sifted wood ashes to render the glue of the consistence of varnish. It is to be applied while warm to the objects to be joined together, which are to be tightly pressed. When cold and dry, the surfaces will be found so strongly united, that it is seldom possible to separate them, and the fracture is quite different from that of surfaces joined with common glue. Hones, mullers, and similar articles have remained perfectly united after being submitted to rough usage for upwards of a year.

## Photographic Notes and Queries.

### The Manufacture and Prices of Lenses.

Sir,—Being in search of information with a view to purchasing a pair of stereoscopic lenses, will you have tho goodness to explain to me how it happens that the prices of various makers differ so very considerably.

If I understand tho manufacture of lenses rightly, the glass is ground in moulds, or basins (or whatever the term may be), to certain curves, and the moulds being accurately made, it follows (?) that the lenses ground in them, whether by Ross, or Dallmeyer, must be the same as those ground in them by Tom, Dick, and Harry.

Dallmeyer charges for stereoscopic lenses £3 10s.; Ross £4 0s., I think. Here, however, there is but little difference; but a man who ground lenses for *Ross* for *several years* (and consequently those which were and are sold at £4 0s.), having left his employment, grinds lenses on his own account, and sells them for one half the above sum.

What I, therefore, want to know (being not over rich), is whether Ross and Dallmeyer charge this extra amount on account of their "standing" and professional knowledge (which would be quite legitimate), or whether their lenses are actually and *bonâ fide* 50 per cent. better than those made by other persons, considering that in all cases the work is not performed by the *master*, but by the *workman*. My object is simply to get a good lens at a cheap rate, and I shall feel much obliged by your giving me information on the subject.—I am, sir, your obedient servant, Lens.

*London, June* 2, 1862.

[We insert this letter *in extenso*, instead of replying in our "Answers to Correspondents," for the purpose of more fully pointing out the fallacy in the idea involved, and which we have heard not unfrequently before expressed. At the outset it must be apparent that a workman who had been in the employment of either of the opticians mentioned could scarcely be in possession, honestly, of his employer's moulds; but even if presented with a complete set, it would amount to little or nothing; as modifications in one part of the process require making continually to meet modifications existing in other parts. Every fresh sample of glass, for instance, may have a different density and refracting power, this will render necessary perpetual modification in the curves of the lenses to suit each sample. It is not the mechanical workman, or machine, who grinds the lens, but the intelligent head which devises, superintends, and controls the operations, upon which the excellence of the result depends. And it is to the scientific skill and careful personal superintendence of our first English opticians that the reputation for the universal excellence of their work is due, and not simply to any merely mechanical excellence in the workmanship. That their lenses are as much superior as the price is higher may be easily deduced from the fact that some of the best Continental artists use them, notwithstanding the skill of Continental workmen and the low price of French lenses. —Ed.]

### Plate Holders.

Sir,—Presuming that you fully endorse the special article by Mr. Window in your last number, as to the great importance of an efficient glass plate holder for the collodion photographic process, and as to the manifest deficiency of every description of such in the market up till the present date, as elucidated by him, even for the single purpose of developing the image; and also that you would consider the production of one, in every way suitable for that purpose alone, as "conferring a great boon to all grades of photographers both professional and amateur," I hereby beg your permission to announce through the medium of your ably conducted, and extensively circulated Journal, that unless I am surreptitiously forestalled, I trust I shall shortly be able to produce in the market, under my own personal superintendence, one suitable for all sizes of glass plates, at a very small cost, which, after seven years' personal practical experience, supported by a special endorsation from two of the most scientific and eminent photographers in this country six years ago; and which I guarantee will not only effectively meet the desired want, but through which, during all the various processes of grinding the edges, cleansing, sensitizing, developing, fixing, and varnishing, absolute immunity from staining or injuring the hands is secured, and and other manifest advantages realised.—I am, Sir, yours, &c.,

*London, 12th June*, 1862. Donald McNicoll.

## Talk in the Studio.

A COUNTRY FAIR IN THE STEREOSCOPE.—Mr. Elliott has just issued half a dozen instantaneous views for the stereoscope, the subjects being the various scenes in a country fair, photographed by Mr. Valentine Blanchard during the past spring. Few subjects could present greater difficulties to the artist, nor would many be more effective in the stereoscope. The scenes, in many instances, have had to be taken at close quarters, which would have rendered the slightest movement glaringly apparent, but in this respect the slides are, on the whole, very successful. Some of them present hundreds of medley figures in surging confusion amongst stalls, booths, raree shows, &c. The scene of some of the slides is the front of the "Female Blondin's Travelling Circus," on the open stage or platform of which are clown, pantaloon, sprites, and others, gentlemen in tights and ladies in spangles, and all in motley; a placard informs us that admission to the theatre is one penny, whilst from the position of the clown we feel sure that he is adjuring us to "Walk up," and "be in time." The majority of the figures are very sharp, and the effect good. The series forms an interesting record of a time-honoured institution, which is dying out, we believe, for in many places already the statute fair has ceased to exist within the last few years.

THE INTERIOR OF THE EXHIBITION.—Perhaps the most complete record of the International Exhibition, the record which will enable persons in other countries or in after times to form the best idea of its contents, will be the Stereoscopic Company's stereoscopic views of the interior and its contents, by Mr. England. From a sample dozen or two before us, we ascertain that he is much more successful than from the difficulties existing we had believed possible. The photography is characterised by that delicacy and softness, combined with vigour and roundness, which have generally distinguished Mr. England's pictures; whilst the selection of subject, point of view, &c., is in most cases very happy. We cannot conceive anything more delightful to those unable to visit the Exhibition than a few hours with stereoscope in hand and this series of slides before them; whilst few who do visit the building will, we apprehend, willingly neglect to secure such a valuable souvenir of its contents. The series, so far as it has gone, consists of general views of the interior from the various commanding points; views of the different national departments; views of various special courts; and views of single objects of interest, such as Gibson's tinted Venus, which, by the way, looks in the photograph still more like an undressed young lady than in the original. If the Stereoscopic Company are as successful in all their views of the interior and contents as in the examples before us, the result will be one of the most interesting and valuable collections of photographs ever published.

PREPARED SILK FOR DARK ROOMS.—Mr. C. W. Smartt has been for some time past devoting his attention to the production of a varnished silk for the windows of dark rooms, tents &c., and has succeeded very perfectly. The silk originally used in "Smartt's Tent" was pretty good, but we found on a spectroscopic examination made some time ago, that traces of actinic light were admitted. Since then Mr. Smartt has experimented largely with a view to obtain a silk which might be used to admit plenty of yellow light, without any risk of chemical action. The two samples he has sent us, are of a rich deep orange tint verging towards scarlet by transmitted light. The first received showed in the spectroscope a mere trace of green light; but a second sample exhibiting a further improvement within the last few days, is quite impervious to all chemical rays. It does not admit quite as much non-chemical light as yellow glass, but this may be compensated for by using a larger area which may be safely done. Mr. Smartt has submitted it to a practical test, which he thus describes:—"I took a dark slide, and having made twelve apertures 1¼ in diameter, I filled each with one of the media in use, as orange flashed glass, orange pot metal, yellow tammy, ditto calico, and the silk I have hitherto made for my tents, &c., also my new silk. I exposed the whole simultaneously to the full sunshine for one and a half minutes, and the result is that the *whole* of the apertures give a deposit on the plate more or less dense, with the exception of the new article, which left the plate perfectly protected, and without *the slightest trace of action*." Mr. Smartt has sent us a print from the negative thus obtained, which altogether bears out his description. The orange flashed glass appears to present scarcely any obstacle to the chemical action of light; the orange pot metal, however, exhibits the merest trace of deposit, whilst the new silk shows no action whatever. We understand it will be sold by Murray and Heath.

## To Correspondents.

J. WIGHT.—One ounce of chloride of silver contains a trifle more than three quarters of an ounce of pure silver. In estimating the value of the chloride you have collected, you must be certain it is quite clean; several washings will remove all soluble matter.

N. J., Berlin, sends us a print, in which, whilst the albumenized face is perfectly pure and white, the back presents a lavender or mauve tint. The colour appears to be the result of a deposit of gold, but what has caused this deposit we cannot tell. The colour is of singularly little depth, as on splitting the print, which can be easily done, the colour does not seem to have penetrated beyond the surface of the paper.

AN ASPIRANT.—We have no information as to the proportions to be used in patented toning formulæ to which you refer. You will find some remarks on the subject on p. 349 of our fourth volume.

J. W. R.—We have taken thousands of Daguerreotypes, and examined tens of thousands, but we have never seen one fade. They sometimes become tarnished by exposure to dampness or air; but may with care be easily restored. Make a fresh 30 or 40-grain solution of cyanide of potassium. Then take the plate, and having first flooded it with strong alcohol to remove any traces of greasy finger marks, &c., wash till the water flows evenly. Now flood with the cyanide, and watch until the tarnish disappears, then quickly and thoroughly wash under a tap, finally rinsing with distilled water. Dry with the flame of a spirit lamp held at the back of the plate, beginning at the top corner, and assisting by blowing gently so as to drive the moisture before the breath to the bottom corner, which is held by the pliers. This precaution is necessary in drying to prevent stains which could not be removed.

A.—The pale green tint of your solution of nitrate of silver made from the coin of the realm, arises from the presence of a little nitrate of copper. We should not apprehend any evil consequences from its presence in a printing solution; we have on the contrary heard of the addition being made purposely. If, however, you wish to remove it, adopt Mr. Barber's method, as follows: evaporate until the mass begins to fuse to drive off all excess of acid. Then rub down the salt in a mortar with a little oxide of silver, add distilled water and boil. The oxide of silver will displace the copper, which will fall as in oxide, and may, with any excess of oxide of silver, be removed by filtration.

A NEGLECTED ONE.—In societies where the duties of all the officers are unremunerated, it is desirable to limit these duties as much as possible. Hence it is generally customary for members to obtain information on all necessary points by attending the meetings, and thus save the honorary secretary from unnecessary trouble in letter writing. Mr. Wall has been a very hard working officer; and the unavoidable duties of the office have now accumulated to such an extent as to compel him to resign. The presentation print is obtainable at the meetings on the second Thursday in the month, or of Mr. Wall, 35, Westbourne Grove, Bayswater. Tickets for the Crystal Palace were sent, we understand, to all paid-up members. If you have not received yours it is from some mistake. Apply either to Mr. Wall, or to Mr. Howard, 12, Whittingham Villas, Studley Road, Stockwell.

P. X. Y.—It is not an invariable rule that when the picture flashes out rapidly it has been over-exposed Some conditions of chemicals will cause this rapid development when the exposure is just right. No definite rule, as regards time, can be laid down for development. Photography cannot be thus reduced to a matter of rule and line; observation and judgment must continually be used to vary the manipulation to the varying conditions. As a general principle, however, the high lights are visible within a second or two after the developer is poured on a properly exposed wet plate. As a general principle development with iron may be continued as long as any additional detail can be brought out; if the chemicals are in proper condition, the model properly lighted, and the exposure right, there is no danger of producing flatness. The chief fault in the print enclosed appears to have been over-development or over-intensifying.

W.—In some cases the front lens of a portrait combination may be used without much disadvantage for views; but as all portrait lenses are not exactly alike, it follows that all these front lenses will not be equally suitable for view purposes. One disadvantage which generally attends the front lens of a portrait combination is the improper position of the stop which is generally placed in the groove which serves, in the compound, for the Waterhouse diaphragm. This is too near to the lens to produce the best result for landscapes. You may try the front lens of any of your portrait combinations, and use them if the result be satisfactory; but it would not be wise to purchase a portrait lens chiefly with this view. We should prefer an ordinary view lens to the Petzval for landscape purposes. As a general rule, the single lenses of all respectable opticians may be relied upon for doing their work.

R. TAYLOR.—Try the process with honey and tannin, recently described in our pages.

A. B. C.—For converting positives into negatives, see article on Intensifying Processes in the PHOTOGRAPHIC NEWS ALMANAC for this year; in which you will also find the information required on printing, toning, &c. For a dry process, try the honey and tannin.

W. MATTHEWS.—The pyroxyline made as described ought to dissolve in the proportion of five or six grains to the ounce of solvents without difficulty. It seems probable that your temperature was not high enough, or that the acids were somewhat too strong. With the cotton already made, you must use less in the solvents. To the collodion made add ether until it is of the right thickness. With the next batch of pyroxyline, use the temperature higher, or add a little water to the acids. The flocculent particles in the collodion indicate that the whole of the cotton had not been perfectly acted upon. They will gradually settle.

PUNJABEE, M. A., C. B., J. W. T., J. TULLY, and other correspondents, and several articles already in type, in our next.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 198.—June 20, 1862.

## MODES OF ENLARGING PHOTOGRAPHS.

A challenge given and accepted, is at any time certain to excite a certain amount of interest, especially if some important question is to be settled by the encounter. We have no doubt that many of our readers looked with considerable interest for the issue of the friendly contest between Mr. Vernon Heath and M. Claudet, to decide the merits of the modes of enlargement which they had respectively adopted. The little affair "came off," however, as our readers are aware, without materially altering the question, or bringing about any decision. M. Claudet and Mr. Heath each produced very excellent specimens of their methods, which were generally admired: some commended those of M. Claudet because they were developed prints on plain paper, and were soft and round; others admired those of Mr. Heath because they were on albumenized paper, and were sharp and vigorous; but no general decision was, or indeed could, be made.

The truth is, that the question in the form it finally assumed, never ought to have existed. As Mr. Heath stated, he never intended to put the case in such a form; by some misconception, however, it drifted into the position of ordinary camera enlargement *versus* solar camera enlargement, and ended by deciding nothing. The important question for photographers is not so much which of these methods is best, but are either or both good, or at least sufficiently good to be worth practising? Our own conviction often expressed is, that for certain purposes, and within given limits, they both are good and useful; and each is best in turn as circumstances may vary.

That very excellent photographs can be produced by means of the solar camera there is not room for question. Let those who have the slightest doubt on the subject visit the Exhibition at South Kensington, and examine the various enlarged specimens exhibited, the examples in the British department, even despite the very occasional willingness of the sun to lend his direct countenance to photography on such a scale. If any doubt exist after seeing these specimens, then proceed to the various foreign departments, inspect those of Disderi and others in the French Court, of Albert in the Bavarian Court, of Hansen in the Swedish Court, or of Ghémar in the Belgian Court. The last especially: we have no hesitation in pronouncing the full length portrait of the Compte de Flandres the most perfect enlargement in the exhibition, and as little short of perfection as a photograph. The picture is about three feet high, the figure, which is enlarged from a card negative a little over two feet high. Every part of the picture appears to be in perfect focus; head, feet, and hands; carpet, curtains, and accessories; everything is well and delicately defined. The picture is, moreover, at once soft and forcible, free alike from the insipid feeble greyness, or the hard blackness which characterizes some enlargements. To say that it is absolutely untouched is more than we can venture upon; but we cannot perceive any touching; and we are assured by a friend, who had an opportunity of inspecting a copy in M. Ghémar's studio, that the touching is confined to the spot of light on the eyes, and the decorations of gold, silver, and brilliants on the breast: objects like these, reflecting light so vividly from every facet, on the slightest movement caused by the heaving of the chest, become, as every photographer knows, blurred in the negative, and their need of touching in no way detracts from the merits of the solar camera enlargement. The flesh, hair, draperies, furniture, &c., are all, we are assured, pure photography, and quite untouched. We can add that they bear every appearance of being so. M. Ghémar's pictures are not developed, but "printed out" by the sun, an exposure of three or four hours being necessary.

With results like these before us, notwithstanding the force of theoretical objections, we are satisfied that very perfect results are to be obtained by means of the solar camera. There may be theoretically, and to some extent practically, dispersion and diffraction of light, and diffusion or confusion of the image; but if these evils are practically found in such a minimized degree as to be, in good work, imperceptible, photographers may well afford to disregard them; and even if the results were such as served only the purpose of the artist to work in pastels or oil colours, we should still regard the solar camera as a most important aid to the photographer.

It may be urged, we know, that there is no evidence that many of the Continental photographers use the solar camera. On this subject, however, we have evidence that the majority of the Continental photographers do use the solar camera, or some modification of it. M. Ghémar states that he does so, and so do many of the French artists. A very fine enlargement of a portrait of Mr. Negretti, produced in Italy by an artist who is stated never to have seen a solar camera, turns out, however, on a description of the appliances to have been produced exactly on the solar camera principle. Whether that principle be new or old, is now, since the patent has ceased to exist, a question of very little importance. That the solar camera is in principle the same as the solar microscope, cannot be denied; nor can it that the solar microscope was long ago applied to photographic purposes. To Mr. Woodward is due at least the credit of a revival, and also of an extended application of the principle. Practically he brought to bear upon enlarging processes a method of using the maximum of light with the minimum of aperture, and directed that the aperture, or what is equivalent, the focus of the condenser, should be at that point which secures the greatest flatness of field, namely, in contact with the front lens.

Having admitted to the solar camera, however, all which can be claimed for it, the position Mr. Heath assumed before the Photographic Society at the meeting in May, is in no wise altered or destroyed. If the solar camera were more perfect even than it is, and all its perfections universally admitted, there cannot be a question that for the greater part of the year in this country, it must be entirely idle; direct sunshine is imperative; the idea of using a reflector and condenser in diffused light is simply useless. Even in Paris, where sunshine is a little more plentiful and constant than in this country, it is not sufficiently plentiful and constant; as M. Disderi, we understand, has founded an establishment in Algeria for using the solar camera, whither he sends all his negatives, from which amplified prints are required. But even if the instrument were admitted perfect, and the light unquestionably always sufficient, it is not every photographer, especially every amateur, who possesses or would care to possess, a solar camera, and devote a room entirely to its use. Mr. Heath, then, had given considerable attention to the improvement of a method long known, but little practised, whereby enlargements, not simply of the single prints, but of the negative, could be produced by a trifling addition to the appliances already in the possession of every photographer. That the enlargement was the result of two operations, was a small objection, seeing that, as we have remarked, when produced it was a negative, from which any number of prints could be obtained by the ordinary processes of printing.

That such a method must be a boon to amateurs there cannot be a question. To be able, either in the operating-room or the field, to produce small, perfect negatives requiring short exposures, and involving very little labour or difficulty at the time, and afterwards, at leisure, enlarge them easily and perfectly to sizes of, say 10 by 8, or 12 by 10, is such a tempting prospect, that every photographer, certainly every amateur, must covet it. This was the prospect Mr. Heath wished to hold out: the range of enlargement he proposed and that usually effected by the solar camera were two distinct things, in no way competing or clashing with each other, and there was no need to put them in competition, or suppose them to be in any sense antagonistic.

It is a somewhat singular fact that long as the method referred to by Mr. Heath has been known, it has not been successfully practised; hard, coarse negatives being its general results. That this is not necessarily the case, we have long been convinced, and the specimens shown by Mr. Warner and Mr. Fry in the International Exhibition prove; although some of these leave something to be desired. Mr. Heath also, at the meeting in question, exhibited pictures which proved pre-eminently that delicacy could be obtained. He felt, however, that in a process so desirable and yet so little practised, it was worth while to enlist general interest in the improvement of its details. It unfortunately happened that, instead of this result, a dispute as to its merits ensued, and, so far as discussion could aid it, the matter stands where it was. The subject has engaged much of our attention, and we have experimented for many months past at intervals in improving the manipulations. On a future occasion we shall have something further to say on the subject and some hints to offer. In the meantime we commend it as well worthy of attention and experiment, to all interested in obtaining the best results by the simplest means.

## SOUTH LONDON PHOTOGRAPHIC EXHIBITION.

In returning to the South London Exhibition at the Crystal Palace, our attention is arrested to the reproduction of a clever pictorial *jeu d'esprit*, sketched by Mr. Wall entitled "An Essay on Photographic Criticism," and dedicated to the *London Review*, and *Saturday Review*. It consists of seven heads, portraits of the various critics, whose opinions are often heard on matters of photographic. The portraits are described as follows:—

1. The critic who thinks that "photographs always give a receding effect to the forehead."
2. The critic who thinks "photographers should never light their sitters from the top."
3. The critic who states that "photographers always exaggerate the prominent features."
4. The critic who asserts that "photographs make her look so old, quite like a woman of thirty."
5. The critic who thinks "photographs invariably give one such an unpleasant expression."
6. The critic who thinks "you always look so silly in your photographs."
7. The critic who "is generally very well satisfied with a photograph."

We may add that each grumbling critic, if he receive simple justice from the camera, will conceive that he has the strongest facial reasons for spiteful feeling. Nos. 1 and 6 are receding foreheaded, shallow-pated spoonies; No. 2 is a beetle-browed gentleman, the whole of whose brain seems to have taken lodgings in a pent house over the eyes; No. 3 is a youth whose most salient features occupies nearly one-half of his face; Nos. 4 and 5 are portraits of ladies of about —well, a "certain age," and have apparently been disappointed in life; No. 7 is the head of a lovely girl, who may defy the most truth-telling lens to make her other than lovely. In the centre are "That arch caricaturist, the camera, as it appeared (after taking several glasses) conspiring with the sun against the surrounding critics." The camera wears the focussing cloth as a cowl, and seems to enjoy the fun, whilst the sun fully enters into the spirit of the thing. The sketch is a capital pendant to M. Claudet's recent able letter on the subject. We commend it heartily to the critics of the *Saturday* and *London Reviews*, and all whom it may concern.

Amongst the most noticeable pictures at the Exhibition are the contributions of Mr. Earl, with whose large and excellent views of Raglan Castle many of our readers are familiar. His chief contributions here are a series of very large photographs of Witley Court with the surrounding grounds, fountains, &c. These pictures are very large, perhaps 24 by 18, and the photography very good; a photograph of one of the fountains, consisting of a fine Andromeda, is especially good in many respects. We must confess, however, that except for special subjects, we do not admire such large photographs. We give these all praise, however, for the excellence of the work, and the care in preparation.

Mr. Tyley sends some remarkably fine architectural photographs. A view of Bristol Cathederal is equally good as a picture, and as a photograph. Two examples of different photographic treatments given to a "Memorial Design" are both admirable pictures, and instructive illustrations of the effect of dark and light backgrounds.

Some of the most charming pictures in the Exhibition are scenes in Venice, contributed by Mr. W. H. Warner; they are executed, however, by an English amateur, who, for private reasons, is not desirous of appending his name in publishing them. The "Bridge of Sighs" is a very perfect picture, the point of view is well chosen, and the photography very brilliant without being hard. The deep masses of shadow are in admirable keeping with the subject, whilst the soft irregular reflections in the water are admirably rendered. Various other views by the same hand do more or less justice to the "Queen of the Adriatic." Here is the Bridge of the Rialto, and here the Cathedral of St. Mark; here is the Mole past which "silent rows the songless gondolier." The whole of these pictures are good, and the subjects fraught with unusual interest. Here also are a few examples of Ponti's admirable views of Venice, in which the photograph is carefully coloured. We have rarely seen photographic views of architectural or landscape scenery with any attempt at colour, that have not been entirely spoiled by the operation; but these views of Ponti's are tinted in water colours with so much care and judgment, that we are compelled to admit, that, for Venetian scenes especially, the colour is an improvement on the monochrome. The reference to these pictures reminds us, that in a gallery at the Crystal Palace, not far from the Photographic Exhibition of the South London Society, there is a large array of photographs by Ponti and others in every stage of green and yellow decomposition and fading. We do not know to whom they may belong, but we should be glad for the credit of the art to see them removed from public exhibition.

Mr. Spode sends some good landscapes, of which we may mention "Sheephill Cove, Isle of Wight," and "At Armytage, Staffordshire," amongst those which please us best. Mr. Haigh sends several Australian views, which, though photographs, are chiefly interesting from their localities. Mr. Olleys contributes some excellent specimens which interest microscopists; they consist of transverse sections of various trees and plants, and some entomological subjects, enlarged by what is described as the reflecting process. Mr. Mainwaring exhibits some frames containing a class of subjects he has made peculiarly his own; we refer to his exquisite photographs of flowers, singly and grouped; some of these groups are perfect gems. Many photographers will remember Mr. Roger Fenton's groupings of fruit flowers, *bric-à-brac*, &c., *à la* Lance. Some of Mr. Mainwaring's groups are very similar, with this difference and advantage, that they are much smaller, none of them exceeding half-plate size. In Mr. Fenton's pictures, reproducing flowers, fruit, &c., the same size as nature, the absence of the colours of nature was unpleasantly felt; the pictures also were equally unfitted for mural decoration and for convenient keeping in a portfolio. These pictures of Mr. Mainwaring's, are, however, just the size for preservation in albums. The photography, the grouping, the arrangement of background, &c., are all equally good. Some of them are very nicely tinted; we believe by Mr. Mainwaring himself.

Turning to the examples of the dry processes, although we are disappointed at not meeting with works of some of our best men, such as Mudd, Sidebotham, and others, as we have to regret the absence of some masters in the wet processes, yet we find dry photography on the whole ably represented. It is a somewhat singular fact, however, that but one gentleman sends specimens of the Fothergill process, which, but a few years ago, was so largely practised: and what is not less singular, Mr. Fothergill, the originator of that process, himself contributes in conjunction with Mr. Branfill, some admirable specimens done by the tannin process.

By this process some very excellent pictures are exhibited. Mr. Thomas Annan, of Glasgow, who also contributes some good landscapes by wet collodion, sends some very fine tannin pictures: "The last Stooks of Harvest" is a magnificent photograph, and a very fine picture in the most comprehensive sense of the term. The subject, the composition, the lighting, and general photographic treatment, are alike good; and the great breadth of the picture is not spoiled by a mass of white paper for sky. Both this and another large tannin picture sent by Mr. Annan, "Loch Ranza," have fine skies and clouds. These, we have before understood Mr. Annan to say, are printed in separately, but they are joined with sufficient skill to prevent attention being called to the subject. We have before expressed a conviction that this is perfectly legitimate, and as effected by Mr. Annan, there cannot, we think, be the shadow of an objection to it. He remarks in a communication to us some months ago, "my skies are generally dense enough to print pure, or where they are not, I protect them in printing by some simple appliances, *always taking care that the horizon is not interfered with*, and then I print in my clouds which are taken from nature." The words we have italicized are of the utmost importance in such matters; and it is in reference to the impossibility of preserving the delicate aërial line of the horizon that we have always condemned utterly the practice of blocking out the sky. Double printing executed with taste and judgment we hold to be perfectly legitimate; and the success or want of it in the result is the true test. All Mr. Annan's pictures are successful, and his "Last Stooks of Harvest" is a genuine work of art.

Mr. Penney of Cheltenham exhibits a few very fine soft and detailed tannin pictures. Mr. J. J. Cole exhibits some excellent pictures by the same process, to which we refer in another column. It is somewhat singular, that whilst the dry processes generally have had a reputation for hardness, and the tannin process, especially at one time, appeared likely to obtain a reputation for hardness, all the pictures by dry processes, and by this process pre-eminently, are soft and full of detail and of atmosphere. Mr. Cole's architectural pictures, illustrating the works of Sir Christopher Wren, are all extremely delicate and soft. Mr. Cole also exhibits some good pictures taken on Dr. Hill Norris's plates.

Admirably illustrating the possibility of obtaining the utmost delicacy and softness on dry plates are Mr. G. C. Buxton's views in the East. The best views of these scenes by the wet process, produced by the first photographers, do not surpass these in all that constitutes good photography. There is one picture which is a perfect gem in its rare and beautiful rendering of a broad stream of sunlight slanting down on the "Hypathial Temple, Philæ." Mr. H. Petschler also contributes a series of examples of the collodio-albumen process, or rather of his own and Mr. Mann's modification of it. Mr. Petschler's pictures possess great artistic and photographic merit. If we are not mistaken, we saw some of the same specimens at the Manchester Exhibition last autumn, when they struck us as a little heavy; whether that was due to the light in which they were hung, or the special characteristics of the prints then exhibited we cannot tell; but certain it is that these appear in all respects satisfactory. Most of these pictures possess pleasing skies, diversified by low-lying clouds near the horizon. Whether these are natural clouds, or produced at two printings, or the result of skilful working on the negative, after the fashion of Mr. Mudd and others of the Manchester school, we cannot with certainty determine. We incline to the latter view; but when we state that we have heard it very closely discussed by good photographers examining the prints, without any conclusion being reached, our readers will infer that the result is good. It is unquestionably a great improvement to the pictures, and we repeat again the dictum that success is the touchstone of legitimacy. We commend the specimens to the attention of such of our readers as may visit the Exhibition, and especially advise an examination of Mr. Petschler's "Matlock High Tor," "Wingfield Manor," "Haddon Hall," "At Bettws, North Wales." "Stone Quarry, Derbyshire."

The only Fothergill specimens are exhibited by Frank Howard, late Treasurer of the South London Society. We have on repeated occasions before had occasion to speak of the very successful efforts of Mr. Howard with the Fothergill process. The specimens here exhibited, both stereoscopic and whole plate, are distinguished alike by careful manipulation and artistic feeling.

The calotype process, we are glad to say, is fairly represented. We should be very sorry indeed to see the earliest, and still by no means the worst photographic process, entirely numbered amongst the things of the past. We had hoped to see a frame of specimens from Dr. Diamond's exquisite calotype negatives, of which we know he possesses some hundreds. His duties as a juror have, we understand, prevented the fulfilment of a promise to contribute. Captain Sellon exhibits some very interesting prints of Indian scenery, &c., from calotype negatives. Mr. Bayhnam Jones also exhibits one or two good pictures from calotype negatives.

Mr. Bartholomew, whose communications on the value of organic salts in collodion have recently appeared in our columns, exhibits two frames of stereoscopic pictures from negatives produced by the processes described. Besides their own merit as pictures, they possess great value as illustrating the method of production, and we commend them to the attention of visitors. Our space warns us to defer further remarks until next week.

## BROMIDES AND IODIDES: THE IMPORTANCE OF PROPER PROPORTIONS.

BY CHARLES HEISCH, F.S.C.

Dear Sir,—As an early advocate of the use of bromides in photography combined in proper proportions with iodides, I shall feel obliged if you will allow me to say a few words on the subject which is now attracting the attention it really deserves. You will remember, that as early as 1852 I expressed an opinion that iodide and bromide in the proportion of two equivalents of the former to one of the latter gave more rapid and satisfactory results, especially where objects of various colours were to be copied, than anything else. From this opinion no subsequent experience has made me swerve. But it is to the circumstances necessary to render any experiments on various modes of iodizing strictly *comparable* that I wish now to call attention. I do not consider that the truly *relative sensibility* of two collodions to *light* can be tested if different developers be employed. All then proved is that one collodion will bear a stronger developer than another without fogging. On the other hand, no experiments are comparable in which the iodized collodion contains a given quantity of iodide, and the bromo-iodized the same quantity of iodide with the addition of some bromide.

A point of very great importance in attaining the maximum sensibility, either in iodized or bromo-iodized collodion, is the proportion between the quantity of pyroxyline and the quantity of silver deposited in the film, whether as iodide or bromide, and to make experiments comparable this proportion should be constant, so that when bromide is added to a collodion the iodide should be proportionally diminished. If too little silver be precipitated in the film the particles of iodide or bromide are so surrounded by pyroxyline as to lose much of their sensibility, if too much silver be present the precipitated salts hang loose in the film, and are apt to wash out and cause patches. The result of a number of experiments has led me to the conclusion that 6 grains of good pyroxyline will bear satisfactorily sufficient iodide, or mixed bromide and iodide, to combine with 2·5 grains of silver. In all the experiments which I have at various times made on the best proportions of the two salts, this point has been carefully attended to, a result always in favour of the proportion of bromide and iodide before mentioned, the bath and developer being always the same. I believe much of the discrepancy in the results obtained by different experimenters, is to be traced to a want of attention to such points as the above, which would go far to reconcile apparently contradictory results, which, as has been well remarked, "contradictory as they seem, are all true, but are truths imperfectly understood."

*Middlesex Hospital, June 17th*, 1862.

## The International Exhibition.

### THE BRITISH PHOTOGRAPHIC DEPARTMENT.

The Jurors have now completed their labours, and rendered their reports. At what period those reports will be published, we are unable to state; it is indeed undecided as yet by the Commissioners themselves. As one of the primary clauses of "Instructions to Jurors" is an injunction to secrecy in regard to their discussions and awards, information of a definite character cannot at present reach the public; the traditional "little bird," however, which has from time immemorial prated of secrets, has whispered sufficient to make us hope that the adjudication will be on the whole satisfactory, that nearly a hundred exhibitors will be made happy by the receipt of bronze medals, and considerably more than that number will be distinguished by "honourable mention." For details, however, expectants must wait for Time, the revealer.

The irregular arrangement and hanging preclude any satisfactory consecutive notice of the pictures, whether in relation to the numbers, subjects, or artists, we shall therefore pursue such order as we can in glancing at the most noticeable contributions. We may mention here that we are glad to perceive that our intimation as to the effect of the damp walls has induced some contributors of pictures tinted in water colours, to remove those which had been injured. Others remain as witnesses of the destructive action going forward. What will be the state of some before October, we will not at present contemplate.

We commence our present notice by calling the attention of visitors to two of the most interesting contributions in the room, but which are, nevertheless, very likely to be passed over by many entirely unnoticed. They consist of two thin quarto albums, laid upon a table in a corner of the room, opposite the visitor, and at his right hand in entering. They are numbered 906, and 907, and are contributed by Mr. R. Harmer, in whose name we have pleasure in recognizing a member of the South London Committee. The first album contains specimens of photography as it may be applied to book illustration; but it is chiefly interesting to the photographer for the examples it contains of effective fancy printing. The especial object is to show that a proper margin of white paper may be secured round a print of any shape, without the necessity of mounting. Here, each on a quarto sheet of paper, are prints of all shapes, oval, square, &c., with a pure white margin of the photographic paper. Perhaps the most effective specimens are those in which the appearance of an India paper tint is produced around the print, and beyond the tint white margin, giving three distinct tints—that of the photographic background, the India paper, and that of the white margin, but all produced on one piece of paper by skilful masking whilst printing. Another style of printing not less pleasing illustrates the effect of apparently vignetting on tinted paper: the image graduates into a pale warm grey or drab, instead of into a background of white, the whites in the image itself, however, being kept quite pure; whilst around the pale grey into which the vignetting is merged, is a margin of white. This style has somewhat the effect of a crayon drawing on tinted paper, with the high lights put in with white chalk; but is infinitely superior to anything of the kind in its delicacy and force. Other vignettes are printed entirely on a tinted ground, the paper apparently having received a little general exposure before or after printing the negative. This method, which would apparently be so destructive of anything like pure or vigorous prints, becomes very effective in certain cases; for instance, here is a head from a negative which is manifestly hard and over-intense; with ordinary printing it would be chalky in the extreme; but here there are no high lights, the vigour is subdued, the empty patches of white without detail cease to be offensive, as the whole has simply the sketchy suggestiveness of a chalk drawing. Many of the photographs are in themselves very excellent, but under the treatment they have received in printing they become some of the most charming photographic pictures we have seen. Altogether this album is a most instructive contribution, full of suggestion to the printer ambitious to excel in securing the most artistic effects of which his negative is capable; and we heartily commend every photographer who visits the Exhibition to spend a quarter of an hour examining this album. We must not omit to add that the prints are on paper albumenized on both sides, a method proposed in our columns by Mr. Harmer some time ago, as both improving the quality of the prints, and for book illustration giving uniformity of appearance to the paper in prints not intended to be mounted.

Mr. Harmer's other album contains half-a-dozen chromo-photographs, by a method which has been more than once suggested; but not before, to our knowledge, tried. The photographs are printed on papers prepared with the graduated tints produced by lithography, for pencil or chalk drawings. Most of our readers are doubtless familiar with these prepared papers, which are usually sold at repositories for drawing materials, and possess tints graduated for various effects; generally commencing, however, with warm browns for the foreground, running into sunset tints of yellow and red, and these again into the blues. It is upon these tints that Mr. Harmer has contrived by careful printing to produce half-a-dozen landscapes. We understand that no special treatment was adopted; the ordinary processes of sensitizing, fixing, and washing, having been used, but great care exercised throughout. The result is decidedly successful: a new field for the judicious exercise of taste in printing is here not merely suggested, but practically illustrated; and Mr. Harmer, we conceive, deserves well of his photographic brethren for these very pleasing and instructive contributions.

There are scarcely so many subject pieces or *genre* pictures as might have been anticipated; probably from the uncertainty in which photographers were kept as to their ultimate position in the Exhibition. This cause we know operated in a detrimental manner upon the contributions in various ways, giving little time and less heart for the preparation of especial pictures. Foremost amongst the contributors of this class are the two names, often mentioned conjointly, of

Rejlander and Robinson. The former exhibits two or three frames, containing some charming pictures, of some of which we have already spoken; and all of which have, we believe, been before exhibited and noticed. They are mostly hung too high for careful examination: in one frame we can conceive the presence of a variety of little naked cherubs may have influenced this. We should have been glad to see the other frames in a position more worthy of their merits. These contain the well-known art photographs "The Wayfarer," "God Speed Him," "The Scripture Reader," "Absence of Mind," &c., &c. Those who would examine them carefully must provide themselves with a ladder; or better still, visit the publisher, Mr. Victor de la Rue, or the artist himself in the Haymarket, whom we have pleasure in taking this opportunity of welcoming as a resident Metropolitan photographer.

Mr. Robinson sends several old favourites, including the earliest which first called attention to his unquestionable genius, namely, "Fading Away," and "She never told her Love." "Little Red Riding Hood," "Here they come," "Top of the Hill," "Holiday in the Woods," &c., are also exhibited. "The Lady of Shalot," his most recent composition picture is also here, and despite criticism, and despite some real faults, it excites much attention and admiration. The general public, who do not give photography credit for the production of such things, after examining attentively, and admiring, generally pass on, exclaiming, "Undoubtedly a very clever copy of a painting." If photography has contributed, as it undoubtedly has, much to the spread of præ-Raphaelitism amongst painters, unquestionably the præ-Raphaelite painters have reacted on some of our photographers. Mr. Robinson has beyond a doubt come under their spell, and to their influence and example some of the faults in this picture are attributable, as any one examining Millais's paintings in the Picture Gallery in the Exhibition, especially the "Apple Orchard," may readily see. Despite all this, however, it is a noble picture, full of true poetry. Mr. Robinson also exhibits "Elaine, with the Shield of Launcelot," which we noticed at the Manchester Exhibition. We then pointed out some short-comings in the story as told by the picture, and we have since ascertained that it was merely a preliminary sketch for a more ambitious picture, and preserved because of some good points it possessed. It is unquestionably good as a photograph, although defective in some parts as a picture, and we cannot help here defending it from some amusingly ungrounded strictures in a notice of the South London Exhibition appearing in a contemporary. The writer in a notice of that Exhibition, on the whole interesting and well intended, takes entire exception to this picture, especially on the ground of its violation of historic truth in depicting the draperies and accessories, the shield meeting with especial censure. The writer says:—

"Heraldic devices upon the shield were only invented when, locked up in complete steel, the warriors had no other resource left by which to make themselves known to their friends and followers, therefore the rampant lion is out of place. And, once again, the shape of the shield is one which we have every reason to believe our rude forefathers never adopted—all the British shields, of which we have any account or relics remaining, being flat and circular, ornamented more or less with metal knobs and bosses. In the British Museum a shield exists which might well have served as a model for Launcelot's."

We cannot help regretting, whilst reading this waste of historic and heraldic lore, that the writer had not taken the trouble to read the Laureate's poem, a glance at which spares us the necessity of comparing dates and costumes. Mr. Robinson has, we know, studied the poet with a reverent admiration, and has, in these details, at least endeavoured to render him correctly. Let us see how far a device at all, or this especial device is true to Tennyson's description, upon whom, therefore, the onus of its presence must rest, and, who, if *he* failed to make himself familiar with all that pertained to Arthur's time is—well, he is to blame, and the critic is, under such circumstances, right. Tennyson tells us that the "Lily Maid of Astolat," having this shield in her care,

> " ——— fashioned for it,
> A case of silk, and braided thereupon
> All the devices blazoned on the shield
> In their own tinct."

Further, Launcelot going forth in disguise to contend for the diamond at Camelot, asks of the Lord of Astolat a shield:—

> " ——— and the shield—
> I pray you lend me one, if such you have,
> Blank, or at least with some device not mine."

So much then for the presence of a device on the shield. Now let us see if the device be a correct one. Mr. Robinson's shield has a rampant lion; in the "Idylls" we find the matter thus:—

> "And when the shield was brought, and Gawain saw
> Sir Launcelot's azure lions, crowned with gold,
> Ramp in the field."

So much for the rampant lions.

All this, we know is not exactly photographic; but it bears pertinently upon photographic criticism and upon the historic correctness of a photograph, and we feel it important that photographic criticism should not lose all value by indulging in baseless or ill-informed strictures. Errors of judgment all are liable to, but it is important to avoid errors of fact. If Mr. Robinson ever carry out his original idea, we shall doubtless have a better representation of "Elaine the fair, Elaine the loveable," and although we shall have the shield with his device of the ramping lions, it will bear indisputable traces of the stern blows which awoke the sympathy of the "Lily Maid of Astolat."

Mr. Mayall contributes some *genre* studies, which will, however, bear out his reputation for being unequal. Some of these are very charming pictures, and deserve a much better light than that in which they are hung "The Great Light shines through the Smallest Window" is a very beautiful picture; the scene is an humble cottage in which a little child reads the Book which contains the words of hope and peace to man; to which an aged peasant listens with evident attention. The subject, the composition, and the photography, are alike good. "A real Ten-pounder" is another good picture, an illustration of an election *jeu de mots*, the ten-pounder not merely representing a ten-pound householder, but a ten-pound note, which the "hon. member for Tipem" has slipped into Hodge's hand whilst asking his "vote and interest." The story is cleverly told, the photography is good, and the picture is interesting to many, as containing an admirable portrait of Mr. Mayall himself, and one of Alfred Crowquill, as the "honourable member." There are some other pictures of the same class, and one entitled, if we remember rightly, "One more Unfortunate," which is a sad travestie on Solomon's "Drowned, drowned," exhibited at the Academy two or three years ago.

Mr. Charles Critchett exhibits a couple of studies, "The Nun," and "The Dairy Maid," which have considerable merit. Messrs. Ross and Thompson have several frames of very fine studies, in which the feeling and arrangement generally are very excellent; but there is an unfortunate heaviness and blackness, which sadly mars the effect in other respects so good. Heath and Beau exhibit a few pretty vignetted heads possessing much character and archness. There are a few other similar contributions which do not arrest our attention by any especial characteristics.

## PHOTOGRAPHIC CHEMICALS.

The first thing that must strike the visitor upon entering the department of the International Exhibition devoted to chemicals, is the very great advance which has been made in this branch of science during the last ten years. As compared with the Exhibition of 1851, the display is far in advance of anything there shown, whilst the beauty of the individual specimens is also very superior. We have already alluded to the fine specimens of rock salt, which form a trophy just at the entrance to the chemical annexe. This is exhibited as the support and centre ornament of a fine collection of the different varieties of salt met with in commerce. Here this very necessary photographic chemical may be seen in all varieties of form and purity, whilst the damp position in which the whole is exposed, shows the difference between the various qualities, and warns the photographer not to use any but the best variety for his purpose: all the specimens in this case, except those which are very pure, rapidly running to liquid.

Passing on from this trophy, which is included in Class I., as a mineral product, we enter the domain of chemistry proper. Among the first cases of photographic interest which here meet the eye is one shown by Messrs. Johnson and Sons, of Basinghall Street, No. 541. This firm exhibits a large dish filled with massive crystals of nitrate of silver, which, although they have been exposed to the full action of light and air, almost since the opening of the building, scarcely seem affected at all in colour. They have also a good assortment of nitrate of silver prepared with especial reference to photographic requirements. Little cakes of fused nitrate, not, however, of a very brilliant white colour, weighing exactly one ounce, being done up in pill boxes. We do not like the plan of keeping this salt in contact with organic matter. It may not be rendered any worse for the association, but photographic chemicals, nitrate of silver especially, should be, like Cæsar's wife, not only pure, but above suspicion. A far better plan of storing this salt is also to be seen in this case: little tubes of yellow glass having 180 grains, the quantity required for a quarter-size nitrate bath, hermetically sealed up in them. This has many advantages for the tourist and amateur photographer, as it not only saves the trouble of weighing out, but prevents any danger of contamination from dirty scales. For larger quantities of nitrate, Messrs. Johnson and Sons have yellow glass bottles. A few other silver salts are also exhibited in small bottles, such as chloride of silver, cyanide of silver, oxide of silver, as well as the precipitated metal. The chemist and photographer will each appreciate the beautifully crystallised chloride of gold, which is also seen in this case. The crystals are large, and very dry; the same may also be said of the chloride of platinum, each of which salts are shown, sealed up in glass tubes for photographic purposes, and containing definite weights of chloride with the equivalent also given in pure metal. We notice also some delicate-looking test papers, both litmus and turmeric, in books, some white-looking lumps of kaolin, and some good crystals of nitrate of uranium. They likewise exhibit pure silver wire, and also some soft iron wire, coated with gold, for dentists' use. We think the photographic instrument maker could make use of this wire very advantageously for the corners of frames, in the dark slide, and for dippers and other purposes, where silver is now used. We do not know its price, but for equal strength it would certainly be cheaper than silver wire, whilst the metal, gold, would be even better than silver for regular contact with the silver bath. There are also an instructive collection of mineral ores with the pure metals extracted from them, and also some large show crystals for druggists' windows.

Not far from the above case may be seen a nice collection (No. 588) of colours, red, green, blue, and yellow; carmine, vermillion prepared in the wet way (of a very beautiful colour), dye extracts and aniline mauve; all of which are of interest to the artist. The same firm, Messrs. Roberts, Dale, and Co., Manchester, exhibit hyposulphite of soda in large crystals, and considerable apparent purity, as well as caustic soda, tannic acid, and oxalic acid. These specimens of soda are, however, eclipsed by the magnificent blocks of alkali sent by the Jarrow Chemical Company (540); their mass of carbonate of soda is amongst the finest in the building, whilst their caustic soda is almost equally good.

(*To be continued.*)

## PHOTOGRAPHIC CHEMICALS:

### Their Manufacture, Adulterations, and Analysis.

*Potassium salts* (continued).—The sulphate of potash has already been described. The bi-sulphate may, however, be mentioned briefly, as possessing some valuable properties, which render it a useful adjunct to the ordinary materials of a laboratory. It is formed on the large scale in the preparation of nitric acid from nitrate of potash. When this acid is liberated from nitre by distillation with oil of vitriol, a residue is left behind in the retort, which, according to the quantity of oil of vitriol used, consists either of sulphate of potash $KO.SO_3$, or bi-sulphate of potash $KO.SO_3.HO.SO_3$. At first sight it would appear the most economical plan to add just sufficient sulphuric acid to liberate the nitric acid from the nitre, thus

$$KO.NO_5 + HO.SO_3 = KO.SO_3 + HO.NO_5.$$

It is, however, found that there are disadvantages attached to this plan. The operation is obliged to be performed in glass retorts, and, consequently, economy must be directed towards the retort, as well as to the oil of vitriol. The residue of sulphate of potash forms a solid hard cake, not readily soluble in water, and, consequently, offering considerable resistance to any attempts which are made to remove it from the retort. In four cases out of five the glass is cracked during the operation. It has been found, however, that if a double quantity of sulphuric acid be employed thus—

$$KO.NO_5 + 2HO.SO_3 = KO.SO_3.HO.SO_3 + HO.NO_5$$

the residue in the retort consists of bi-sulphate of potash, which can be removed without difficulty with warm water. Oil of vitriol is very cheap, and the value of the extra equivalent is trifling in comparison with the saving effected in the value of the glass retorts. After the bi-sulphate has been entirely dissolved out, the solution is to be evaporated. The bi-sulphate may also be obtained by dissolving 87·2 parts (1 atom) of sulphate of potash in forty-nine parts (1 atom) of oil of vitriol; the hot solution, especially if a little water be present, yields crystals of the bi-salt immediately on cooling, and the remaining quantity of the salt can be procured by evaporating and heating the supernatant liquid to dull redness. The bi-sulphate crystallizes in the anhydrous state in fine needles, melting at a temperature a little below redness. It is also obtained in the hydrated state when crystallized from an aqueous solution, forming oblique prismatic crystals; they fuse at a trifling lower temperature than the anhydrous salt. Bi-sulphate of potash dissolves in about half its weight of boiling water; the solution solidifies to a mass of needles on cooling. When dissolved in a larger quantity of hot water and allowed to crystallize, decomposition takes place to some extent; neutral sulphate of potash crystallizing out on cooling, leaving free acid in the solution. It seems as if an excess of water overcomes by its affinity for sulphuric acid that of the sulphate of potash for the same. When the powdered salt is diffused through a considerable quantity of cold water, the whole of the free acid may be removed, leaving neutral sulphate of potash behind. The equivalent of hydrated acid present in this salt, acts in many instances as if it existed in the free state, and on this account is of great use in the laboratory, being a convenient form of applying this energetic body at a high temperature, as for instance, in fusing and decomposing refractory minerals, cleansing platinum crucibles, &c.

*Iodate of Potash.*—This salt being formed whenever iodine and potash come together, and being liable to be present in many photographic compounds, a short account of its properties may prove interesting. It may be prepared by dissolving iodine in caustic potash, until a permanent brown colour is just produced. Six atoms of caustic potash, and six atoms of iodine, forming one atom of iodate of potash and five of iodide of potassium, thus—

$$6KO + 6I = KO.IO_5 + 5KI.$$

The liquid is to be evaporated to dryness, and the residue exhausted with alcohol sp. gr. 0·81. The iodide of potassium dissolves, leaving the iodate undissolved. Upon solution in water and recrystallization the iodate may be obtained pure. It forms small white cubical crystals which are anhydrous, and are unaltered in a dry atmosphere. At a low red heat it melts and evolves 22·59 per cent. of oxygen gas, being converted into iodide of potassium. The residue, however, is generally alkaline, owing to the escape of iodine along with the oxygen. Sulphuretted hydrogen also converts the aqueous solution of this salt into iodide of potassium with deposition of sulphur. This method, however, does not yield it sufficiently pure for photographic purposes, as it is almost impossible to get rid of the sulphur compounds formed at the same time. When heated with hydrochloric acid, chlorine, and afterwards iodine, are evolved, and if sufficient of the acid is employed, chloride of potassium alone is left; an intermediate compound of ter-chloride of iodine with chloride of potassium being however produced. Iodate of potash dissolves in thirteen parts of cold water, and more readily in a solution of iodide of potassium. Its presence in commercial iodide of potassium may be easily detected by adding a little sulphuric acid to the solution. In either salt separately this acid produces no marked reaction, as the liberated hydriodic and iodic acids are colourless; when, however, they both are liberated together in a solution, the oxygen of the iodic acid unites with the hydrogen of the hydriodic acid forming water and liberating iodine, which communicates a reddish brown colour to the liquid.

*Bromate of potash.*—The same remarks which we have made above respecting iodate of potash, apply equally well to bromate of potash. It is formed by saturating a moderately concentrated solution of potash with bromine. The greater part of the bromate of potash crystallizes out immediately, and the rest may be obtained by evaporation, whilst nearly all the bromide of potassium remains in solution; it may be purified by recrystallization. Bromate of potash forms crystals belonging to the regular system. At a red heat it evolves ten per cent. of oxygen gas, leaving a residue of bromide of potassium. It is decomposed by acids in a very similar manner to chlorate of potash.

*Fluoride of potassium.*—The best method of obtaining this salt consists in mixing hydro-fluoric acid with carbonate of potash, leaving the acid in slight excess; the liquid must be evaporated to dryness in a silver or platinum vessel, and heated strongly to expel the excess of acid, it must then be dissolved in water, and crystallized by evaporation at a gentle heat in a platinum or silver dish. Fluoride of potassium crystallizes in long radiating crystals which deliquesce rapidly in the air, are very soluble in water, but insoluble in alcohol; they contain 39·44 per cent of water. This must be borne in mind when weighing out crystals for photographic purposes.

*Oxalate of potash.*—This salt is frequently used in photography, both by itself and as a source of oxalic acid. It is obtained either from vegetable juices, such as sorrel, &c., in which it exists in the form of binoxalate, or by the direct union of oxalate acid with potash. In the ordinary state in which they are obtained in commerce they contain two atoms of waters. Upon being heated the whole of the water goes off, and after being heated to redness the salt leaves a residue of carbonate of potash; the crystals dissolve in three parts of cold water. The commercial salt is usually very pure, it is not likely to contain any impurities which are not removed by recrystallization.

*Binoxalate of potash* is produced by dividing an aqueous solution of oxalic acid into two equal parts; exactly neutralizing one of them with carbonate of potash, and adding the remaining oxalic acid to it, the salt crystallizes out upon evaporation; it can be purified by solution in water and recrystallization. In this form the salt contains two atoms of water, and crystallizes in the oblique prismatic system, it is permanent in the air, and has a sour, rather bitter taste; it dissolves sparingly in cold water, and in fourteen parts of boiling water. Boiling alcohol likewise dissolves a small quantity of it. It is to the presence of this salt in the juice of sorrel and various species of oxalis and rumex that the pleasant acidity of their juices is owing.

*Quadroxalate of potash* is formed by dividing an aqueous solution of oxalic acid into four parts, neutralizing one of them with carbonate of potash, and adding the other three parts to it. It separates in the form of very acid needles. often of great size, which require about twenty parts of cold water for their solution. The compound known among druggists as salts of lemon, and largely employed for removing iron moulds and other stains from linen, generally consists of this salt.

## WET OR DRY COLLODION.*

BY M. L'ABBE DESPRATS.

*On the part electricity plays in photographic manipulation.*—We have now arrived at the developing solution, at that stage of our operations which is at the same time so interesting and so mysterious. The sensitive film, acted upon by light, upon its removal from the camera, contains a latent picture, which we proceed to render visible. What is the action of light upon the sensitive film? what is its nature? And as this action is real, although invisible, what are the means of completing it, and of rendering its effects apparent to the eye? Hitherto, a decided reply has not been given to the first question; as to the second, it is, if not perfectly, at least very nearly resolved. However, as these two questions have an evident connection, we may say that the solution of the latter will be really perfect only on the day when the first has become fully elucidated. We have certainly no pretension to raise the thick veil beneath which the luminous operation takes place; but there is, it seems to us, no doubt that electricity plays a very important part in this case. In admitting that, in photogenic phenomena, electricity concurs with light, it will, it is true, always be very difficult to establish its particular action, but when it has been proved that this action exists we should take account of it, and seek the means, either of regulating its effects, or of rendering it more efficacious. It is this consideration which has determined us to give a summary of the experiments we have made in this direction.

It may be admitted, as a general law in physics, that every change, in the state of a body, is accompanied by a rupture of the equilibrium of their electric condition. Combinations, simple or complex, are the most powerful sources of electricity, but they are not the only ones, the passing of solid bodies to the liquid state, from the liquid to the gaseous, and reciprocally, also furnish signs more or less appreciable of electricity. In the various circumstances where electricity acts by shocks, science furnishes the means of measuring the fire in a very vigorous manner, in others on the contrary, when, for example, the electric action is slow, it is not possible to employ the same means of appreciation. Nevertheless when, after the lapse of a time more or less considerable, entirely new compounds have succeeded those under consideration, analogy compels us to admit that they are the effects of a similar cause, the action of which, always fruitful, is slow only from the fact of the circumstances under which it is forced to act. Reflecting ever so little upon the whole of the different manipulations which concur to the formation of a photographic picture, we perceive that they all have the effect of producing new combinations of known elements. We see, also, that these combinations, which, for the moment, seem perfectly definite, are, nevertheless, unstable; from this we are led to conclude that if as first there is electricity by shocks, there is also a slow action which reacts upon the result produced by the first. This second action, silent and persistent, may sometimes be very favourable, but more frequently it betrays itself by effects the more disastrous, inasmuch as the electro-motive force causes are very often concealed and inappreciable. In our opinion it

* Continued from Page 66.

is to this second mode of electric action that we must attribute the alteration, which ultimately manifests itself in the photographic preparation of proofs either negatives or positives.

As may be seen, the question that now occupies us is full of interest, unfortunately, it is also full of mysteries. We repeat we have not the slightest pretension to explain them; but persuaded that the path of experiment is that which must be preferred in advancing a science or an art, we proceed to indicate some of those which have more especially led to the subject before us. These experiments, or other similar ones, are not new, they have been repeated by many physicists and chemists; only as our mode of experimentation is very simple and very easily performed, we proceed briefly to explain it.

The multiplicator we employ, although but slightly sensitive, is nevertheless sufficiently so to appreciate the electric forces to which it is submitted—it is Mellone's thermo-electric multiplicator with astatic needles. Each end of the conducting wire of pure copper is terminated by a platinum wire six inches long armed at its free extremity with a plate of platinum one to one and a half inches square. If the copper wire terminates with these two plates there is a risk of developing by the mere warmth of the hand, a thermo-electric current sufficient to modify the results, but with a length of six inches of the platinum wire this inconvenience is no longer to be feared, and, on the other hand, the platinum plates being unoxidizable, there is no other electricity except that developed by the combination of the bodies placed in contact.

We first proceed to determine the direction of the current; this is ascertained by a plate of zinc being put in contact with one of the plates of platinum and separated from the other by some folds of blotting paper moistened with water acidulated with a few drops of sulphuric acid. When the circuit is complete, we shall perceive the system of needles, at first established parallel to the conducting wire, place itself at right angles with it, and always in the same direction every time the circuit is broken or renewed. The better to fix it in the mind, we call the current thus given by the zinc *positive;* and *negative* that of which the direction is opposite.

We now proceed to experiment, electrically, with some of the ordinary and familiar combinations in photography. The platinum plates being superimposed, but separated by pieces of moistened bibulous paper of nearly twice their size, no electricity is developed, the needles remain fixed. Upon pouring on to the paper some drops of a solution of iodide of potassium, still no effect; but if, upon the paper being moistened with iodide, we let fall some drops of a solution of nitrate of silver, the needles are instantly diverted more than ninety degrees from their fixed position, and the direction proclaims a *negative* current. By causing the paper to imbibe first, nitrate of silver, and in the second place, pouring upon it iodide of potassium, a current takes place as energetic as the first, but in an opposite direction to the first, that is, *positive*; double decomposition being accomplished, that is to say, after the complete formation of iodide of silver all electric action ceases, and a stable equilibrium, for the minute at least, is definitely established. The results are identical if we operate in the same manner with hydrochlorate of ammonia and nitrate of silver; identical also with this latter salt and hydriodate of iron, except this difference, however, that in this last double decomposition the electric currents developed are much more energetic. The addition of iodide of iron to collodion with the view of obtaining greater sensitiveness is disapproved by some photographers; for our own part, we have proved that the addition of this preparation to albumen is evidently accelerating. May we not be permitted to suppose that there is a certain correlation between these two different phenomena, on the one hand, disengagement of more intense electricity, on the other, exaltation of photogenic sensitiveness.

We cannot decide upon this point, but it seems to us at least worthy of examination; and then the case we have instanced is not the only one. There is at least one of a very similar kind. Pursuing our researches with the aid of the multiplicator, it has been easy for us to compare the electric action of pyrogallic acid and sulphate of iron upon nitrate of silver. We know that by means of the second reducing agent, the duration of the luminous action is generally diminished, in a word, it is a greater accelerator than pyrogallic acid. So we find that it is from its reaction upon nitrate of silver that the most energetic current results. With pyrogallic acid we obtained scarcely 45 degrees of deviation, while with sulphate of iron, the needle, suddenly diverted from its position, makes almost the entire circuit of the scale. We repeat, a correlation so manifest between two such different classes of phenomena, seems to us worthy of attention, and further researches in this direction would perhaps not be without profit for the progress of art.

In the preceding experiments, as well as in a host of others analogous, the effects obtained are due to instantaneous electricity, or that acting by shocks. These effects, always realizable at the pleasure of the observer, are, as may be perceived, of ready appreciation and measure. But it is not the same with the effects caused by a slow electricity. Too often the elements submitted to its action are inappreciable; moreover, if, during the intervals of electric action, these elements vary with respect to number and quality, combinations which may be clearly defined for a moment may be destroyed and give place, later, to new combinations.

We can easily sound the latent elements upon which a force is exercised, as little understood as electricity still is, being made evident, effects will result which it will be as difficult to foresee as to prevent. We stated at the commencement, that we were induced to think that the instability of photogenic preparation is due to this slow action of electricity, either electricity acts upon the elements peculiar to these preparations, or they are associated with others which carry them with them; therefore, an absolute fixity of photographic portraits will probably continue for a long time problematical. Still, in the absence of clearly defined facts, a kind of intuition, which may sometimes follow an attentive observation, may prove of great assistance; it is thus, that positive paper which but lately changed in a very short time, may now be maintained in all their integrity, since we have learned or divined that it was sufficient to preserve them from the action of moist air. It was very difficult to judge *à priori* of the efficacy of these means, but now that this efficacy is no longer doubtful, it is, if not certain, at least very probable, that in positive paper exposed to moist air, there is a decomposition of water by the nitrate of silver, and, consequently, electric action. We quote only this single example offered to us by the change and preservation of positive paper, and it is sufficient, it seems to us, to prove that in referring these effects of change to an electric cause, we put forth a view which is not entirely void of probability.

We limit ourselves, therefore, to these general considerations. The subject before us would furnish a crowd of others, interesting, without doubt, but, unfortunately, more or less vague, and not yet capable of furnishing us with rigorous conclusions. There is one, however, which has been our starting-point in this study, but which we do not mention in this place, reserving it for the occasion when we speak of the sulphate of iron developing solution.

(*To be continued.*)

## PROGRESS OF PHOTOGRAPHY IN AMERICA.

At the annual meeting of the Photographic Society, in America, the president, Professor Draper, gave an interesting address recalling and reviewing the photographic events of the year. We commend the idea to presidents of photographic societies in this country. We make some condensed extracts which will interest our readers. After some general observations on the national troubles and their influence on the art, he proceeds :—

"From these general remarks I may pass to a summary of some of the special topics that have occupied our attention, referring to them in a chronological order.

"Professor Seely presented us with some new views of toning, printing and fixing, in which he drew in a clear manner the limits of use of the nitrate of silver, the chloride of gold, and the hyposulphite of soda. From his observations he concludes that we should first remove all the free nitrate from a print by washing in clean water, at the end changing to a weak bath of chloride of sodium ; second, that for toning, the print should be immersed in a weak bath of chloride of gold, of one or two grains to the ounce of water ; third, that it should be rinsed in water to remove any free chloride of gold ; fourth, fixed in a bath of pure hyposulphite of soda, and, finally, washed in clean water. He offered evidence from his own experiments that by following this process we may secure photographs of almost any desirable tone, and what is of the greatest importance, photographs which are permanent. The process is also obviously economical. In these views and conclusions, Mr. Kuhns, who has had so large an experience in the printing of photographs, agrees.

In connection with this method of obtaining unfading photographs, Mr. Johnson has offered some illustration of the permanency of daguerreotypes, about one thousand of which, made previously to the introduction of the gilding process of Fizeau, are in his possession. Of these a majority are in perfect preservation. Where change has occurred it appears as a film of deposited matter, which commonly commences to form at the mat. It has been observed that ungilded Daguerreotypes fade sooner if kept in a warm place, this being perhaps due to the vaporization of the mercury of the amalgam constituting the lights.

"Mr. Charles Fontayne exhibited his machine for the rapid printing of photographs, by which it is possible to produce twelve thousand prints in one hour.

Mr. Snelling read to the society a communication on that important subject, to which Professor Seely had already drawn its attention—the fading of photographic prints; differing from him in some of his views. He thinks, that in the durability of our pictures, instead of advancing we have been retrograding, and enforces the opinion by an exhibition of proofs collected within the last ten years. It is his conclusion that failures arise from many causes, such as bad paper, impure chemicals, fixing and toning in the same room in which other operations are carried on, toning in the light, the use of water impure or insufficient in quantity, the heat and gas from stoves, the operations of mounting and printing, soaking the paper too long in the salted solution, toning bath, or washing trough : and too long or too short a time being given to the final washing. Among minor causes, not without interest, of the deterioration of retouched prints, he points out tobacco, the artist moistening his brush with saliva while at work. On making a direct experiment, retouching with India ink or water colours contaminated with saliva impregnated with tobacco smoke, decomposition at those points set in, and gradually spread, while other portions not so treated remained unchanged. He says he has toned and fixed separately, and has used the toning and fixing solutions together, but upon the whole cannot give decisive preference to either method, so far as permanency is concerned. He prefers printing in diffused light to printing in direct sunlight, since proofs so printed tone better, keep better, and are in every respect finer. The longer the printing the more solid and brilliant the picture. Sunlight pictures are the first to fade.

"Mr. Tillman read a paper on the optical phenomena of the recent great eclipse, remarking that the French astronomical expedition to Spain, under the charge of Leverrier, accomplished more during the three minutes and fourteen seconds of total obscuration of the sun, than has ever before been done during a similar phenomenon.

"The attention of the Society has also been directed to the application of photography to military purposes, more particularly to balloon photography, in reconnoitering encampments, hills, bridges, roads, &c. The President of the Society was directed to communicate with the Secretary of War in reference to this subject, and offer the Government its services.

"Mr. Tillman read a paper on the Analogy of Light and Sound, with a view of representing a new method for the arrangement of musical intervals, and imparting a clearer view of the relative position of colours. He showed that for all practical purposes a right angled triangle, whose sides are as 3, 4, and 5, will show the relations of the intervals of the minor common chord, and of a triad of colours, in which the indigo or darkest ray is substituted for the blue ; this relative arrangement producing up through the eye the same depressing effect that reaches up through the ear by the use of the minor mode.

"In reference to Balsamo's phosphorous process, it appears that for a long time that substance has attracted the attention of scientific men, experiments having been made upon it more than fifteen years ago in the university of this city. Photographs of the solar spectrum were obtained on pure phosphorus by the president of the society, so perfect as to show the fixed lines beautifully. For this purpose, the phosphorus was enclosed in a thin sheet between two plates of glass.

"Dr. J. M. Saunders communicated to the society what he considered to be a great improvement in collodion, especially that for ambrotypes. It consists in the addition of a drachm of water to each pint of collodion.

"Professor Seely made a verbal communication to the society on the Chemical History of Gun Cotton, and Professor Joy explained some of the recent discoveries by the use of the Spectroscope, leading to the detection of two new alkaloid metals, rubidium and cæsium ; these remarks being elicited by the exhibition of an instrument constructed according to modifications suggested by Dr. Gibbs, and in part carried into effect by Mr. Fitz.

"Another new spectroscope of German construction was exhibited to the society by Professor Joy, together with drawings of the spectra produced by various bodies. It is a modification of the spectroscope originally invented by Frauenhofer, and employed by the president of the society many years ago, at the time when he first discovered that the spectrum of incandescent solids, such as platinum, contains no fixed lines, and that the spectra of other bodies vary with their temperature, as is shown by combustions in air compared with those in oxygen gas. These results were published in the *Philosophical Magazine* for May, 1847, and February, 1848, but appear to have been overlooked by those European experimenters who have been paying attention to this subject.

"Mr. Johnson exhibited to the society a camera made by himself and Mr. Wolcott, and some specimens procured by it in 1843. The lens is a plano-convex of short focus, and is intended to make a picture on the interior of a concave plate to be used on the magic lantern. It appears that evidence is in existence that Messrs. Wolcott and Johnson had at that time nearly succeeded in perfecting the albumen process.

"Mr. Tillman read a paper on the Causes of Actinism, his object being to determine how the undulations of ethereal waves, having no distinguishing characteristics but a relative decreasing length, and an accelerated tranverse motion, can produce instantaneous and peculiar effects, when brought in contact with sensitive compounds used by the photographer. Adopting the atomic theory of Ampere, he showed how a series of wave forces generated by the sun, when acting upon such sensitive matters, may so modify the forces of cohesion and chemical affinity as to produce all the phenomena under consideration. The diverse effect of undulations of the same medium may be thus briefly stated :—the longer ethereal waves have the power of giving vibratory motion to a whole molecular chain, the shorter waves the power of moving each particular link of that chain. The longer penetrate and disturb the whole substance, thus evolving heat; the shorter act superficially, influencing the minutest component part of the surface, thus generating actinism.

(*To be continued.*)

## PREPARATION OF PHOTOGRAPHIC COLLODION.

A Lecture before the Antwerp Scientific Association.

BY M. CLEMENT OMMEGANCK.

The ordinary formulæ may be generalized by the following quantities—

| | | |
|---|---|---|
| Ether (sp. gr. 0·72) ... ... | 66 | parts |
| Alcohol (sp. gr. 0·81) ... ... | 33 | " |
| Iodide ... ... ... ... | 1 | " |
| Bromide ... ... ... | 0·25 | " |
| Pyroxyline ... ... ... | 1· | " |

If we make use of a weaker ether or alcohol, and one consequently containing more water, the collodion will be fibrous in texture in consequence of its containing too much water.

Of the 33 parts in the formula it will even be advantageous to take one-third of absolute alcohol. When operating at a high temperature, it is advantageous, and even, perhaps, indispensable, to modify the formula, and take equal portions of ether, and absolute alcohol (sp. gr. 794).

Most formulæ take little account of the greater or lesser fluidity which the quality of the pyroxyline communicates to the collodion, or of the influence which the iodides introduced may exercise upon this fluidity. Now, for a portrait of large dimensions we require a thicker collodion than for a smaller one, the delicacy of detail being in exact ratio with the fluidity, this delicacy, indispensable in the latter, will give to the former an unfavourable degree of transparency and hardness.

Very frequently the difficulty in obtaining the wished-for opacity in negatives depends upon the too great fluidity of the collodion. Without wishing to proscribe other formulæ, I give those which have given me the best results. For all kinds of negatives obtained by short exposure, a collodion consisting of, in 1000 parts:—

| | |
|---|---|
| Ether ... ... ... ... ... | 667 |
| Alcohol ... ... ... ... ... | 333 |
| Iodide of ammonium ... ... ... | 6 |
| Iodide of cadmium ... ... ... | 6 |
| Bromide of cadmium ... ... ... | 3 |
| Pyroxyline ... ... ... ... | 12 |

This collodion is sure to be thick enough: if too thick, however, it can be rendered more fluid by the addition of a suitable quantity of ether, or of absolute alcohol: if the quantity of this addition exceeds one-tenth of the original volume, it will be desirable to dissolve in the ether or alcohol added beyond this tenth, the quantity of iodide and bromide corresponding to the formula; that is, 1 grain of iodide and ¼ grain of bromide to 100 grains of liquid. We should never alter a collodion by adding iodides not already contained in it, nor mix collodions differing in composition; the results given by these capricious mixtures are almost always unsatisfactory.

*Formula for Landscapes, Views, and Direct and Transparent Positives, with Wet or Dry Collodion.*

The following formula has proved the most satisfactory:—

| | | |
|---|---|---|
| Ether... ... ... ... ... | 667 | parts |
| Alcohol ... ... ... ... | 333 | " |
| Iodide of zinc ... ... ... | 6 | " |
| Iodide of cadmium ... ... ... | 6 | " |
| Bromide of cadmium ... ... | 3 | " |
| Pyroxyline ... ... ... ... | 12 | " |

All the general remarks made respecting the first formula are also applicable to this. With one, as with the other, we commence with weighing the salts, and put them into a bottle of the proper capacity, then add the alcohol, and dissolve the salt by shaking it; then add the ether, and mix: lastly, introduce the pyroxyline, small quantities at a time, and shake the solution until the cotton is dissolved.

These collodions will be fit for use in from eight to fifteen days.

The first will keep good a very long time; the second is much less stable, but presents a superiority in the representation of foliage, the green colour of which is always rendered black in the image; it gives much delicacy of detail, and an incomparable purity in delineation. For direct positives we have found no collodion equal to it.

The first requires an exposure of only six seconds in summer, and twelve in winter, for a portrait of small dimensions, *carte de visite* for example; and an exposure of fifteen seconds in summer, or of twenty-five in winter for a whole plate negative, in an operating room suitably lighted with a good objective, and employing an iron developing solution. The time of exposure under very favourable circumstances may be diminished one half, and even be made instantaneous.

Collodions and processes which necessitate longer exposure are little to be recommended, because with most persons immobility is difficult, and even impossible to persons not accustomed to *pose*, when the exposure exceeds twenty seconds.

The use of iodide of potassium in lieu of iodide of ammonium may present certain special advantages, but it gives a less permanent collodion; the potassium possessing a more energetic decomposing action upon the pyroxyline.

The exclusive employment of the salts of cadmium rarely affords sufficient sensitiveness, at least when the collodion is not old, and then, as may be proved by analysis, it contains a good proportion of iodide of ammonium. For if it be treated with a little caustic potash, shortly after it has been prepared, it exhales a feeble ammoniacal odour, while after the lapse of six or eight months, the introduction of some small pieces of caustic potash, produces a very strong ammoniacal odour, as if it it had been prepared with ammoniacal salt at first; it is, therefore, simpler to introduce it at the beginning.

At the time it is prepared the collodion usually assumes a red colour, but in the course of ten or twelve days it becomes almost colourless; if, however, it becomes quite white, it is advisable to bring it to a straw colour, by the addition of an alcoholic solution of iodine, and renew this addition until the straw colour becomes permanent.

The employment of a thick, non-iodized collodion, to be subsequently iodized by means of alcohol holding iodides and bromides in solution, seems to use a useless augmentation of bottles, and frequently gives rise to error in proportions. As by mixing an alcoholic iodide solution with a plain limpid collodion, we obtain a preparation fit for immediate use, we are led to suppose it is advantageous; but there is an inconvenience in this respect, we are always tempted to employ a too recent collodion, and liable to uncertain results.

# Proceedings of Societies.

## South London Photographic Society.

The annual meeting was held at the City of London College, on Thursday evening, June 12th. The Rev. F. F. Statham, M.A., F.G.S. in the chair.

The minutes of a previous meeting having been read and confirmed,

The Secretary then read the report of the committee (see p. 285 in our last). He also read a letter from Mr. Borchert.

resigning his position in the committee from pressure of private duties, and expressing his deep interest in the continued success of the society, and his gratification at the complete success of the society's exhibition at the Crystal Palace.

Mr. Howard, the Treasurer, then read his report. He had the pleasure of congratulating the society on the fact, that for the first time since their existence he held a balance in their favour. Last year, it would be remembered, the year's accounts concluded with a balance of debt to the amount of £3 16s. That amount was nearly cleared off by the volunteer contributions of some gentlemen at the annual meeting. This year, however, he held a balance of £9 16s. 11d. in favour of the society. This arose partly from an increase of income derived from additional members, and partly from decreased expenses in not sending a journal to members. He thought, however, it would be admitted, that the society had more than compensated members for the loss of the journal, in securing them a half-year's season ticket for the Crystal Palace. The balance-sheet had been examined by the auditors and found correct, and now nothing more remained for him but to congratulate the gentleman who had consented to undertake the duty of treasurer, on the fact, that he would commence office under such satisfactory circumstances, with a balance in hand.

The Chairman, in putting the admirably drawn-up report, and the satisfactory balance-sheet, for the approval of the society, felt that it must be to every one a source of deep regret that they should have to consider the possibility of the captain and the chief mate, who had been mainly instrumental in bringing about a result so gratifying, now leaving the ship. It was a source of great satisfaction that the especial end the society had aimed at had been largely attained. The promotion of photography, in its relation to art, had been an especial object of the society; and the many valuable papers which had been read on the subject, must have effected much good. He did not wish to bring a blush to the face of their excellent Secretary by praising him, but in expressing what he felt must be the sincere regret of every member at the resignation of Mr. Wall, he must remind them how much of the success was due to him: he had been present at every meeting, prepared the minutes of all the proceedings, and during the intervals had exerted himself in securing papers for the meetings which were to follow. In addition to this he had written many excellent papers, and had contributed largely to the interest of their discussions by his share in them. He feared that it would be difficult to unite all these qualities again in one individual, and without derogating from the capabilities or willingness of a possible successor, he doubted if they should find a gentleman so well suited to the duties, and he would suggest that Mr. Wall be invited to retain the office, and that an Assistant-Secretary be appointed to share his labours. Mr. Howard had also helped to form and sustain the society by similar exertions. He, however, felt that his numerous engagements were incompatible with his continuance in office, the members must indulge the hope that they would find an efficient successor. He (the President) might be allowed to say for himself that he should like also to have withdrawn his name, since he felt that gentlemen might be found better acquainted with the science, for the advancement of which the society was founded, than himself; moreover, his duties in the large parish of which he had the spiritual charge prevented him from giving that attention to the subject which he desired. If, however, the members thought that the little attention he could bestow, and the exercise of common sense, as distinct from practical knowledge of the subject, would be useful to them, his services were at the disposal of the society. If they could appoint a gentleman who would be of more practical value to the society, he would be very happy to withdraw altogether, or he would feel pleasure, if they so willed it, in retiring to the position of a vice-president, if, in that position, he could be of service to them.

Mr. T. Clark Westfield had pleasure in proposing a vote of thanks to the president, treasurer, and secretary.

Mr. Wharton Simpson, in rising to second a vote of thanks, echoed the chairman's regrets as to the loss of the secretary and treasurer. In regard to the suggestion of the chairman in relation to providing an assistant secretary, said that he had endeavoured to induce Mr. Wall to accede to a similar arrangement, and was now prepared to announce that a member of the society would be happy to enter upon his vociate as secretary, by undertaking the position of assistant secretary for one year, performing the duties under Mr. Wall's direction. He would now put the vote of thanks to the meeting.

The vote of thanks was carried by acclamation.

The Chairman, in acknowledging it on his own part, again regretted that his duties did not permit him to give more time. He should have stained his fingers with the nitrate of silver long ago if he could have commanded leisure.

Mr. Wall explained that he would be placing himself in an unfair position if he undertook either the honour or responsibilities of secretary, and did not actually perform the duties. His own imperative engagements did not permit him any longer to perform the duties satisfactorily, and although during the three years he had held the office he did not think he had neglected them. He would now take the opportunity of apologizing to some gentlemen whose letters he had recently not answered, when they did not absolutely need a reply. There might be a few such, whose letters in his press of duties had been laid aside.

Mr. Howard felt that it was desirable that a change in the active officers should occasionally be made, and allow younger members to take part.

After some further conversation, the following officers were elected for the ensuing year:

*President.*—Rev. F. F. Statham, M.A., F.G.S.

*Vice-Presidents.*—Mr. Sebastian Davis, Mr. G. Wharton Simpson, and Mr. Alfred H. Wall.

*Committee.*—Messrs. Ackland, Blanchard, Foxlee, Harmer, Howard, Leake, Martin, and Newcombe.

*Treasurer.*—Mr. Noel E. Fitch.

*Secretary.*—Mr. Alfred Harman, 3, Albert Cottages, Hill-street, Peckham.

Mr. Martin proposed, and Mr. Simpson seconded, that the Committee meetings should take place on the same evenings as the monthly meetings of the Society, one hour before the commencement of the usual proceedings.

Some discussion arose in which Mr. Wall urged the importance of holding the Committee meetings at least a week before the regular meeting, in order to provide for papers, discussions, &c. Mr. Martin's proposition was finally adopted.

Mr. Wall proposed a vote of thanks to the vice-presidents, to whose active interests in the society much of its success was due, and especially did the Exhibition, now so successfully opened in the Crystal Palace, owe much to their labours.

Mr. Simpson, in responding, took occasion to propose a vote of thanks to Mr. H. P. Robinson, for the extreme liberality of his dealings with the society in the matter of the presentation prints. When asked if he could supply the beautiful photograph, "Early Spring," he at once acceded, leaving the terms of remuneration entirely in the hands of the society.

Mr. Wall seconded the motion, which was carried unanimously.

Mr. Larchin suggested that as the society had a balance in hand, some substantial recognition of the services of retiring officers should be made.

Mr. Simpson suggested that such a step was scarcely within the powers of the society, but might easily be carried out by a subscription amongst members in their individual capacity.

Mr. Wall called the attention of the members to the interesting out-door meetings of former seasons. After considerable conversation, it was resolved that during the coming summer the meetings take place on the first and third Saturday in every month, at from one to half past one o'clock, as might suit trains at the following places;—

1. Jack Straw's Castle, Hampstead Heath, to be reached by omnibus or rail.
2. Richmond Station, by rail from Waterloo Station.
3. Charlton, by North Kent line from London Bridge.
4. Beckenham Station, by Mid-Kent line from London Bridge.
5. The Eagle, Snaresbrook, from Shoreditch Station.
6. Barnet, by omnibus, or by Great Northern Railway.

Mr. Martin proposed a general meeting of the members at the Crystal Palace on the last Saturday in September. After some conversation it was agreed that the committee would meet at 433, Strand, on the third Friday in September, to arrange for such a meeting at the Crystal Palace.

It was announced that the address of two or three members was unknown, and that their Crystal Palace tickets awaited their application.

The proceedings then terminated.

## Talk in the Studio.

The Works of Sir Christopher Wren.—Mr. J. J. Cole has produced, or is producing, a series of cabinet photographs which will be highly prized by all admirers of good architecture, consisting of the Churches of Sir Christopher Wren. The specimens we have received are excellent photographs, and possess the additional advantage of having been taken from the best available points of view, the positions being selected with the technical judgment of an architect and man of cultivated taste. The negatives are taken on tannin plates, and are admirable examples of the softness which may be obtained by that process carefully managed, even with the difficulties of a London atmosphere and light. Of those which please us best, we may mention St. Paul's, from Ludgate Hill, and St. Mary-le-Bow; both pictures are admirable examples of the grace which characterises Sir Christopher Wren's architecture, and as pictures they are not spoiled by white paper skies; one possesses an atmospheric grey tint, and the other, although partially stopped out, is most skilfully managed, the line of the horizon being broken with clouds in such a manner as to preserve breadth. The series is published by Messrs. Griffiths and Farren.

Philosophical Instruments in the Exhibition.—The philosophical instrument division has for so many persons a special interest, that we may claim the indulgence of our general readers while we endeavour to do justice to the collection of objects comprised in class 13, and mostly displayed in the gallery of the North Court. First among the exhibitors in this scientific department we are inclined to place Mr. Ross, if only because he, with perhaps the single addition of Mr. Dallmeyer, can challenge comparison with the great Voigtlander himself for photographic and other lenses. The case furnished by Mr. Ross contains several microscopes of the newest and best construction. Some of them are binocular, and give a stereoscopic relief to the object, an effect both useful and pleasing. We observe a little photographic picture, which might be passed over as a common-place production obtruded in a show of philosophical works. On looking closer at this photograph, we perceive a pencil note in the margin, which informs us that the view was taken with one of Sutton's panoramic lenses; and truly the picture is almost panoramic, being clearly defined to its utmost extremities, and in admirably true focus, with an angle of 100 degrees. Such a thing we never saw before, and we believe it to be perfectly unique in the history of photography. Messrs. Smith and Beck exhibit what they appropriately call a museum microscope, which shows 500 objects in succession, and which includes an ingenious contrivance, too complex to describe here, for varying the powers. Messrs. Powell and Lealand, in a small case, submit for critical judgment a few binocular and other microscopes, of really first-rate workmanship. The show of Mr. Dallmeyer, as might be expected, is a varied and very excellent one, being specially strong in microscopes and telescopes. They also display two or three photographic views, taken with very large angles, and with a plain lens. It may be noted, in passing, that Mr. Dallmeyer is the exhibitor of the astronomical telescope in the nave. Messrs. Negretti and Zambra, opticians and meteorologists, have a great number of original objects. Their sensitive thermometers—the first ever constructed—were designed for service in the late balloon ascents for scientific investigations on the laws of atmospheric temperature. They have a gridiron form of vessel for the mercury, instead of the ordinary bulb, and they therefore expose a much greater surface to be acted upon in the same space of time. The instruments in the same case comprise pocket barometers smaller than a watch; and, so far as we were able to discover, the only actual novelty in field-glasses, the lenses being made of rock crystal. Before leaving the British display of Class 13, in which we have sought only to bring forward the names of real producers, and not mere dealers, we cannot omit drawing attention to the excellent show of philosophical instruments, and especially photographic apparatus, furnished by Messrs. Murray and Heath. A principal object in their collection is a new reflecting stereoscope, in which Professor Helmholtz's principle of telestereoscope is applied with marvellous effect.—*Telegraph.*

## To Correspondents.

Old Subscriber.—Some experiments we have made with the ammonia-nitrate bath, or rather the solution of oxide of silver in nitrate of ammonia, as described in the American journals, and transferred to our columns, have been very successful; and we have heard also some good accounts from others who have used it. 2. The camera should not be tilted in taking card negatives: neither is it necessary to have a raised dais or platform for the model. In standing figures the lens should be placed opposite the chest: when lenses of short focus are used, some operators prefer a camera with a swing back, in order to bring the feet into better focus. 3. We have not had any experience with the new card lenses of the makers you name.

Enlarged Negatives.—Mr. Warner asks us to inform a "constant subscriber," who has applied to him to enlarge a negative, that it is impossible to enlarge the figures without also enlarging the plate. Surely such information ought to be unnecessary; but Mr. Warner has nevertheless been asked to do it. "Constant Subscriber" must have failed to express his wants properly; the slightest thought must have convinced him that if a group of small figures fill a small plate, the same figures will require, when enlarged, a proportionately larger plate.

J. W. T.—The print enclosed is a very bad example of mealiness; not the "measles." Read the various articles which have appeared in our pages on the subject. See that your silver bath is not very acid, and change your sample of paper. The chief fault is probably there.

C. B.—An old positive silver bath evaporated down to the proper strength will rarely give a good printing bath, and we regard it as bad economy to use it for this purpose. If it can no longer be used for its original purpose, precipitate the silver as chloride, and reduce it in the ordinary way. It will certainly contain iodide of silver, which is not desirable in a printing bath; it will also probably contain free nitric acid, which is in any quantity inimical, both to sensitiveness and rapid toning. The paper enclosed, so far as we can judge from appearances, is very good. The prints are certainly under-toned. The negative also is faulty, and without a good and moderately vigorous negative good tones cannot be obtained. Excess of carbonate of soda in your toning solution will cause it to tone tardily.

Demens qui Nimbos.—The streaks to which you refer can only arise from the condition of your bath or collodion, and not from anything in the subjects to be depicted. Probably using an old collodion, which is most suitable for photographic clouds, will remove the difficulty. If the bath be the cause, it may arise from deficiency of acid, or from accumulation of ether and alcohol; or possibly from scum or floating particles on the surface. The lens you are using is one of the best possible for the purpose. See Mr. Wilson's pictures in the International Exhibition.

W. B—r.—The defects of your prints are due to imperfect fixing, and not to anything in the toning. The hypo is too weak, or is exhausted, or the prints have not remained in long enough. Hyposulphite of silver is formed, but not dissolved, and in the course of washing becomes decomposed, presenting the mottled yellow, dirty appearance which the prints exhibit. We have not time to write private letters in answer to such questions, but have pleasure in answering them in this column.

Lens.—The object of immersing the plates in a bath of distilled water, with a little acetic acid added, as described by Mr. England, is simply, we apprehend, to serve the purpose of acid in the bath. Persons using a bath nearly neutral, in good condition for wet plates, are thus saved the necessity of making a fresh bath for tannin plates. That was the object for which we used it, and we presume was the object also for which Mr. England recommended it.

Rolandi.—Gum is not good for mounting photographs, freshly made; starch paste is the simplest and best material for general use. Good glue may also be used. If the slightest trace of hypo were left in the print, alum might be injurious, but not otherwise. Some have recommended its use in the final washing, but we think it is best avoided.

A. B.—Hints on albumenizing paper are scattered broadcast through our pages. We may refer you to p. 14, No. 28, vol. ii.; p. 179, No. 67, vol. iii.; p. 245, No. 107, vol. iv.; p. 260, No. 104, vol. iv., and many places in vols. v. and vi. The chief points to be cared for are good paper to begin with, fresh eggs, thoroughly beaten, about 15 grains of salt to the ounce, floating the paper a short time, manipulating carefully, and performing the operation in a very warm room, say a temperature of about 80° Fah. It is an operation requiring experience to succeed in. Our time is too fully occupied to admit of our writing private letters on such subjects.

J. Tully.—So far as we can judge, your proposed alteration will be an improvement. Your present room would be better if a large portion of the top light over and immediately in front of the sitter were cut off. We could judge better by seeing some of the results. Good lighting is unquestionably an important auxiliary to good pictures; but more important still is adapting the general treatment to the character of the lighting.

A New Subscriber.—It is somewhat difficult from your general description to point out the source of failure. The use of some samples of old collodion will cause insensitiveness, but it ought not to cause fog, which your description of a universal drab deposit without any trace of an image indicates. This may proceed from many causes; light getting to the plate whilst it is in the bath would unquestionably produce fog. The nitrate bath should be kept in the dark, but if it be in good condition, a stray glimpse of light occasionally would not hurt it; if it be in bad condition, and producing fog without other cause, rendering it neutral, and then exposing for a few hours to the sun will probably improve it. The use of a paraffin lamp will be decidedly injurious, because if unscreened the light will be too brilliant, and will cause fog; and because the exhalations are likely to have a detrimental influence on the sensitive film, and will probably thus cause fog. The test papers sent would indicate that both baths are sufficiently acid. We do not know anything of the cases you name.

M. A.—Neither of the markings which trouble you have any connection with the lenses used; but are manifestly due to chemical or manipulative causes. The dark veil at the top of the plate is most probably caused by the film having dried somewhat at that part before immersion, which would cause insensitiveness in that part. Its regular form is somewhat against that supposition, but it is the most probable conjecture we can offer. Such a mark might occur with a new bath, from the iodide being partially re-dissolved by the bath. But for the stain the picture has many excellent qualities. The straight lines in the other picture are so faint and indefinite, that it is difficult to trace their cause; but they are certainly not due to the lens. They might be caused by the developer not covering perfect at one sweep, or by irregularity in the thickness of the film, or by the plate not being quite clean. We have tried the plate-holder, but not to any extent. In our limited time for work in the dark room, we find time is economized by using the fingers only, and we have acquired the habit of doing so without difficulty or much soiling of the fingers.

Several correspondents in our next,

Vol. VI. No. 199.—June 27, 1862.

## BROMIDES IN COLLODION.

As discussion progresses, it becomes more and more apparent that the influence of bromides in collodion remains but imperfectly understood. Our own conviction, held for many years, as we have repeatedly remarked, is, that in proper proportions, they are in all ordinary cases an improvement, and in most cases accelerators, and no argument and experiment we have hitherto met with has disturbed that conviction. Mr. Dawson, of King's College, has recently addressed a communication to our Liverpool contemporary on the subject, in which, admitting their value under some circumstances, he nevertheless urges that under some circumstances they are injurious. Without entering at large into the general subject, we will just make one or two remarks, before reproducing Mr. Dawson's communication on the subject. We would, in the first place, call attention to Mr. Heisch's interesting paper in our last, on the importance of the proper condition for rendering experiments in this direction fairly comparable. We next have to suggest, briefly, for the consideration of experimentalists, a possible reason for the alleged retardation of bromides in the presence of a pyrogallic acid developer. The allegation is, that the addition of a bromide to collodion, in any proportion, small or great, actually retards the production of an image, and renders necessary a longer exposure than when an iodide only is used; and it is often stated that exposure, which would suffice to give with the latter a passable picture, would, if a bromide were present, yield results thin, feeble, and entirely worthless. We believe this is true, but that it is, nevertheless, rather a question of intensity than of sensitiveness. An under exposed, simply iodized plate has generally excess of density, but lack of detail; the same exposure, if bromide were present, would probably yield more half-tone, but less density. The under exposed iodized plate might be made to print and produce one of the hard black and white pictures which have done so much to ruin the artistic reputation of photography, and impress art critics with the impression that it could not render soft reflected lights and tender half-shadows. The bromo-iodized plate, under the same circumstances, would probably have yielded nothing at all, and would at least have prevented the operator from producing an imperfect picture. Again, we have no hesitation in admitting that, as a general rule, bromides make development more tardy. The image of an iodized plate, whether with iron or pyrogallic acid development, generally springs much more rapidly into existence, and much more readily fogs under prolonged development, than that of a bromo-iodized plate. Those who have been chiefly accustomed to the use of an iodized collodion are, therefore, very liable to be deceived as to the amount of development necessary and permissible with the bromo-iodized collodion, and failing to give the proper amount of development, they are apt to imagine a plate under-exposed, and charge the collodion with slowness, simply because it was really under developed. Without entering further into the subject here, we may just enumerate those advantages arising from the use of bromides, which have received universal acknowledgement, not only from those who advocate their use, but from those who regard them as in some respects injurious and retarding.

In the Daguerreotype process, bromine was an unquestioned accelerator, besides giving roundness, delicacy, and harmony to the pictures. It was the addition of bromine, or, as it was technically termed, "a quick," or "quick stuff," which rendered portraiture possible by the Daguerreotype process.

In the waxed paper process it is an unquestioned accelerator.

In the calotype, and all paper development processes, it is an unquestioned accelerator. By its aid only could the magnetic and meteoric registrations be preserved at the Royal Observatory at Greenwich and elsewhere, where the slightest perturbation is rendered by means of the momentary photogenic action of a gas jet, upon bromo-iodized paper. In solar camera printing, its accelerating principle is described by those who use it as enormous.

In the dry collodion processes its accelerating influence is, we believe, unquestioned by any one.

In the wet collodion process its accelerating and beneficial influence in the presence of an iron developer is generally admitted. We submit, then, that with so much admitted on all hands, it becomes necessary to pause before allowing that under its own best conditions and fair experiment it is ever absolutely a retarder.

We shall now quote Mr. Dawson:—

"The question of bromides in collodion has again, I see, become the subject of strong contention in some of your contemporary journals. About five years ago, when the pyrogallic acid developer for negatives was almost exclusively employed I, in conjunction with a friend well versed in photographic chemistry, went through a series of experiments for the purpose of settling the point at issue. We worked independently of each other with different chemicals, and only compared notes at the end of the series. Our conclusions were pretty nearly alike in all points; but in this opinion we were perfectly agreed, viz., that the use of a bromide, combined with an iodide, had a retarding instead of an accelerating effect, and tended strongly to the production of feeble negatives. It should be borne in mind that we worked only with pyrogallic acid and the potassium and ammonium salts. This conclusion, forced on us by the facts, seemed the more surprising, inasmuch as a previous series of experiments in connexion with the waxed-paper process showed that the addition of bromide, in the proportion of one to two of iodide, reduced the time of exposure by nearly one half; while farther addition began again to exercise a retarding and fogging effect. We made some attempts to reach the cause of this curious anomaly, but failed in our endeavour.

"Having had occasion during the early part of the present spring to repeat my experiments, considerably modified, and on a more extensive scale, both with iron and pyrogallic developers, and with the iodides and bromides of different metals, I still remain of opinion that with a pyrogallic developer the presence of a bromide in the collodion is a positive injury, and remarkably so when conjoined with the iodide of potassium or ammonium. With the iodide of cadmium the effect is slightly different. For instance, supposing we have dissolved a sufficient quantity of pyroxyline, free from all trace of acid, in pure fresh-washed ether, and the proper proportion of alcohol, specific gravity ·805, and iodized with cadmium, we shall find great difficulty, even in a slightly acid bath, of obtaining anything better than a faint, blurred, foggy negative, until the collodion has been kept for several weeks. The addition of one grain of any bromide to each ounce of the collodion at once corrects the fault; and, although it does not seem to me to increase the sensibility, it undoubtedly gives greater clearness. But pyrogallic acid as a preliminary developer is fast giving place to iron, and here it is that the advantage of bromides is very conspicuous. My experience will not warrant me in saying that their presence increases the sensibility of collodion or the opposite; but they do give a clearness and incipient vigour to the image, which is easily raised to a fine gradation of tone by subsequent redevelopment with pyrogallic acid and silver.

"The value of the bromides in the dry processes is undoubted, both in increasing the sensibility and clearness of the negative. They may be used, I dare say, in something like the same proportion I have found the best for the waxed paper, viz., one of bromide to two of iodide. I do not pretend to explain this seeming anomaly. The fact is nevertheless certain, and deserves a more careful and methodical investigation than it has hitherto received."

As regards the rapidity with which bromide of silver is formed in the collodion film when immersed in the nitrate bath, Mr. Dawson agrees with our recent remarks in answer to Mr. Sutton. He says:—

"Mr. Sutton, while discussing this subject, has said:—

"'The film of bromide of silver is very slowly formed in the nitrate bath, requiring, sometimes, as much as a couple of hours to convert the whole of the bromide of cadmium into bromide of silver. But the film of iodide of silver is fully formed after the plate has been immersed a few minutes in the bath. If, then, a plate is removed from the bath after it has only remained on it a few minutes, some undecomposed bromide of cadmium will remain on the film, and this will, no doubt, render it less sensitive. But we are now speaking of a pure neutral nitrate bath. Suppose the bath or the film to contain traces of a strong acid, such as nitric or oxalic, it is then easy to see that this will attack the cadmium and liberate the bromine, allowing it at once and promptly to combine with the silver, and form bromide of silver in the film. The proof of this is, that if you add nitric acid to a solution of bromine of cadmium you at once liberate bromine and form nitrate of cadmium in the solution. It appears, therefore, that a strong acid in the film (produced by free iodine or oxalic acid in the collodion or nitric acid in the bath) assists the rapid formation of the bromide of silver, and thus renders the bromo-iodized collodion more sensitive.'

"This is very ingenious and plausible; but let us examine the theory a little more closely. Is it true that the bromide of silver is less rapidly formed than the iodide? The change, indeed, is, in both cases, effected immediately a sufficiency of the nitrate has come in contact with the other salt, and the presence of no acid will hasten or retard the decomposition. Although a bromized film will not assume the creamy appearance of an iodized film, it does not follow that the whole of the bromide has not been converted into bromide of silver, since there is no more difficulty in the nitrate permeating the film and decomposing the bromide than the iodide. All photographers must have observed that some specimens of collodion fully iodized will, even after a lengthened immersion, give a pale opalescent film, while others containing less iodine will show greater density and creaminess. I believe the nature of the collodion itself has more to do with this than the quantity of iodide or bromide which it may contain.

"Again: let us suppose the collodion contains free acid. Surely the effect of this would be to decompose the bromide and iodide—not during the few minutes immersion in the bath, but previous to the coating of the plate, whilst the collodion was reposing for weeks or months, as the case might be, in its bottle. When decomposition of this sort takes place, and it can only occur under the conditions mentioned, it will make itself very manifest in the high colour of the collodion; and every one knows that this state of things is anything but conducive to sensibility. In short, an acid, whether in the bath or in the collodion, cannot in any way consistent with chemical laws, assist in the formation of bromide of silver. The great affinity of bromine for silver renders their combination complete the instant they come in contact; and it is only the nitric acid thus set free that will combine with the base of the other metal, both being in the nascent state. Should any free nitric acid have been in the bath before the plate was immersed it will remain there in the same quantity as before. The same is true of oxalic or any other acid. Neither oxalate of cadmium nor ammonia (or whatever the base of the bromide is) will be formed during the immersion of the plate, whether the acid exists in a free state in the collodion or in the bath. In the former case the oxalate is already formed before the plate is coated, and in the latter there is no tendency to its formation. If, therefore, it be true, as Mr. Sutton asserts, that the formation of a bromised film is hastened by presence of free acid, we must look for the explanation in a different direction to that which he has indicated, and probably we shall find it depends more on mechanical than chemical action."

Regarding the influence of bromides on dry plates, we call attention to an article by Mr. Sutton in another page.

## TABLE OF THE BEST KNOWN ORGANIC SALTS OF SILVER, THE PROPERTIES OF WHICH HAVE ANY INTEREST IN PHOTOGRAPHY.

BY DR. VAN MONCKHOVEN.

| Names of the Substances. | Chief Properties and Observations. |
|---|---|
| Croconate | Insoluble. ? |
| Xanthamylate | " Is blackened by light. |
| Cetyl di sulpho carbonate | " " " |
| Phenyl carbamate | " ? |
| Nitrate of silver and of glycocolle | ? ? |
| | Soluble in water. Very sensitive to light. |
| Glycollate | ? ? |
| Homolactate | Soluble. ? |
| Formiate | Not very soluble, is easily reduced. Not very sensitive to light. |
| Onalate | Insoluble. |
| Amyl onalate | Crystallizes, is soluble. Sensitive to light. |
| Onamate | Not very soluble. Very sensitive to light. |
| Phenyloxamate | Soluble, crystallizes. |
| Cobalti-cyanure | Insoluble. Not affected by light. |
| Cyanate | " |
| Cyanurates | There are two. One of them becomes violet at 300°,* but is scarcely sensitive; the other has given magnificent positive impressions. |
| Nitrate of silver and of urée | Soluble. |
| Sulpho-cyanure | " |
| Selenio-cyanure | Insoluble. Very sensitive to light. |
| Nitrate of silver and of melamine | Soluble. |
| Sulpho-mellonate | Insoluble. Not affected by light. |
| Mellonure | " |
| Cyamelurate | " |
| Uroxanate | " |
| Urate | " |
| Cyanurenate | " |
| Alloxanate | " |
| Purpurate | " |
| Mesoxalate | " |
| Oxalurate | " This salt is not very sensitive, as it is not colured deeply in half an hour. |
| Inosate | " Same remark. |
| Methylsulfite | Not very changeable by light. |
| Chloro methylsulfite | Extremely sensitive to light. |
| Bichloro ditto. | " " |
| Trichloro ditto. | Very sensitive to light when wet, less so when dry. |
| Cacodylate | ? ? |
| Aldetrydate | A curious substance, sometimes under certain conditions it is extremely sensitive, sometimes not. Soluble in collodion and gives a good film, but under these conditions it is totally insensitive to light. |
| Alaninate | Soluble, crystallizes. Sensitive to light. |
| Lactate | " " " |
| Acetate | Not very soluble. Not very sensitive. |
| Clor. acetate | Very sensitive. Combines some curious properties to which we will recur. |
| Trichlor-acetate | Very sensitive to light. |
| Sulpho-glycerate | Very soluble. |
| Acrylate | Not very soluble in cold water. Is blackened slowly by light, but rapidly at 100°. |

* Centigrade.

| Names of the Substances. | Chief Properties and Observations. |
|---|---|
| Malate | Has given superb positive impressions. |
| Maleate | Crystallizes, is soluble. |
| Tumarate | Insoluble. |
| Tartrate | ,, Blackens in the light, but slowly. |
| Para-tartrate | ,, |
| Ethyl tartrate | Soluble, crystallizes. |
| Pyro-tartrate | Insoluble. Is blackened quickly by light. |
| Pyruvate | Crystalline. Slowly turns brown in the light. |
| Citrate | Insoluble, is reduced by hydrogen at 100° into a violet citrate of the suboxide of silver. |
| Phenylcitramate | Same properties. |
| Aconitate | Insoluble. |
| Itaconate | ,, |
| Citraconate | Crystallizes in fine crystals. |
| Mesaconate | Not very soluble. |
| Bromo-triconate | ,, |
| Phenyl itacomate | Dissolves in boiling water, taking a violet tinge. |
| Moreate | Insoluble. |
| Saccharate | ,, Scarcely sensitive to light. |
| Pyromucate | The solution turns brown on evaporation. |
| Ethyl mecconate | Remains a long time in the sun without turning black. |
| Ethyl sulphite | Soluble in alcohol. |
| Ethyl sulphate | ,, ,, and in water. |
| Ethyl phosphate | The crystals are but little soluble. |
| Propionate | Not very soluble. Is changed slowly by light. |
| Angelate | Soluble in boiling water. |
| Succinate | Is reduced to a sub-salt by hydrogen at 100°. |
| Chloro-succinate | Not very soluble. Sensitive when hot, not very sensitive when cold. |
| Sulpho-mannitate | Very soluble, and very stable. |
| Butyrate | Not very soluble or sensitive. |
| Bichloro-butyrate | ,, ,, but sensitive. |
| Quadrichloro.-butyrate | ,, ,, ,, |
| Valerate | Is blackened quickly by light. |
| Trichloro.-valerate; Quadrichloro.-valerate | Salts soluble in nitric acid; under the action of light the solution deposits violet chloride of silver, a circumstance which is of the highest importance in the study of the theory of the formation of the positive image, and to which we shall recur. |
| Nitro-valerate | Not very soluble. |
| Amyl sulphite; Amyl sulphate | Salts both soluble in water and in alcohol. |
| Caproate | Not very sensitive to light. |
| Tuberate | Insoluble. |
| Sebacate | ,, |
| Rutate | ,, Is rapidly blackened by light, but not while dry. |
| Laurate | ,, Not changed by light when it is well washed. |
| Cocinate | Soluble in ether. |
| Myristate | Crystallizes in ammonia. |
| Margarate | Insoluble. Not very sensitive. |
| Atearate | ,, ,, ,, |
| Anamirtate | Is coloured by light. |
| Erucate | Very sensitive to light. |
| Trichloro.-phenate | Pale yellow, precipitates. |
| Binitro phenate | Soluble in alcohol. |
| Picrate | Very soluble in water. Yellow. |
| Picramate | Insoluble. A fine red. Not very changeable by light. |
| Chrysanisate | ,, ,, Yellow. |
| Oxybicrate | Soluble. |
| Phenylsulphite | ,, and crystallizable. |
| Quinate | Very sensitive to light. |
| Formo-benzoilate | White. Insoluble. Is gradually blackened by light. |

| Names of the Substances. | Chief Properties and Observations. |
|---|---|
| Benzoate | White. |
| Nitro-benzoate | Not very soluble. |
| Sulpho.-benzoate | Very soluble. |
| Hippurate | A white precipitate. Not very soluble. |
| Nitro-hippurate | It is rapidly acted on by light when moist. |
| Benzo-glycollate | Is quickly acted on by light. |
| Salicylure | Yellow precipitate, which is easily reduced. |
| Chloro-cinnamate | Acted on by light. |
| Sulpho.-naphtalate | Soluble in water (water 100, sulpho. naph. 10.) |
| Isatate | Soluble in water. Yellow. |
| Cuminate | White precipitate, is blackened rapidly by light. |
| Resinate | ,, ,, ,, |
| | Soluble in spirits of turpentine. |
| Camphorate | Precipitate, coloured by light. |
| Cholate | ,, ,, ,, |
| Cholalate | ,, ,, ,, Soluble in alcohol. |
| Litho-fellate | ,, Very sensitive to light. |
| Euxanthate | ,, Yellow. Sensitive to light. |
| Mellate | Gives a sub-salt with hydrogen. |
| Pyro mellate | White. Not altered by light. |
| Gallo-tannate | Red brown. |

## Scientific Gossip.

Manufacture of Chloride of Ammonium—Chemical Transformations—Potabilization of Sea-water by means of the Electric Current—Application of Hyposulphite of Soda in Preserving Meat—Spectral Examination of Coloured Glass.

Dr. Playfair, in one of his recent lectures at the Royal Institution, gave a most admirable history of chloride of ammonium. This salt is so largely used by photographers that we are tempted to give a *resumé* of the principal points touched upon in the Doctor's lecture. Taking the name in the first instance, this salt carries us back to some of the earliest historical ages, the word ammonia being derived from one of the titles given to Jupiter, "Jupiter Ammon," near whose temple in Upper Egypt ammonia was for many generations manufactured from the refuse of camels, which was collected and distilled, when it gave off ammonia or some of its salts. Hence its name. It is now prepared almost exclusively from gas-water, a badly-smelling, black liquid from the gas-works. The uses of ammonia and its salts were familiar in this country, and their applications to manufactures were known long before this source was discovered for it. When a ton of Newcastle coal is distilled, ten gallons of a watery solution comes over from it, containing sulphide of ammonium and carbonate of ammonia. Now, sulphuretted hydrogen and carbonic acid are both volatile gases, it is, therefore, only necessary to add a strong acid to obtain whatever salt we please from these compounds of ammonia. Chloride of ammonium, known in commerce as muriate of ammonia, or sal-ammoniac, is manufactured on the large scale in this way:—The gas liquor is run into a deep cistern, which is connected with a chimney, and there is poured into it muriatic acid. This expels the sulphuretted hydrogen and the carbonic acid, and forms a solution of sal-ammoniac. The sulphuretted hydrogen, which, as most of our readers know, is a very bad smelling gas, like rotten eggs, is passed up the chimney, and removed from the locality of the works to be given to people living at a distance. Sal-ammoniac solution, obtained in this way, is very impure, and has to be sublimed in order to be obtained in that state in which it is usually seen in commerce. When the crystals are perfectly dry it is removed to a still, formed of an iron pot surrounded with a leaden dome; a fire being placed below it, the sal-ammoniac vapourises from its impurities, and condenses at the top as a crystalline solid. About 4,000 tons of sal-ammoniac are made annually in this country from gas-water. It is extensively employed in making the more common salts of ammonia. Another method of making it is by taking the gas-water, and instead of saturating it with strong acids, like muriatic acid, to distil it with lime. The gaseous ammonia goes over and very readily condenses in water or acids, when it forms various salts. This process is much the best, as the badly smelling sulphuretted hydrogen gas is retained by the lime. There is also another way of manufacturing this sal-ammoniac by acting upon sulphate of ammonia with common salt. Sulphate of ammonia is another salt very largely manufactured from gas-water, by adding oil of vitriol to the ammonia of the gas liquid. Carbonate of ammonia is made from this sulphate by distilling it with chalk. A double decomposition takes place, the sulphuric acid going to the lime, and the carbonic acid to the ammonia, forming carbonate of ammonia. The mixture is placed into retorts and distilled, the carbonate of ammonia being volatile, sublimes, and is condensed in chambers. The *liquor ammoniæ*, or hartshorn of pharmacy, is made by distilling sulphate or chloride of ammonium with caustic lime, this keeps back the acid, and the free ammonia comes over. Besides its uses in photography it is largely employed in medicine, and also in ladies scent bottles, some aromatic substance being generally mixed with it. What a wonderful transformation is thus effected by the application of chemical agency: the refuse of camels, the offal of the streets, and the fœtid water of the gas-works have become so transformed under its influence that the most fastidious ladies preserve them in their scent-bottles as a cherished luxury.

A most ingenious application of electricity for the purification of water has recently been made known by Dr. Phipson. We do not suppose that this process will be much employed by our readers, but still it is possible to conceive that cases might arise in which such a method of getting rid of the impurities in water might be of great value. The doctor says, that reflecting upon the powerful decomposing chemical force with which we are furnished by the voltaic pile, it occurred to him that we might be able to render sea-water potable by decomposing and extracting its salt by means of a moderately powerful battery. The experiments were made at Ostend a few years ago. The apparatus consisted of three vessels containing sea-water, the centre one contained the water to be operated upon, the two others communicated with the two poles of the battery. The three vessels were connected by two bent ∩ tubes filled with sea water. As the only battery procurable at Ostend was rather weak, the current was passed through the water for about fourteen hours, after which one of the outside vessels had become acid and the other alkaline. The sea-water was then filtered through charcoal, and was nearly drinkable. It would have been, doubtless, quite potable, had the battery employed been more powerful, but with the one in use it was found difficult to extract the last portions of salt, and the water, after subsequent trials, still presented a slightly brackish taste. Dr. Phipson has not since had an opportunity of repeating this experiment, but from the results obtained it is quite possible that sea-water might be rendered potable by means of the electric current.

This reminds us of Sir Humphrey Davy's memorable experiments upon the production of fixed alkali by the electrolysis of water. Upon electrolysing the purest water that could be procured, placing it in two cups connected together by threads of amianthus, it was always found that the water in the negative cup gained the power of giving a slight blue tint to litmus paper—the water in the positive tube rendering it red. This had been noticed by many English and foreign chemists, and some of them had expressed the opinion that there was a veritable production of acid and alkali by the electricity. After a great number of experiments, conducted with the most minute precautions, Sir Humphrey Davy read a paper before the Royal Society, in November, 1806, in which he proved that the acid and alkaline bodies were derived from a minute trace of soluble salts, which had been dissolved by the water from the glass, &c., in which it was distilled, and which the electricity had decomposed in the manner mentioned above by Dr. Phipson.

An ingenious application of hyposulphite of soda, not however for fixing and preserving positives from change, but for fixing and preserving provisions from change, may be seen in the International Exhibition, in the Food Department, exhibited by Mr. M'Call. In preserving cooked meats, he adopts the old plan of expelling air by boiling, but he adds an ingenious contrivance of his own. All who have been condemned to live on preserved meats are well aware that a little decomposition almost always takes place in them, and few who eat them escape without some ill effects. Probably the air is never completely replaced by steam in the boiling, or some air may make its way again into the cases before they are soldered, down, so Mr. M'Call has a plan by which he expects to effect the absorption of any oxygen remaining in the case. In the top of his cans is a small capsule, in which he places a button of fused hyposulphite of soda, which, by a little contrivance, is exposed when the can is soldered and becoming dissolved, is expected, by the decomposition familiar to chemists, to absorb any oxygen left in the vessel. Whether it really does so, we will not undertake to say; but at all events the case of beef open on the table is quite free from taint, and looks remarkably good.

A specimen of orange glass has been forwarded to us by "Photos" for examination in the spectroscope, It is flashed on one side of a very good deep orange colour, and when examined in a good light is seen to cut off all the chemically actine rays. The spectrum is entirely intercepted down to the middle of the green, showing that light filtered through this glass would be quite harmless in a photographer s working laboratory.

## The International Exhibition.

### PHOTOGRAPHIC CHEMICALS.*

Those chemicals which are of more especial interest to photographers are so scattered about the building that it is impossible to observe any particular order in the notes which we have made of them. The catalogues also are here of no use, as under the term "chemicals" everything rejoicing in that name, and a few which have not the remotest claim to it, are classified. We will, therefore, proceed with some of the cases in the eastern annexe, taking them in somewhat the order of their position.

The well-known firm of Hopkin and Williams (530) exhibit several of the scientific preparations for which they are famous. A mass of iodide of cadmium, which is shown in this case, is the finest specimen we have ever seen. It has that peculiar neutral-tint appearance which is so characteristic of this salt, owing, doubtless, to the remarkable pearly lustre of the crystals. We also notice here some remarkably white cyanide of potassium in fused lumps, representing the commercial article usually sold under this name, and also a beautifully crystallized specimen of the pure compound. It has exactly the appearance of coarse table salt. It is very white and nicely crystallized, and as far as can be judged from appearance, quite pure. They also exhibit some very white and well-crystallized pyrogallic acid: the largest, if not the finest, specimen of this salt which we have yet noticed in the building is, however, exhibited by E. Schering, of Berlin (Prussia, Class XIV, No. 1433), about which we shall have more to say presently. Messrs. Hopkin and Williams also exhibit a case of chemicals in the photo-

* Continued from p. 294.

graphic department, a notice of which we must defer till a future occasion.

Messrs. Huskisson and Sons (536) exhibit a beautiful series of iodides. bromides, &c. One remarkable point about their case is the attention they seem to have paid to the crystallographic characteristics of the various salts exhibited. We may notice especially some large jars of iodide and bromide of potassium, the crystals of the former salt being in some cases nearly an inch and a half cube. They also exhibit some pure neutral iodide of potassium for photographic purposes, as well as iodides of ammonium, calcium, magnesium, silver, mercury, lead, iron, zinc, antimony, arsenic, phosphorus, and sulphur. Their iodide of arsenic is a magnificent preparation; it is exhibited in a large hemispherical bowl with a flat glass cover. The sides are lined with a fine mass of brilliant red crystals, resembling a beautiful collection of miniature ferns or sea-weeds, and totally unlike the ordinary run of chemical crystals. The companion dish of iodide of mercury is also exceedingly fine; but the third of iodine will be looked upon with especial interest. There are many exhibitors of iodine in this department, but few, if any, show a specimen equal to this.

J. Ward and Co.'s case (619) will be regarded by the scientific photographer with some interest, illustrating as it does the utilisation of kelp, the technical name of the ash obtained by the incineration of sea-weeds; it is valuable from the potash salts and iodine which it contains. We have here exhibited a beautiful specimen of crystallized iodine, and several samples of iodide of potassium extracted from this source.

W. Bailey and Son, Wolverhampton (465), also exhibit some good chemicals, nearly every article used in photography being manufactured by this house. They prepare an impervious varnish for the preservation of paper photographs, and specially adapted for taking colour, which is said to render the touch equal to working on ivory: and also an encaustic paste, which produces an equal and homogeneous surface on the picture that neither damp nor water will effect, making the colour transparent like glazing in oil. The value of this is most apparent when uncoloured photographs are stippled with sepia or the like, which on albumenized paper injures the surface and spoils the effect. The paste is to be gently rubbed all over the picture with the finger, and after remaining there for ten minutes, rubbed off again, when the photograph will be found to have acquired great brilliancy and clearness of detail.

## AWARDS OF JURORS.

The following official circular, relative to the declaration of the awards of the juries, has been issued by order of the Commissioners:—

1. The declaration of the awards of the juries at a State ceremony on Friday, 11th July, 1862, at one o'clock, will be made by an International representative body of Royal and distinguished personages, specially named by the various nations which have taken part in the Exhibition.

2. The Queen has named his Royal Highness the Duke of Cambridge, K.G., as her Majesty's representative to receive and distribute the awards to the exhibitors of the United Kingdom and its colonies and dependencies. The special representatives of foreign countries will receive and distribute the awards to foreign exhibitors.

3. The various ceremonies will take place in the Exhibition Buildings and in the Horticultural Gardens, which will be treated as part of the Exhibition for that day.

4. The special representatives will be received by her Majesty's Commissioners on the upper terrace of the Horticultural Gardens, if the weather be favourable; if unfavourable, in the Conservatory; and the International juries will then deliver their awards to the special representatives.

5. The special representatives after receiving the awards will pass in procession along the arcades to the Exhibition Buildings, and at various stations will deliver the awards to the chairmen of the British Class Committees, to the Colonial Commissioners, and to the Foreign Commissioners in or near those parts of the buildings where the principal objects of each class or country are placed.

6. Upon the arrivals of the special representatives at the different stations for distributing the awards, the national airs of the respective nations will be played by military bands, British and foreign. After the distribution, &c., the procession will assemble again on the upper terrace, when "God save the Queen" will be performed by all the military bands.

7. The public will be admitted between the hours of 10 and 12.30 by season tickets or by special tickets to be purchased before the 8th July at 5s. each. On and after that day the price will be 7s. 6d. each. Tickets will be ready for issue on the 30th June.

8. Exhibitors who may not have season tickets may obtain a free ticket of admission upon personal application at the offices in the Exhibition Road, on or before the 8th July.

## DECOMPOSITION IN COLLODION.

BY M. AUG. TESTELIN.*

In studying the decomposition of collodion, we began by examining the reciprocal action which each of the constituent elements of this product exercises upon the others, and we also, though very incompletely, indicated the reactions and the principal products resulting from them. We now proceed to the examination of the changes in property which the collodion undergoes.

Collodion, properly so called, that is to say, the simple solution of pyroxyline in ether and alcohol, has never presented to us a very striking example of spontaneous decomposition. Still, however, we believe that this collodion will ultimately become decomposed when it is not protected from the influence of light.

But when the pyroxyline is not chemically pure, and retains traces of the salts which have served in its preparation, or of the hyponitric acid which, in some extremely rare cases, is left behind, then the collodion is always decomposed in the course of a very limited space of time. For nitric acid very readily decomposes ether, even without combining with it: this reaction gives rise to a great number of products, the nature of which varies according to the degree of concentration of the acid, and the temperature at which these reactions are manifested. When the acid is very diluted, or the temperature is very low, there are formed simply nitric ether and aldehyde; but if the acid be concentrated, there are formed beside, oxalic acid, carbonic acid, acetic acid, formic acid, and formic and acetic ether.

These several products are very injurious to the photographic preparation, because they always acidify it in the course of a short space of time, and because some of them, as acetic ether for example, cause the pyroxyline to undergo a molecular modification which renders it unfit for photographic purposes; the film given by a collodion thus modified is of a dull white colour, and non-adherent to the glass.

The gun-cottons of commerce always retain a greater or lesser quantity of free acid. To prove this fact, it is sufficient to put a specimen of 10 or 20 drachms into a glass-stoppered bottle; upon opening the bottle at the expiration of a few days, a very strong odour of hyponitric acid escapes, which will be found fixed between the capillary fibres of the cotton, and which repeated washings fail to remove.

Now, at the moment when the cotton becomes dissolved in any liquid, these capillary spaces are distended, and even become dissolved, upon disengaging the acids they contain; from which necessarily follows a partial decomposition of the solvent, when the latter is susceptible of being destroyed by oxygenizing bodies as energetic as hyponitric acid.

The solution of pyroxyline in ether is then a prime cause of acidification, for beside the substances whose formation we have indicated, the compound ethers also produced at

* Continued from p. 222.

the same time, becoming acidified, are soon decomposed. The result is, that at the time of preparing the collodion the iodides are attacked, the iodine is liberated and colours the liquid, while the equivalent quantity of the bases of the latter combine with the formic, acetic, oxalic, and other acids.

But while these combinations are slowly effected, the iodine which at first colours the solution, acts upon the formyle and the oxide of ethyl, producing organic iodides (compound ethers), which are nearly colourless.

These facts clearly explain to us the spontaneous changes in colour that collodion generally undergoes, and even while admitting that the pyroxyline exercises no influence in causing the primary acidification of the collodion, and consequently, the decomposition of the salts it contains, we have seen that this condition is established, even by the effect of the solution of the iodides solely.

Colourless collodions possess an alkaline reaction in proportion as the absence of colour is more complete. This alkalinity is principally due to the presence of free metallic oxides, the formation of which is probably favoured by the affinity of the iodine for hydrogenized substances, with which it produces organic iodides, while the major part of the base set at liberty combines with the formic, acetic, and oxalic acids.

We do not yet clearly understand in what manner the reactions are effected, so that there can remain a quantity, whatever it may be, of free metallic oxide in the liquid; for while the elimination of the iodine of the iodides is produced by the acids, it must make quantities exactly equivalent to those of the metal which was as first united, and which the acids have removed.

It must then be admitted that the iodine is not expelled from its first combination, but that it forms, with the compounds of ethyl and of formyle, new bodies, probably more stable under these circumstances, and thus abandoning the metal, which then oxidizes, and uniting in part to the acids which the liquid may contain, which will naturally be only in equivalent relation.

Proceeding now to the change of properties in collodion, we commence by remarking, that immediately after its preparation, it usually furnishes two distinct results. For one proof obtained with this product, under given circumstances, developes only feebly under the action of the reducing agent, the shadows presenting no detail, while the lights are strongly marked; and if, to avoid this effect, we prolong the exposure to light, the details come out well in the portions feebly lighted, but they present no harmonious relation with the shadows in the negative. In the other case, the image is sometimes formed very rapidly, sometimes with excessive slowness, and is always extremely feeble and superficial; every part comes equally grey, even those which have not been submitted to the influence of light, and the negative acquires no greater intensity by the ordinary means of intensifying.

The first of these two results proceeds, not from the free iodine which may be disengaged, but from the presence of the acids we have shown to be formed in this case, and the neutralization of which cannot be effected at the time of preparing the collodion, for it often requires many days to complete these transformations.

The second result can manifest itself in so short a time only when alkaline substances are employed, but we may always remark during the bleaching of the collodion, either that it takes place spontaneously, or is determined by some cause or other.

When the collodion is completely bleached, it is neutral or alkaline; "then it will be remarked that it becomes more fluid, that the film it forms is thinner, generally iridescent after dessication, more permeable in those parts which correspond to the shadows of the model, and the silver is reduced with a metallic aspect upon the glass plate; the slightest defect in cleaning, therefore, becomes a spot."*

The fluidity bleached collodion acquires arises from the neutralization of the acid substances which are developed, and which possess the faculty of thickening the collodion by acting upon the pyroxyline in the same manner as the mineral acids do.

When the collodion bleaches spontaneously, some alkaline matters are formed, as has been shown, and this reaction is always accompanied by oxidation of the ether, which gives rise to compounds of aldehyde: now these compounds enjoy the peculiar property of reducing the salts of silver with that brilliant metallic aspect remarked upon plates prepared with old collodion.

As a concluding remark upon the spontaneous changes of colour in iodized collodion, we have shown that when this product, colourless at first, or bleached ultimately in the dark, acquires a red hue more or less deep, this effect is due to the decomposition of the organic oxides, the principal of which is the periodide of formyle, which is decomposed with great facility under the influence of diffused light, although feeble. *(To be continued.)*

* Barreswil et Davanne.—*Chimie Photographique*, p. 117.

## BROMIDES IN DRY PLATES.*

THE further we go on in experimenting on the action of a bromide in collodion, the more interesting and instructive our experiments become. In the rapid dry processes a bromide seems destined to play an important part, and we will now discuss this branch of the subject.

On examining, by daylight, the colours of different sensitive films of iodide, or bromo-iodide of silver, they will be found to vary greatly—some being of a whitish-yellow, and others of a deep greenish-yellow tint. Films of the latter colour appear to be the most sensitive in the dry processes, and it therefore becomes important to ascertain upon what the colour of the film depends, and to know how to produce a film of a pale or deep colour at will. For this purpose it is necessary first to examine separately the films of iodide and bromide of silver—and afterwards to examine them in a state of mixture or combination.

Let us first confine our attention to the iodide of silver alone.

If you add iodine to plain collodion, and then coat a plate with it and immerse it in the nitrate bath, an intensely yellow film is very quickly formed; and you may make this as creamy as you choose, by adding a sufficient quantity of iodine to the collodion. This, however, gives a very insensitive film in the wet process, chiefly on account of the large quantity of nitric acid which is set free in the film. But if, instead of adding iodine to the collodion, you add iodide of cadmium or potassium, the colour of the film becomes much whiter. Again, if you add a few drops of a solution of nitrate of silver to a solution of iodide of potassium you produce a white turbidity in the liquid, and the iodide of silver thus formed is not entirely precipitated, but remains suspended. If, however, you add a few drops of a solution of iodide of potassium to a solution of nitrate of silver, the iodide of silver formed is at once thrown down in flakes, and is of a much deeper yellow colour.

Our readers are of course aware that iodide of silver is entirely soluble in a strong solution of iodide of potassium; but when that solution is not strong enough entirely to dissolve the iodide of silver it seems to form with it a sort of double iodide of silver and potassium, of a whitish colour. It will readily be believed that this complex salt is not, *cæteris paribus*, so sensitive as the pure, deep, yellow-coloured iodide of silver.

If we perform similar experiments with bromide of silver, we do not arrive at similar results. The bromide of silver obtained under any circumstances appears to have a whitish colour, and never a deep yellow. Whether the collodion contains bromine, or bromide of cadmium or ammonium, the film is still white, like a film of chloride of silver, and not yellow like iodide of silver; and it turns grey, and eventually dark blue, by exposure to light, so that you can, if you like, obtain vigorous sun prints upon bromide, in the

* From the *Photographic Notes*.

same way as upon chloride of silver, a property which iodide of silver does not possess.

The yellow colour of a sensitive film of bromo-iodide of silver depends therefore upon the iodide, and not upon the bromide of silver; and if you wish to make the film as deep a yellow colour as possible, you must add free iodine to the collodion, and not iodize it with iodide of cadmium or potassium.

Collodion iodized with iodine is of a very dark colour —as dark as port wine. It may contain at least 6 grs. of iodine to the ounce.

Collodion, sufficiently bromized with bromine, is about the colour of pale sherry.

These two collodions may be mixed, and the best proportions seem to be in the ratio of the atomic weights of iodine and bromine. The film is beautifully clear and even, and the collodion flows remarkably well upon the plate.

You cannot produce a film of pure bromo-iodide of silver in the manner described without setting free nitric acid; but the effects of this can be neutralized in the dry processes in the following way:—

In the first place, the excited film is well washed in distilled water, which removes a great deal of the nitric acid. The remainder may be neutralized by immersing the plate in water containing a trace of carbonate of soda; after which it should be thoroughly washed again. This soda bath has the double effect of neutralizing the nitric acid in the film, and of renovating the free nitrate which is entangled with it into insoluble carbonate of silver. After which a preservative of gum and honey may be applied for the purpose of giving density to the image; and it seems probable that the preservative may be used without the addition of any free nitrate; for we have lately prepared very sensitive plates containing the smallest imaginable trace of free nitrate. There must be either free nitrate or carbonate of silver present in the film, in order to confer sensitiveness upon the iodide of silver, and it may turn out that the substitution of carbonate for nitrate may be a grand improvement.

[It will be seen here that Mr. Sutton treads closely upon the heels of Mr. Bartholomew, whose process with gelatine and carbonate of soda appeared in our pages at the beginning of the year.—Ed.]

## PROGRESS OF PHOTOGRAPHY IN AMERICA.*

"Professor Seely communicated to the society his views respecting the Composition of the Photographic Image, the question being, as to whether the dark material is to be considered as metallic silver, an oxide, or a chloride. There are some experiments published in the *Philosophical Magazine* in May, 1858, which appear to have bearing on this subject, and show that the black substance arising from the decomposition of white chloride of silver by light is probably silver in an allotropic, or passive state.

"Professor Seely presented his views on the subject of the Strengthening of Negatives, comparing in this particular those that have been developed by sulphate of iron, and those by pyrogallic acid. The cleanliness, cheapness, rapidity, evenness, and delicacy of the former, has led in America to its universal use, although negatives made in that way commonly require to be strengthened for printing. In the discussion that ensued among the members of the society on the views of Prof. Seely, Dr. Henry Draper remarked that the protochloride of palladium, first discovered by him as a strengthener, would increase the density of an image sixteen times, without changing the thickness; the advantages it offers being quickness, purity, and evenness of action, all the parts being acted upon in their order of darkness, and no extraneous stains ever arising. Mr. Rutherford was of opinion that the aid of strengtheners is always at the expense of detail, and that it is better whenever possible to obtain negatives of the proper degree of intensity in the first instance. In this view the society seemed generally to concur.

"Mr. Rutherford communicated his recent experiments in Astronomical Photography. The chief difficulties he had encountered in obtaining impressions of the moon, were owing to the want of coincidence between the chemical and visual foci of his achromatic telescope. He had, therefore, caused to be constructed a Cassegrainean reflector, with a silvered glass mirror, after the manner of Steinheil, and had already obtained several lunar photographs by its use.

"Dr. Henry Draper has also been engaged for three years in the construction of mirrors for his large reflecting telescope, of sixteen inches aperture, and thirteen focal length. It was built expressly for celestial photography, and a description of it read before the British Association for the Advancement of Science, in 1860. At first he used the ordinary metallic speculum, but soon gave it up for silvered glass. He has now three large mirrors. They were silvered from the ammonia nitrate by oil of cloves, and reflect very much more light than the best achromatic of equal diameter can transmit. He has with this instrument taken many lunar and solar photographs. He finds that the silver keeps its polish very much better than would have been expected. His telescope is of the Newtonian form.

"Mr. Johnson exhibited an instrument for the purpose of illustrating on the large scale the complex curves executed by the vibrations of an elastic tube, made to revolve by suitable mechanism. Through the tube a current of gas was pesmitted to pass, and lighted at the end. The flame made visible all over the room the symmetrical figures of the vibratary tube, and by the changes of its colour from yellow to green and blue, illustrated the principle that as the energy of combustion increases, the refrangibility of the emitted light increases. At the points where the flame came momentarily to rest, the tint it emitted was yellow, but when at its maximum of motion the tint was violet, this being in accordance with the principle which connects rapidity of chemical action with rapidity of molecular vibration. Mr. Johnson likewise exhibited a number of daguerreotypes, etched by sulphuric acid about twenty years ago. Some of them were very beautiful. They were accompanied by prints made from them with a copper-plate press.

"Such is a statement of our transactions since the last annual meeting. We may, therefore, congratulate ourselves that we have not been altogether idle. The progress of science in modern times is, however, so rapid, that where even great things have been accomplished, still greater things are expected. The history of that special branch of knowledge which it is our business to cultivate, offers us many interesting and instructive lessons. It took more than thirteen hundred years to correct the great fundamental error of optics. The Alexandrian scientific men, to whom we are only beginning to concede the merit they may justly claim, treated of optics on the principle—not that rays proceed from objects to the eye, as is known to us, but that issuing from the eye they impress on each object, and make us sensible of its presence and qualities in a manner somewhat analogous to touch. Euclid, the celebrated geometer, composed his treatise on optics on that fallacious conception. The occasion does not permit me to relate how this singular error became mixed up with some of the most important theological doctrines. It maintained its ground until more than a thousand years after Christ, when it was overthrown by a Mohammedan writer, Alhazen, the author of many other physical discoveries, which, considering the age in which he lived, might almost be spoken of as supernatural. Thus he showed that whenever a ray of light falls perpendicularly on the atmosphere, it pursues its path downward to the earth in a straight line, but that in every other position it moves in a curve that is concave to the earth, compelled to do so by the increasing density and refractory action of the air. He demonstrated that as the consequence of this, we live in a world that is full of illusion; that the

* Concluded from p. 298.

stars are not in the places in which we think we see them, and that—incredicle to be said—we perceive the sun and moon long before they have actually risen, and long after they have actually set. Upon these principles he gives the explanation of the twilight received by us as true, though modern times have disingenuously misappropriated the merit to themselves. With singular sagacity he demonstrated from the facts before him that the earth's atmosphere must be about fifty miles high.

"I have said, and said truly, that, considering the age in which these discoveries were made, they were almost supernatural. At that time in all Europe there was not a single man who could comprehend what the great Mohammedan philosopher was writing about. Through ignorance, justice to his merit could not be done to him in his own day, through jealousy it has been denied to him in ours.

"What a contrast between the slow development of optical truths in the old times, and their rapid development in ours. But more than this. We work at our ease, and without fear. It was not always so. When Antonio de Dominis first essayed to give a physical explanation of the rainbow, on the principle that it is caused by the reflections and refractions of light, by drops of water falling at a certain angle before the eye, he was brought into collision with the popular idea that it was the weapon which the Almighty had rested against the cloud. For this, and similar offences, de Dominis drew upon himself the hand of authority; and though a sudden death snatched him from his persecutors, with an exquisite refinement of vengeance they dug his body out of the grave, that the earth might not be polluted thereby, and burning it in the fire, cast his ashes to thewinds, to prevent as far as it might be possible for human agency to do, his participation in the resurrection to the lifeto come.

"But truth will force its way at last in spite of opposition. The physical theory of the rainbow, as depending on the reflection and refraction of light, was independently developed by Descartes, though he was at one moment on the point of burning all his manuscripts on this and other physical topics, for fear of impending punishment. It was at last under happier auspices, completed as we now find it by Newton, as a consequence of his great discovery of the different refrangibility of the rays of light.

"And it is under such happier auspices that we also live. We may occupy ouselves in full liberty with problems in science ,and operations in art. The origin and rapid advancement in photography is an illustration of this. But privileges imply duties. If our predecessors under disadvantages so great accomplished so much, what ought we not to do who have not a single obstacle in our path."

## A NEW RAPID DRY PROCESS.

The *American Journal* says:—We have received the following from Mr. J. M. Masterton, of Bronxville. New York:—

"Enclosed please find a print which I promised to send you; the negative was taken on a tannin plate prepared as usual with iodide of potassium and bromide of cadmium. When exposed it was about four weeks old, the exposure was about thirty-five seconds, and developed with *cold* spring water, as usual, except the citric acid solution, which was made one hundred and sixty grains to the ounce of water, with very little silver (probably about six drops of a twenty-grain solution doing the development), and used freely; the exposure was given intending to use hot water, but afterwards concluding to try an experiment, I used the strong citric acid, and I think got as good an effect as if I had used *hot* water. I leave you to judge of the merits of the picture, hoping that others may try the use of strong citric acid, and report the effect."

The editor adds:—The print received is evidently from a negative fully exposed, without a trace of fogging, full of detail, and at the same time of proper density. The view is of a shady locality in Greenwood. Mr. Masterton's modification of the tannin process is exceedingly simple, and if his experience is confirmed by others, the strong acid developer must at once come into general use.

[The idea of using excess of a very powerful retarding agent as an accelerator is certainly as droll as it is novel. We fear the problem of an instantaneous dry process will not be solved by using excess of citric acid.—Ed.]

## DISORDERED BATH.

A correspondent in western New York thus describes his troubles:—

"I am meeting with a difficulty in my negatives which is new to me, and am not able to define the cause or apply the remedy. The difficulty is this: the negative, after being developed with the usual iron developer, is filled with holes part way through the film; not like pinholes, as there are some of those, but look somewhat as if the negative had been covered with sand, or something of a light character, and had left the marks in the film, making numerous holes or indentations in the film, but the holes are not quite through.

"If you can give me the cause and remedy through your Journal, or any other way you see fit, I shall be much obliged."

We print the above chiefly on account of the very plain description of a difficulty which every one of long experience must meet and understand. Many of our readers will recognise an old acquaintance in the sandy film, and need not be told the remedy. For our correspondent. and perhaps many others, we repeat the explanation which has been given in former numbers of this Journal.

The trouble in question generally appears only after a bath has been a long time in use, and is most noticed in baths which are very strong in silver; also it is apt to show itself at a late hour of a day when the bath has been much used. If a plate which on development would become sandy be washed with water immediately it comes out of the bath, the developed picture will not be sandy. If a sandy film be examined with a microscope, crystals will be seen in various places, particularly if the washing has not been so violent as to dislodge them.

These crystals forming on and in the film by roughening it are the immediate cause of the sandy appearance. The crystals are supposed to be iodide of silver, with which the bath is super-saturated.

The simple and practical remedy is to add five or ten per cent. of fresh solution which contains no iodide.—*American Journal.*

## CLEANING THE GLASS.

This is one of the most important operations in practical photography, it being very essential to have a plate thoroughly cleaned before attempting to produce a negative upon it. Various modes are practised, but it is only necessary to point out those which are considered the best. First, immerse the glass in a dilute solution of nitric or sulphuric acid, one part to eight or ten of water, and after remaining in a little time, take it out and rinse thoroughly with water. Rear the plate upon the corner and let it drain, or wipe dry with a clean towel.

Next, fasten the plate in a vice constructed for the purpose, apply a few drops of alcohol from a bottle with a perforated cork, and rub thoroughly with a piece of cotton flannel, with a circular motion, till the alcohol has evaporated. The glass may be first scoured with a mixture of alcohol and fine rotten-stone. and finished with two or three drops of alcohol, polished off with a clean piece of flannel. The glass is known to be clean when the breath will lie evenly upon it without streaks or marks of rubbing.

Considerable time may be saved in cleaning glasses by coating them with albumen diluted with an equal quantity of water, and placing them in a grooved plate-box, to exclude them from dust while they are drying. They need but little rubbing off before they are coated, and the albumen film makes a fine clean surface to receive the collodion.—*Humphrey's Journal.*

The quantities A and B are the factors of the same product, which is always 100; and one being given, the other may be found by dividing 100 by the quantity known.

If we take the column A for the distance of the negative, the column B will indicate the proportion of enlargement and the distance of the image. If we take the column B for the distance of the negative, the column A will indicate the reduction and the distance of the image.

* See M. Claudet's "Rule for Finding Distances," p. 282, No. 198.

## COLLODION FOR NEGATIVES.

The conditions of a good negative collodion are: 1. That it must possess the properties of intensity to a considerable degree. 2. That it must possess good flowing qualities in order to obtain an even and structureless film. 3. That it must have body to give a negative of sufficient density.

To secure these qualities it is necessary to use the purest chemicals that can be obtained. The pyroxyline or soluble cotton has more to do with the excellence of collodion than any other ingredient, and great care must be used in testing and selecting an article which will best answer. A good article of soluble cotton is harsher to the touch and shorter in the fibre than ordinary cotton. If it is very short and powdery it may have considerable solubility, but it is apt to give a film full of opaque spots, and is unsuitable for collodion. If it does not differ much in texture from ordinary cotton, it is not sufficiently soluble, and should also be rejected. The criterion of good pyroxyline is, that it should possess the maximum of solubility, and at the same time give a transparent film when poured upon glass and allowed to dry.

If an article can be found which will dissolve in the proportion of eight grains to the ounce in the mixture of ether and alcohol, and give a perfect homogeneous and transparent film, it may generally be relied upon as a good article for negative collodion. No sample should be used which makes a film too thick after dissolving six grains to the ounce in the alcohol and ether.

Pyroxyline which exhibits a glutinous appearance in dissolving, will flow in a slimy manner on the plate, and is not fit for use. The best cotton will fall slowly to the bottom in the alcohol and ether, and will dissolve with liberation of beautiful air-bubbles, with little or no appearance of glutinosity. It should leave no flocculent matter, and deposit but a very slight sediment on standing. It is necessary to observe also that the soluble cotton should be quite free from acid when it is used. Pyroxyline, when it is kept for some time in close stoppered bottles, partially decomposes, forming oxalic acid. It may, moreover, be found in an acid condition from imperfect washing in the process of manufacture, so that the acids used are not thoroughly cleansed from it.—*Humphrey's Journal.*

# Correspondence.

## A HINT TO PHOTOGRAPHIC TOURISTS.

Dear Sir.—Having recently paid a visit to the Isle of Man, it has struck me as a very singular thing, that photographic tourists seem to ignore the existence of a place possessing so much interest and beauty.

In passing through the streets of London, no one can fail to observe that the views from the Isle of Wight, Jersey, Guernsey, and many places of much less interest, are abundant, while views of that fine old historical relic, Peel Castle, or the beautiful picturesque town of Douglas, are nowhere to be seen.

That it does not arise from paucity of subject I can myself testify, for in my humble opinion the Isle of Man affords more variation and boldness of scenery than the Isle of wight, and almost every nook and corner of the latter place are familiar to all the little shoeblacks of the Strand. Peel Castle is quite as interesting as Tintern Abbey, but, as I before observed, that is not to be obtained, while to get a *fresh* view of Tintern Abby is almost impossible; unless some enterprising photographer where to engage the services of Mr. Coxwell, and even then I should doubt its originality.

Again, I might compare Douglas and Ryde, but, Mr. Editor, I will leave your much more able pen to assign a reason and suggest a remedy for this, contenting myself with the remark, that in no place will photographic tourists find more hospitality and kind assistance than in that much neglected, but beautiful spot, the Isle of Man.—Dear sir, truly yours, Leo Daft.

2, *Queen Square, Westminster. S.W.*, 16*th. June.*

## BROMO-IODIZED COLLODION AND IRON DEVELOPMENT.

Dear Sir.—I cannot understand how Mr. Sutton could have fallen into such an error with regard to iodides and bromides in collodion, it seems contrary to the experience of every photographer of my aquaintance.

I think Mr. Sutton does not use chemicals more pure than I do myself, so *that* cannot account for it.

The nitrate of silver which is recrystallized, I obtain from R. W. Thomas of Pall Mall, which I am perfectly sure cannot be surpassed in quality, and the collodion I make myself from the purest materials I can purchase, and with all this, my experience is totally at variance with that of Mr. Sutton.

A few days ago I was engaged in copying some pictures, and while counting the time for exposure, a person spoke to me, which distracted me for a few seconds from what I was doing, and by that means caused the exposure to be prolonged to nearly double the required time. Wishing to save the negative if possible (for I knew if I developed it with my usual developer, which is iron, it would be much over exposed) I proceeded to develop it with pyrogallic acid mixed in the usual way, thinking by that means the resulting negative would be perfectly good. But what was my surprise to find that it was not more than half exposed enough. I think this will prove that bromo-iodized collodion and iron development is far superior where rapidity of action is required.

I feel assured the cause of so much controversy of opinion is, that with bromo-iodized collodion some persons use pyro as a developer, and some use iron, without doubt when pyro is used as a developer a plain iodized collodion is best, and *vice versa*, therefore an advocate for pyrogallic used a plain iodized collodion as being best suited for his purpose, he is recommended to try iron and does so, but does not trouble to obtain any suitable collodion for it, the result is, he produces negatives wanting in detail, which entirely disgusts him with the *iron age*, and makes him a still greater advocate for his old friend pyro.—I am, sir, yours very respectfully. Alfred Harman.

*Peckham, June* 13*th.*

## ON ENLARGING NEGATIVES.

Sir,—My name having been somewhat prominently brought before the public in connection with the above, I feel myself called upon to come forward and state my experience upon the subject which is occupying the attention of so many gentlemen, both amateur and professional, at the present time.

Nearly two years since, I had constructed for me a deal box, in which I fitted a single lens by Valentin, 3 inches in diameter, 10 inches focal length, which afforded me very tolerable results, and also gave me many hints for future guidance. I continued my experiments therewith for some months, until I considered that I had perfected myself sufficiently to ask the public to support me professionally. Feeling justified in making a beginning, in the early part of last year, I instructed Mr. Ross to prepare me a camera for the purpose, to be furnished with the lens best suited to my requirements, viz., his No. 2 carte de visite lens. On its delivery in September last, I made some experiments which were tolerably successful; and in October I applied for space in the International Exhibition. At the latter end of January in this year, I received intimation that 30 square feet had been allotted to me in the "Garret" now devoted to the purpose, where toys and dolls, dressed and undressed, black and white—miniature impositions upon "the human face divine"—reign supreme, referring one back to the nursery days. I was then very seriously ill, and forbidden to work by my medical man. However, on the 14th February I set to work, and by the 12th of March (notwithstanding the dull damp weather which prevailed at that time), with the light from a western sky, I had taken four dozen positives, and converted them into four dozen enlarged negatives; out of these I selected three dozen for the Exhibition, which were printed, mounted, framed, and sent in before 31st March, wholly untouched (not even rolled, as the boards are nearly three feet square), as a sample of enlargement from negatives 3¼ by 2¾ to a whole plate, and 10 by 8 inches. The negatives from which enlarged copies were made, were all taken by myself, some as far back as four years ago. They were also taken with all kinds of lenses, upon which I should like to say a word or two. I speak now of the small negatives which were taken with ¼-plate lenses—by Lerebour (compound); Secretan (compound); Valentin (compound); by Andrew Ross (single 4½ stereos); and by Thomas Ross (compound stereos).

The collodion was a mixture of Bolton's and Ponting's. The first for half-tone, the latter for density.

The developers were various; but I found this fact, that those which were developed with iron, as far as skies went (see view of Goodrich Court), never gave so clear, so pure, so thoroughly good a result, as those developed with pyro and citric acids. In architecture, I found the iron gave very good results, but the old 3-gr. pyro and acetic acid better (see picture, the Blind Harper, St. Michael's Doorway, Teignmouth; Doorway at Bishop Teignton). It must be recollected that I am speaking of negatives, as if taken expressly for enlargement.

Of all the lenses mentioned above in the taking of these small negatives, I must give the preference to the compound by Lerebour (the first I ever bought, and which I hope never to part with) and the single 4½ stereos. by Andrew Ross. With both these lenses, especially the latter, I have taken instantaneous pictures of all kinds (see pictures of "Oscar," "Clouds," "Bringing Home the Faggots") dogs, sheep, cattle, horses, clouds, &c., &c., all of which were developed with citro-pyro developer.

Church architecture has special charms for me, above ordinary views, perhaps because I am a freemason, perhaps also because my bent in early life was to be an architect and civil engineer, although I was wedded to the law for some years. Be that as it may, I have turned my attention now for some time past to the taking of the interiors of cathedrals. They, of all pictures, are the most difficult, but I think them (and I am happy to say the public think so too) the most beautiful. The difficulties in taking them lie in many little things, which are to be overcome only by practice; of these I may speak some other time.

I have digressed thus much from the main question, because it is to this class of negative that enlarging will specially apply. Either the portrait negatives, of which the portrait is the one principal feature in the picture, or the architectural, that covers the whole plate evenly and sharp, are the ones for enlargement. In this I may be mistaken—I hope I am—but my present experience is as I have stated.

And now to speak of the camera and lenses used for the purpose.

Whether Mr. Vernon Heath's principle or M. Claudet's (solar camera) be the best, remains to be shown; but taking our English climate into consideration, its want of sun, and its many drawbacks in the shape of damp, I certainly must lean towards my countryman's view of the matter, and I think many will bear me out in my opinion. At the same time, with all courtesy and deference to M. Claudet, to whom I am, personally, a total stranger, I am rather sanguine of success in the long run.

I therefore suppose I am working with Mr. Vernon Heath's apparatus, taking such for my foundation, and applying my own experience to the matter, I must say that the 4½ lens of Ross, which I have, gives, up to 8½×6½, very fair and satisfactory results.

Not having had an opportunity of trying any other lens, I cannot say more, but even up to that size, to get depth and perfect sharpness over every part of the picture, a very much smaller stop must be used than that usually sent out with the lens. I use one an eighth of an inch, and expose in full sunshine seven minutes.

Having been frequently applied to since March to enlarge cartes de visite heads to life size, I set about thinking whether the lens (4½ focal length) I was then working with would answer my purpose; upon instituting experiments thereon, I found it did so, but in order to secure definition I lost much light. I therefore applied to Mr. Ross for assistance, but without avail; I next got a triplet from Mr. Dallmeyer, still the same fault, although considerably modified. At last I went back to the old original lens of all, and succeeded. I am therefore making arrangements to enlarge cartes de visite pictures to 15 × 12 *so that every portion of the picture shall be equally sharp*, full of half tone, and the general effect satisfactory. Your advertising columns will inform the public when I am in this position.

Many of your readers have by this time seen, from the reports of the various journals, the doings of the Photographic Society at its last meeting. M. Claudet *did* certainly show us that the solar camera could distort a head larger than life; but he failed to convince many others besides myself that his image was equally sharp all over the focussing screen. And, supposing that in the place of a paper positive, as the final results of the operations of the solar camera, a negative by a second operation is produced, what proportion of sharpness, let me ask you, Mr. Editor, would this bear to the original negative, when in the enlarged positive the PRESENT results are so dreadfully indistinct?

I am prepared to construct an apparatus, without much extra expense, that shall enlarge to the same extent as the solar camera, *and yet give perfect and equal definition all over the plate*. Whether the demands of the public may justify me in carrying out these ideas is another matter; it is for them to decide—for me to follow.

But I have not yet done with the matter. I believe it will be found that to enlarge a small picture *well*, up to 10 × 8 and over, long-focus lenses of large diameters will ultimately carry the day, as the rays of light, having to travel further, lose much of their intensity after having passed through a short-focus lens of small aperture, and in consequence the exposure is considerably lengthened; while on the other hand, if a long-focus lens of large aperture were used, the rays, although having to travel the same distance in proportion, are strengthened, or made equivalent to that distance, by the larger refracting surfaces derived from the greater diameters of the lenses.

Of the many lenses offered to the photographers of the present day, there is none that gives better results than the orthographic; it may be used in a confined space, and it may be tilted, and it gives good definition with the whole aperture, especially in interiors, and, were it not for its unfortunately giving pictures of a pincushion formation, it would be a very valuable lens. Whether the triplet of which I have spoken does otherwise, I am not prepared to say, but this I may state, that it will take a landscape 10 × 8 without distortion and without using by any means the smallest diaphragm. It will also take a head life-size (see enclosed) *direct* in the camera. It will copy without reduction of subject, and will give both texture and water-marks without any diaphragm at all in letter paper.

In conclusion, I would add, that as I am guided by the wants and wishes of the public, that if Mr. Ross, Mr. Dallmeyer, or Mr. Anybody-else, will make a lens that will offer greater advantages than those of the present two celebrated English makers, I for one will be happy to be a purchaser, and will strive to make the lens committed to my care tell its fullest capabilities to "a discerning public."

Apologizing for the space I have occupied, I am, dear sir, yours truly, W. H. WARNER,

*Ross.*

## Photographic Notes and Queries.

### MR. SUTTON'S QUICK DRY PROCESS.

SIR—I have been trying Mr. Sutton's rapid Taupenot process, but found no increase of sensibility. Would you be kind enough to inform me if I have made any error in the manipulation? I used Keene's dry process collodion, sensitized in a 40-grain bath faintly acid, washed thoroughly, poured over the albumen solution, drained, and then dried before a bright fire, making the plate quite hot; when cool, I immersed it for half a minute in a 20-grain bath, and finally washed in a 10-grain bath, both acidified with 1 drop of acetic to the ounce, but *without* any iodide of potass, like the first bath. After all this trouble the plates were not to be compared to the honey and tannin I made according to the formula given by you in No. 192, either in sensibility, smoothness of the film, or keeping qualities. It may be my inexperience, but I shall be sorry if I have made two extra baths of no use to me.—Yours very truly,

BLUNDERBUS.

[We have not experimented ourselves with Mr. Sutton's quick process. We know him to be, however, a very careful experimentalist, and a thoroughly good, practical photographer, and he has, doubtless, produced the results he describes. Probably your bath may require a little more acid. To give the process the utmost fair play, it would be well to try some of his collodion with it. In our own hands the honey and tannin has proved the best dry process we have tried. We are glad to hear your favourable account of it.—ED.]

### RAPID DRY PLATES.

SIR,—In a late number of your very valuable journal I observed some enquiries from Mr. Taylor and yourself regarding Mr. Louis Floyd's instantaneous dry plates. That gentleman having accepted an appointment in Russia, I do not know whether or not I might be justified in imparting his *modus operandi* through your columns, he having given me his formula some time since; but from a variety of circumstances I have not yet been able to try it. I have put myself in communication with him, and should he give his permission I will send you the details as soon as I have tried the system. I think it will be no breach of confidence to state that it is a slight modification of the Hill Norris formula, and totally distinct from Mr. Sutton's method. The instantaneous effects are caused by moistening the plates previous to exposure with a solution, but they require to be developed within twelve hours after, otherwise stains result.—Yours, &c., THOMAS D. BELL.

*Windermere, Monday, June 22, 1862.*

## Miscellaneous.

A NEW CEMENT OF VARIED USE.—New uses have been suggested for a combination of pitch and gutta-percha, as to which we some years since gave instructions for the prevention of damp in walls. Professor Edmund Davy has read a paper to the Royal Dublin Society on the subject. He obtains the cement much as we suggested, by melting together in an iron vessel two parts by weight of common pitch with one part of gutta-percha. It forms a homogeneous fluid, which is much more manageable for many useful purposes than gutta-percha alone, and which after being poured into cold water, may be easily wiped dry and kept for use. The cement adheres with the greatest tenacity to wood, stones, glass, porcelain, ivory, leather, parchment, paper, hair, feathers, silk, woollen, cotton, linen fabrics, &c. It is well adapted for glazing windows, and as a cement for aquariums.—*Builder.*

## Talk in the Studio.

Photographic Exhibition.—An exposition of works of fine art is about to be opened at Spa, and wo notice with pleasuro that under the directors recognize photographs as coming distinctly that designation. Tho Secretary writes to our contemporary, the *Bulletin Belge de la Photographie*, inviting contributions from photographers, and stating the regulations which will govern tho exhibition, ono of which is somewhat unusual, namely, that roproductions of engravings, statues, &c., will not be admitted.

Mr. Mudd, whose name our readers have known as one of our first landscape photographers, perhaps *the* first dry plato photographer, has yielded to tho pressuro in the shape of demauds made upou him for portraits, and has resolved to devote a portion of his timo to portraiture, as well as landscape. We shall be sorry if tho latter is at all sacrificed to the former.

Application of Photozincography.—It is stated that a proposition is under consideration for sending a photographer to Simancas, in Spain, to copy some of the dispatches in cipher deposited in the royal archives there, and which are supposed to relate to important events somo time before and after the reign of Elizabeth.

Honey and Tannin.—A correspondent who has been successful says:—"I think Mr. England deserves the thanks of all dry-plato photographers for his modification of tho taunin process; any one with ordinary care must succeed."

New Copyright Bill.—This Bill still remains beforo the Select Committee of tho House of Lords. A petition has been presented by Lord Overstono from certain goldsmiths, silversmiths, and porcelain dealers, that their works, comprising art designs, might be included in tho protection of the Bill.

Tax Upon Photographers.—A new tax Bill, under consideration in the United States, imposes an annual tax upon certain trades and professions. Photographers are charged with a tax of two pounds a year.

Fulminating Silver.—If you pass a current of coal gas through a neutral solution of nitrato of silver, you obtain a crystalline precipitate, which when dry explodes under the action of heat, or the blow of a hammer, like fulminating silver.

Gun Cotton.—Every tissue from vegetablo origin, like cotton, linen, &c., can be transformed into gun cotton. To distinguish gun cotton prepared with nitric and sulphuric acids, from the oue prepared with nitrate of potash and sulphuric acid, dip them into a mixturo of 100 parts ether and 25 parts alcohol, the first will not dissolve, while the lattor dissolves entirely.

## To Correspondents.

Punjabee.—Vulcanized india-rubber would exercise an injurious effect on coming in contact with the nitrate bath, on account of the sulphur it contains. Boiling the India-rubber in a strong solution of potash is said to remove all sulphur from the surface. It is a better plan, however, to cover the vulcanized surfaee with a thin piece of gutta-percha, about the thickness of paper, or with vegetable parchment; this will not interfere with the elasticity or perfect pressure of the india-rubber on the water-tight lid. 2. Where acetic acid has been added to a bath it is difficult to eliminate it. You will find some information on the subject in one or two recent communications in our pages. You may neutralize either with oxide of silver, or with bicarbonate of soda before sunning your bath. We have given from time to time all the information of a practical character which has been published on the panoramic lens. It has not come much into general use, but there is no especial reason beyond its novelty, and involving the necessity of a complete equipment of baths, slides, printing frames, &c., to prevent it. See a recent paper by Mr. Dawson on its practical working.

Interior.—A variety of plans have been proposed for preserving the plate from drying during very long exposures. Such as adding some neutral deliquescent salt, like nitrate of magnesia, to the silver bath, covering the plate with some preservative, sueh as oxymel, honey, glycerine, or glycerine and honey, laying a sheet of wet blotting paper at the back of the plate, &c. The method we have generally used ourselves coasists in using a porous collodion, which does not dry so rapidly as a horny one, and when we have in hot weather observed partial dryness, we have washed the film with a little distilled water, aud then added this water to the developer. This in our hands has always succeeded, and given entire immunity from stains. It is sometimes recommended to redip the plate in the nitrate bath under such circumstances, and there are occasions when this caa be done with advantage, but if there be the slightest tendency in that direction it causes fog. It is important ia long exposures to let the plate rest on a piece of blotting-paper at each corner.

Derby.—Benzole or chloroform will remove crystal varnish from a negative. 2. You may probably obtain a bellows body of aay of the practical camera makers: the cost we cannot tell you. 3. The front lens of a portrait combination, having a focus of 10 inches will, if properly stopped down, probably cover about 7 in. by 5 in. 4. Marine glue is said to be made of shellac and India-rubber; but its exact composition is a trade secret. We are glad to hear of your success with honey and tannin.

Cornish Chough.—You have no reason whatever to be dissatisfied with your results, they are both very fine photographs of trying subjects. The smaller one is especially pretty and satisfactory.

W. J. C.—The charge is a foolish and improbable one, inasmuch as nothing could possibly be gained by abstracting or changing some of the glasses. It is certainly quite possible to remove part of the combination and substitute other glasses, inasmuch as all the lenses of a given size are similar, and, we believe, in the common French lenses, are put together without much selection, large quantities being ground to the same curves, and subsequently fitted without very specific attention. It is not probable that the respective lenses of such a combination will be marked so as to admit of identification. If the lens really be in any way out of order, it is possibly from the lenses being put in the wrong position, or not placed quite true iu their proper position. Your only mode of setting yourself right is to show the absurdity and uselessness of such an exchange as you are supposed to have made.

Cassandra.—The silver from old hypo baths should be precipitated with liver of sulphur, and nitrate of potash may be used as a flux in reducing the sulphide to metallie silver. See page 50, vol. v. of the Photographic News. The spot on the enclosed picture appears to be caused by a drop or splash of some chemical on the print, probably an acid, but we cannot tell what. We shall have pleasure in receiving your method of manipulating.

W. X. G.—Excess of acid in a gold toning bath made by any formula should be neutralized with a little bi-carbonate of soda.

J. Dyson.—The best varnish we know for coloured glass positives is Newman's Colouring Varnish, or the Alabastrine Varnish sold by Squire. The colour will always be a little lowered by varnishing; but may be easily retouched.

J. F.—The keeping properties of dry plates after exposure and before development is a subject about which some doubt and difference of opinion exists. We have heard of tannin plates keeping perfectly, but then we have heard of some that have not kept. The use of honey and tannin is so recent that we have little information of the keeping properties of the plates, but we have heard some complaints that they do not keep so well as tannin alone. We believe the safest process for keeping is the collodio-albumen, especially if the plates after sensitizing aad washing, receive a final coat of gallic acid, as suggested some years ago by Major Russell. 2. You are under a misapprehension as to the mode of using a portrait lens for landseape purposes. The allusions you have seen refer to the removal of the back lens entirely, and then reversing the position of the front lens. If your portrait combination is not arranged properly for using in this manner, your best plan is just to stop it down and use it as it is.

R. G.—The prints are on the whole very good, and the negatives free from over exposure. The conditions of lighting might have been a little better, aud a little more brilliancy, perhaps, might have been secured by management in developing and intensifying. The question of intensifying before or after development much depends upon the character of the original image; more softness is generally obtained by intensifying before fixing, more brilliancy by intensifying afterwards. Some operators do both: there is no reason, when the negative which has been intensified appears to lack vigour after fixing, why it should not be intensified again. By the application first of a solution of iodine, aud then applying pyro and silver, and if need be continuing this alternately, any amount of intensity can be gained. We shall be glad to see the 12 by 10 specimen covered with a lens of 11½ inches focus.

J. G. M.—It entirely depends upon the fittings of the combination, and if the front lens is intended to be used as a single lens, as to what steps you must take iu using it for landscapes. The usual method is to remove the back lens, and, having unscrewed the hood, turn round the tube and screw that part into the flange which was screwed iato the hood. That is one method, but different plans are used by different makers. It is necessary to be able to reverse the front lens, turning that side inwards which was out, and to be able to place a stop at the proper distance in front of it.

F. M.—Save all your clippings and waste prints, without fixing. Then at some convenient opportunity burn them and save the ashes. These may then be reduced with a flux, such as borax, nitrate of potash, &c., in the usual manner.

G.—In using any substitute for ground glass, in putting up transparencies, always place the prepared side next to the transparency; it will not then rub off. Of course wax, or starch, or any such preparation will readily scratch if exposed. The method of deadening glass with an acid about which you enquire will give a very fine dead surface, but is a little troublesome, and needs great care from persons unaccustomed to chemical manipulations. To deaden glass in this way the vapours of hydrofluoric acid may be used. The bottom of a leaden or gutta-percha vessel is covered with powdered fluor spar, over which sulphuric acid is poured, and gentle heat applied, which causes the generation of hydrofluoric acid fumes, above which the glass to be deadened is to be placed. Hydrofluoric acid is very corrosive, and should be used very carefully. The application of the acid itself would not produce deadness. 2. Photographs for exchange can be sent to the secretary of the Exchange Club at any time. The exchanges take place every month.

G. G.—The mark you describe is probably caused in the preparation of the plate by irregular draining or drying; but we cannot say with certainty. Where the unaltered iodide has not been entirely removed, the plate may be wetted again, and treated with hypo. If there be any crack in the film of course very great care will be required.

H. R.—You will find several descriptions of dark tents in our last volume. Perhaps Leake's tent is the simplest and cheapest. You will find a description on p. 381, vol. iv., Photographic News.

W. Morgan.—Use the alkaline gold toning bath, and abandon the mixture of gold and hypo. Try:—

| | |
|---|---|
| Chloride of gold ... ... ... ... ... ... | 1 grain |
| Acetate of soda ... ... ... ... ... ... | 30 grains |
| Distilled water . ... ... ... ... ... | 5 ounces. |

Mix one or two days before using. Tone in this until the print is a little deeper than required, then rinse and fix in a bath of fresh hypo, one ounce in five of water. See article on toning, &c., in the Photographic News Almanac for this year.

Several correspondents in our next.

# THE PHOTOGRAPHIC NEWS.

VOL. VI. No. 200.—*July* 4, 1862.

## FADING OF POSITIVE PRINTS.

THE dampness of the walls at the International Exhibition, ruinous as it is to the beauty of many of the photographs, mortifying, as it must be, to many of their exhibitors, need not be regarded as an unmitigated evil, and may possibly become auxiliary to a valuable lesson. The fading of positive prints has, we are happy to believe, become during the last few years much less common; it has certainly excited less attention and discussion, has been less prominently before the eyes of the photographic world than a few years ago. We believe there is no question as to the fact that since the introduction of the alkaline or neutral gold toning system, fading has been much less common than it used to be.

The damp walls of the Photographic Department of the building at South Kensington bring before us, however, in a startling manner, the fact that permanence is not the invariable rule even in the productions of first-rate photographers. Every visit convinces us more painfully of this fact. We see the productions of men standing high both in the professional and amateur ranks, showing the incipient or the advanced stages of decay in the yellow "cheesy" colour of the lights. That at least fair and ordinary care in carrying out of their respective processes has been used, may fairly be assumed in regard to the works of such men as Mudd, Robinson, Wardley, Watkins, Verschoyle, Colonel Stuart Wortley, Lord Caithness, and others of high reputation. The question then arises, if the process were properly worked, and ordinary care taken, which process was used? Are these, or any of them, the result of the old hypo toning system, or are they the produce of gold toning? Were they fixed in fresh hypo, or old hypo? What method of washing was used, or what means were taken to secure efficiency? Were any tests ever used, and what were they?

It is quite possible that these prints, or many of them, might have remained for years without exhibiting the same signs of decay which are now most evident; the damp of the walls is something worse than would be readily believed; the card-board at the back of mounts, we are told, is in some instances absolutely in the condition of pulp. What gaseous exhalations may be emitted by the bricks and mortar, and plaster, we cannot pretend to say, but it is by no means improbable that these may be injurious. Notwithstanding all this, however, some of the prints placed in the same condition show no sign of decomposition whatever, but retain their primitive purity. It becomes interesting to know, also, under what treatment these were produced. Some of the best of them, we know, have been toned in an alkaline gold solution, fixed in fresh hypo, and very carefully washed. The question arises, have any of those which are permanent been produced under the old system, and if so, with what precautions?

That prints toned in the old hypo and gold toning bath were not unfrequently permanent, cannot be denied. We have prints produced nine or ten years ago which are yet unchanged. Most old photographers can offer similar evidence. We recently inspected a frame of specimens shown by Mr. T. R. Williams, at the first exhibition of the Photographic Society, some nine years ago, which were intended to illustrate the effect of leaving the print in the old bath of hypo and gold for different periods. The first specimen was immersed for five minutes, the second for ten minutes, the third for fifteen minutes, and so on, increasing the time five minutes with each example. The number of prints was about two dozen, so that the last print would be immersed for two hours. These prints were washed with the ordinary care, customary to a careful operator, and although nine years have elapsed since they were produced, the majority of them are at the present moment entirely unchanged. The last few prints showed unmistakeable evidence of the action of sulphur at the time, and it is difficult to say, therefore, whether they have gone further or not. All the earlier prints are, however, good in tone, and at present quite permanent. The system was, however, there can be no question, an uncertain one; and we by no means recommend a return to it. Notwithstanding the result of the specimens in question, Mr. Williams has long since abandoned the old bath for the more certain, philosophical, and trustworthy, alkaline gold toning solution, and fresh hypo fixing solution.

We do not intend here to enter into the question as to the causes which may have been in operation, to induce the fading of the prints now in the Exhibition, but rather to call attention to the subject, and the important considerations involved. No subject of greater importance to photography and photographers can be conceived. The permanence of its productions is unquestionably the consideration of all others, upon which the value of the art most depends. It is very desirable then, as this mortifying reminder of the instability of photographic prints, under certain conditions, has been thrust upon our attention, that some valuable use should be made of it. It may be regarded as a test upon a grand scale, and under the most trying conditions, of the value of various printing processes, or modes of working them. We would strongly urge upon those gentlemen whose pictures have become yellow, or are otherwise decomposed, to place upon record the details of their printing operations; so that the cause of decay may, if possible, be detected and published. The proximate cause is, doubtless, the damp to which they have been subjected, but we want to trace the ultimate cause in the method employed, which left in them the elements of decomposition. Accounts of the method of producing those which, subjected to the damp, have entirely withstood its influence are also desirable. We shall have pleasure in receiving and publishing communications on either subject. Or, we would suggest that no more interesting and important topic could engage the attention of the first meeting of the Photographic Society after the summer recess, and that if the gentlemen concerned furnish the necessary information, a discussion might ensue which would possess more interest and importance than any which has for a long time been held.

## CIRCULAR PANORAMIC PICTURES.

As our readers are aware, we have always felt considerable interest in the panoramic lens and in any development of its powers, as, indeed, of any lens which, by including a wide angle of view, has contributed to the pictorial advantage of photographers. We extract the following article from a recent number of the *Photographic Notes*, rather as an illustration of the ingenious method by which difficulties may be met, than from any strong conviction that it will come into practice. Our friend, Sutton, some time ago complained of our referring to him as an enthusiast, and emphatically proclaimed the matter-of-fact caution which governed his ideas. We think that those who read the following article will scarcely wonder at our reference to his enthusiasm. Let us not be misunderstood, however, or thought for one moment to use the term with any intention of disparagement. Without enthusiasm there would be little progress. Every great inventor, every courageous innovator, has been an enthusiast, and without the steadfast faith which laughs at impossibilities, and the large hope which has taken no heed of present difficulty, but seen only in the future good, almost all the great triumphs of art science, and civilization would have been lost to the world. Mr. Sutton says :—

"It has been the reproach of panoramic photography that you cannot include the 90° of subject in height, and all other directions, as in width; that is to say that you cannot take a picture upon the segment of a sphere subtending an angle of 90° at the centre. The difficulty of doing this does not, however, depend upon any infirmity of the panoramic lens, but is entirely a difficulty of manipulation, in the case of taking the negative, and of afterwards printing from it. The panoramic lens will as easily and as perfectly cover a field of 90° every way upon a spherical segment, as of 90° in width and 50 in height upon a cylindrical segment. With a modification in the diaphragm, which can easily be made, the panoramic lens will do all that is required in height as well as breadth, and it only remains to master the difficulties of taking negatives upon the inside of a bowl, and of printing from such negatives. It is important to consider in what these difficulties really consist, and how they may be successfully overcome, because if they *can* be overcome, the photographic artist will have a new world open to him, and the means of leaving far behind all that has been previously done in landscape photography.

"We do not anticipate that there would be any great difficulty in getting glass bowls, made of suitable radius, upon which to take the negatives. Glass spheres could be blown to the proper radius, and segments of the right size cut from them, avoiding as much as possible any blemishes in the glass. Neither do we suppose that such glasses would be very expensive, or difficult to pack in boxes. Let us imagine all this done, and that a suitable camera has been made, with a slide to hold such glasses. The next thing will be to coat the glass with collodion. This is not, by any means, the difficult job we fancied some time ago. We have been trying lately to coat the insides of various vessels of a spherical form, such as glass scale pans, saucers, saucepan lids, &c., and there does not really appear to be any more difficulty than in coating the cylindrical glasses which are now used with the panoramic camera. Assuming then that the glass can be coated with collodion, you would proceed in the following way to excite and develop :—You would use a common wire dipper, put the flat side of the glass against it, and dip it into a vertical nitrate bath in the usual way, then remove it into a second bath containing distilled water, and cast off the free nitrate; and lastly, pour the tannin solution into it, let it flow all round, and set the glass up to dry. The development would be equally easy. You would wash the glass by pouring water into it, then put it upon a holder, which would be a simple wire hoop fixed into a handle, and pour in weak developer at first, and keep it moving over all parts of the glass until the image was visible in all its details, then intensify by adding more silver. To fix with hypo and wash would be easy enough, and then the varnish could be applied in the same way as the collodion. The varnishing would be rather nervous work at first, for fear of forming lines and ridges on the film, but after a little practice this difficulty would probably be overcome.

Assuming then all to have gone right so far, and that we have obtained an excellent tannin negative upon the interior of a glass bowl or spherical shell, subtending 90° at the centre of the lens, and including 90° of subject in all directions, we have next to consider how to print from such a negative.

"We will not now stop to consider how a *transparent* positive could be printed, because that would involve some peculiar difficulties, and it is a mode of printing which has not yet become so popular as it deserves. We will confine our attention for the present to the question of printing an ordinary positive, to be looked *at* and not *through*, and to be mounted upon a card, or exhibited in any other convenient way.

"Our readers will perceive at once the impossibility of printing upon *paper* by contact with such a negative as we describe. If you attempt to apply a piece of paper, however thin, to the inside of a spherical bowl, it becomes puckered in all directions. Paper is, therefore, out of the question for this purpose, but, happily, we have in certain fine elastic textile fabrics a suitable material. For instance, if you lay a white silk handkerchief upon a globe, you can get close contact over a large extent of surface, without a crease or pucker. A sheet of paper is composed of fibres felted together, and closely interlacing in all possible ways and directions, but a woven fabric is composed of threads which cross each other at right angles, and leave spaces between, which can be made to assume all sorts of shapes according as the material is stretched in different ways; and thus it is that such a fabric can be made to fit against a spherical surface without creases, and to be as closely in contact with it as a sheet of paper againt a plate of glass. Fine white silk, or fine jaccinet muslin or linen, would be suitable for printing upon from spherical negatives, and report says that there are now on view in the International Exhibition some very beautiful photographs upon silk.

Having now in imagination made a stride over the practical difficulties of this subject, and taken a beautiful positive print upon silk from a panoramic negative including 90° of subject in all directions, let us next discuss the optical qualities of such a picture—the nature of its perspective—how it ought to be mounted, and so forth.

"If we agree to treat such a print solely as an artistic study, and without any reference to absolute truth of perspective, or freedom from distortion, we should simply mount it upon a flat card, and in the printing should vignette out all the details which were superfluous, or injurious to the subject. Thus the round picture would be cut down to an irregular outline by any of the common modes of vignetting, and only such parts left as were required to make a pleasing composition. In a view of this kind, when flattened out, the vertical lines of a building near the margin would be curved, and in order to straighten them, the silk might be stretched a little at the corners. When a first print had been treated in this way and properly mounted, a flat negative might be copied from it, and from that any number of prints could be taken in the usual way. If our readers will open an illustrated book of travels, they will find numerous examples of views of places which could not have been taken by a common camera, or even by a panoramic camera for cylindrical glasses, but which would afford fitting subjects for the wide-embracing spherical negative, and the mode of printing and treatment which we have described. Anyone with a knowledge of landscape drawing, and a taste for that branch of art, will understand the class of subject to which we allude, and perceive that it includes the majority of good views.

"But if we desire in a photographic view something more than an artistic study, and that it should satisfy the conditions of true perspective, then it would be absolutely necessary to mount the print upon the convex side of a glass similar to that upon which the negative was taken, and view it through the glass, the eye being placed at the centre of the sphere. Prints mounted in this way in a circular frame would be very pretty, and the perspective would then be rigorously correct.

"With respect to focus, that would be perfection in every part of the picture, except where an object happened to be nearer to the spectator than ten or a dozen yards. This would rarely happen, except in the immediate foreground of views in which the camera was placed upon the level ground, and not upon a height. The focus of views taken from high ground would be absolute perfection in every part, and infinitely better than in a common photograph upon a flat plate, taken with common lenses.

"If our readers will think over what we have now suggested they may greatly assist us with hints as to the best kind of fabric to print upon; and if some of them would kindly experiment upon such fabrics, and inform us of their results, we should greatly value such assistance. The end to be accomplished is worth any amount of trouble, and that it lies within the reach of our present knowledge and means there can scarcely be a doubt. The other day a lady friend showed us a D'Oyley upon which a very pretty sketch had been made with a pen dipped in marking ink, and her enquiry, whether similar views could not be taken by photography, suggested the idea which has called forth this article. But before similar photographic views can be printed upon D'Oyley's, the negatives must include a much wider angle than the comman lenses give. It is not one photographic view in a thousand that can now be called a picture. At present they are mere bits of detail, and bear no resemblance to pictures such as artists love to take."

## AN EXPERIMENT UPON MOSER'S IMAGES.

BY M. D. VAN MONCKHOVEN.

Photographic images are, as it is well known, formed of pure silver, disseminated in a transparent film of pyroxyline, albumen, or other porous substances. We are reminded also of the celebrated discovery of the sculptor Rauch, who, having left an engraving in contact with a plate of glass, saw the image of his engraving reproduced upon it after the lapse of a certain time.

Many years since we observed an analagous fact. A glass which covered a photographic picture presented, after cleaning, the same image on its surface, when the breath was condensed upon it. And, moreover, the image was not easily effaced.

We have recently observed the same fact again. The glass which sustained the film is green: it is a glass having soda for a base, with a small quantity of lead. It had upon it a collodion portrait, taken in 1857, and since that date has been kept in a very dry and dimly-lighted room, with some fifty other glass plates.

Some weeks ago all these glasses were cleaned. Chance led me to discover that one, when breathed upon, displayed a very intense image. It might be called a Daguerreotype portrait. Viewed by reflected light, the image is a negative. It corresponds, therefore, exactly to that of the collodion film. Among all the glass plates this was tho only one that exhibited this phenomenon.

From information obtained from very reliable sources, this fact, I find, occurs frequently to professional photographers, who preserve their negatives. With respect to the theory of the Daguerreotype, it will be very useful to have their attention directed to this fact, in view of the curious experiments to which it gives rise.

The glass plate described was now coated with iodized collodion, sensitized in a bath of nitrate of silver, and placed in an ordinary camera pointed to the model. The negative obtained was double, the new image and a second, very weak; beneath it resembled the invisible image, imprinted upon the glass plate.

The experiment, repeated several days subsesequently, in the fear that we had to do with one of the phenomena of "stored-up light," described by M. Niepce de Saint Victor, still gave two images: that newly obtained, and a second, very weak one, beneath it, but still quite visible.

We were much occupied with this fact, when the idea occured to us of operating in the dark, without exposing the plate in the camera. This time, after fixing, we could discover only a scarcely perceptible image. It is well known that the polarization of light, resulting from reflection from the surface of metals, does not possess the same properties as that from non-metallic reflecting surfaces. We took advantage of this property to render the preceding image visible. To this end, it sufficed to examine with a Nicol's prism the film containing the image under the angle of incidence necessary to polarize the light, and to turn the prism so as to extinguish the light reflected by the glass. We succeeded better by blackening the back of the glass. The silver, constituting the image, did not participate in the properties of ordinary polarized light, the image, which has been visible only because we suspected its existence, became fully visible even to persons who previously could see nothing. This means of recognizing the silver, may prove very useful on account of its extreme sensibility, to ascertain, for instance, if the light in ordinary photographic processes, really decomposes the iodide of silver, or if it only communicates to it new physical properties.

Now what can be the mysterious cause of the impression of an image upon the surface of a glass plate and which afterwards gives to it the properties of reducing iodide of silver. There cannot be a doubt that this is not a phenomenon of the "storing up of light" for very glass plate covered for a certain time with a photographic image and exposed to light, should present analogous properties. If it is a molecular modification of the surface of the glass, under what conditions does it act? from whence comes its property of acting upon iodide of silver?

It is certainly only by collecting a great number of facts and discussing them, that we can arrive at a sound hypothesis upon this series of phenomena.

## The International Exhibition.

### PHOTOGRAPHIC CHEMICALS.

The large manufacturing chemists, as might be expected, make an excellent show in the Eastern Annexe, and nothing shows the importance of photography more than the prominence given to chemicals which are used exclusively, or nearly so, by the cultivators of this art. Some very fine samples of pyrogallic and gallic acids are exhibited by Messrs. May and Baker, who also show some large slabs of commercial cyanide of potassium, upwards of eighteen inches across and three thick. This, however, does not look very pure, but the same firm has a smaller sample of cyanide which is beautifully white; their speciality seems to be mercury and bismuth compounds, some magnificent crystals of calomel and corrosive sublimate being in the case. The former is, however, becoming very discoloured, probably by the light; this seems to point to some photographic qualities of this salt which are not generally known.

A beautiful series of acetates and some samples of acetic acid, are shown by the well known house of C. Foot and Co. They have also a large quantity of dried albumen, still retaining its solubility in water. The substance labelled "egg albumen," seems, from its colour and general appearance, as if it would prove of considerable value to photographers when eggs are scarce, but the article styled "blood albumen" is not sufficiently tempting, either from its appearance or origin, to justify us in recommending its employment for photographic purposes, although, from its low price, we have no doubt that it frequently enters into the composition of the extra-cheap albumenized paper. We also noticed in this case a bottle of formic acid, a body which has on several occasions been recommended for use in photography, and which, from its energetic reducing properties, cannot fail to be of considerable use when it is better known. Messrs. Foot and Co., we understand, are now enabled to supply this acid at a comparatively low price, and we would, therefore, at once suggest its employment in both positive and negative developing solutions, in which it might partially, if not entirely, replace acetic acid. Acetic acid is also shown by the large makers, Cox and Gould, who exhibit an interesting series, explaining the different stages of its manufacture, from the rough log of wood, and the crude pyroligneous acid, which is a product of its destructive distillation, up to the purified glacial acetic acid. Two remarkable looking objects in the same case would puzzle any photographic chemist to identify them; one is a lump of fused iodide of potassium, and the other a corresponding lump of fused bromide of potassium. The only substance to which we can compare them, is a piece of excessively fat meat, with streaks of lean showing themselves here and there. These are, of course, only shown to illustrate one stage in the manufacture of these salts, tho crystallized compounds being also exhibited in a very pure state.

Messrs. Davy, Macknurdo, and Co. show several preparations of photographic interest. One in particular we may specify. A largo bottle of dry and apparently pure chloride of gold in fine crystals. Near it is a corresponding bottle of chloride of platinum almost equally good. Their iodide of sodium, bromide of ammonium, and iodide and bromide of cadmium, may also be specially commended for their purity and definite crystalline appearance; the iodide of cadmium crystals are especially large. Amongst the other chemical compounds of scientific interest which this firm exhibits, we may mention valerianic acid, and some valerianates, not, however, so much for their photographic value, as in reference to the powerful and unpleasant odour of valerian which is so strongly noticed near the case.

The old-established firm of Howard and Sons devote a great portion of their space to compounds of quinine, and other alkaloids, for the manufacture of which they are so justly famous; they have, besides, some fine cadmium salts as well as iodide and bromide of potassium and Rochelle salt. This case also contains the largest crystals of nitrate of silver which we can remember ever having seen, some of the tables of this salt being upwards of three inches square.

The articles exhibited in Mr. Versmann's case—Wolfram ores and various metallic tungstates—are of considerable interest apart from the anti-inflammable property which they communicate to ladies dresses, inasmuch as they furnish two new and very beautiful colours, namely saffron bronze, and magenta bronze; the appearance of these, when the sun shines on them is beautiful in the extreme.

---

## BRITISH PHOTOGRAPHIC DEPARTMENT.

Portraiture must ever be one of the most important departments of photography, nevertheless, we are disposed to believe, at the risk of being charged with photographic heresy by some, that as yet it has scarcely received full justice. We do not mean to say that there are not some pre-eminently able portraitists; but we think it would be very easy to prove, that portraiture has rarely been pursued with the loving enthusiasm by amateurs, which has been given to landscape and other branches of photography. Very few educated amateurs have given it any attention at all, whilst of the profsssional photographers who pursue photography as a business, how very few are by natural aptitude or education, fitted to excel in this most difficult branch of the art? To attain the highest excellence here, not only should the operator be perfectly familiar with all the principles of art which pertain to this department, and be at the same time a thoroughly accomplished photographer; but he should also possess that rapid, almost intuitive perception of character, which will enable him at once to perceive what style, position, lighting, and general arrangement, will be most conducive to perfect *vraisemblance*, and to satisfactory pictorial results, together with sufficient of the magnetic charm of manner, which places the sitter at once at ease, and induces the happiest expression during the sitting, for unless the idea of a dentistical operation, entertained by so many persons, can be dispelled, there can be no chance of a successful portrait.

Notwithstanding, however, that we believe it is possible to attain a higher standard in photographic portraiture generally, we are fully prepared to admit that there are many very fine examples of this branch of the art in the International Exhibition, both in the British and other departments. It is with the former, however, we are now concerned. Prominent here, as might be anticipated, are the various examples of card portraiture. The fashion which has prevailed for the last couple of years, for these small photographs, has done much, we believe, to improve the manipulative part of photographic portraiture. Not that bad photography is entirely uncommon in this department still; but the general quality of the results, or at least such as belong to the merely mechanical part of photography, are materially improved. Moderately good manipulation has become imperative where slovenliness might pass before. The time was, a very few years ago, when the cut-out backgrounds, which originated in France, and touched pictures, were common in portraiture, or when coloured pictures were largely in demand, very moderate and often very bad, results were deemed good enough for touchiug or colouring, and the obligatiou to produce clean even backgrounds; sharp, round, well defined images, was by no means imperative. The card mania has, however, changed all that; and the photographer who would maintain any reputation, *must* manipulate well, whether he be an artist or not. The public have begun to acquire discrimination enough to form some judgment as to the mechanical department; the artistic appreciation is, perhaps, yet to come, although even in this respect, it generally happens that the most artistic photographs please best.

By far the best card pictures, to our taste, here exhibited, are those of Mr. H. P. Robinson, of Leamington. The frame (703, in the photographic catalogue,) is a small one, containing only half-a-dozen pictures, but these are gems. Excellent in composition, easy and natural in pose and general arrangement, soft and delicate, yet, withal, rich and brilliant, they are altogether charming. Pictorial backgrounds, so commonly misused as to render them generally disgusting, are here employed with good taste and natural effect, especially in a standing group, and in the picture of a lady, sitting sketching. Perhaps, next in quality amongst card pictures are those of Mayland, of Cambridge. These are soft, vigorous, and round, generally quiet and well arranged, free from the meretricious and incongruous display of accessories, which is but too common in this class of portraits. Mr. Kilburn, or, rather, his successor, also displays some very good card portraits. Mr. King, of Bath, sends a very extensive collection of specimens, small and large, for which he is fortuuate in having obtained so much space. Of the large pictures, we have yet to speak; but his card pictures are, however, best, and these are very unequal, some being very good, some moderate, and many very poor indeed, both as photography and art, being hard and patchy, and crowded with "loud" accessories. Mr. Kiug has been fortunate in sitters, his specimens including the elite of the professional world in music, art, and letters, as well as stars of the drama and of the pulpit. It is always a source of regret when we see, from some of the specimens of an artist, that he can do good work, to find at the same time that from hurry, carelessness, or the lack of a sufficiently delicate appreciation. he sends forth, side by side with the good, other results which are entirely bad.

We find on looking over our notes in regard to card portraits, that a very large proportion of the contributions are marked as "middling." Many of these have excellent points, but are still in some respects wanting; and many of these, too, by artists of good position; amongst these we may mention such names as Mayer Brothers, Caldesi, and some others whose pictures are hard; Beard, Claudet, and others, who exhibit some very fine pictures, but some of which lack the perfectness of definition desirable in such pictures, or are cold and wanting in richness and vigour. Mr. Hering exhibits some very good card pictures, but immediately in contact with them is a large frame, containing some scores of heads, arranged so closely together in long uniform lines, row over row, as to have a most unsatisfactory and unpleasing effect, giving the appearance at first glance of an immense chess-board. The photography is probably good, but it is impossible to form a good opinion of it displayed in such a style. Messrs. Maull and Polyblank exhibit some very commonplace card pictures, and the London School of Photography some still worse. Descending still further, not by a mere stride, but by an immense leap, we come to a frame, or a series of frames by L. Birnstingl; as we stand before these, we pause and wonder, and as we remember that this department represents British photography, and that the world is invited to examine the display, we feel a hot flush, half of shame, and wholly of annoyance. These are portraits of the "Guarantors," the representative patrons of science and art in the country, and the portraiture is by the gentleman who obtained the contract for photography in connection with the Exhibition whilst the building was in progress; so that these pictures possess a quasi-official character, and might naturally be regarded as in some sort representing national character and national photography. We must confess we are truly sorry for it. The work is irredeemably bad in every sense. If we believe the photographers, and they *should be* good evidence, the men of science, art, letters, and wealth, who are prepared to sustain a possible loss in the erection of this monument of the world's progress, are a herd of the most vulgar, snobbish, and commonplace-looking personages, without one trace of the characteristics of English gentlemen. If the noble lords now considering the Bill for Artistic Copyright, who are impressed with the idea that all photographs are alike, and that it would be impossible to distinguish between the works of different artists, will glance at these frames, they will at least see what monstrosities can be perpetrated by the art when not in the hands of a skilled artist; but we fear a glance at such productions would be sufficient to exclude all chance of photography remaining in a Bill for the protection of fine art. Seriously, it is too bad that some discrimination or control as to the quality of the work was not exercised in the first photographic contract; it is too bad that the Guarantors should be gibbetted in such vile guise in what is to some extent their own building; but it is far worse that such pictures should occupy so much precious space, representing British photography.

In larger portraits, pre-eminent now as ever, stand the productions of Mr. T. R. Williams, who exhibits only vignette heads, thus avoiding the necessity for accessories of any kind. This style is, in our estimation, by far the most pleasing and successful style of photographic portraiture, especially for gentlemen: the interest is entirely concentrated on the most important part, the head. There are no awkward legs or arms to dispose into passable lines; and bring within the defining powers of the lens. All this is favourable to success; but there is about the portraits of Mr. Williams a perfectness and completeness which we have rarely, if ever, seen in any other photographs, whether vignetted or otherwise. It becomes an interesting question, to what this especial pre-eminence is due. Some persons who have examined these pictures have answered it readily, "Oh, it is simply due to skilful 'touching'! the pictures are elaborately worked up; here is a whole eyebrow put in, and there the hair is worked upon, etc." It were an easy thing to answer that we have never seen touched work that could compare in beauty with good untouched photography; but we can go further—and we do so because we always deprecate the idea that good work is due to any adventitious aid—we have before us at this moment unmounted duplicates of the photographs in question, and can vouch that they are entirely genuine, pure untouched photography. To what then is this superiority due? "How is it" we are frequently asked by some anxious student, "that I cannot produce such pictures? I have the best lenses, I use the best collodion, and have tried almost all the makers; I get the very best chemicals, but my pictures are not good. Is it the lighting or the lenses, the chemicals or the formula, the exposure or development, which makes the difference between my productions and those of first class photographers?" All these things unquestionably have their share in the result, but perhaps none in any pre-eminent degree. Good lenses, that is suitable lenses for the work, are undoubtedly necessary; for large heads, lenses with sufficient depth of focus to define all parts moderately well, without that cutting sharpness which makes the head appear as if chiselled out of marble. Judicious lighting has perhaps more to do with perfection of results than any other one thing; sufficient direct light to give vigorous and well marked contours, and sufficient diffused or reflected light, to give texture and modelling. It is a very easy thing to obtain texture which degenerates into wiry rugosity; but a careful selection of the lens, and management of the light is necessary to secure in large heads texture without coarseness. Good chemicals are necessary and easily obtained; good formulæ we constantly publish. Judicious manipulation must depend upon nice appreciation and carefully garnered experience; exposure and development must be in proper relation to each other, and to the condition of chemicals: harmonious relation of every part to every other part is the great secret: other things being equal skilful development is perhaps most important. But every step so depends upon the whole, that especial stress cannot be justly placed upon any single operation. We have digressed from criticism into questions of process, because we have often been asked lately, after describing various good pictures, to say something special about the method of producing them, and because Mr. Williams' pictures are unsurpassed in all that constitutes good photography: wondrous delicacy; perfect roundness and modelling; fleshy texture and transparency, without magnified wrinkles and freckles; great vigour and brilliancy; rich tone; exquisite definition, as well as good taste and fine feeling.

Next, to our taste, in portraiture, are the productions of Mr. Hennah, of Brighton, whose pictures always make us wish that such a thing as albumenized paper had no existence. Mr. Hennah is one of the few, if he be not the only one, who has not been seduced by the charms of surface possessed by albumenized paper. He adheres to plain paper and the ammonia-nitrate printing process. His contributions to the Exhibition are magnificent specimens of the tones obtainable by that process, and many of them, as specimens of portraiture, leave nothing to be desired. Some whole-plate portraits of children, one (420) especially, are perfect gems. John and Charles Watkins contribute largely to the examples of portraiture, and amongst the large number exhibited are many thoroughly excellent pictures, good in every respect; we regret, however, that there is some inequality, some of the pictures are considerably touched, and some yielding to the extreme test of the damp walls show signs of incipient decay, which circumstance makes the touching more apparent. We can conceive that some of these would not have been exhibited but for the interest attaching to the portraits, which comprise such names as Landseer, Millais, Faed, Hook, Webster, and others amongst painters; Dickens, Jerrold, and others, amongst men of letters, as well as many royal and noble personages. Mr. Herbert Watkins also exhibits some good portraits of celebrities, one frame of good photographs consisting only of various portraits of Ristori in different characters.

Mr. D. O. Hill contributes a large frame of pictures, which are subscribed as "Contributions towards the further development of fine art in photography." These pictures, partly because, we apprehend, of their stepping a little out of the conventional treatment of portraiture, and partly because of the somewhat ambitious description just quoted, have excited some animadversion. They are unquestionably pictures of unusual merit, and it should be remembered that the artist is a gentleman well qualified to aid the art progress of photography, being a painter of considerable reputation, and Secretary to the Scottish Royal Academy of Painting. He is, moreover, a staunch and old friend of photography, having in conjunction with Mr. Adamson, many years ago, executed some of the finest calotype portraits ever produced. These pictures may offend some by being large and bold, and in some instances, tending slightly towards coarseness in their massive vigour, but there is, nevertheless, an amount of true art and good photography, which must challenge admiration. There is a daring use of unusual accessories, which is in some cases very effective. A large group of "Dr. John Brown and his Cousin," which obtained a silver medal at the last exhibition of the Scotch Society, is a very fine photograph; massive, round, and well composed; a portrait of Dr. Brown alone is also very good. "Through the Trellis" is a very pleasing group, consisting of three girls, one of whom is seen through a wire trellis and the creeping foliage which surrounds it; the subject is a difficult one, but is well managed and effective. "Our Dear Old Nurse" is another very good picture. Some of the specimens, "The Story of the Bruce," for instance, would have been as well omitted from the frame; but, as a whole, we strongly commend the pictures to the attention of photographers.

M. Claudet exhibits a large number of very excellent examples of portraiture which have many pleasing qualities. M. Joubert exhibits some exceedingly artistic portraits. Mr. Hering contributes some good pictures, some of which, unfortunately, have been slightly touched in body colour, and show the action of the damp walls. The whole-plate portraits of Maull and Polyblank are in many respects good, and altogether much better than their card pictures. Mr. Charles Newcombe contributes some pleasing pictures. Ross and Thompson's portraits have many artistic qualities. Heath and Beau exhibit some characteristic heads. Mr. McAndrew has some fine bold round vigorous heads. McLean and Melhuish have some specimens, many of which display very excellent qualities.

Touched portraiture is, we are happy to say, only contributed by very few persons. Why it is contributed at all, or why admitted at all, after the announcement to the contrary, we cannot understand, unless it be that unscrupulous persons sent in such pictures to fill the space granted to them, and it was thought better to wink at the broken condition than leave bare walls. Certain it is that some are there. Mr. King, of Bath, sends a large number of these spoiled photographs very gaudily done, and some of which are showing yellow stains of decomposition already. Mr. Mayall sends some very carefully worked pictures in black and white, which are, to our taste, infinitely inferior to untouched prints from the same negatives, some of which we have now before us. Mr. Eastham, of Manchester, sends a large composition group, which is very good, but being touched has no business here. The same may be said of some positives by the tannin process upon enamel glass.

The examples of solar camera enlargement are not numerous in the British Department. M. Claudet contributes the largest number, and many of them are very fine indeed; but some of them are touched. Mr. Owen Angel, of Exeter, has sent some very good enlargements; but apparently as conscientious in his regard to the conditions issued, as others have been unscrupulous, he has not even touched out slight accidental spots. Messrs. Smyth and Blauchard exhibit some very fine enlargements (609), which are to our taste the finest in the department. On the same screen, as if hung as a foil to that just named, is a picture about half life-size, by Cramb, Brothers, of Glasgow. This is minutely described as being taken direct in the camera without enlargement. We can only regard it as having been sent as a specimen of what to avoid, as anything more hideous, clumsy, or inartistic we have rarely seen.

## PHOTOGRAPHIC CHEMICALS:

### Their Manufacture, Adulterations, and Analysis.

*Potassium Salts* (continued).—*Acetate of potash*, and the corresponding soda compound, are of frequent use in the laboratory, photographic as well as chemical, to replace a strong acid such as nitric, sulphuric or hydrochloric by a weak organic acid. For instance, free nitric acid in the silver bath, the presence of which gives rise to well-known objectionable qualities may be replaced by acetic acid by the simple addition of one of these salts. We may as well briefly point out the *rationale* of this replacement. When a certain amount of acetate of potash is brought into contact with a liquid containing free nitric (or other mineral) acid, a decomposition takes place. The potash finds itself in the company of two acids which have a strong but unequal liking for it; and the attraction being reciprocated in the same degree, the potash combines with the acid for which it has the greater affinity. Nitric acid and potash having a far greater affinity one for the other than acetic acid and potash, unite and form a solution of nitrate of potash, leaving free acetic acid instead of free nitric acid in the liquid. Of late years the exact and sharp decomposition here described has been doubted by some writers, who consider that the solution, under the above circumstances, would contain a mixture of nitrate of potash, acetate of potash, nitric acid, and acetic acid. Whether this theory be correct or not, it would be very difficult, if not impossible, to say, but it is sufficient for our purpose to know that a liquid treated as above acts as if there were only free acetic acid present.

Acetate of potash may be readily prepared by neutralising carbonate of potash with acetic acid and evaporating. If the acetic acid and carbonate of potash are pure, the resulting acetate will be ready for use at once; as, however, the former generally contains traces of empyreumatic matter, this will have to be removed from the acetate in the following manner:—evaporate the mixture with continual addition of acetic acid, so that the potash may never be in excess from evaporation of the acid, as that would cause decomposition and introduce further impurities. The concentrated liquid is mixed with one-tenth of its weight of animal charcoal, then evaporated to dryness, and the mass heated until it fuses; the fused mass is then dissolved in water and the liquid filtered; a little carbonate of potash that may have been reproduced by the fusion is then neutralized with strong acetic acid, and the solution is to be evaporated to a syrup and allowed to crystallize. It may also be prepared by double decomposition between acetate of lead and sulphate, or carbonate of potash. We do not, however, recommend this, as the process in inexperienced hands, is liable to give an impure product. Acetate of potash in the dry state melts below a red heat, forming an oily liquid, which on cooling solidifies to a white, opaque, crystalline mass. The aqueous solution, when evaporated to dryness, with constant stirring, becomes covered with a white crust of anhydrous salt, until the whole liquid is converted into a dry powder. If the evaporation be stopped as soon as the crust begins to form, and the liquid then allowed to cool, large transparent prismatic crystals are formed which contain water of crystallization. The salt has a warm and pungent saline taste. When the anhydrous salt is heated above its fusing point it is decomposed, yielding acetic acid, and several other liquid and gaseous products, having a residue of carbonate of potash and charcoal. Acetate of potash deliquesces very rapidly in the air, and dissolves at the ordinary temperature in less than one-fourth of its weight of water. When it is dissolved in a considerable quantity of water, and allowed to remain for some time (as in the test bottles on the laboratory shelves), a decomposition takes place, carbonate of potash is formed, with production of fungi. Acetate of potash when dissolved to saturation in boiling water forms an oily liquid, boiling at 169° C., containing one part, by weight, of water to eight parts of salt. Acetate of potash also dissolves very readily in alcohol, requiring only three parts of the cold or two parts of hot liquid, from this solution carbonic acid precipitates carbonate of potash.

*Tartrate of potash.*—Before describing the neutral tartrate, we think it will be more convenient if we give a short account of the acid compounds, as it is from this that most of the potash of commerce is obtained. Bi-tartrate of potash is the salt commonly known as cream of tartar. The crude tartar or *argol* is partially purified by solution, filtration, and crystallization. The lime is then separated from it by treatment with dilute hydrochloric acid and washing. The salt then forms a white hard crystalline powder, having a slightly acid taste, and being permanent in the air. It is very slightly soluble in water, and is of no especial interest, except as a means of forming the

*Neutral tartrate of potash.*—This is formed by treating the bi-tartrate with water and carbonate of potash, until the acid reaction is neutralised. By slow evaporation the salt is obtained in transparent colourless prisims. These are permanent in the air, but very soluble in water. Tartrate of potash is of interest, as it offers a ready means of obtaining the corresponding silver salt by double decomposition. Tartrate of silver has not yet been much employed as a photographic agent, but it possesses many qualities which would render its further investigaton in this respect desirable.

*Citrate of potash.*—The silver salt of this acid has been used in photography with marked success, and on account of its potash salts, which is the one most usually employed in preparing, it will be of immediate as well as of future interest. Citrate of potash is formed by neutralising citric acid with carbonate of potash. Upon allowing the solution to evaporate spontaneously, the salt separates in the form of transparent colourless needles, united in stellate groups. The salt thus formed is tribasic, containing three equivalents of base to one of acid (citric acid being in this respect analogous to phosphoric acid, already described). The crystals have an alkaline taste, and are very deliquescent, dissolving readily in water. Citrate of potash is insoluble in alcohol. The monobasic citrate of potash (containing one part of acid to one part of base), is formed by exactly neutralising one part of the acid with carbonate of potash, and then adding another part of the acid. Upon allowing the solution to evaporate at a gentle heat, the salt is deposited in large transparent prisms, permanent in the air and having an agreeable sour taste. They contain four equivalents of water of crystallization which are entirely given off at the boiling point of water, leaving a gummy liquid, which on cooling solidifies completely into a radiated mass of needle-shaped crystals of the anhydrous salt, which are decomposed at 150°C. The salt dissolves slightly in boiling alcohol and crystallizes therefrom on cooling.

*Formiate of Potash.*—Now that formic acid and its salts are likely to be employed in photography, it is of some importance to the experimentalist to be enabled to know what are the characteristics of these bodies. The neutral formiate is formed by neutralizing the acid with pure carbonate of potash, and evaporating. It crystallizes in white transparent cubes, which are anhydrous. They taste bitter and caustic at first, and afterwards saline and cooling. They deliquesce in the air. An acid salt is also known, but it is even more deliquescent than the neutral salt. It is prepared by dissolving the latter in concentrated formic acid and evaporating. It is of no particular interest.

## SOUTH LONDON PHOTOGRAPHIC EXHIBITION.

WE proceed briefly to conclude our notice of the pictures exhibited at the Crystal Palace, by the South London Photographic Society, which, we believe, continue to excite a large share of attention amongst visitors. The specimens of coloured photographs are not numerous, the committee, as we understand, having rather repressed, than encouraged, contributions of that kind, as not of a strictly photographic character. There are a few very fine coloured pictures, however, one to which we may especially refer, is a portrait of a Spanish girl, by Macandrew, painted by M. Lafollie. This is an admirable specimen of oil painting upon the photograph; the colour is quiet and mellow, low in tone, but still rich and vigorous. The olive tint of the Spanish complexion is delicate and transparent. Altogether, the head is thoroughly well painted. Mr. Wall exhibits the only solar-camera picture contributed; this is a life-size head of a lady painted in oil, a plain print from the original quarter-plate negative placed beside it, shows how admirably the likeness is preserved. The painting is brilliant, but not crude or glaring, the flesh being rich and transparent. It is one of the best oil coloured solar-camera pictures we have seen. There are some other coloured pictures not needing especial notice.

Mr. Warner contributes some prints from enlarged negatives, some of which are very good indeed, and well worth the attention of photographers generally, who are interested in enlarging their negatives by a method within the reach of every one. Here are exhibited, side by side, prints from the original negatives, and prints from the enlarged negatives, affording full facilities for comparison.

Amongst some wet collodion specimens, which it seems arrived late, and hence were not placed in their regular order, are some very fine landscapes by A. K. Macdonald. All these are very good, and some very fine indeed. We may especially mention "Castle Acre, Norfolk," a fine old ruin, with overhead an angry-looking sky, giving a peculiarly picturesque effect to the photograph. "At Woolmer, Hants," is another very fine picture; as is also the "Wagoners' Walls, Hants." A photograph of the "Begonia Rex" is a good picture, and an effective example of a photographic difficulty overcome.

Mr. Gladwell sends specimens of a series of very large photographs, by continental artists, amongst whom are Alinari, Cuccioni, and others. The majority of these are magnificent photographs, and many of them of subjects new to the country, and are well worthy of careful examination.

We before omitted to notice, as by far the best card portraits in this Exhibition, three small frames sent by Mr. Hawke, whose pictures we have before noticed in these pages. Round, vigorous, and singularly brilliant, these qualities are obtained without any sacrifice of delicacy or softness. The tone is rich and warm, and the pictures are in every way satisfactory.

Mr. Skaife sends a neat glass case, containing a pistol camera, and a selection of the very charming little photographic gems, which he styles chromo-crystals, as well as some very respectable enlargements on paper, about quarter-size, produced from the miniature glass positives yielded by his waistcoat-pocket camera.

The only contribution in apparatus which has come under our notice is one of the excellent rolling presses of Bury Brothers, of Manchester.

Several other interesting contributions have, we understand, been promised, but have not, as yet, from some cause, made their appearance. Amongst those promised specimens, were a series of Mr. Breese's exquisite stereoscopic transparencies; we shall hope to see them in the Exhibition shortly.

The South London Society's first Exhibition is, as a whole, decidedly a success, with but very few drawbacks: the chief of these is, perhaps, the catalogue, which is scarcely so perfect or correct as might be desired, possibly, from being managed by a committee, instead of one responsible officer, in such matters the old adage relating to too many cooks often proving true. As a whole, however, we congratulate the society on the successful issue of the undertaking.

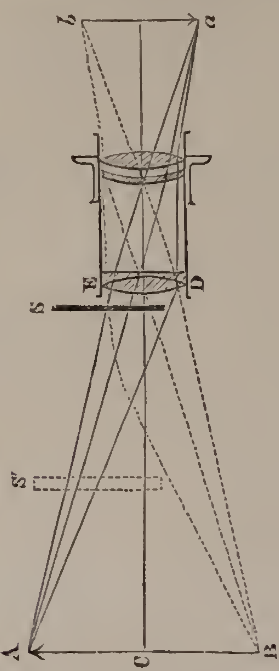
## NEW INSTANTANEOUS SHUTTER.

BY A. MANN, M.A.

So many contrivances have of late been brought before the public for regulating and reducing the time of exposure of the prepared plate in the camera, that, were it not for the great importance now attached to instantaneous photography, some apology might be deemed necessary for again calling attention to this subject. The difference between the so-called instantaneous pictures and those produced by a much longer exposure, both in commercial value and artistic merit, is now inducing the majority of photographers to turn their attention eagerly to this branch of the art, and the question so often asked is, not whether it be worth while to aim at instantaneous results, but how can they best be obtained. For this purpose, in addition to very sensitive chemical preparations, it is important to have a lens capable of being used with a large aperture, so as to admit a considerable amount of light into the camera in a very limited time. The quick-acting lenses, however, now manufactured by the first English opticians, seem admirably adapted to supply the wants of the photographer in this respect; but it occurred to the writer, some time since, that none of the arrangements used for affording the exposure rendered sufficiently available the advantages which these lenses possess. The most common method of giving what is termed an instantaneous exposure is, by removing a plate, or some opaque substance, from before the lens by lifting it up or drawing it to one side, and replacing it as quickly as possible. A little consideration will show that this does not afford the kind of exposure required for the purpose.

On referring to fig. 1, where A B represents an object in front of a double combination lens used with the full aperture, *a b* the image formed in the prepared plate, and S the

Fig. 1.



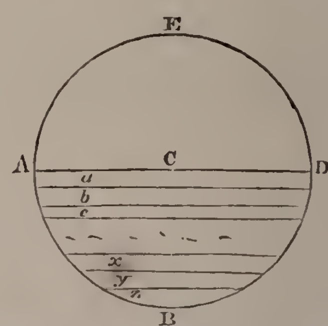
shutter placed just in front of the lens, it will be seen that as soon as the shutter begins to rise, and uncovers the edge of the lens, as represented in the figure at D, part of the rays forming the pencils emanating both from A and B, will enter the lens and be refracted to a focus at *a* and *b* respectively. The same will be the case with the pencils of rays emanating from all intermediate parts of A B; so that as soon as soon as the shutter begins to rise an image is formed over the entire plate, very feeble at first, and confused by the diffraction suffered by the rays in passing through the narrow opening, but gradually getting brighter until the lens is entirely uncovered, when the illumination reaches the maximum. This, however, is no sooner attained than the shutter must again begin to descend, gradually cutting off the light; and on its approaching the edge of the lens, again causing indistinctiness in the image by diffraction. In this way, instead of the requisite amount of light being admitted in the least possible time, a prolonged, partial exposure is obtained. But it is also well known that the effect of an exposure of this kind upon a sensitive plate is different from that produced by the same amount of light admitted in a much shorter time; in the latter case the tendency is to produce an intense and vigorous negative, but in the former a flat and feeble one, and want of intensity is one of the chief difficulties to be contended with in the prosecution of instantaneous photography. These causes, it is true, can only exert an influence for a very short time, but as that is all the time allowed for the formation of the latent image, it becomes a matter of considerable importance to attend to them, the more so as a plate adapted for this kind of work may be entirely spoiled by that which would produce no effect on a less sensitive one. If the shutter be removed to some distance apart of the lens, as indicated at S′, in the figure, it is evident that an excess of exposure may be given to the foreground of a landscape; but the same objection applies, as before, for rapid work, since the field of view will be longer in being entirely cleared. These remarks apply principally to the use of double combination lenses with the stop in a central position, such being now universally used for quick work.

With a view to the obviating of these disadvantages, the writer contrived the new shutter, the properties of which he is now about to describe. This consists essentially of two opaque plates, or membranes (both being used) provided with rectangular openings at a distance from each other equal to that between the lenses. These plates are so placed that each covers up one-half of the lens, and the exposure is afforded by their moving simultaneously in opposite directions in a plane at right angles to the axes of the lenses, which are thus uncovered from the centre outwards, and again covered up from the edges toward the centre by the plates still moving onward. In this way the principal part of the lens remains uncovered from first to last, thereby affording nearly the maximum illumination to the image during the whole time of exposure.

The difference between the amount of light admitted into the camera during an instantaneous exposure by this contrivance, and that admitted by the ordinary one, will become more apparent on comparing the amount which will pass through one-half of a lens when uncovered by a plate sliding from the centre towards the edge, and from the edge towards the centre respectively.

Let A, B, D, E, (fig. 2) represent a lens, and let the half A, B, D, C, be supposed to be divided into any number of parts of equal breadth, and let the areas of these be denoted by the letters $a, b, c, \ldots x, y, z$. These areas will evidently

Fig. 2.



decrease rapidly in size towards B. In the first case, then, when the plate is drawn from C to B, the largest areas, $a, b, c$ will remain entirely uncovered during the time occupied by the plate in passing over all the other areas; but the small areas, $x, y, z$, near the edge, will scarcely remain uncovered any length of time. On the other hand, when the plate moves from B to C, the small areas at the edge are first uncovered, and the largest and most important parts near the centre scarcely remain uncovered for any time at all. Now, as the amount of light admitted in any case must be proportional to the area of the lens exposed, and also to the time it remains exposed, it will be proportional to the product of these. If the respective amounts of light admitted into the camera in these two cases be calculated by the application of mathematical formulæ, they will be found to be very nearly in the proportion of 3 to 2; and since, even in the most perfect lenses, the margin is of less value than an equal area at the centre, we shall not be guilty of any exaggeration, at least in adhering to these numbers.

In uncovering the lens, A, B, D, E, by the new shutter above-described, one limb will descend from C to B during the time (supposing the exposure to be of the same duration in both cases) in which the single shutter rises from B to C, and the amount of light admitted by it in that time will be represented by 3, compared with that admitted by the single shutter as 2; but during the same time the other will have moved up to E, and admitted the same amount of light through the other half of the lens, so that by the time the single shutter will have uncovered one-half of the lens, the other will have uncovered the whole of it, and have admitted thrice as much light in that time. The lens will now remain entirely uncovered by this method during all the time the single shutter is moving from C to E and back, and will be covered up during the time occupied by its descent from C to B, three times as much light being again admitted in that time as with the single shutter. In this way three times as much light will be admitted into the camera during one-half of the time of exposure, and during the other half the lens remains entirely uncovered, while, with the ordinary shutter, the amount of the lens uncovered during that period varies between the half and the whole surface. Combining these two, and taking into account the close proximity of the new shutter to the lens, the respective amounts of light admitted in the two. cases during the exposure will be found to be about as two to one.

When a small central stop is used, it would be advantageous to have the arrangement placed in a central position also; but instantaneous pictures, however, are now being generally taken with nearly, or altogether, the full aperture of the lens. When the objects are situated at nearly equal distances from the lens this is easily effected by the ordinary portrait combination; but fine views are now being taken by Dallmayer's new triplet lenses, with the full aperture, where the definition is perfect, even from the extreme distance to within a few yards of the lens.

Before constructing this shutter, the writer had recourse to a contrivance placed inside the camera, immediately in front of the dark slide, which, by pulling a cord caused a longitudinal aperture to descend in front of the prepared plate, and permitted the maximum power of the lens to act upon the various parts of it in succession for a very short time. There are disadvantages, however, attending the use of this contrivance, which render it available for instantaneous pictures only, and but for a certain class even of them. Suppose, for instance, that this slit be an inch in depth and the plate four inches, then each portion of the plate will be uncovered only one-fourth of the whole time of exposure; and if a large moving object has to be photographed, so as to fill up a considerable portion of the picture, some of the parts will continue to move after others have been impressed, which must lead to distortions and indistinctness of the image. In such a case it will be seen that, by the shutter already described the same amount of exposure may be given in one-third the time, since all the parts of the image are formed simultaneously. The only circumstance in which this is suitable is for an instantaneous sunlight view, comprising a number of small or distant objects, and where a change in their relative position is of no importance.

The most important application, however, of quick photography is to subjects which are not necessarily in motion, but very apt to move, and where the exposure need not be altogether what is understood by the term instantaneous, but may last from one to two or three seconds. For this purpose the writer believes the new shutter will be found very well adapted, as it is concealed from view and entirely under the control of the operator, thus enabling him, by a gentle touch to uncover all the lenses simultaneously (if he uses more than one) at the proper moment, and devoting all his attention to the sitter, to cut off the light the instant any motion is perceptible, as a slight deficiency in the exposure may, to a certain extent, be compensated for in the developing. The shutter may be placed either inside the camera, behind the lenses, or outside, in front of them, in which position it is provided with folding hood, which projects, at pleasure, considerably in front, and acts as a shade. One part of the hood admits of being so used as to give an excess of exposure to the foreground, whenever that is desirable.

The exposure may be effected in several ways, according to the convenience of the operator. One is by gently pulling a string which uncovers the lenses, by causing the plates to glide in opposite directions, and the light may be shut off, by tightening the cord, to make them pass onwards, or by allowing them to return to their former position by a retrograde motion. When extreme rapidity is desired, the plates are first drawn into the proper position by tightening the cord, and are, at the proper time, let loose by twisting a small trigger with the finger, when they flash across the lens, and give the requisite amount of exposure. With this arrangement and sufficient sensitive preparation, especially with the dry process, the use of a stand might be dispensed with, and if a view meter were fixed on the top of the camera, the operator, as soon as a chance presented itself, might take aim and pull the trigger.

Some of the peculiarities of this form of shutter: these are, that it may be applied to cover any number of lenses—is perfectly under control—and affords a convenient mode of uncovering the lenses for ordinary work in the studio; it can be used without any danger of shaking the camera, which is not the case when any rigid body has to be taken hold of for raising the shutter; when used for instantaneous work, it will admit about double the amount of light into the camera that the ordinary form will at the same time, or give an equal exposure in about half the time; or, in other words, produce equal results in that time on preparations about half as sensitive as those required by the ordinary form. By producing a well illuminated image during nearly all the time of exposure, it will assist in counteracting the tendency to feebleness, characteristic of instantaneous negatives. In conclusion, it may not be out of place to mention that the instrument in its varied forms, is patented; but that its manufacture has been undertaken by Mr. Dallmeyer, who is now supplying the public with it, and if it be found to meet the wants for which it is intended, the writer will not consider his labours thrown away.

## THE URANIUM TONING BATH.

We have received the following from Mr. S. Fisher Corlies, of Philadelphia:—

"I have been so much pleased with the use of chloride of uranium in addition to the alkaline toning bath that I send you my formula:

"Make up the toning bath in the usual way, and after allowing it to stand for half an hour, add one drachm of solution of chloride of uranium (one grain to drachm) for every grain of chloride of gold in the bath, and proceed to tone. The prints are softer and of a beautiful colour, and will not change scarcely any in the hypo bath. I have not seen any formula given for its use, and as it is quite popular among operators here, it certainly deserves being generally known."

The reports we have received thus far on the use of *nitrate* of uranium are quite conflicting; we do not consider it fully settled that it is advantageous; we commend the subject to experimenters. Prove all; hold fast that which is good.

Our correspondent is a very high authority, and we do not think he can be deceived; therefore we are inclined to be of the opinion that the *chloride* of uranium is a good thing to put in the toning bath. We hope it will be tested. Many people think that the virtues of the use of this or that chemical in photographic processes, may be accurately determined in advance of trial, on already established principles. But they are in error. Photographic reactions are very subtle; the causes and conditions are too nice for our awkward scrutiny. Thus many questions discussed for years are still undecided, as, for example, the changes of the salts of silver under the action of light, the changes of collodion, etc. Who could tell in advance that iodide of potassium will make plain collodion thin, and iodide of nickel make it thick as jelly. The toning process is especially a knotty subject. Our science is truly lagging far behind our facts. Our progress in good degree is empirical. Yet what science we have we should use; a rush-light is better than a pitchy darkness; our science is more trustworthy than facts which rest on supposition or ignorant observation.

We know something concerning uranium salts which is pertinent to their photographic use. The proto salts are deoxidisers; the per salts are reduced to proto salts under the action of light. All the salts give precipitates with proper reagents, which are of various colours. Uranium salts in their properties are strikingly like the iron salts; what one does it may be expected the other will do. Iron photographs have been made of various colours, so ditto uranium photographs. Proto salts of iron develop collodion pictures; will not proto salts of uranium do the same thing?

Now as to the toning bath. Proto salts of uranium are deoxidising agents, *i.e.*, reducing agents. They should reduce the gold of the toning bath, perhaps make the toning more prompt and more beautiful, and—perhaps prove worthless. If uranium salts prove advantageous, try iron salts as a substitute, etc. What proto salt to use, and how much, must be found out by the practical men.

Thus we have reasoned before, with our little science, at the same time calling upon the careful, practical men with their facts to help us.

Mr Corlies' testimony in the case goes a great way with us; we think it will be confirmed by the experience of others.—*American Journal.*

## Proceedings of Societies.

### Photographic Society of Scotland.

The Sixth Annual General Meeting of this Society was held in the Society's Hall, 51, George Street, on Tuesday, 13th May, 1862, Mr. Walker in the chair.

Professor Macdonald read a paper on the subject of Stereoscopic or Straboscopic vision, in which he explained, assisted by diagrams, how this effect was produced. After referring to the paper of Dr. Carpenter, where it was clearly shown that Mr. Wheatstone had in 1833 constructed a reflecting telescope, and also a prismatic one, and thus was entitled to the credit of having invented the principle of the stereoscope in its modern form, he also referred to a conversation between Sir D. Brewster and an eminent teacher in St. Andrews between 1841 and 1843, where Sir D. Brewster showed the prismatic form was most probably that already proposed by Wheatstone.

Referring to the photographs of Chimenti's drawings, he contended that the slide was really as stereoscopic as the near similarity would admit.

In connexion with this subject, the Honorary Secretary read extracts from a communication addressed by Professor Tait to Sir David Brewster, in which he said that, putting the argument in its feeblest form, in asserting that it is at least 1,000 to 1 that the sketches were designedly drawn as views by separate eyes or a single eye displaced.

The Honorary Secretary then read the following Report by the Council:—

In accordance with the rules of the Society, the Council have to present their Report at the conclusion of the sixth year of its existence.

They regret that it is not in their power on this occasion, as has previously been the case, to offer their congratulations to the Members on the continued progress of the Society.

In common with many kindred institutions, and with the country at large, they have to lament the death of His late R. H. the late Prince Consort, the Patron of the Society. As is known to the Members, it was considered to be the duty of the Society to present an Address of Condolence to Her Majesty.

The Council regret also to have to report that the Monthly Meetings have not been so successful as might have been expected in a Society holding so high a position, and including among its Members so many ardent photographers. The Council are aware that an idea is generally prevalent, and has affected other photographic societies as well as this, that the object for which it was instituted has now, to a large extent, been fulfilled, and that the interest of the Meetings and the usefulness of the Society will be partially nugatory until some new and important discovery is made in one or other of the departments of the art. While admitting that such a discovery would give a great impulse to the art, and necessarily increase the attractiveness of their Meetings, the Council cannot avoid repeating an observation made by them on a previous occasion, that there is ample opportunity for maintaining the interest and success of the Monthly Meetings, in the free and unreserved communication by Members of the results of their investigation and experience in connection with known processes; and they would again urge upon Members to assist them in this way in maintaining the efficiency of the Society.

Looking to the experience of the past year, the Council are disposed to recommend that in the meantime the regular Meetings of the Society should be limited to three, to be held on the second Tuesdays of December, February, and April; and that, in addition to the reading of papers, an effort should be made to add to the attractiveness of the Meetings by the exhibition of works interesting from their novelty or successful manipulation;—the Council having power to call extra Meetings whenever they think it advisable to do so.

As the Society is aware, the Annual Exhibition was opened in Mr. Hay's Fine-Art Saloon, George Street, in December last, and continued open about three months. Like all similar exhibitions, it suffered from the prevailing public depression caused by the lamented death of the Prince Consort, and has resulted in a loss to the Society of about £40.

The Exhibition itself, it is scarcely necessary to remind Members, was one of the best which has been held under the auspices of the Society. On this occasion, three Silver Medals were offered as prizes. For the best portrait or group, the prize was awarded to Mr. D. O. Hill, R.S.A., for his artistic picture of "Dr. John Brown and his Cousin Dr. John Taylor Brown;" for the best frame of six *cartes de visite*, Mr. H. P. Robinson, of Leamington, was the successful competitor; and for the best photograph of any other kind, the Medal was awarded to Mr. Mudd, for his beautiful picture of "The Tay above Dunkeld."

The Council have alluded to one cause of the unsatisfactory result of the Society's last Exhibition, in a pecuniary point of view. They have also for a considerable time been aware that the present place of Exhibition is not well situated for the purpose, and that this operated largely against the success of their Exhibitions. While, therefore, it is very far from their wish to recommend that the Society should discontinue holding their Exhibitions, notwithstanding the loss which has been sustained this year, they would suggest that it should be left to the Council to fix whether or not there should be an Exhibition next year, according as they may succeed in finding rooms better adapted for the purpose, or may otherwise have reason to expect that the Exhibition will not be attended with loss to the Society. In the event of an Exhibition being held, the Council would recommend that the Society's Silver Medal be again offered for the best *portrait* or *group*, and the best *landscape*; and, in addition, that a Medal be given for the best *instantaneous picture*, embracing figures in motion, and of a size not less than 7 inches by 9 inches.

As recommended at the last General Meeting, the Council selected from the Exhibition, and distributed among the Members, a number of valuable photographs. Any Member who may not, from residing in the country or otherwise, have received his copy, will do so, on application to the Honorary Secretary.

As required by the laws of the Society, the President, the Senior Vice-President (Mr. Sheriff Moir), the four senior Members of the Council (Messrs. Scott Elliot, Walker, Kinnear, and Moffat), the Honorary Secretary, and the Honorary Treasurer retire upon this occasion, but are re-eligible.

The Council would suggest that the President, Secretary, and Treasurer be re-elected to their respective offices; and that Mr. Kinnear, who filled the office of Secretary so satisfactorily, be elected a Vice-President; and that the vacancies in the Council be filled up by the re-election of Mr. Elliot, and the election of the Rev. T. D. K. Drummond, Mr. Moir, and Mr. Tunny.

The Treasurer's accounts are herewith submitted to the Society, and a state of the funds is annexed, showing the sum at the Society's credit to be £356 9s. 7d., as compared with £386 18s. 11d. at the close of the preceding year.

After some discussion as to the propriety of reducing the stated Meetings of the Society, it was agreed to leave the matter in the hands of the Council. And,

On the motion of Major Bell, seconded by Professor Macdonald, the Report was unanimously adopted.

On the conclusion of the ordinary business, an exchange of photographs among the Members took place.

*State of the Funds at 1st May, 1862.*

*President.*—Sir David Brewster, K.H., F.R.S., &c.
*Vice-Presidents.*—Horatio Ross, C. G. H. Kinnear.
*Council.*—Alex. Young Herries, T. B. Johnston, J. Ramsay L'Amy, Findley Anderson, Wm. Scott Elliot, Rev. D. T. K. Drummond, George Moir, James Tunny.
*Honorary Treasurer.*—H. G. Watson.
*Honorary Secretary.*—A. F. Adam.
*Honorary Auditor.*—John Cay.

### Manchester Photographic Society.

The ordinary meeting of this Society was held on Wednesday, the 4th ult., 1862, John Parry, Esq., Vice-President, in the chair.

Mr. Consterdine presented two views for the Society's portfolio, and which were interesting as illustrating the process of Messrs. Petschler and Mann. The pictures were much admired; and, although the exposure given for the negatives was considered to be beyond that required for collodio-albumen, the process certainly improved in general estimation.

Mr. WARDLEY remarked that the length of exposure required was, perhaps, due to the condition of the collodion. In the Taupenot process this was not an element that affected the result; but it was otherwise with this, for which a sensitive collodion was required for the most rapid results.

Mr. CONSTERDINE also showed some pictures obtained by the microscopic apparatus, explained by Mr. Parry at a recent meeting of the Society, and the instrument which he had constructed was handed round the room.

The CHAIRMAN showed the last result of his experiments in panoramic photography, with an ordinary view lens. In the negative exhibited to the members the joining of the two pictures could scarcely be perceived. He stated that he was persevering with that method of obtaining pictures, and should be able, he believed, to produce satisfactory specimens at the next meeting, and he would then go fully into the subject. At present he would merely observe that the two pictures were taken with one lens, and that he did not cause them to overlap each other.

Mr. NOTON stated that he had an aceto-nitrate bath, which after it had assumed the brown tint which follows the immersion of albumenized plates, became quite colourless; but upon adding acetic acid it again became discoloured.

Mr. WARDLEY said that the usual bath for the Taupenot process always behaved in that manner when the acetic acid had gone off by evaporation: the more acid that the bath contained the darker would be its colour. Taupenot plates, he added, might be excited in a neutral bath which would retain its purity, but they would not keep.

Mr. OFFER asked whether that plan would not also induce blisters?

Mr. WARDLEY thought not. In reference to blisters, he observed that they might frequently be avoided by increasing the strength of the silver bath.

Mr. NOTON said that during the last cold weather he had been troubled much with blisters.

Mr. WARDLEY said that in all photographic processes great attention should be paid to the temperature of the laboratory, when it fell below 60° difficulties were certain to arise.

Mr. HERBERT had observed that humidity in the atmosphere was a great cause of blisters: he had noticed that steam arising from the hand during the coating of the plate often induced them.

Mr. PETSCHLER said a deposit of moisture must of course take place if the plate were colder than the atmosphere.

Mr. ROGERSON said that photographers were in the habit of holding the plate too near the mouth, and a condensation of moisture was therefore inevitable. He thought it a good plan to warm the plate slightly before coating it with collodion. It was also a common practice to hold the plate at one corner, and there the film was always loose, because the moisture from the thumb prevented the collodion from actual contact with the glass.

It was generally thought that much in photographic operations depended upon the temperature of the room, to which Mr. Rogerson added "and that of the operator."

Mr. PETSCALER exhibited some prints taken from negatives on Dr. Norris's dry plates. The subjects were exceedingly interesting, they being groups of ladies and gentlemen taken during a recent excursion of the members of the Field Naturalists' Society.

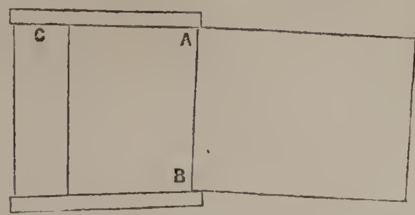
Mr. NOTON said that in working with his double albumen process he had been making some attempts to get iodide of silver into the film by placing it in the albumen previously to coating the plate—his object being to open out the material.

Mr. WARDLEY thought if the thing could be accomplished, without detriment to the picture, that it would not be likely to answer the end in view. He thought that it would rather tend to harden the film.

Votes of thanks having been accorded to Mr. Consterdine and the Chairman, the meeting was brought to a close.—*British Journal.*

# Photographic Notes and Queries.

## A SIMPLE PLATE-HOLDER.



DEAR SIR,—The above is a sketch of a plate-holder of my own invention, which I have found very useful for small plates ¼ or ½-size. If properly made, it will hold the plate quite securely in any position when developing, &c. It may be made of gutta-percha, or wood coated with rosin and wax varnish.

| | |
|---|---|
| Rosin ... ... ... ... ... ... | 4 parts |
| Wax ... ... ... ... ... ... | 3 |

You will see by the above sketch that the thick part of the wood is cut in rather a slanting direction at C, so that the top arm presses firmly on the plate. There is a small place hollowed out at A for the *point* of the plate only, and at B a groove about ½ or ¾ in. long and $\frac{1}{16}$ of an inch deep, just the width of the plate. The arms should be at such a distance than when a plate is put in, the top arm has to be slightly raised, and rests like a spring upon the corner at A, keeping the plate firmly in the groove at B.—Yours most respectfully, D. WARD.

*Manchester, June 21st*, 1862.

P.S.—If made of wood, care must be taken to put a wet plate in after well coating with the hot cement, and whilst the cement is hot, to keep the groove at B, and the round hollow place at A, from being quite filled up. If made well it will hold a plate in the position shown above as firmly as if held in the hand.

# Miscellaneous.

COAL TAR MADE PICTURESQUE.—If coal be regarded as the product of ancient sun-force, then the "light of other days," which has not faded, may be reproduced in colour of every shade and hue. Every one knows that when coal is distilled gas is produced, is carried away and collected, and that among the refuse products of the process is coal, which was formerly sold at a very low price. Coal tar is a very complicated body, and, when carefully distilled, it yields certain volatile fluids, smelling more or less of tar, among which is a naptha called "benzole." Small bottles of benzole are sold for removing grease stains under the name of *benzine collas.* Benzole is next acted on by nitric acid, and by that means changed into nitro-benzole—a liquid having so exactly the smell of the essential oil of bitter almonds that it is substituted for it in the manufacture of almond soaps and of cheap perfumery. When iron filings and acetic acid act upon the nitric benzole it is changed into aniline, and this aniline when acted on by arsenic acid, bichromate of potassium, permangamic acid, stannic chloride, &c., yields a great variety of very beautiful colours. These coal-tar dyes are a characteristic feature of this exhibition. In Perkin's case the visitor will see a cylinder of solid aniline purple, which could easily be carried under the arm. It is worth at least £800, and required for its production the tar obtained from 2,000 tons of coal. It is in tinctorial potentiality equal to 100 miles of calico. Thus are we reminded that death in nature is but new life. Force is, indeed, indestructible; form alone it is which changes. The actual elements caught up from the air millions of years ago, and then quickened into vegetable life by the sun that shone on earlier scenes than Eden, are now delighting the eye and gratifying the taste. The elements of the decayed forests of a pre-Adamite earth are quickened in 1862, and, re-assembling, show that "a thing of beauty is a joy for ever."

## Talk in the Studio.

Saving the Silver.—We have reason to believe that the operation of saving the silver from washing waters, clippings of prints, &c., is much less practised than it might be. It should be remembered, that not more than about ten per cent. of the silver used goes to form the completed picture, and that thus ninety per cent. is wasted, unless precautions be made for its recovery. Mr. S. Fry showed us an ingot the other day weighing upwards of fifteen ounces, for which he received five shillings and two pence an ounce, the produce of washing waters and clippings during two or three months. This did not include developing or fixing solutions. The result is, surely, worth a little trouble. Besides the individual gain, it is a saving, in the gross, to the commercial world, as in the case of waste, so much silver goes, practically, out of existence, and is lost to the world.

South London Photographic Society.—The first out-door meeting of the season will take place on Saturday next, at Hampstead; Jack Straw's Castle being the trysting-place; the hour from one to half-past. We hope the weather will be favourable, when a large attendance may be anticipated.

Requiescat in Pace!—The City of Glasgow Photographic Society, which for upwards of twelve months has been in a languishing condition, is now, we understand, entirely defunct.

Francis Bedford has arrived in England from his Eastern tour, with a large number of very fine negatives.

Marine Glue.—This cement is stated to be made according to the following recipe:—Take one pound of india-rubber, cut into small pieces, and dissolve it in about four gallons of coal-tar naptha; the mixture being well stirred for some time till perfect solution has taken place. After ten or twelve days, when the liquid has acquired the consistence of cream, two parts by weight of shellac are added to one of the liquid. This mixture is put into an iron vessel, having a discharge pipe at the bottom, and heat applied, the whole being kept well stirred. The liquid which flows out of the pipe is spread upon slabs and preserved in the form of plates. When required for use, it is heated in an iron pot to about 248 Fah., and applied hot with a brush.

The Electric Light.—The great advantages of printing by means of this light in winter, have been rendered unavailing to photographers by reason of its costly character. We hope, shortly, to be able to lay before our readers some information regarding a method of forming a cheap and powerful battery, invented by Mr. Fitzgerald, editor of *The Electrician*.

## To Correspondents.

J. P. C.—Much depends on the character of the lens, as to whether it is suitable for enlarging or not. Of course it is desirable to have a very flat field, and the flatter the field, the more perfect the marginal definition. We cannot tell you what you will be able to do with the lens you have; experiment only will inform you on that point. Remember you may be very easily deceived as to the exact amount of marginal definition you actually obtain, from the fact that it is very probable that the original negative often falls off a little to the edges; and that although it may be so slightly as not to excite attention in the original, it will be very palpable in the enlargement. The lens of 4½ inches focus, to which we referred in the article in the Almanac, has a very flat field. Perhaps you may gain something by using the front lens only of your combination for enlarging, stopping it well down. 2. The stereo enclosed is in all photographic qualities very satisfactory indeed.

H. B. B.—Whenever we describe a certain quality of collodion as suitable for a given process, we refer the reader to the formula by which it is produced at the same time. We admit that it may be somewhat tantalizing to those who have no facilities for manufacturing collodion, to refer to such samples, but it is the only course we can pursue. We are only familiar with commercial samples by occasional trial, and cannot speak positively at all times of their qualities, and it would be obviously unfair therefore to dogmatize on the subject, or even recommend any especial maker. That which you refer to as having proved slow, is the one to which we refer as proving slow in our hands. We can only offer suggestions as to those you enumerate, as we have not tried several of them for dry plates; we should give the preference, however, to some one of the first four; perhaps No. 1 will be as likely as any to answer the purpose.

Photos is desired by a correspondent to send us the address of the house at which the orange glass, noticed in our last, as suitable for the dark room, was obtained.

S. J.—You do not state whether you are referring to negatives or glass positives. We presume the latter. The surface reduction to which you refer is really a certain amount of fog, and is not uncommon with certain conditions of chemicals, especially in hot weather. The use of a weaker iron solution, with more acetic acid, is one method of getting rid of it. The addition of a little tincture of iodine to the collodion will sometimes remove it. If these fail, it is probable that the bath is at fault, render it neutral with oxide of silver or carbonate of soda, then sun it, and afterwards acidify properly again. The use of new collodion is often a cause of a similar trouble.

Nemo.—Pure chloride of silver contains a fraction more than three-fourths of its weight (when dry) of pure silver. It will be therefore just three-fourths of the value of pure silver, less the cost of reducing it into the metallic state, which would be but a trifle. We cannot tell you what price you would obtain for it of the refiners. We believe they hesitate to purchase it untried, as it might contain insoluble foreign matter. They prefer to reduce it for a small charge, and hand over to the customer either the silver obtained, or its value as ascertained after reduction. In such case you must trust to their honesty in rendering a correct account.

M. H., M.D.—We are much surprised at the conduct you described, it is utterly indefensible, and if not gross neglect, looks like dishonesty. Regarding the pictures and the process, you do not lose much by not receiving the specimen you have paid for. Judging the process by these specimens we certainly should not recommend it. We should unquestionably recommend the collodio-albumen process in preference, as easier to manipulate, and producing decidedly better results. We are disposed to regard the collodio-albumen process as the best and most certain in result of any of the dry processes. If, however, the tannin and honey prove on further trial as satisfactory as we have hitherto found it, we should give it the preference to any we have tried.

W. H. B.—If the lenses be fixed, without any lateral motion, they may be placed at a distance of from three inches to three and a quarter. The address of Messrs. Hopkin and Williams is New Cavendish Street, Cavendish Square.

Experimentum.—Pure gold leaf is very suitable for converting into chloride of gold. Rub it down first in a mortar, to get it into as small bulk as possible, then pour over it nitric acid 1 part, and hydrochloric acid 2½ parts, water three parts, sufficient to cover it well, and digest with gentle heat. If the whole of the gold be not dissolved in an hour or two, add more of the aqua regia. When all is dissolved, evaporate to dryness over a water bath to get rid of the acid. 2. The grey powder is chloride of silver. It may be reduced to metallic silver by placing in a crucible with twice its weight of equal parts of carbonate and nitrate of potash, and submitting for several hours to a great heat. You may then either sell the silver or convert it into nitrate of silver by digesting it with nitric acid, as described on page 6 of our fifth volume.

G. W. R.—The spots have every appearance of having been caused by the print having been touched with hypo previous to fixation, or with nitrate of silver just after fixation. Gum is the worst substance you can employ for mounting. Use good glue, gelatine, or freshly made starch paste.

A Tanner.—Acetic acid is better than nitric acid in a bath to be used for dry plates.

G. L. Morris.—There are two or three articles on the subject you name, in the numbers published during August and September last. Remember, however, that there is no successful method of turning positives into negatives. That is, if they are good positives they will not become good negatives. A little longer exposure, and more complete development with the iron, are always necessary for a good negative than would have sufficed for a good positive. With a sharp, well detailed, and slightly over-exposed positive, you may proceed thus: moisten the film with water, and then pour over it a solution consisting of one grain of iodine and two grains of iodide of potassium in an ounce of water. After this has remained on a few minutes, wash the plate well; now take a solution of two grains of pyrogallic acid and one grain of citric acid in an ounce of distilled water, to which add a few drops of a 20-grain solution of silver, and proceed to intensify and obtain the right density. You will find full information on modes of intensifying in the Photographic News Almanac for this year.

W. G.—The films of spoiled collodion positives may be saved with the clippings of paper prints, and burnt at some convenient season. The ashes may then be placed in a crucible with a flux, such as borax, or nitrate of potash, and by means of great heat reduced to metallic silver.

F. L. G.—The strength of the fixing solution is varied by different operators. We prefer one ounce of hypo in five of water; but it may be used a little weaker or a little stronger. If it be too weak, imperfect fixation is apt to ensue; if too strong, the tone is too much impoverished. Cyanide is too energetic to serve as a fixing agent for paper prints. 2. The silver may be obtained from old fixing baths of hypo, by precipitating it as a sulphide with liver of sulphur. 3. We cannot form any idea of the size a lens should cover from a statement of the diameter of the lens. It is the focal length which governs the size of the area of definition.

G. U.—If your positive bath contain much nitric acid, it will not give you dense negatives; the image will be thin and grey. The stronger the bath, the more acid it will require, as a general rule, to enable you to work clean.

Verdant Green.—Flatted crown glass answers for glass positives perfectly well. It may be used for negatives also, if proper precautions are taken to avoid breakage of the negative in the pressure frame. The best plan is, to try all glasses intended to be used for negatives, by screwing them down first in the pressure frame. It is better to have a plate of common glass break, than a negative, and the per centage of breakages will not be so large as to make the glass, anything like as costly as patent plate. One side of the glass is generally better than the other, and that should be selected for the collodion film. 2. There are a variety of good cleaning preparations: for new glass alcohol and rotten stone answers very well; if the glass have been used, and especially with iron development, nitric acid should be used for cleaning. Unless a leather have been perfectly cleansed, it is more likely to dirty the plate than to improve it. If the skin have been washed in alcohol, it is then valuable for giving the final polish.

R. G. and Alfred Harman.—Received: notice in our next. Several correspondents in our next.

Advertisements and Communications for the Publisher for the current number, to be addressed to the Office, 32 Paternoster Row, not later than 3 o'clock every Thursday. Post-Office Orders are to be made payable to Mr. Thomas Piper, at the Money-Order Office, St. Martin's-le-Grand.

THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 201.—July 11, 1862.

## THE "PHOTOGRAPHIC TRADE," AND INFALLIBLE DRY PLATES.

On another page we print an interesting article on "Photography for Tourists and Travellers," from the pen of Professor Pole, F.R.S., in which he urges upon tourists and travellers generally the immense accession of interest and value their excursions may derive from the aid of photography. For simplicity and convenience, he recommends the use of a dry process, and shows how a suitable stereoscopic equipment, with a stock of dry plates, may be added to the tourist's luggage, without, to any extent worth naming, increasing his travelling *impedimenta*.

The article is an interesting one, well calculated to augment the usefulness, by increasing the practice, of our art, and we thank Professor Pole for it. In the course of the article, however, the worthy professor makes some remarks which are, we think, scarcely fair, either to his readers or the photographic trade. After pointing out to the tourist that he may, if he choose, become a photographer, without either preparing plates or developing them, by purchasing sensitive dry plates, exposing them, *en route*, according to instructions, and then getting them developed by a competent person on his return, he asks how it is, since the advantages of such a plan are undeniable, that it is not more frequently used? And, he answers, that is simply because "dealers in photographic apparatus have never yet had the enterprize to establish a manufacture and sale of dry prepared plates, in such a way as to insure their popularity;" and, he adds, that this is not from any imperfection or difficulty in dry processes, that "dry plates *can* be made, satisfying all the conditions named," and "might be rendered thoroughly trustworthy." The conditions referred to are, as we glean from preceding remarks, these:—

That they shall keep "long enough" before and after exposure.

That they shall not "fail in sensitiveness."

That they shall not "spoil soon after they are opened."

That they shall be free from "liability to stains, irregularities, blisters, and all sorts of troublesome and annoying defects."

That these conditions are not fulfilled is attributed chiefly to the "indolence and obstinacy of the trade," and it is hinted that there is room to doubt, "whether some dealers may not be obtuse enough even to encourage defects, from the short-sighted notion of increasing the sale." Now, these are very hard words for "photographic dealers" and "the trade." They are hard words, and, we believe, very unjust ones. That photographic rubbish of all kinds may be bought plentifully enough there is no doubt: demand creates supply; and the demand for "cheapness" has, in the photographic trade, as in all others, introduced, we regret to say, sadly too much "cheap and nasty" material into the market; but that this is universally the case, or even the rule, we utterly deny; and we question whether in any trade more amateur enthusiasm, as well as honest commercial enterprise, has been brought to bear upon its products than in the photographic trade. We have always steadfastly opposed this rage for miscalled cheapness; we have condemned it in every form: we fully endorse the remarks of a contributor in another column on this subject; but at the same time we fearlessly aver that good materials of every kind, both in apparatus and chemicals may always be procured, by the exercise of moderate judgment and the payment of a fair price.

All this is by the way, however. We hasten to the chief object of our comments: Professor Pole assures us that dry plates *can* be prepared fulfilling the conditions named. We think we are fairly entitled to ask him to describe the process; this much is, we think, due to his readers. We are fully aware of the value of the various dry collodion processes; we have seen, nay, we have produced, good pictures by all or the majority of the known methods; but we must confess that we do not know any process by which plates can be produced and placed in the hands of inexperienced amateurs which shall then fullfil all the major conditions, to say nothing of entire immunity from "stains, irregularities, blisters, and all sorts of troublesome and annoying defects." Every one who is familiar with photography knows that even the most skilled operator, with the best understood processes, cannot *always* avoid some of those defects. Is it to be supposed then, in regard to dry processes, in regard to which so much both of theory and practice is yet to be learned, plates can be prepared and placed in the hands of persons imperfectly informed, or often careless as to the conditions of keeping, exposure, &c., without, at the same time, inevitably meeting with a large percentage of failures? Perhaps the largest manufactory of dry plates in existence is that of Dr. Hill Norris, at Birmingham. We hear very frequent accounts of the successes obtained with these plates; and we hear occasional accounts of failures; it is quite possible that such failures may be from a variety of causes unavoidable, but we may state a plan which Dr. Norris himself informed us he constantly practised. When complaints arrived of the imperfection of any of the plates sent out, the purchaser was invited to send back a sample of the imperfect plates. so marked that he could identify them again. On such plates it has happened nine times out of ten the purchaser has received back again perfect negatives. This we have ourselves known to be done repeatedly. Professor Pole states that he knows "no maker who will guarantee the sincerity of his wish to make good plates, by consenting to allow for them if they turn out bad ones." The simple offer to do such a thing, would, we fear, be ruinous to any dealer; for whilst it may be fairly affirmed that the failure might probably, in eight times out of ten, be due to carelessness, or incapacity in the operator, it is scarcely to be expected that he would in half of these cases be either conscious of it, or admit it.

The truth is, that there are two or three primary reasons why the preparation of dry plates has not been practised largely as a commercial enterprize. The processes have been uncertain, the plates have not been largely required, and their manufacture has often been unremunerative and unsatisfactory.

That some uncertainty as to results must exist where the rationale is imperfectly understood, needs scarcely to be affirmed.

That, in an art like photography, where the difficulties to be overcome are amongst its chief charms to a large class of amateurs, the demand for ready prepared should not be large can be well understood. To an Englishman, at least, the prospect of difficulty is generally very seductive. To the knight errant of old, if danger were added to the difficulty, the temptation was irresistible:—

"For if a pass were dangerous known
The danger's self were lure alone."

It is scarcely less so in the present day; the danger and difficulty form no small item in the giving the zest to an ascent up the most steep Alpine crags, or in riding across country after the hounds, in deer-stalking, yachting, and a score of other pursuits. In a modified degree the same pleasure is felt in the overcoming the troubles of photography; there is a keen satisfaction in running a persistent difficulty to earth, or getting the weather side of an obstacle. Many an enthusiastic photographer would not thank you for the pleasure of exposing a plate if he had not prepared it, still less if he could not secure the satisfaction of developing it, as there is, perhaps, no greater pleasure in photography, than to witness the gradual birth and progress of the image in a series of negatives after an excursion. To the tourist who simply requires a record of the scenes he has visited, and cares nothing for the *modus operandi* of producing them, nothing can be more desirable or legitimate than prepared plates ready for use; but of these the number has not hitherto been sufficiently large to cause a very large demand, or render the extensive preparation of such plates an important branch of the trade.

Hitherto the preparation of such plates has not been, generally, a very remunerative or satisfactory undertaking. We remember, less than twelve months ago, having some conversation on this subject with, unquestionably, the ablest dry-plate photographer in this country, or indeed, we may say, without hesitation, the ablest in the world. He had at one time been in the habit of preparing plates for sale; his process was the most certain of all dry processes—the collodio-albumen: his plates, in his own hands, were absolutely certain, or as nearly so as possible. But he could not guarantee that they would be so in other hands; and he finally gave up the practice of preparing plates for sale, as it afforded neither satisfaction nor profit.

We may remark, in conclusion, that we shall be glad to know the process which Professor Pole has found most successful, and we think we can assure him, from our knowledge of the photographic world, and the amount of enterprize in it, that when the demand for prepared plates becomes increased, it will be met with a supply as perfect in quality as the present knowledge of the art will permit to be produced. As to the boon dry-plate photography offers to the tourist, we cordially agree with him, and trust that his advocacy will secure a large accession to the photographic ranks.

## REMARKS UPON SOME OF THE APPARATUS EMPLOYED IN PHOTOGRAPHY.*

BY F. R. WINDOW.

The apparatus and instruments which I have reviewed in the preceding articles, form but a portion of those employed by the photographer; and it was my intention to have carried out the series to greater completeness before bringing it to a close; but a press of private occupation intervening, I am prevented, at least for the present, from extending these "Remarks" beyond the present number. At an early period I hope to be able to resume my half completed task, and examine some of the minor items of the apparatus which we use in our art.

There is one subject, however, upon which I am unwilling to postpone my observations, for although it does not come properly under the heading of photographic apparatus, it concerns it too closely to be passed by without mention. I refer to the unfortunate mania for *cheapness* which has so fatally obtained in all things photographic.

Cheapness is the bane of the photographer. It has done more to produce failure and disgust in this beautiful art, I believe, than all other causes combined, and I regret to perceive that the evil is daily progressing. Photographers have cheapness thrust upon them in every stage of their operations, to the detriment of their productions, and in the greater number of instances, the remedy is beyond their reach. At the same time it is extremely difficult to know upon whom to fix the blame. A respectable dealer may sell worthless articles, sometimes from being practically unacquainted with their nature and use, and through placing confidence in the manufacturers who supply him with them. Manufacturers again are generally ignorant of the details of the practice of photography, and their endeavours are less directed to the production of something better than what is made by others, than to the supply of something cheaper, with little regard to its real comparative value. With respect to the manufacturers of chemicals who deliver adulterated specimens under the name of pure salts, the plea of ignorance cannot be urged, as they must be perfectly aware of the nature of the goods they make. Yet we all know the difficulty there is in obtaining pure photographic chemicals. In this case, again, the mere dealer is not *necessarily* to blame for supplying impure chemicals, as he may have bought them in good faith for what they profess to be.

Be the blame, however, where it may, the competition in every branch of the photographic market is now become such, each vendor trying not to excel, but to undersell his competitors, that in many localities good things are not to be bought at all, even by the photographer willing to pay a proper price for them, while the commoner goods are everywhere in plenty. It is also a thing to be borne in mind that both manufacturer and seller generally reap a larger profit upon common cheap goods than is to be obtained on those of a higher class, and therefore, it is frequently their interest to push on the unwary purchaser the cheaper article in preference to the dearer one.

It is a very difficult matter to suggest a remedy for such a state of things, as at the very outset one is met by the fact that photographers are most frequently not in a position to decide for themselves upon the positive goodness, or otherwise, of their apparatus and chemicals. Many photographers are not sufficiently mechanicians to decide upon the workmanship of their apparatus, and to such, a brilliant coat of French polish will hide bad work. Still fewer photographers are familiar enough with chemical manipulations to be able to decide upon the purity of the chemicals which they buy; therefore, in either case they are likely to be led by advertisements, which may either set forth truly the value of the wares, or be simply mendacious puffs. Unfortunately, the chances are nearly equal.

It would be very unwise to counsel the photographer, in the absence of more direct knowledge to guide him in his purchases, to eschew entirely articles because they may be cheap, as this advice would be directly opposed to the spirit of the age. But I would recommend him never to buy a thing *because* it is cheap; to purchase his goods only of tradesmen upon whom he believes he can rely, and who have a reputation to lose (fortunately there are plenty of such); and lastly, before deciding upon the purchase of any article, cheaper than can be had elsewhere of an apparently similar quality, to carefully ascertain whether the real thing can be manufactured and sold profitably for the price asked. For instance, in nitrate of silver there is 64 per cent. of the pure metal, which, at 5 shillings and 2 pence per ounce, which is a fair commercial price for pure silver, makes 3 shillings and 3 pence halfpenny worth of metallic silver alone, in every ounce of the nitrate. To this has to be added the expense of manufacture, together with the manufacturer's and the retailer's profits: therefore, if we find the nitrate sold for 3 shillings and 4 pence per ounce, as it sometimes is, we may fairly conclude that its purity is doubtful.

I make the preceding observations with the certainty that they will not be misinterpreted. The many respectable and trustworthy houses which use their best endeavours to supply photographers with really good things at remunerative prices, will gain by being distinguished from those who are less scrupulous, and I imagine it is only these latter who will be inclined to cavil at my remarks.

* Concluded from p. 243.

## Scientific Gossip.

Discovery of New Metals in the Sun, Calcium, Aluminium, and Magnesium—Identification of Frauenhofer's Lines—Igniting Point of Coal Gas.

Since we last reported on the subject of the solar spectrum, some very interesting as well as important researches have been published by Angström which led to some further conclusions respecting the composition of the solar photosphere. It may, he considers, be taken for granted that the Frauenhofer lines for the most part originate in the sun's photosphere, or the gaseous envelope that immediately surrounds that body. As an objection to this hypothesis, it has been urged that the lines in that case ought to appear stronger and more distinct when the rays come from the centre of the disc. According to an oft quoted observation of Professor Forbes this has not been thought correct. Forbes' observation, however, took place during the occurrence of a solar eclipse, under which circumstances it would be very difficult to preserve the appearance of the spectrum accurately in the memory. Angström therefore considered that the experiment was worth repeating. He used for this purpose an optical theodolite with two telescopes, one of which was furnished with a slit-opening to admit the sunlight. The height of this aperture was reduced very considerably, and the sun's image was projected upon it from a Dolland object glass of about ten feet focus. The diameter of the image thus formed was about an inch: and by allowing the rays from different parts of this image to fall successively upon the opening, it was easy to see whether the Frauenhofer lines underwent any change. No very remarkable difference was perceptible; all that could be noticed was, that the intensity of the spectrum light is somewhat less when the ray comes from the edge than when from the centre of the disc; this being evidenced by the circumstance that the fainter Frauenhofer lines show themselves in the latter case comparatively stronger, whereas when the light comes from the centre of the solar disc, the fainter lines will sometimes even totally disappear, while the stronger lines, some of the iron lines for example, appear with correspondingly increased brilliancy: this observation is not repugnant to what we already know concerning the absorbing power of gases, and does not, therefore, militate against the hypothesis of the metallic composition of the sun's atmosphere. Angström has verified Kirchhoff's statements respecting the coincidence between the lines of iron, magnesium, nickel, and the chromium, and corresponding ones in the sun's spectrum. The iron lines identified by Angström are not quite so numerous as affirmed by Kirchhoff but are quite sufficient to establish beyond a doubt the presence of iron in the solar atmosphere. These lines are the most characteristic in the whole solar spectrum: and if a sufficient magnifying power be employed, or the light be refracted through more than one prism, the stronger ones among them appear perfectly black.

It has been further remarked, that the lines belonging to the air or to the gas through which the electric spark passes when working with an induction coil, are less distinct, and wider, in proportion as the strength of the electricity is increased; whereas, the lines belonging to metals, especially when somewhat refractory, like iron, remain perfectly sharp under these circumstances. The metal lines may also be distinguished, in some measure, in the solar spectrum, when examined with adequate magnifying power; with moderate power, certain lines appear somewhat prominent, and imbedded, as it were, in a mass of fine lines, which, upon the application of increased illumination, appear to withdraw themselves, and disappear, while the first-mentioned lines, on the contrary, only stand out in stronger relief. These are metal lines, and the most remarkable among them almost invariably belong to iron. Thus, between H and G we have fifteen stronger iron-lines, all having their counterparts in the solar spectrum. The two strongest of these lie $\frac{1}{4}$ and $\frac{3}{4}$ of the distance between H and G, and that nearest to G is double, as belonging also to calcium. Moreover, at G, and in its immediate neighbourhood towards F, we have five strong, besides eight fainter lines; at F, again, five; and lastly, around E, a numerous group, all answering to dark lines in the solar spectrum. An additional fact is also given respecting magnesium; the third of the lines, marked *b*, reckoning towards F, is double, and belongs, accordingly, both to magnesium and iron. The existence of four bodies in the sun has been shown by Kirchhoff; and to these, Angström now proposes to add calcium, aluminium, and manganese, and also, in all probability, strontium and barium. *Calcium* has three strong lines at the violet end of the spectrum, of which two are especially remarkable as being identical with the well known pair of lines H, and the third in order forms, with one of the iron lines, the strong double line mentioned above. Calcium has also several lines in other parts of the spectrum, all of which have their counterparts in that of solar light. *Aluminium* is also characterized by two strong lines lying between the H lines of the solar spectrum, and there corresponding to two dark lines. Manganese gives a spectrum which very much resembles that of iron; the different groups between G and H, and thirteen manganese lines between G and F, closely approach similar ones in the iron spectrum, and are also identical with corresponding lines of the solar spectrum. Strontium has two strong lines between F and G, which apparently correspond to solar lines, and this also seems to be the case with the line F. It must, however, be mentioned, that the presence of strontium in the sun is very uncertain, owing to the very brilliant blue line which this metal shows between F and G, having no corresponding line in the solar spectrum. Barium has four lines between F and D, which seem to have their counterparts in the solar spectrum; this also requires confirmation.

To give in a general view the principal coincidences between the Frauenhofer lines and those in the artificial metallic spectra, we have the following general view:—

| | | | |
|---|---|---|---|
| The line | B | belongs to | potassium. |
| ,, | C | ,, | hydrogen. |
| ,, | D | ,, | sodium. |
| ,, | B | ,, | magnesium and iron. |
| ,, | F | ,, | strontium and iron (uncertain). |
| ,, | G | ,, | iron. |
| The 2 lines | H | ,, | calcium. |

The remainder of Angström's paper goes into theoretical and mathematical discussions on the theory of the reciprocity of radiation and absorption, and of the theory of thermometric heat, those of our readers who care to pursue this interesting subject in its further details, will do well to refer to the entire paper which will be found at length in this month's number of the *Philosophical Magazine*.

Some interesting experiments have been lately tried by Dr. Frankland on the temperature at which coal gas ignites. The heterogeneous mixture of gases and vapour known as coal gas may for this purpose be assumed to consist of—olefiant gas and other luminiferous hydro-carbons, light carburetted hydrogen or fire damp, hydrogen, carbonic oxide, and bi-sulphide of carbon, as under certain circumstances these gases can become separated to some extent, it was thought advisable to examine separately their respective igniting points. Olefiant gas required to inflame it, the heat of an iron which appeared of a cherry red colour in diffused daylight. Light carburetted hydrogen can be inflamed by white shot sparkling iron, but not by iron at a red heat; it is, therefore, less inflammable than hydrogen, carbonic oxide, or olefiant gas. Hydrogen requires for its ignition, an iron heated to a temperature beyond visible redness in a tolerably well lighted room. Carbonic oxide inflames at a little higher temperature that that required to set fire to hydrogen. Bisulphide of carbon vapour was found to ignite at as low a temperature as 300° F. Owing to the law of the diffusion of gases, these several constituents of of coal gas, would diffuse into the atmosphere through leakage or any large opening in the pipe, with different velocities, and thus it is possible that when gas is escaping into a room, the mixture may have different igniting points, close to, and at some distance from the pipe. A great many experiments were tried by Dr. Frankland on the igniting points of different mixtures of the gases: thus, a mixture of carbonic oxide with about three per cent of bisulphide of carbon vapour, issuing from a jet into the air was readily ignited on the approach of a glass tube containing oil heated to 410° F.; hydrogen and bisulphide of carbon igniting when the temperature of the oil tube was 420°. Fortunately, however, it was found that the presence of a minute trace of olefiant gas, instantly raised the igniting point of the mixture, and neutralized the ill effects of the bisulphide of carbon. The Doctor therefore concludes that under the most favourable circumstances, coal gas cannot be inflamed at a temperature below that necessary to render iron perceptibly red hot by daylight, in a well lighted room; this high igniting point being due to the presence of olefiant gas and other similar hydro-carbons. A mixture of coal gas and air is however more easily ignited than the explosive mixtures in coal mines, and therefore the safety lamp in ordinary use in mines is not considered safe in a mixture of coal gas and air; this latter being also readily inflamed by sparks struck from metal or stone. Thus, an explosion may arise from the blow of a tool of a workman against iron or stone, from the tramp of a horse upon pavement &c.

# The International Exhibition.

## PHOTOGRAPHIC CHEMICALS.

One of the most important chemical manufactures of the country, and one also which is indirectly of the utmost importance to photographers, is that of soda. The process of preparing the pure caustic alkali from sea salt is a triumph of scientific ingenuity, and is well illustrated in many cases in the British chemical department. Leblanc's process for making carbonate of soda is scarcely of sufficient interest to our readers to merit a detailed account; but we will just glance at the principal operations as a preliminary to the manufacture of caustic soda, which is an entirely novel branch of manufacture, and one which, before long, will be of considerable importance for household and manufacturing purposes.

Sea salt or chloride of sodium is first of all to be converted into sulphate of soda. For this purpose it is necessary to have large quantities of sulphuric acid, and as this is not an article which can be carried about safely, it is always prepared at the soda works. Either pyrites (bisulphide of iron) or sulphur is burned in a furnace with proper arrangement for oxydizing the resulting sulphurous acid into sulphuric acid, which is condensed in enormous leaden chambers, the bottoms of which are covered with water. This acid is then allowed to act on the salt, when hydrochloric is evolved and sulphate of soda is produced. The crude sulphate is then mixed with coal and chalk, and the whole heated together in large reverberatory furnaces, when the so-called black ash is produced. This is exhausted with water and yields a solution containing considerable quantities of caustic soda. The old process was to convert this by successive steps into carbonate of soda, but now caustic soda is prepared in a great measure from it. The crude alkali has lately been converted into an almost absolutely pure product by a very ingenious plan, carried out by Dr. Pauli, of the Union Alkali Works, St. Helen's. He takes the commercial caustic soda, in quantities of about three tons at a time, containing excess of water, alumina, and all the impurities which commonly occur in this substance, and fuses them in a cast iron pot. During the evaporation nearly all the carbonate, and by far the larger quantity of the other salts separate out on the surface as a scum, and can be easily removed. The liquid mass is then heated to dull redness, and kept at that temperature during the night. In the morning the mass appears perfectly transparent, the sides and bottom of the vessel being coated with cauliflower-shaped masses of crystals, consisting of silicate of alumina, with chloride and sulphate of sodium, and a little lime. The clear fused liquid is ladled off from these crystals, and when cooled is ready for use. The soda prepared in this way is perfectly free from alumina; a small quantity of the soda was fused in a platinum crucible and some pure alumina added. This remained undissolved in the fused mass, swimming about like a precipitate in the red hot liquid. On cooling, water was added to this fused mass, and the alumina was found to dissolve completely. If the commercial soda contains oxide of iron, this also separates out completely during the process of fusion. Lime, on the other hand, is dissolved in large quantities by the caustic soda, but it is completely separated by solution in water. The caustic soda prepared in this way is hard and brittle, and can easily be obtained as a fine powder by attrition in an iron mortar. It contains only a trace of carbonate of soda.

We have devoted more space than we intended to a description of this body, but it is before long destined to play an important part in many manufactures, and will prove an invaluable adjunct to the photographic laboratory, for neutralising acidity in the bath or other solutions, which it will do in a manner at once certain and unexceptionable. The great difficulty has hitherto been to get it pure; now this is accomplished, its uses will be manifold.

## BRITISH PHOTOGRAPHIC DEPARTMENT.

The contributions of coloured photographs to the Exhibition do not call for extended notice, especially in a photographic point of view. Such interest as the coloured portion of the Exhibition did possess is now materially diminished. The majority of the contributors concerned have taken our hint as to the dampness and removed their pictures. Almost all the water-coloured specimens are gone; some also of the yellow and fading plain pictures have been removed, so that bare walls in many cases meet the eye instead of photographs. The most noticeable coloured pictures, or certainly those which will attract the most attention, are the coloured enlargements of M. Claudet. Strictly speaking, these are not photographs at all, that is, they are not drawings by light. M. Claudet recently described the method by which they are produced by projecting the image of a small negative on to canvas by the aid of a solar camera and artificial light, and then tracing the principal features on the canvas by means of a crayon. The general outline, chief shadows, &c., are thus secured in their due proportion as a basis for the further operation of the skilled painter, who is further aided by a print from the small negative to serve as a guide. We know that exception has been taken to the presence of these pictures amongst photographs; but we scarcely think the exception is just. They are at least valuable applications of photography; they are produced from small photographic negatives, and the enlarged image is produced by photographic appliances. As the final image is not produced by the chemical action of light, they are not, as we have just said, in the strict sense of the word, photographs; but they are so nearly related to the art, and the result of such an interesting and valuable application of it to the purposes of portrait painting, that we think there is no more legitimate place for them than the photographic department; and it must be distinctly remembered that they are not put forward as photographs, but the method by which they are produced is described. Some of those exhibited are very admirably painted, and excellent likenesses. The portrait of Mr. Chance, of Birmingham, is a very fine piece of painting, vigorous and forcible, yet, withal, quiet and low in tone, free from the laboured smoothness of finish which is generally known as "tea-boardiness." Several other of M. Claudet's pictures, both enlargements and those taken direct, are exceedingly well painted. Whilst referring to the productions of M. Claudet, we may call attention to a couple of his pictures which have recently been added to the French department. These consist of two large groups, taken direct, one consisting of portraits of the secretaries of the English and French Photographic Societies, Dr. Diamond and M. Laulerie; and the other of five persons, the jurors of Class XIV, Photography. Both these pictures are admirable, and are as fine specimens of photographic portraiture as are to be found in the Exhibition. The photography leaves nothing to be desired; the composition is good; the tone is rich; the images are round, soft, vigorous, and well defined. The likenesses are also admirable. Those in the group of two are perfect in this respect, and full of character. We commend visitors to see those pictures, both for the interest of the subjects, and the excellence of the photography.

Mr. Kilburn, or rather his successor in his name, contributes some very good specimens coloured in oil, and some which are styled "demi-tinted" in water-colours, which are almost as bad as possible.

Mr. T. R. Williams exhibits some of the finest oil-coloured specimens in the department; true and natural in colour, they give both the hue and the texture of flesh; the colouring is indeed well worthy of the photographs, and that is saying a great deal. We must except, however, two specimens apparently coloured by another hand, the portraits of "A Lady and Child," and of "A Highlander;" these are cold and crude, and certainly, to our taste, inferior to the rest of Mr. Williams's contributions. A tinted enlarged portrait by Mr. Williams is hung too high for criticism, but it appears very good. Mr. Brothers of Manchester exhibits a coloured photograph on ivory, which is very good, and a large coloured group, which, so far as we can see at the height at which it is hung, is also very good. Messrs. McLean and Melhuish exhibit a frame of coloured miniatures, which are also hung too high for careful examination, but they appear very perfect indeed, and have all the character of ivory. M. Bassano exhibits a large coloured group of officers which has very little art, and is thoroughly unsatisfactory as a picture. Mr. T. Price has some very good miniatures in oil. Mr. Bowers has one or two very good coloured enlargements. Messrs. Smyth and Blanchard have a coloured solar camera picture, which is far inferior to their uncoloured work. Messrs. Gush and Ferguson, Mr. E. Sutton, and Messrs. Lock and Whitfield have some very carefully coloured miniatures, but with the majority of which visitors to former exhibitions are familiar; they have many beauties, but are marred by some exaggerations in drawing. The latter firm exhibit a very fine life-sized head of a child; this is well painted, and a very charming picture. Mr. Mayall exhibits a few coloured specimens, some of which are good, but none of which we think are equal to his best plain untouched pictures. We regret to observe a growing tendency in photographic colourists, of which this Exhibition furnishes many examples, to the production of mere prettiness, to the entire sacrifice of all true art qualities; transparency, solidity, and the sober quietness of nature are sacrificed for the purpose of obtaining a brilliant display of colour, and that smoothness and miscalled "finish" which is destructive of all texture, vigour, or appearance of life. This arises, doubtless, in good artists, from the habit of constantly painting according to "descriptive particulars," instead of from life; inferior artists will follow bad examples; and in addition to this, we fear that too often the public desire and patronize this "pretty," but unnatural style of colouring.

The colouring of photographic landscapes has from some cause never received much attention or favour. How far it might be done successfully by good artists, we cannot tell; but we doubt if the result would ever be worth the pains it would require, if done properly. Certain it is that most exhibited attempts have been failures; of all the vile things of the kind, however, we have never seen anything worse than the "Views coloured in Tempera and Bistre," exhibited by Mr. Poulton, the photographs are spoiled without anything approaching in the remotest degree to art having been obtained; the result is coarse and gaudy, inferior to our taste to the commonest coloured engravings.

We append one or two extracts from the criticisms of the daily press on photography. The opinions of the outside press are always more or less valuable as fairly representing the opinions of the general public. The article in the *Daily News*, which we give first is in the main thoroughly just, and appreciative. The incongruity of the classification is shown in a forcible light by the heading appended to the article being simply thus:—

"Machinery: Photography." After this heading comes the criticisms on pictures, premised, however, by a few trenchant remarks on the classification:—

"It is very evident that at some period of their existence, the powers that be at South Kensington have been made the distorted victims of some incompetent photographer, for the incessant war that Her Majesty's Commissioners have never ceased to wage against the votaries of the camera plainly indicates a grievous wrong done on one side, only to be wiped out by the most implacable revenge on the other. They commence by classifying photographs amongst machinery, because, forsooth, a camera is a philosophical instrument, a principle which, if carried out, would place lithographs in Class 1 amongst stones, and engineering in Class 31 with copper-plates. A very fierce opposition to this sapient decision was immediately raised, photographers from all parts of the kingdom uniting in protesting against the arrangement. But the opposition was useless, the only result being an enormous mass of official correspondence, all sound and fury signifying nothing. Having insulted the new art by a false classification, the next thing was to burke its display by hiding it from the public. It was accordingly placed in a lofty, though cheerful garret, called the Central Tower, far above the high struggling mark of even the soundest winded visitors. To further degrade it, the Commissioners mixed it up with toys. What, in the name of Cremer, photography has done to be placed side by side with baby jumpers, wax dolls, and other appliances for the improvement of the infantile mind, we do not undertake to determine—we only know that in our opinion the union seems to be at least incongruous.

"Had the search for this attic been ten times as long, and the stairs twenty times as many, we should have been fully repaid for our exertions by the splendid display of photographs of all kinds contributed under the depressing influence of an unjust classification. In spite of their first determination not to exhibit, the best houses have come forward with their best works, determined to show to the world that a photographer is not a mechanician, and that photography is something more than a manufacture. It is at all times a most difficult thing to criticise photographs. There are so many influences at work which may destroy at any moment the result of unceasing pains and educated skill, that the photographic critic is continually in danger of blaming the photographer for shortcomings utterly beyond human control. There is, too, great difficulty in viewing photographs from a medium point just between manipulatory excellence on one side, and natural beauty on the other. The photographs exhibited are, perhaps, the best collection ever brought together, numbering nearly one thousand frames, containing works by all the best photographers, very few of which are below mediocrity. They fall naturally into four divisions—portraits, landscapes, reproductions, and scientific photographs.

"We would warn our readers that the list of exhibitors contained in the ordinary shilling catalogue is useless, and advise every one to procure the detailed catalogue published by Trounce, and sold in the room, the numbers given in it being made use of in the following remarks.

"Commencing at the south-west corner of the room, the first frame of portraits we come to is a collection of studies by an old public favourite, Mr. O. G. Rejlander (2), which are placed so far out of the line that it would be unjust to criticise them rigorously. From the distance, they appear to be worthy specimens of manipulatory skill and artistic humour. J. B. Dancer (17, 18) exhibits two frames of what appear to be microscopic portraits; but as there is no means of viewing them, nothing can be said about them. R. F. Barnes (33). This gentleman sends portraits of several musical celebrities, but they appear to be coarser than most of his former productions. Ross and Thomson (34, 35) contribute two frames of excellent portraits, which are, however, much diminished in merit by the backgrounds being generally much too dark. These two frames are very good illustrations of the great difference in type between English and Scottish physiognomy. On the south-east screen (732) is another frame of portraits, from the same artists, containing some very meritorious efforts in artistic grouping. The heads of the sitters are, however, generally too large. T. R. Williams (49-52, 55-57, 166, 399-404, 414, 821-829, 835) sends a number of exquisite vignettes in his well-known style. It appears to be now generally allowed that vignettes are the most artistic of all photographs. The reason of this no doubt is that a greater amount of artistic feeling is requisite to procure a good result by shading off the background exactly in the proper place and with the right amount of gradation. The productions of Mr. Williams are, as a whole, the best portraits in the exhibition. John and Charles Watkins (58-60, 64-66) exhibit six frames of first-rate portraits, the *cartes de visite* being the best in the exhibition. These gentlemen excel in placing their sitters in a characteristic position, generally with one or two well-disposed accessories. The lighting, too, of their pictures is excellently managed, the head of the sitter being the most brilliant portion of the picture, the other parts being illuminated distinctly but feebly. Apropos of these very beautiful little works of art—we see a great tendency in other photographers to use backgrounds, more or less badly painted, on which are depicted in the worst taste the pillar, curtain, balustrade, and gathering storm of the ancient La Creevy school of art. This is surely a retrogression. A photograph, to be an artistic production, needs no extraneous aid in the way of bad scene-painting; and we point to the *cartes de visite* sent by Messrs. Watkins as the best proof that we are right in our notions. Herbert Watkins (24, 85, 96, 135) sends a frame of portraits of Ristori, in eighteen or twenty of her dramatic creations. The photographs are all that could be desired in the way of artistic treatment, but the effect is marred by the absence of spontaneity in the position and expression of the actress. This must always be the case in photographing expression, dramatic effect consisting in the very instantaneity of the movement.

"H. P. Robinson (128-132, 142, 572, 594, 595, 703). The productions of Mr. Robinson are always pleasing from the amount of beauty always contained in his pictures. They are, as our readeas are no doubt aware, subject pictures, made up in a very ingenious manner from several different negatives. "The Top of the Hill" (128), is simple and good, the action of the girl being extremely natural. "The Holiday in the Wood" (131), with its bevy of children enjoying themselves to their heart's content, is too well known to need description. The greatest effort yet made by Mr. Robinson is "The Lady of Shallot" (132). She that "floated down to Camelot" is a very beautiful girl, (well known to us through "Fading away," and other of Mr. Robinson's productions), lying, with dishevelled hair in a boat, that barely ripples the surface of the black stream down which it is gliding. The scene is laid in early spring, and the calmness of the surrounding landscape appears to indicate that the time is evening—a supposition borne out by a strong side light that falls in a magical manner on a willow on the opposite shore. This picture is the best of Mr. Robinson's works, and will, we hope, bring him the fame he deserves.

"Mayall (152, 153) exhibits two frames of portraits in which the photograph is quite hidden by the black and white touches added by the artists. This gentleman's show is by no means what it should be; he should either have not exhibited at all, or have sent specimens worthy of his established reputation. The same remark applies to Kilburn, Mayer Brothers, and one or two more, whose success has no doubt rendered them somewhat careless of fame. Mr. H. N. King, of Bath, sends a large number of theatrical portraits, which would be much better with plain backgrounds. It is really a pity to see good pictures spoiled by ill-painted scenery introduced. Maull and Polyblank exhibit a number of large portraits of celebrated men, which, but for a certain uncomfortable air which they all possess, would be entitled to a foremost place. C. Wright (151) sends a number of portraits with very spotty backgrounds. The general treatment of these photographs appears to indicate that Mr. Wright has great artistic ability; but why should he mar the effect of good work by careless manipulation? A very characteristic group of "Young Toole" and "Old Paul" is exhibited by Mr. C. T. Newcombe (171). He also sends some excellent *cartes de visite*. T. H. Hunnah, 182, 183, 201, 202, 415-422. These are the best plain portraits in the exhibition. To say at once that everything in them is good, is the best criticism to give them. In general treatment, in position, in lighting, in printing even in mounting and framing, they are worthy of the imitation of every photographer. Joubert exhibits some charming little *cartes de visite*, the effect of which is entirely marred by the slovenly way in which they are mounted in a very shabby frame.

"There are several enlarged portraits exhibited by A. Claudet, but they cannot be called anything more than successful attempts. Enlarged photographs are, in our opinion, a great mistake. It is not the province of photography to supersede the crayon or the life-size canvas. There are many other portraits that we cannot notice from want of space. Our readers must not therefore suppose that silence is necessarily indicative of censure.

"The coloured portraits are numerous, and for the most part good. Foremost in excellence are those of Messrs. Lock and Whitfield. These gentlemen certainly have succeeded in collecting together, in one frame, an amount of female and infantine beauty rarely seen. Having such models to work upon, and being, as they undoubtebly are, our best photographic colourists, the result could not be otherwise than super-excellent. Next come the very beautiful propuctions of Mr. Williams, 821-829, which consist principally of vignetted heads, charmingly coloured in oil. The rest of the display is made up by Messrs. Claudet, Heath and Beau, Kilburn, and Mayer Brothers, whose productions are well known to the public. There is a large coloured group of officers, which has received a place to which it is certainly not entitled. It is a large group of military men, made up from a number of negatives, taken at differeut times and under different conditions of light. The colouring is very bad, and the officers appear to have no connection with each other; in fact it reminds one strongly of the well-known plates in 'Le Follet,' and other books of tailoring art. There are several frames of guarantors' portraits, about which the less that is said the better. M. Claudet contributes a stand of daguerreotype stereoscopic portraits, which come back to one like a dream of ancient days."

Some other extracts from the daily press, and comments thereon, are compelled to stand over to our next.

## DECOMPOSITION IN COLLODION.

BY M. AUG. TESTELIN.*

We have often remarked that crystallizations of a peculiar kind are produced in collodion whenever we introduce into it slips of metal, the rough surfaces of which present salient angles and asperities, upon which these crystals, of an

* Continued from p. 306.

elongated prismatic form, preferably deposit themselves, and finally completely cover them.

We believe that this body is an isomeric modification of aldehyde, known under the name of metaldehyde. For the analogy of the characteristics we have remarked completely confirm this opinion. Thus, the formation of the crystals of metaldehyde is greatly favoured by the asperities of metallic fragments, such as zinc and iron turnings, and heat volatilizes without melting them. But a very remarkable phenomenon, which we have not always succeeded in reproducing, and which shows the identity of these two bodies is, that the vapour arising from the volatization of the crystals which gather together in the air, condense under the form of light, snowy, flakes.

In winter, we sometimes remark, when these collodions are exposed to very severe cold, that there is formed in the centre of the liquid long and thin transparent needles, resembling frozen water. We have found it impossible to isolate this substance from the collodion, as it appears to melt as soon as the liquid is disturbed; and if we happen to succeed in isolating it, it disappears by evaporating immediately it comes into contact with the air. This substance must be elaldehyde, another modification of aldehyde, which is found whenever there is an oxygenation of ethereal substances.

The formation of similar prismatic needles had been previously observed in old collodions, but they were regarded as being nitrate of potassa, produced at the expense of the nitric acid, attributed to the decomposition of the pyroxyline. This mode of regarding it does not explain the properties of the body in question. Besides, we have remarked these crystallizations in collodions which contained no iodide of potassium. Those of iodide of ammonium, zinc, cadmium, iron, and others of organic bases, produce just the same phenomenon.

We conclude by remarking, that it is an error to introduce any metal whatever into collodion, with the view of rendering it colourless, and making it keep longer. In this case, the reactions are hidden from the eye, but they take place just the same, and even more rapidly, as we have already stated.

Besides, it is from want of experience that we believe it so absolutely necessary to have the collodion colourless, in order for the photographic operations to proceed successfully, especially when we make of it a generality which must be extended to all modes of working. In most cases it is, in fact, advantageous that the collodion be not too much coloured by iodine, when the development of the picture is effected by means of a weak reducing agent, such as gallic or pyrogallic acid; but, on the other hand, there is an inconvenience—an obstacle even, when the development is effected by sulphate of iron, a case in which the best specimens are those obtained with a collodion reddened by the addition of a considerable portion of iodide, and a weak and acid sensitizing bath.

There is a very material difference between a collodion reddened by decomposition, and another reddened by the addition of free iodine. In the latter case it loses none of its sensibility when its normal state is that of slowly becoming colourless. Then, whatever be the quantity of iodine added within the limits of $\frac{1}{1000}$ to $\frac{2}{1000}$, it always tends to become colourless when sheltered from the influence of light.

We often make use of collodions to which we add a very strong dose of free iodine, and still obtain as much sensibility as when these products are neutral; but it is then necessary to employ weak and acid nitrate of silver baths, prepared with commercial nitrate of silver, crystallized; while with a neutral and concentrated bath, the obtaining of an animated subject will be impossible, however long the exposure may be prolonged.

Iodine added to collodion does not diminish its sensibility when the silver bath is prepared in accordance with it, but with a neutral or alkaline bath the impression will be extremely slow. The same thing takes place when the collodion is neutral, and the silver bath possesses an acid reaction. But when we employ iodine in the collodion, and the sensitizing bath is feeble, and contain a quantity of free nitric acid, in equivalent proportion to the acid disengaged from the article by the free iodine, we then obtain the maximum of sensibility, with weak and acid products, which offers undoubted advantages.

Free iodine in collodion produces not only nitric acid by its contact with nitrate of silver, but it must be remembered that the alcohol and ether, which also moisten the film at the time of its immersion, tend to complicate the phenomenon by giving rise to nitrous or nitric ether, which the iodine decomposes by oxydizing at the expense of the oxygen of the nitric acid, a part of which is thus transformed into aldehyde and aldehydic acid, ether properly so called, which was united to the compounds of nitrogen.

The elements resulting from this reaction, and which are principally nitrous ether, iodous acid, and hyperiodic acid, act in their turn upon the silver of the nitrate, with which they form special salts, the presence of which very probably modifies the sensibility of the collodion film, to the degree of communicating to it the precious qualities it possesses when there exists in the collodion a quantity of iodine limited to the circumstances.

For collodions reddened by iodine we must employ acid baths; but in place of adding nitric acid to the solution, or of preparing the latter with crystallized nitrate, as is generally done, we infinitely prefer to employ pure fused nitrate of silver, to which, after it is dissolved in water, a certain quantity of alcoholic solution of iodine. To this end we add the iodine solution drop by drop, until the precipitate of iodide remains palpably in excess. The sensitizing bath is in this manner saturated with iodide of silver, at the same time there occurs a formation of special products of a strong and penetrating odour, the presence of which is extremely favourable to the luminous impression.

Among these products we have identified particularly the presence of iodic and hyperiodic acids, which greatly participate in the properties of chloric and hyperchloric acid, and exercise upon the collodion film an action analogous to that of the hyperchlorite of lime upon positive proofs when it is introduced into the toning bath: that is, these acids keep the collodion film clear and clean, without diminishing the sensibility; on the contrary, they seem to augment it considerably, either because of the dilatation they produce in the organic film (pyroxyline), or on account of the salts which these acids form with the silver of the nitrate bath.

*(To be continued.)*

## STUDY OF THE WET COLLODION PROCESS.

BY E. REYNAUD.

Examination of the Principal Chemical Products Employed in this Process—Researches into the various Accidents which Occur in Practice, and upon the Means Employed to Prevent them.

The wet collodion process is, undoubtedly, the most extensively employed in photography, on account of the many advantages it possesses over most other processes. Still, however, it is not free from defects, and a very brief experience with it is sufficient to convince us that, although it has undoubted advantages, especially as regards rapidity, it is also, like them, liable to many causes of failure.

To study these causes, and to overcome them, has appeared to me a profitable task; and it is in this hope that I have collected and classified the instructions which have furnished me with the method I now practise.

This task will, then, form a methodical and classified picture of the numerous failures which frequently occur to the operator, especially when he first begins the practice of this process, and has not acquired sufficient experience to be able to recognize immediately, by habit, the disturbing causes to which he must attribute the accidents that occur.

Before commencing this vast study, it appears to me necessary to indicate briefly the simplest means, by the aid of which the operator may satisfy himself of the purity of the materials he employs. No one can be ignorant that this purity is an indispensable condition of success, and that most of the failures and imperfect results are due solely to the employment of adulterated or impure chemicals.

This is particularly the case with the products employed in the preparation of collodion, and the sensitizing bath, to which the presence of foreign bodies, even in minute proportions, is injurious.

Among these products the pyroxyline, or gun-cotton, as it is improperly called, as regards the quality of the collodion, has most influence on the results, I therefore begin with the examination of this substance.

A powdery cotton, too much acted upon by the acid and salt employed in its fabrication, gives a brittle non-tenacious film, which offers but a poor resistance to the action of the liquids with which it is covered, and yields only mediocre pictures. We cannot, by simple inspection, judge if such a cotton will give an unsatisfactory result or not; therefore, to satisfy ourselves on this point, we must dissolve a small quantity in a mixture of alcohol and ether, in suitable proportions. For example, 1 drachm of cotton in 20 of alcohol and 40 of ether; and, after allowing it to stand a sufficient time for the undissolved fibres to subside, cover a small piece of glass with it, allow it to set, and then, with the finger, break up the film: the aspect of the fracture will enable us to ascertain the quality of the cotton; if this fracture shows a film without cohesion, if the part separated does not adhere to the glass, the cotton is of bad quality; if, on the contrary, the rupture takes place with difficulty, and if the part separated adheres strongly to the glass, if the film presents the aspect of thin parchment, then the cotton combines all the indispensable physical qualities.

To satisfy ourselves that this substance fulfils all the conditions necessary in the preparation of a good collodion, it only remains to discover if the cotton has been sufficiently washed to remove all traces of the acids employed in its fabrication, The simplest means to this end consist in putting a sample of the cotton to be tested in a bottle with a given quantity of water, shaking it well, and then by means of a piece of litmus paper, testing the water for acidity.

Commercial rectified ether is generally sufficiently pure for photographic purposes. It almost always contains a little alcohol, which however, cannot naturally disturb the photogenic properties of the collodion. The presence of an acid, on the contrary, is a very serions defect, and will produce the most mischievous results. The proportion of water contained in the ether has also to be taken into consideration.

The most suitable density is that which corresponds to 62° of Cartier's areometer.

It is also necessary to examine the nitrate of silver employed in the sensitizing bath, as its good quality is indipsensable to success in this process.

An excellent method of ascertaining whether the nitrate of silver contains foreign salts, consists in precipitating its aqueous solution by means cf hydrochloric acid, (carefully avoiding leaving an excess of acid or of silver salt in the liquid), filtering and evaporating the solution, which should leave no residue.

If the liquid leaves a residue it will be easy to recognise its nature, and determine its weight, and obtain the exact composition of the nitrate tested.

A simpler method in most cases, consists in dissolving in 60 grains of distilled water, 12¾ grains of the nitrate to be tested, and then adding, drop by drop, an aqueous solution of chloride of sodium (pure), containing 18 grains of salt to 100 grains of distilled water. By briskly agitating the liquor after the addition of each drop of the salt solution, it is easy to determine the exact moment when the precipitate of chloride of silver causes to be produced, and noting the volume of salt solution which has been employed, we may deduce the quantity of nitrate of silver really contained in the nitrate tested.

To this end, it suffices to take note that the proportions of nitrate of silver, and of chloride of sodium, indicated above, are equivalents, and that, consequently, if the nitrate of silver be pure, the 20 grains of its solution will require 20 grains of the salt solution to be exactly decomposed. If, therefore, instead of employing 20 grains of this solution, we take only 15 grains, this shows that the nitrate contains 15 parts of pure nitrate of silver, in 20, or 75 per 100.

Sometimes the nitrate of silver may contain a little acid and water without any detriment to photographic success; to test for these it is necessary to dry the nitrate completely.

I do not speak in this place of the other substances employed in photography with collodion. Distilled water is readily procured pure, but it must be kept securely corked, to prevent access of dust and atmospheric impurities. Sulphate of iron is also easy to obtain pure; and the purity of the other articles employed has no sensible influence upon the result.*

I shall here conclude this preliminary, and proceed to the study of the causes of the accidents most frequently encountered by the inexperienced operator, and analyse each of them in succession, concisely, and determine, as fully as possible, their causes, and the means of avoiding them.

*(To be continued.)*

## FORMULÆ FOR COLLODION.

BY M. DISDERI.

Extreme sensitiveness in collodion is an indispensable quality for a good representation of living objects, but is not of itself sufficient for the perfect execution of a portrait, which requires that the artist have time to pose his model, arrange the drapery, and modify the effect: he will lose all the benefit of the rapidity of the luminous impression if the sensitive film dries too quickly. With the collodions whose composition I give, this result need not be feared: they remain humid a long time after being removed from the silver bath. In winter, the film retains all its sensitiveness for nearly an hour; and, during the hottest summer weather for twenty minutes at least.

### For Winter Operations.

*1st Formula.*

| | |
|---|---|
| Alcohol of 42° ... ... ... | 400 |
| Ether of 62° ... ... ... ... | 600 |
| Pyroxyline ... ... ... ... | 11 |
| Iodide of ammonium . ... ... | 6 |
| Iodide of cadmium ... ... ... | 4 |
| Bromide of ammonium ... ... | 0·6 |
| Bromide of cadmium . ... ... | 0·4 |
| Iodine ... ... ... ... ... | 0·5 |

*2nd Formula.*

| | |
|---|---|
| Alcohol 42° ... ... ... ... | 400 |
| Ether 62° ... ... ... ... | 600 |
| Pyroxyline ... ... ... ... | 11 |
| Iodide of ammonium . ... ... | 5 |
| Iodide of potassium ... ... ... | 5 |
| Bromide of ammonium ... ... | 1 |
| Bromide of potasium . ... ... | 1 |
| Iodine ... ... ... ... | 0·5 |

Dissolve the iodide and bromide of potassium in a few drops of distilled water, to facilitate their solution: if too much water were added it would produce striæ in the film: and on this account we must reject weak alcohol.

These two collodions are very sensitive, and give vigourous pictures. We must not expect extreme delicacy from them.

The silver bath must be of the strength of 10 per cent.

* The acetic acid must, however, be weighed, in order to ascertain if it be of the requisite density.

*3rd Formula.*

| | |
|---|---|
| Alcohol at 42° ... ... ... | 400 |
| Ether at 62° ... ... ... ... | 600 |
| Pyroxyline ... ... ... ... | 10 |
| Iodide of ammonium . ... ... | 6 |
| Iodide of cadmium ... ... ... | 4 |
| Bromide of ammonium ... ... | 1·5 |
| Bromide of cadmium . ... ... | 1·5 |
| Iodine ... ... ... ... | 0·5 |

The results obtained with this collodion are extremely delicate.

In the above three formulæ for collodion, the proportion of bromides and iodides differ. The first formula must be employed with a good light; it will not fog: the second with a medium light: the third may be employed when the light is weak. This collodion is strong in bromides, and well adapted for giving all the details of a feebly illuminated model. It fogs if the light be too strong.

For Spring Operations. At a Medium Temperature.

*1st Formula.*

| | |
|---|---|
| Alcohol at 42° . ... ... ... | 500 |
| Ether at 62° . ... ... ... | 500 |
| Pyroxyline ... ... ... ... | 10 |
| Iodide of ammonium . ... ... | 5 |
| Iodide of cadmium . ... ... | 5 |
| Bromide of ammonium ... ... | 1 |
| Bromide of cadmium . ... ... | 1 |
| Iodine ... ... ... ... .. | 0·5 |

*2nd Formula.*

| | |
|---|---|
| Alcohol at 42° . ... ... ... | 500 |
| Ether at 62° ... ... ... | 500 |
| Pyroxyline . ... ... ... | 10 |
| Iodide of ammonium . ... ... | 5 |
| Iodide of potassium ... ... ... | 5 |
| Bromide of ammonium ... ... | 0·5 |
| Bromide of potassium . ... ... | 0·5 |
| Iodine . ... ... ... ... | 0·5 |

The silver bath must be of the strength of 8 per cent. This collodion will suit a strong light

For Summer Operation. At High Temperature.

| | |
|---|---|
| Alcohol at 52° . ... ... ... | 400 |
| Ether at 62° . ... ... ... | 600 |
| Pyroxyline . ... ... ... | 8 |
| Iodide of ammonium ... ... ... | 5 |
| Iodide of cadmium ... ... ... | 3 |
| Bromide of ammonium ... ... | 0·5 |
| Bromide of cadmium ... ... ... | 0·2 |
| Iodine ... ... ... ... ... | 0·3 |

The silver bath must be 7 per cent. During very hot weather the silver bath must be 6 per cent.

This collodion gives very fine pictures: it may be used with a strong light

The Silver Bath.

*Composition of the Silver Bath according to the Season and the Temperature.—In Winter.*

| | |
|---|---|
| Water ... ... ... ... ... | 100 |
| Nitrate of silver ... ... ... | 10 |

*In Spring and Autumn.*

| | |
|---|---|
| Water ... ... ... ... ... | 100 |
| Nitrate of silver ... ... ... | 8 |

Developing Solution.

| | |
|---|---|
| Water ... ... ... ... ... | 1000 |
| Sulphate of iron ... ... ... | 40 |
| Acetic acid ... ... ... ... | 40 |

Strengthening Solution.

| | |
|---|---|
| Water ... ... ... ... | 100 |
| Nitrate of silver ... ... ... | 3 |
| Acetic acid ... ... ... ... | 3 |

*Another Formula.*

| | |
|---|---|
| Distilled water ... ... ... | 500 |
| Pyrogallic acid ... ... ... | 4 |
| Acetic acid ... ... ... ... | 40 |

For strengthening. The same solution as above.

Fixing.

| | |
|---|---|
| Water ... ... ... ... ... | 500 |
| Hyposulphite of soda... ... ... | 50 |

When the negatives have been exposed too long, and have a grey, feeble, and foggy aspect, they may be strengthened, after fixing, with the following solution:—

| | |
|---|---|
| Water ... ... ... ... ... | 1000 |
| Bichloride of mercury ... ... | 3 |
| Hydrochloric acid ... ... ... | 6 |
| Chloride of gold ... ... ... | 1 |

Varnish.

| | |
|---|---|
| Benzine... ... ... ... ... | 100 |
| White picture varnish . ... ... | 15 |

Another Varnish.

| | |
|---|---|
| Benzine ... ... ... ... | 100 |
| Copal ... ... ... ... ... | 7 |

## PHOTOGRAPHY FOR TRAVELLERS AND TOURISTS.

BY PROFESSOR POLE, F.R.S.*

It is the natural wish of most persons who visit a new locality to bring back pictorial representations of the scenery; and this want is usually met in one of two ways—either by published views or by sketching. In well-frequented places, published views are generally to be had, and command a large sale; and the accuracy of these publications has of late been much increased, and their circulation much promoted, by the more general introduction of landscape photography, and the great increase of its professional practitioners.

But the facility of obtaining views in this way is not without its drawbacks. In the case of engravings, both the accuracy and artistic merit may be anything but satisfactory; ordinary photographs, though they must be tolerably true, may not represent the particular objects, or show them in the particular way the purchaser may desire; and it need hardly be said that there are vast numbers of localities visited by both travellers and tourists, particularly the former, where neither engravings nor photographs are to be found, and of which it is, for that very reason, most peculiarly desirable to get accurate views. To meet these difficulties, the only resource has usually been hand-sketching. Now, the power to sketch well is undeniably one of the greatest advantages that a traveller can possess; but, unfortunately, though drawing is now one of our stock school accomplishments, only a small minority of those who travel are able to transfer efficiently to paper what they see; and even in favourable cases, though clever and artistic pictures may be produced, the faithfulness of the representations must always be more or less uncertain.

Doubtless, the idea must often have occurred to almost every traveller, what an advantage it would be if he could himself take photographs, where he likes, of what he likes, when he likes, and how he likes. But such an idea must soon have been dismissed, from the supposed incompatibility of this with ordinary travelling arrangements. The usual notions of photographic operations comprehends a fearful array of dark rooms, huge instruments, chemical paraphernalia, water, and mess, which no sane person, out of the professional photographic guild, would think of burdening himself with, on an ordinary journey, and which only a practised adept could use if he had them; and so the idea of a traveller taking views for himself on his tour is generally dismissed at once as an impracticable chimera.

Now, it is the object of this article to show that such a view of the matter is a delusion, and that any traveller or tourist, gentleman or lady, may, by about a quarter of an hour's learning, and with an amount of apparatus that would go into the gentleman's coat pocket, or the lady's reticule, put himself or herself into the desirable position we have named.

* From *Macmillan's Magazine.*

It is not our intention to write a treatise on photography; but we must state generally what the operations are, in order to make our explanations intelligible.

The process, then, of taking a photographic picture consists essentially of three main divisions, namely—1. Preparing the plate; 2. Taking the picture; and 3. Developing the image; and the most common and best known arrangement of these is as follows:—A glass plate of the proper size is coated with collodion, and made sensitive to light by dipping in a bath of a certain solution. It is then, *while it remains moist*, placed in the camera obscura, and exposed to the image formed by the lens; after which, *but still before the plate has had time to dry*, it is taken out, and treated with certain chemicals which have the property of developing the image so obtained. The plate is then what is called a "negative;" from which, after it has been secured by varnish, any number of impressions, or "prints," may be taken at any time.

Now, it will be seen, by the words we have printed in italics, that, according to this method of operation, the whole of the three parts of the process must be performed within a very short space of time; and, since the first and third require to be done in a place to which daylight cannot enter, a dark room, supplied with a somewhat extensive assortment of chemical apparatus, must be provided *close to the place* where the picture is taken. This method, from the necessity of the plate remaining moist, is called the *wet* process. It is always employed for portraits, and has the advantage not only of great beauty of finish, but of extreme sensitiveness, requiring only a few seconds' exposure in the camera.

The wet process was the first, and we believe, for some time, the only collodion process in use. But, in a happy moment, it occurred to somebody to inquire whether it was really indispensable that the plates should be kept *moist* during the whole operation, and it was found that, by certain modifications of the process of preparing them, they might be allowed to *dry*, and that some time might elapse between the preparation and the exposure, as well as between this and the development. The immense advantage this promised to landscape photography led to extensive investigation; and several processes have now been perfected which will secure this result. Plates may be prepared at any convenient time and place, and may be carried about for months, ready for use at a moment's notice; and, after the picture has been taken, they may also be kept some time before development. The only price we pay for this advantage is the necessity for a little longer exposure in the camera; which, for landscapes, is of no moment at all.

The bearing of this discovery on our more immediate subject will be at once apparent, as it gets rid of the necessity of providing, on the journey, for the preparation and development, with all their cumbersome and troublesome apparatus, and limits what is necessary to the simple exposure, or taking of the picture. And another advantage of still more importance follows from this—namely, that the plates may be prepared and developed, not only in another place, but by another person. The knowledge, care, and skill required for photography, as well as the stains and all other disagreeables attending it, refer almost exclusively to the preparation and development; the exposure to take the view is an operation of the simplest kind, which anybody may learn in a few minutes, and which is attended with no trouble or inconvenience whatever.

Limiting, therefore, the traveller's operation to the taking of the picture, let us consider what this involves. The first question which affects materially the portability of the necessary apparatus, is the *size* of picture to be taken. We are accustomed to see very large and beautiful photographs of scenery and architecture; but these would be impracticable for the traveller, as the dimensions of the plate increase so materially every portion of the apparatus. Differences of opinion and of taste may exist as to the degree of inconvenience it is worth while putting up with; but the writer of this paper, after considerable experience, has come to the conclusion, that the smallest size in ordinary use—namely, the *stereoscopic* plate—is by far the most eligible one for travelling. The object is not to make large and valuable artistic pictures—that we must always leave to the professional man—but it is simply to preserve faithful representations; and this may be done as well on the small as on the large scale, and with infinitely less trouble. For, though the size is small, the delicacy of detail procurable with well-prepared plates, even in a large extent of view, is something marvellous, as may be easily seen in some of the magnificent stereoscopic views that are to be had in the shops; besides which the stereoscopic effect gives an air of reality to the view, which greatly enhances the value of the representation.

The camera for taking stereoscopic views has now been reduced, by ingenious contrivances, to a very portable size. The one used by the writer is nine inches long, five and a half inches wide, and three inches high—about the dimensions of a good-sized octavo book. It weighs a little over two pounds, and hangs by a strap round the neck in walking with no inconvenience. The stand folds up into a straight stick, which is carried easily in the hand. A stock of eight plates, in slides ready for use (sufficient generally for a day's operations), go into two folding pocket cases. The tourist can thus walk about without the slightest sense of incumbrance, and is prepared, at any moment, to take a perfect stereoscopic view of anything he sees—an operation which will occupy him from five to fifteen minutes, according to the light, and the time he may take to choose his position.

Considered as adding to the baggage of the traveller, these things are hardly worth mentioning—as, with the exception of the stand (which travels well in company with an umbrella), they will all lie snugly in a spare corner of a portmanteau. Of course, however, a stock of plates must be added. A dozen of these, with appropriate packing, will occupy about eight inches long, four inches wide, and one and a half inch high; and from this the space occupied by any number it is proposed to take on the journey may be easily estimated. Suppose there are five dozen—a pretty fair allowance—these, with camera and all complete, will go into a very portable hand-box, or into one of the small black leather bags now so common.

If the operator chooses to go to a little extra trouble, it is highly satisfactory to be able to *develop* the plates on the journey—which may conveniently be done in the evenings, at a hotel or lodging; and the apparatus for which adds very slightly to the bulk of the preparations. A small case of bottles, five inches square and two and a half inches thick, together with one or two small loose articles, are all the author takes with him. The development of a plate takes five or ten minutes, and is a process easily learnt; and the satisfaction of being able to see, the same evening, what one has been doing in the day, is quite inducement enough to do it. But still, we repeat, this is not *necessary*, as the development may be left to another person and to another time.

We think we have shown how every traveller or tourist may be his own photographer, with much less trouble and difficulty than is generally supposed; and we may add that this is no untried plan. The writer of this article has been much in the habit of travelling; and, for years past, when he has gone on a journey, the little camera has been put into the portmanteau, as unassumingly and as regularly as the dressing-case. It has travelled in all sorts of countries, and has cast its eye on scenes which camera never looked at before; it has been a never-failing source of interesting occupation and amusement, and has recorded its travels in hundreds of interesting views, some of much excellence, and very few otherwise than successful.

But it may be asked, Since the advantage and usefulness of this plan are so undeniable, how is it that we do not see it in more frequent use? Simply for the reason that the dealers in photographic apparatus have never yet had the enterprise to establish a manufacture and sale of dry prepared plates, in such a way as to insure their popularity.

The manufacture and sale of photographic apparatus and chemicals is now becoming a very large branch of commerce; but many of the large numbers of tradesmen who prosecute it appear to have a much more earnest view towards the profits of the business than to the advancement of the art—for, since the death of poor Mr. Archer (to whom we owe almost entirely the present state of photography, and who lost a fortune in its improvement), nearly every advance made has been by private individuals. We must not be misunderstood. There are many people who profess to sell dry plates, and these may often be found to possess many of the requisites they should have; but few can be depended on, and *none* combine all the qualities which are necessary to give the system the full benefit of its inestimable value. Some will not keep long enough before exposure; some that will not keep at all after exposure; some fail in sensitiveness; some spoil soon after they are opened; to say nothing of the constant liability to stains, irregularities, blisters, and all sorts of troublesome and annoying defects, which not only spoil the operator's work, but—what is of more importance—destroy all reliance on his operations, and so discourage him from undertaking them. We are not sure whether some dealers may not be obtuse enough even to encourage defects, from the short-sighted notion of increasing the sale; but this we can say—that we know no maker who will guarantee the sincerity of his wish to make good plates, by consenting to allow for them if they turn out bad ones. If this state of things arose from imperfection in the art, we should not grumble, but could only urge improvement; but this is not so. It is well known that dry plates *can* be made, satisfying all the conditions we have named, and which, with care and system in the manufacture, might be rendered thoroughly trustworthy. It is only the indolence or obstinacy of the trade that prevents their becoming regular articles of commerce.

We do not wish, however, to discourage the traveller who may wish to adopt this admirable aid to his wanderings; for the object to be gained is so important that it is worth striving a little for. In the present state of the matter, he must either learn to prepare his own plates—which, after all, is no great exertion—or, if he buys them, he must at least learn to *develop* them, and must, at the same time, lay in with them a certain stock of patience and temper to meet disappointment; and we can assure him that, even at this price, he will find himself amply repaid. But we again urge that the case ought not to stand thus. The application of the dry processes to portable photography offers a boon almost inestimable to, but yet quite unappreciated by, the traveller and the tourist; and it only needs the zealous and earnest co-operation of the dealer, by so conducting the manufacture as to render it perfect and trustworthy, to raise this application into a branch of commerce of an extent, importance, and profit, little inferior to any in the trade.

## Correspondence.

### FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

*Paris*, *9th July*, 1862.

Some important additions to our photographic literature demand a passing notice. Photographic treatises and manuals are superabundant, so much so that it might reasonable be supposed there was little left, that is new, to be expected from them. But, fortunately, the field of photography is a wide one, and different authors occupy different portions of it, and, by pursuing a special branch of the art, an author is enabled to give us the fruit of his experience, which must unquestionably possess an interest and value as such. One lends all his faculties to perfecting the waxed-paper process. To another collodion, wet, dry, or preserved, is the *summum bonum* of photographic bliss; while to another, photographic perfectibility seems to lie in carbon printing.

I shall begin with M. Disderi, to whom photographers are under so many weighty obligations for his efforts in popularizing the *carte de visite* portraits. M. Disderi made them fashionable, and, consequently, universal, setting in motion various branches of industry, the extent of which is incalculable, and whose limits are immeasurable.

The *Art de la Photographie, par M. Disderi*, is a splendid volume of 400 pages, printed on vellum paper, suitably illustrated, and professes to be a complete treatise on the collodion process. Every one who has seen the excellent pictures taken by M. Disderi must have felt some curiosity to know his method of producing them. This volume is intended to gratify that curiosity, and dull indeed must that photographer be who, after carefully studying these pages, should fail to become an adept in the art. At this date, there can be few secrets in photography, although "dodges" may still find favour among those who work by the rule of thumb; but without intelligence, tact, and practical knowledge, the would-be photographer must be like a ship adrift on the wide ocean, without rudder or compass. M. Disderi promises to initiate his readers in all the manipulations of his art, and ensure success to those who follow him, step by step, in the operations he describes.

The book is divided into three sections:—1st. A general introduction and description of the "materiel" of art. 2nd. The collodion process, and positive printing; the 3rd bears the title of *Photographic Esthetics;* this is a new chapter in photography, in which the author acknowledges his obligations to M. Lafon de Carmasac, the inventor of photography on enamel, from whom he has derived esthetic principles specially applied to photography, the extent and precision of which have had a remarkable effect in extending and improving the domain of photographic art.

There is also a chapter on enlarged portraits, to which M. Disderi has devoted his talent; in this he urges the immense aid carbon printing affords to photography. To what perfection carbon printing has been brought, you are doubtless fully informed from inspection of the specimens sent by our most competent artists to the International Exhibition.

This book does M. Disderi great credit. The style is clear and concise without being dry; it is easy to recognise that it proceeds from the pen of a *master* in the art. Especially valuable are the hints as to the causes of failure, and the most rational means of avoiding them, and no less so are the suggestions for varying formulæ, according to the season of the year.

In an *Introduction* to the volume, M. Lafon de Camarsac has given a very clever summary of the present state of the photographic art, from which the reader may gather conclusions as to the *future* of photography. It needs no ghost to tell us that this future must be in the direction of carbon printing.

The reader who searches the pages of this volume for new formulæ, will be disappointed. The author has shown a wise discretion in not multiplying these barriers to success. We have too may recipes already, and our policy should be to prune, not to multiply them. The author gives the formulæ he has found most satisfactory in practice, and such as he daily employs himself.

M. Poitevin has published a "Treaties on Photographic Printing without Salts of Silver." It contains the history, theory, and practice of the methods and processes of carbon printing, of helioplastics, of photolithography, photochemical engraving, &c. In view of the valuable, and highly successful labours of M. Poitevin in these branches of photographic art, his volume is as interesting an one as we have yet perused. There is, however, one chapter which it would have been gratifying to have met in it, and that is—*The Photozincography* of Colonel James, which, from the specimens lately submitted to my inspection, I am led to conclude is one of the most valuable and important applications of the photographic art, yet M. Poitevin's volume has an Introduction, from the able pen of M. Ernest Lacan, one of the editors of *La Moniteur de la Photographie.* The volume is illustrated with specimens of the various processes described.

M. A. Belloc has also published a volume of 420 pages, entitled *Photographie Rationelle; Traité Complet Theorique et Pratique Applicationes diverses.* Some four years ago M. Belloc published his *Compendium* of the four branches of photography. Since that date, one of the four, the Daguerreotype, has completely disappeared from practice; nevertheless, M. Belloc's volume will always retain a certain amount of interest, seeing that it was clearly written and skilfully arranged. The present volume is no less creditable to its author, and deserves a place in every photographer's library.

The attention "enlarged portraits" command at the present time, and the difficulties that beset their production, so far as optical arrangements are concerned, render M. Chevallier's treatise "On Amplification" very acceptable, seeing that it is the production of an accomplished optician, who endeavours to place the matter on a satisfactory basis.

Major Russell's Treatise on the "Tannin Process" has been translated by M. Gerard, Secretary to our Photographic Society, a very convincing testimony of the estimation in which the process is held.

A short time ago there appeared in Germany a "Manual of Practical Photography," from the pen of L. S. Kleffel, which, from its details of the process of instantaneous photography, met with a good reception. Its popularity on the other side of the Rhine has led to the publication of a French translation, which promises to be no less popular than its original.

One more, and I have done. M. Ch. Bride, has published a volume entitled, *L'Amateur Photographe*. It is a summary account of all the leading elements of the photographic art, and if it fails to satisfy all enquiries, it will, at least, be found useful as an indicator of what the amateur may turn his attention to.

## Talk in the Studio.

The Oldest Existing Photographs.—At a recent dinner of "The Photographic Club," we had an opportunity of examining one of the most interesting mementoes of early photographic investigation and experiment. It consisted of a heliograph, in the possession of Mr. Joseph Ellis, of Brighton, whose name will be familiar to old photographers. Mr. Ellis gave some interesting details of the history of the picture, and of his possession of it. M. Nicéphore Niepce, it may be remembered, had obtained permanent photographic pictures many years before the publication of Daguerre's discovery, and in the year 1827 visited this country, in the vain hope of being able to obtain the attention of the Royal Society. It appeared that he resided at Kew, and the picture in question had been given by him to his landlord at that time, in whose hand an inscription at the back is found to the following effect:—"This prototype [probably error for phototype] was presented to me at Kew, in the year 1827, by M. N. Niepce, the discoverer of the art.—B. Cussell." Mr. Ellis had seen it in Mr. Cussell's possession some years ago, and desired to obtain it. Mr. Cussell refused, however, to part with it, regarding it with almost superstitious regard and reverence. For the time, Mr. Ellis had to waive his desire, resolving, however, to keep his eye upon it. He recently learnt that the owner had died, and found, on enquiry, that his effects had been sold by auction. A little search discovered this picture in the hands of a broker, whose chief idea of its value was based on the notion that it was executed on silver. The back had been scratched to test it, and it is to the fact that the metal used was pewter and not one of the noble metals, that this interesting memento, probably one of the earliest sun pictures in existence, was saved from the melting pot. Mr. Ellis purchased the picture, and preserves it with the care naturally pertaining to a picture possessing such historic value. It is a copy of an engraving produced in the camera by the action of light on a film of bitumen, on a pewter tablet. The size was about the ordinary half-plate; the effect is in some respects similar to a Daguerreotype, the image being vigorous and well defined. We may here take occasion to refer the reader interested in the historic details of photography, which are somewhat scarce and scattered, to a couple of published lectures of Mr. Ellis, who, with considerable research, has carefully, and with much ability, traced the earliest known facts, evidently entering upon the task as a labour of love.

Mr. Bedford's Eastern Pictures.—We hope shortly to announce definitely the opening of an Exhibition of Mr. Francis Bedford's Eastern Photographs, most probably in the German Gallery. After upwards of four months of very rapid travelling by every mode of transit, he has arrived at home in excellent health and spirits, with something like two hundred good negatives, having met with no more serious casualty than the smashing of his camera by an Arab to whom it was entrusted to carry up a rock. The bulk of the negatives were by the wet process. A stock of Dr. Hill Norris's plates which were taken, gave excellent negatives during the earlier part of the journey; but some trying changes of temperature having rendered them doubtful, Mr. Bedford, not having time for experiment, confined himself in future to the wet process. The appliances for this, we are violating no confidence in stating, were a stock of Ponting's collodion, and a stock of Thomas's bromo-iodized, both of which were used with the pyrogallic acid development. The former was found very sensitive, but, owing to the very glaring light, solarized very readily. The use of the bromo-iodized collodion obviated this difficulty, and was found therefore most suitable for the work. Notwithstanding the great intensity of the light, a tolerably long exposure was generally necessary to bring out detail in the black shadows. The heat was found very trying, the plate not unfrequently being partially dry before it could be developed; the use of a weak pyro developer was found the best mode of meeting the difficulty. All the negatives were on 12 by 10 plates. The lenses used were a single Ross and a Grubb, both of which we understand did their work very well. His Royal Highness the Prince of Wales manifested a deep interest, we understand, in Mr. Bedford's success, making daily enquiry as to the result of operations, and making an occasional attempt at some of the manipulations. His brother, the Prince Alfred, we may here add, is an enthusiastic amateur, undertaking any department of the work himself, from cleaning the plates to focussing the negative. Messrs. Day and Sons, as we have before announced, will publish Mr. Bedford's pictures.

## To Correspondents.

Hypo.—The dark spots occurring in albumenized prints, is a trouble which most photographers of much experience have occasionally met with. The cause is somewhat uncertain, but there is little doubt it is in some way due to the albumenized paper. It most frequently occurs with old albumenized paper, and sometimes, we believe, with fresh, if the eggs were stale. From its appearance, and the circumstances under which it generally occurs, it is probably caused by some decomposition of the albumen, probably causing some sulphur compound to be formed by the contact with silver. The same cause may have produced the discolouration at the edge where the albumen is thick; or that might have been caused by the fingers not having been free from other chemicals while manipulating during printing. The latter cause, especially if the fingers have touched hypo, is a common cause of such stains. 2. The milky appearance immediately after pouring the developer on the plate, is doubtless due to the use of common water, containing chlorides, carbonates, &c.; and the silver on the plate being thus thrown down, of course robs and injures the image. 3. The proportion of hyposulphite of soda required for fixing prints, is not a constant quantity, and cannot be stated definitely; not only will it be affected by the quantity of chloride of silver formed in the paper in the first preparation, and by the presence or amount of free nitrate, but also by the character of the picture. A vignetted head, for instance, or a landscape with a large extent of white sky, will require more hypo than a print containing a large proportion of black objects, because in the latter case the bulk of the chloride of silver is reduced by light, whilst in the other case it is unaltered, and will require to be dissolved by hypo. Mr. Hardwich says, under ordinary circumstances, an ounce of hypo in six ounces of water should fix forty stereoscopic prints; but he recommends for safety that only half that quantity should be fixed in the solution, which should not be used again.

Tannin.—Negatives generally look a little denser before fixing than after, and in some cases they do actually lose something in the course of fixing, especially where organic matter enters into the composition of the image, as in gelatine plates, such as you describe. The best mode of meeting the difficulty is to develop a little further, and thus allow for the reduction: moreover, a thoroughly well developed plate is less liable to this reduction than one less developed. The hypo solution being weaker, or having a little acetic acid added, may also be tried. 2. Let the warm water remain longer on the film to soak a little; when thoroughly moistened, it will not dry so rapidly as to cause difficulty in covering with the developer.

N.—A light background screen, but not a perfectly white one, is best for vignette heads. The transparency and atmosphere which give relief to the head are lost, if there be no slight cloudy traces of background about the head, merging into the white beyond. A light drab or grey is the best colour to paint the background for such a purpose. Or, if the sitter be placed well in advance, and the screen well in the shade, unbleached calico answers admirably. 2. A sheet of iodized paper, and a film of iodized collodion are not quite analogous, the latter dessicating more completely, or being much less permeable to aqueous solutions after drying than a sheet of paper. Nevertheless, a film of collodion may, as you suggest, be used, with proper precautions. Some of the many preservative processes answer admirably where they have only to be kept a day or two; honey, or glycerine and honey, are good: but dust is the great drawback. But honey and tannin solution is just as easy to apply; the manipulation is very simple, and the results very good. 3. A double thickness of stout calico overhead, projecting a few feet in front of the sitter, will not be too much to protect the head from toplight, especially if there be any chance of direct sunlight.

Amateur.—You require a white reflecting screen to throw a little more light on the shadowed side of the face. The position is not bad; but the two or three sprays of foliage against the background are destructive of artistic, as they almost look as if they grew out of the head. A little longer exposure is necessary.

X. Y. Z.—There are no means of efficiently cementing the halves of a broken negative together. The best plan is, place them together on another plate of similar size, to which they may be attached by a little cement, or canada balsam at the corners, so as to keep them together. Then print in diffused light. A slight mark will probably show; but by adopting this method, the amount of evil will be reduced to a minimum.

A.—Practically the cement described will be very similar to marine glue, and that does not injure photographic solutions. We generally use it for making dippers.

New Subscriber.—There were no prints enclosed in your letter: our answer regarding them must be delayed until they arrive. 2. Albumenized paper prints are best for colouring in oil. Isinglass dissolved in gin or in water, with a little alcohol subsequently added, answers best for preparing the surface. We cannot tell you the exact proportions; for although we have always prepared prints for oil colouring in this way, we never weighed the proportions, but simply used our judgment. Take care not to make the solution too strong, and apply it two or three times, allowing the print to dry between each application. Then try one corner before commencing to paint. We have, however, used gelatine without trouble; you have probably used it too weak. 3. Nos. 188 and 192 contain articles on the honey and tannin process. The price of the Photographic News Almanac is one shilling. You omitted to send your name and address. If you forward these, together with the balance of stamps, the Almanac will be forwarded.

G. Price.—Mr. Alfred Harman, the new secretary, will supply your print if you call on him as you suggest.

Several Correspondents in our next.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 202.—July 18, 1862.

## AWARDS OF JURORS IN THE EXHIBITION.

The second great ceremony in connection with the International Exhibition is over. How processions were marshalled, how addresses were delivered, and bands played, how the grand pageant was performed in all its parts, it is unnecessary to describe here, as our readers are doubtless more interested in the important announcement that the awards are made and published. The record of medals and honourable mentions fills a bulky volume, sold by the Commissioners for five shillings, this being the cheapest rate at which successful exhibitors were apprized of their good fortune, and the unsuccessful that they had been overlooked, or were undeserving of recognition.

In another page we give the awards in Class XIV., with the reasons appended, as published in the official record. In the main we believe the decisions are tolerably just, and will give as much satisfaction as could be anticipated, under the circumstances. We have before stated that the constitution of juries was in many cases far from satisfactory, consisting as they in many cases notoriously did, of nominees of the Commissioners rather than of exhibitors. Nevertheless we believe the work is as well done as is customary on such occasions. That some injustice will be perpetrated there cannot be a doubt. Perhaps in examining the works of twenty-five thousand exhibitors, and awarding nearly seven thousand medals and five thousand three hundred honourable mentions, it would be impossible to escape some act of unfairness. That the jurors generally have been actuated by a desire to be liberal in their awards, is evidenced by the somewhat unusual fact that nearly one-half of the competitors in the race obtain some honour, that considerably more than one in four obtain the highest award, and more than one in five obtain the honourable mention. In the class devoted to photography, it is satisfactory to observe that the proportion of honours exceeds the general average. The total number of contributors in all parts of the world to this class, so far as we can ascertain, are slightly under four hundred, whilst the total number of awards is two hundred and thirty-two. It is somewhat singular, however, that on a further analysis we find that the number of medalists in this class is rather less than the average, the number being eighty-five, or rather more than one in five; the number of honourable mentions is one hundred and forty-seven, being a little more than one in three. On proceeding to ascertain the proportion of these honours carried off by British photographers, we are still less satisfied with the relation between medals and honourable mentions. The number of British contributors is about one hundred and sixty; whilst the number of medals is only twenty-six, or less than one in six: the honourable mentions are fifty-two, or nearly one in three. In France, where the contributors are about one hundred and twenty, the medalists are thirty-two, or over one in four, and the honourable mentions forty seven, or over one in three.

Now, as we are utterly unwilling to admit that the proportion of first-class merit in the British Photographic Department was less than elsewhere, we are driven to other unpleasant conclusions; we are not willing to charge the three French gentlemen, who were on the jury, with being less generous in their decisions regarding the works of British contributors, than they were to the productions of their own countrymen, still less are we disposed to admit some other reasons which might be suggested; but we are impelled to conclude that the wretched position assigned to British photography has affected the judgment of the jurors, as it must that of the public; that the crowded, irregular arrangement, and too often obscure and unreachable position of the contributions, has placed them at a disadvantage which has affected the decisions; that the damp too, which has destroyed their works, has also induced adverse opinions of their merits. That the last cause has, in some cases, been in operation, we have the best reason to believe, and pictures which were marked for medals, have on a further examination, when the damp walls had begun to do their fell work, been reduced to honourable mention merely. Thus the injury to British photography and British photographers done by the Commissioners, pursues them throughout the whole business.

But there is another point in connection with this subject which strikes our attention, and which the circumstance to which we have just referred does not serve to make explicable. We have no wish to cavil with the awards of the jurors. We know that, in the Photographic Department, they were the subject of much discussion and consideration, and that the jury divided again and again in arriving at some of their decisions. But we cannot overlook the singular fact that whilst in the British department there are no medals whatever for photographic apparatus, lenses excepted, there *are* medals for apparatus in the French department. It will scarcely be affirmed by any one that, in apparatus generally, and in cabinet work especially, the French contributions surpass those in the British department. We apprehend that a contrary verdict must be given even by the most prejudiced person. We find in the list of honourable mentions, such names as Ottewill, Hare, and Meagher, amongst manufacturers; and such as Murray and Heath, Horne and Thornthwaite, Bland and Co., McLean and Melhuish, Hockin and Wilson, Solomon, and others, amongst dealers and manufacturers. It may be that there was such uniformity of quality in the articles exhibited in apparatus, that whilst all were meritorious, none so far exceeded the rest as to deserve the distinction of a medal. If such were the case, we cannot see, since medals were sown broadcast in some directions, why they might not have been as liberally bestowed here. Medals for apparatus were given in the French department: with this we find no fault; but we do protest against the distinction implied, when it is notorious that in thorough excellence of apparatus generally, the English manufacturers are unsurpassed, we might say unequalled in the world. We find in one case a medal is given in the French department "for an arrangement for altering the focus of a lens!" This is to M. Derogy for his ingenious method of lengthening or shortening the focus of a portrait combination by the insertion of a supplemental lens. We find no fault with the award in itself, but it does give bitter point to the fact that all the clever invention, and all the excellent workmanship and material in the British department failed to secure more than an honourable mention. Another singular circumstance in connection with the awards for apparatus, is, that notwithstanding the excellence or superiority of their contributions, we do not find the names of such houses as Ross, Dallmeyer, Rouch, and others, referred to at all. It is true that medals have been awarded to the latter for pictures, and to the first and second for lenses, but we fancy that this will scarcely render entire silence on their apparatus generally, satisfactory.

Some of the omissions in the award for pictures are in no sense less singular. If anything deserved recognition in the distribution of honours, we apprehend that steady and successful perseverance in the path of photographic discovery, invention, and application to the arts, should claim a foremost place. M. Joubert, whose name is honourably familiar to photographers, in connection with his process of photographic enamelling on glass, and with his method of carbon printing, known as the phototype process, exhibits fine specimens of both these inventions, as well as some excellent portrait photographs; but his name is not referred to in the award at all, neither with a medal nor honourable mention! It may be suggested that the jurors have perhaps avoided honouring secret or patented processes; but this is not the fact, since numbers of such receive medals. We could point to many more omissions, and to many which receive honourable mention only, which, not our opinion only, but that of the photographic public generally, would place in the very highest position. The task would be, however, an invidious one, and we forbear. In other departments, we believe still more injustice has been done, and protest has been followed by a rectification upon the score, alleged, of misprint in the list of awards! It is possible that some in Class XIV. may be in that position, and may yet be set right.

We turn with pleasure from this part of the subject to glance at that in which we can cordially endorse the decision of the jurors. We notice that good instantaneous photography has in all cases obtained recognition. The London Stereoscopic Company a medal for Mr. England's beautiful instantaneous stereoscopic slides, those of Paris receiving especial mention; Mr. Wilson a medal for his charming pictures of clouds, waves, shipping, &c.; Mr. Breese, a medal for his exquisite transparencies; M. Warnod a medal for his large and unsurpassed cloud, water, and shipping scenes. Mr. Blanchard's instantaneous slides have obtained honourable mention: these we consider more worthy of a medal than some which have obtained it; but, as implying a distinction between the instantaneous productions of a younger experimentalist in this interesting branch of the art, and those of veterans in its practice, we do not complain of the award. We feel especial pleasure in Mr. Breese's medal, inasmuch as it endorses our strongly expressed conviction of the very great excellence of his pictures generally, when we first called public attention to them twelve months ago, and it also tacitly accepts as a fact the moonlight photography about which so much cavil has been made. We may mention here a statement by the superintendent of the department, that the enquiries made regarding these pictures by the public, are forty to one more numerous than about any others. The names of the majority of the established and recognised favourites of the photographic public appear either amongst the medalists, or those obtaining honourable mention, although, as we have said, we regret to miss some, and are surprised to see the name of one or two amongst their superiors.

We may here mention that, in many instances, we have heard much dissatisfaction expressed with the award of "honourable mention" as being worse than nothing, implying comparison, and confessed inferiority, being in short "second best." It should be borne in mind, however, that, as but one class of medals existed, and all could not receive them, honourable mention was the only further distinction available, and does imply superiority; so far as the awards are valuable at all, honourable mention is worth having, and implies that the contributions had too much merit to be passed without recognition.

The distribution of medals is yet to come, and may be expected in about six weeks we believe, when it is not improbable it will be the subject of another ceremony. The medals are of bronze, about two inches and a half in diameter, and are fitted with a morocco case. In about the same time we believe, as the distribution, or shortly after, the Reports of jurors will be published These, it is probable, will be more interesting than the awards, and may possibly do something to dispel the anomalies which now appear to exist. We shall look with interest for that relating to photography, as we know it is in able and honourable hands.

In the ceremonial of last Friday, photography was represented by Dr. Diamond, M. Claudet, and Mr. Thurston Thompson, as jurors; and by Messrs. R. Fenton, T. R. Williams, H. White, and H. P. Robinson, as a committee to receive the awards. The names of the Lord Chief Baron as chairman, and of Mr. Bedford and Mr. Kater, as members of the committee, were also mentioned in the programme of the ceremonial, but only the gentlemen we have named were present.

## THE AMATEUR PHOTOGRAPHIC ASSOCIATION.

We have pleasure in calling the attention of our readers to the fact recorded in another column, that His Royal Highness the Prince of Wales has recently consented to become president of this association. We are glad to record an act which indicates that the Prince is treading in the steps of his lamented royal father, not only as a patron of science and art generally, but of our own art especially. We rejoice, moreover, that his countenance is given to an association which will, we believe, do good work in photography. As our readers may remember when we first called attention to this organization, a little more than twelve months ago, we were not very enthusiastic as to its success. We knew many of the difficulties in the way, and we were, moreover, somewhat jealous of anything which might easily become a trading scheme, under the guise of a society or association. We are glad to say, however, that so far as we have been able to observe, and we have kept our eye on its movements, the association has not only been successful, but in every way trustworthy and praiseworthy in its operations. The object with which it was established, appears to have been thoroughly accomplished. An additional impetus has been given to the operations of a large number of amateurs, the first love revived, and the waning zeal of many being quickened, by finding a public for their productions, and an extensive system of exchange established. And all this has been effected, we are happy to believe, without any interference with the progress or success of the regular trade and professional practice of photography.

Of the excellence of many of the pictures brought out by the association we have before spoken; many of them are to be seen at the International Exhibition, where we are happy to announce, they have secured the highest honour, having obtained a medal. We cannot conclude this very brief notice of the meritorious progress of the association, without referring to the untiring activity, uniform courtesy, and unflagging zeal of its secretary, Mr. Arthur Melhuish, who has succeeded in a manner worthy of the highest acknowledgement in separating a trade connection with the association, in being a member of the firm to whom is secured its printing, from that of the ever-ready and valuable honorary secretary, in which capacity he has contributed largely to the success of the undertaking.

## ON THE EXPENDITURE OF SILVER AND GOLD IN PHOTOGRAPHIC OPERATIONS.

BY JOHN SPILLER, F.C.S., SECOND ASSISTANT CHEMIST TO THE WAR DEPARTMENT.

When the practice of photography is undertaken on an extensive or manufacturing scale, it must always be deemed an object of interest and importance to inquire into the legitimate expenditure of silver and gold salts in the various stages of the photographic processes. To reduce the consumption of the precious metals to the lowest limit consistent with the production of a first-rate result, must assuredly be a chief endeavour on the part of the professional photographer; and very exact information has no doubt been acquired by those who find it necessary to be prepared with an estimate of cost for materials and labour in every step of these commercial undertakings. There is small chance, however, of these nicely calculated results being announced in the columns of our scientific journals, and thus it happens that but few details have been published respecting the exact proportion of silver which may be economically recovered during the production of the ordinary proofs upon albumenized paper. MM. Girard and Davanne were probably the first to show how small an amount of silver remains actually in the finished print; their analytical results led them to conclude that about five per cent. only of the silver originally employed for sensitizing the paper is fixed in an insoluble form, and constitutes the dark colouring matter in the picture. More recently we are indebted for an important addition to our knowledge of the printing process to Mr. W. T. Mabley, who has, through the medium of the Manchester Photographic Society, communicated a series of quantitative results, which indicate clearly the direction in which economy may be practised.

Irrespective of the labours of these gentlemen, I have for some time past, at intervals of leisure, been engaged in investigating the more prominent circumstances connected with the employment of silver and gold in photography, and although my results corroborate in the main the conclusions lately arrived at by Mr. Mabley, there are points of difference, chiefly attributable to variations in manipulation, which appear to me sufficiently marked to justify my submitting them in the character of supplementary data.

The operations of the photographic establishment of the War Department, of which to some extent I have the supervision, include of necessity the reproduction of a great number of impressions from plates, illustrating important achievements in artillery practice, construction, and the means of defence; the printing branch at Woolwich is carried out therefore upon a tolerably extensive scale, and assumes the character of a manufacturing department. During the ordinary course of working, I have frequently availed myself of opportunities of ascertaining and controlling the quantities of silver, gold, and other salts expended upon a known amount of photographic work, and the results have throughout demonstrated the importance of observing a strict watchfulness in regard to precipitating and collecting the silver from the numerous waste solutions which rapidly accumulate during a busy season of photographic printing. In practising the system of recovery, to which I shall presently refer, we have been enabled to return to the photographic laboratory many pounds weight of nitrate of silver, made from the metal reduced from the chloride and sulphide of silver, which are separately forwarded to us in the shape of residues.

A large earthenware jar is provided, in which the whole of the nitrate washings are collected, and therein precipitated with common salt, the chloride of silver being allowed to subside during the night, the supernatant liquid is poured off in the morning to prepare the jar for the reception of another day's produce. The hyposulphite solutions, and the exhausted toning baths are mixed together, and treated with "hepar sulphuris" (crude sulphide of potassium), when the small proportion of gold contained in them will be completely precipitated along with the sulphide of silver, will be reduced with it when fused with carbonate of soda and nitre, and may be ultimately recovered on redissolving the melted lump of metal in nitric acid. As a general rule the "nitrate washings" will be found to yield by far the larger proportion of the silver, usually more than three times as much metal being procured in the state of precipitated chloride as that recovered from the fixing solutions in the form of sulphide of silver.

With regard to the details of the printing process adopted in these experiments, it may be stated that the albumenized paper employed was Spencer's best quality, bearing the maker's name "B. F. K. Rives, 1862," in the water mark; the full sized sheet measured $17\frac{1}{2}$ by $22\frac{1}{4}$ inches, and, as an indication of substance, weighed from 335 to 345 grains. Quarter sheets of this paper were successively floated upon a 70-grain solution of nitrate of silver for five minutes, lifted up and suspended for the same time over another dish to drain, the droppings being returned to the bulk of the solution. The sheets of sensitized paper were used in the pressure frame under negatives having a fair distribution of light and shade; the pictures were then washed in three changes of common water, about a gallon in all being employed for twenty proofs, equivalent to five whole sheets of paper; they were toned in an alkaline gold bath, containing four grains of the chloride of gold, with excess of carbonate of soda; washed once or twice, and fixed in a solution of hyposulphite of soda, containing four ounces of the crystals to a pint of water.

I append the results indicated as the mean of several experiments, made with ordinary care, and with the object of observing the amount of silver which it would be practically possible to recover in the shape of reduced metal, or as valuable silver compounds. The numbers are based upon the consumption of five sheets of paper.

| | |
|---|---|
| Diminution in bulk and strength of the nitrate of silver bath ... | 240 grains |
| Recovered from water used to rinse the dishes—chloride of silver ... | 10 „ |
| The nitrate washings gave of— | |
| Chloride of silver ... ... ... | 121 grains |
| The fixing solution gave of— | |
| Metallic silver ... ... ... | 27 grains |
| Metallic gold ... ... ... | ·5 „ |
| Total amount of silver recovered equal to nitrate ... ... | 197 „ |
| Unavoidable consumption and loss by difference ... ... ... | 43 „ |

Equivalent to 17·92 per cent. of the silver employed.

Other experiments made upon ten and fifteen sheets of paper respectively, furnished results in close accordance with the above. In the latter of these a small bulk of nitrate of silver solution was employed, with a view to ascertain more particularly the degree of exhaustion, or diminution in strength suffered by the 70-grain bath. It had lost in measure nearly six and a half ounces, and had become reduced in strength to a 57-grain solution of nitrate of silver. The amount of silver taken up by the sheet last immersed must therefore have been considerably below the 48 or 50 grains which I found to be usually abstracted from a 70-grain bath.

As a general summary of these analytical and quantitative experiments, it may be stated that the preparation of a full sized sheet of albumenized paper necessitates the employment of 50 grains of nitrate of silver, which at the rate of four shillings per ounce troy costs four pence; of this amount, however, 10 grains only need be actually expended, or one pennyworth of silver per sheet, since the remaining 40 grains, or its equivalent in metal, or silver compounds, are recoverable from the waste solutions and other products obtained in the course of these operations. The value of the chloride of gold expended in the process of toning the prints amounts likewise to one penny per sheet; whilst the whole of the remaining chemicals, viz.: the hyposulphite and carbonate of soda, common salt, hepar sulphuris, and kaolin, all taken together, fall within the limits of an extra halfpenny.

## FORMIC ACID IN THE NEGATIVE DEVELOPER.

We have more than once recently called the attention of our readers to the great advantages claimed by many first-class photographers, for the use of formic acid in the iron developer. We have pleasure in calling attention to a formula, communicated by Mr. Henry Claudet, in which this acid is used with the pyro developer, and by which, it appears, very rapid and fine results are obtained. Our readers may remember a reference in our last to two very excellent groups, by M. Claudet, consisting of the photographic jurors, and the Secretaries of the English and French Societies. These, it appears, were taken with a $5\frac{1}{2}$ in. Voigtländer portrait lens with a $2\frac{1}{2}$ in. aperture, and focus of 20 inches for a distance of seventeen feet from the lens. One of the groups now before us, that of Dr. Diamond and M. Laulerie, of which we spoke very highly last week, is about 12 by 10, and was produced with an exposure of seven seconds in a dull light. We have also received some excellent card portraits, one produced in less than a second, and others in one or two seconds. Mr. Claudet attributes much of this rapidity to the character of the developing solution, which he describes in a letter to Dr. Diamond, a copy of which he has kindly furnished us. We ought to remark here, that a typographical error has inadvertently crept into the formula, as given in our excellent contemporary, the *Photographic Journal*, which, in the letter, as below quoted, is corrected. After referring to the group, and the circumstances under which it was produced, Mr. Claudet says:—

"Acting on the principle of my father, that superiority in photography does not depend on the secret of some manipulation, I did not hesitate to tell you that I had arrived at this extraordinary senstiveness by substituting formic acid in place of acetic acid in the developing-solution, and adding nitric acid to the nitrate of silver bath. I promised that I would give you a full description of my process, to enable you to publish it in the *Photographic Journal* for the interest of all. In fulfilment of my promise, I now give you that description.

"The formic acid I use is made by Messrs. Morson & Son, and in my developing-solution it replaces acetic acid. The nitrate of silver bath must be of the strength of 35 grs. to 1 oz. of distilled water. To 1 pint of this bath I add 3 drops of strong nitric acid.

"The developer consists of pyrogallic acid 20 grs, distilled water $7\frac{1}{2}$ oz., formic acid 1 oz., and 6 drs. of alcohol.

"The plate must be well drained after having been taken out of the nitrate bath; and this is a grand poiut for the success.

"By this process, in an ordinary fine light, with a 3-inch double lens by Voigtländer, of $7\frac{1}{2}$ inches focal length for a distance of 25 feet, I take a portrait in the glass room in less than a second.

"I have found that Thomas's collodion (one-half of his ordinary negative collodion and one-half of his cadmium collodion) is the best for my process, which has the following advantages:—

"1st. The picture is brought on as quickly as with protosulphate of iron, being on a *carte-de-visite* plate, developed in one minute; and the half-tones are as delicate.

"2nd. It does not require intensifying when the exposure has been for the right time.

"3rd. If pictures can be taken instantaneously in the glass room at 25 feet, a process of such unusual rapidity must be invaluable for fixing the image of moving objects. This, for want of time only, I have not yet had the opportunity of attempting.

"I do not know by what process Messrs. Ferrier, Warnod, Wilson, England, and Breese, have been able to produce the beautiful instantaneous views which are admired at the International Exhibition; but I have no doubt that the accelerating action of formic acid, if not known by these successful operators, is capable in their hands of producing results still more extraordinary. HENRY CLAUDET."

We may add that M. Ferrier, some time ago, attributed part of his success in instantaneous work to the use of formic acid. Messrs. Wilson, England, and Breese, all use an iron developer with acetic acid, and a bromo-iodized collodion.

## PHOTOGRAPHIC CHEMICALS:

### THEIR MANUFACTURE, ADULTERATIONS, AND ANALYSIS.

*Potassium Salts* (continued).—*Chromate of Potash.*—This and the bichromate are very important salts in photography. The chromate is prepared on the large scale from chrome iron-ore (a mixture of sesquioxide of chromium and protoxide of iron), by ignition with nitre; the chromium is oxydized to chromic acid, and after strong ignition for some time the mass is allowed to cool and exhausted with water. From this solution chromate of potash is prepared for commercial purposes by crystallization. If bichromate of potash be present in solution with this salt, the former may be converted into the normal salt by the addition of potash; it may be separated from nitre by crystallization, or by fusion, and the cautious addition of charcoal-powder till the violent detonation ceases; the mobile liquid then becomes pasty. and a small quantity of chromic oxide is separated; the mass is then exhausted with water, the solution filtered and allowed to crystallize. The salt crystallizes in right prismatic crystals, which are of a brilliant lemon-yellow colour, changing to a red tint when heated. At a red heat it fuses, previous to which it decrepitates violently by emitting a green light; the crystals have an alkaline reaction, and a cooling, bitter metallic taste; the salt is permanent in the air, and is not decomposed when heated *per se.* It is a powerful oxydizing agent, and causes the rapid combustion of charcoal, cotton, wool, and other organic substances, when they have been dried after saturation with its solution. Chromate of potash dissolves in about two parts of water, at the ordinary temperature, and is slightly more soluble at the boiling point. During its solution the temperature falls considerably. The colorific properties of this salt are very considerable, one part, by weight, imparting a distinct yellow colour to 40,000 parts of water. It is insoluble in alcohol, which also precipitates it from an aqueous solution. Commercial chromate of potash is seldom pure; to separate the impurities it must be freed by recrystallization from silica and alumina, then mixed with nitric acid, and nitrate of baryta dropped in as long as sulphate of baryta is precipitated. The chlorine is separated by adding chromate of silver to the filtrate, as long as chloride of silver is formed, after which the solution is filtered, evaporated to dryness, and the residue ignited in a platinum crucible; it is then dissolved in water, and the solution left to crystallize. When sulphuric hydrochloric, nitric, acetic, and many other acids are added to the aqueous solution of this salt, it gives up half its potash to them, being converted into bichromate, which separates after a slight concentration.

Bichromate of potash forms large, bright red, rectangular, tables and prisms; its powder is reddish yellow; when heated, it decrepitates, and then fuses considerably below redness, forming a transparent red liquid which crystallizes on cooling. The salt is permanent in the air, and is acid to test paper. When heated with oil of vitriol, pure oxygen is evolved; this method is sometimes used for preparing this gas. The salt dissolves in about ten parts of water at the ordinary temperature, and is much more soluble in boiling water. The solution is of a deep orange yellow colour. It is also remarkable for the intense colour which it is capable of communicating to water. Possessing two equivalents of chromic acid for one equivalent of alkali, this salt is still a more powerful oxydizing agent than the chromate; when mixed with organic matter, it has a great tendency to part with some of its oxygen with reduction of the chromic acid to the state of sesquioxide of chromium. This change, however, only takes place under the stimulating action of solar radiation, and on this account bichromate of potash has become a very important addition to the photographic laboratory. Bichromate of potash is liable to contain the same impurities as the neutral chromate, and may be purified in the same way.

*Permanganate of Potash.*—Through the exertions of Messrs. Condy, this salt is now procurable in a state of almost perfect purity, and at a very cheap rate. It is likely to be of considerable use to photographers, on account of the wonderfully rapid and perfect oxydizing action which it exercises on most kinds of organic matter. One of the greatest annoyances in the preparation of photographic solutions is the presence of organic matter in the distilled water. The name distilled is generally considered sufficient guarantee of the purity of water, and its fitness for photographic purposes; this, however, is by no means the case: distilled water, unless prepared especially for chemical purposes, usually consists of the condensed vapour from steam machinery, and then almost always contains greasy matter and other impurities. It is of the utmost importance that such water is never employed for photographic purposes, and hence a test which will at once detect the presence of this injurious impurity in distilled water cannot be too highly valued; such a test is afforded by the salt in question. The salt is prepared by mixing eight parts of peroxide of manganese, seven parts of chlorate of potash, and ten parts of hydrate of potash, dissolved in a very small quantity of water; the mass is evaporated to dryness, during which a small quantity of mineral chamelion is formed: the finely-powdered mass is ignited in a platinum crucible over a spirit lamp, till the whole of the chlorate of potash is decomposed (a low red heat is quite sufficient for this); the semi-fused mass is then reduced to coarse powder, and boiled in a larger quantity of water; the insoluble portion is allowed to subside, and the clear solution decanted off and evaporated rapidly; it is again decanted from the freshly precipitated peroxide of manganese, and the solution is allowed to crystallize by cooling. The crystals are then washed in a small quantity of cold water, dissolved in the smallest possible quantity of boiling water, and the solution left to crystallize by cooling. In this way the salt is obtained in large needle-shaped crystals, amounting in weight to about a third of the weight of the peroxide of manganese employed. If it be desired to filter the solution, in order to avoid the loss arising from decantation, a funnel may be used, having a stopper of asbestos, or gun-cotton, loosely stuffed into its neck. The salt forms dark purple needles, belonging to the right prismatic system. They have at first a sweet, and afterwards a rough taste, and are permanent in the air: they are neutral to test paper. When heated, the crystals decrepitate, evolve oxygen, and are converted into a black powder, from which water extracts manganate of potash. The crystals dissolve in sixteen parts of water at the ordinary temperature. All organic substances exert a deoxydizing action on the solution; alcohol acting with peculiar rapidity, whilst gum, sugar, paper, &c., act more slowly. When the liquid is exposed to the air in open vessels, organic particles falling into it, it is also decolourised in a short time, carbonic acid from the atmosphere combining with the potash. Chemical solutions which have been filtered through paper, and indeed most specimens of distilled and ordinary water, contain sufficient organic matter to decompose permanganate of potash, taking away the excess of oxygen and precipitating permanganate of potash.

## THE INUNDATIONS IN THE FENS FROM A PHOTOGRAPHIC POINT OF VIEW.

Some few weeks ago, our ordinary photographic routine was disturbed by the receipt of a hastily written letter from an enthusiastic photographic friend of ours, it ran as nearly as we can remember as follows:—

"Dear B.—We are on the eve of a calamity, the like of which this district has not seen for 300 years. The middle level sluice has burst, and in consequence of the rush of tidal water into the drain it is full from bank to bank. How long it will stand the strain we know not, but it is only a question of a few hours, for it might break at the weakest point, and then we shall have Marshland fen under water. I would advise you to pack up your photographic apparatus and come at once."

The picture presented to our eyes by the contents of the letter did not tempt us to obey our friend's request. We knew the sluice well, and though it was considered, when first built, some sixteen years ago, quite a triumph of engineering skill, still, in its ruined condition, it would be but a mass of tumbled brick-work, offering but few materials for an artistic picture; and as for the middle level drain it presented no salient point of attack, for a river some seven miles long, and straight as an arrow, even when full from bank to bank, though offering a capital subject for the study of perspective, was no tempting object for the photographer in search of the picturesque; but when, in the next day's paper, we saw that the banks had broken, and each succeeding day's intelligence increased the magnitude of the catastrophe, and that the worst fears had been realized, and Marshland fen was once more in its primitive condition—a vast sheet of brackish water—when we found that the daily papers had sent down special reporters to the scene, and that a column was given daily to the description of events, we must confess we felt a feverish desire to witness the scene with our own eyes, or rather with the eye of our camera. We accordingly packed up and started for the Fens.

We must admit some fond remembrances of boyish days tended considerably to increase the desire to see this well-remembered spot under its new and unexpected aspect, for many a time in years gone past, when we had occasion to ride frequently by train across this country, now submerged, we have looked out upon the vast unvaried scene in the dim twilight, and have quite realized the idea that we were looking out upon an immense inland sea, such a one as Tennyson describes when he writes:—

> "whence we see,
> Stretched wide and wild, the waste, enormous marsh,
> Where from the frequent bridge,
> Like emblems of infinity,
> The trenched waters run from sky to sky."

And we felt desirous to see how like the "counterfeit presentment" was unto the real scene now to be witnessed. We felt, also, that though such an immensity of flatness, with but few incidents to break the monotony, beyond an occasional cottage or homestead under water, presented, under ordinary aspects, but few temptations to a photographer, it might, under the magic influence of the setting sun, give all that could be desired; for how few materials are needed to make a picture. A slimy shore, with water beyond, and a broken boat in the foreground, lit up by the golden glories of sunrise or sunset, and we have a scene that the genius of a Turner but imperfectly depicts after years of labour.

The morning was a magnificent one when we started, and we left town buoyant with hope for successful results; but as we drew nearer to the end of our journey, the day put on a garb of leaden hue, and long before we reached our destination, the rain came down in such a manner as to clearly indicate there would be no photography done that day. We soon found, by the conversation in the carriage, that we were not alone in our desire to witness the catastrophe, for several were upon the same errand. When we got to Watlington, some people entered the carriage, who had just returned from an inspection of the scene. They informed us that they came all the way from Norwich to see the inundation, and they had walked some three or four miles from the station down the disused Wisbeach line until the water barred their further progress, and that though the journey had been performed in the rain, they felt that the strange sight fully repaid them for all toil and discomfort they had endured. All this only served to whet our desires the more, but we had no alternative but to go on to Lynn, and wait patiently for the morrow.

The next day got up dull and heavy, as though still suffering from the effects of the copious libations so recently indulged in. We determined, however, to take an early survey, and select points for future operations; and now came a difficulty we had not anticipated. Lynn was full of visitors, and as everybody wanted to see all they could, and as there was no direct railway communication, all the old fashioned means of locomotion were in requisition, and not a piece of horseflesh, or anything in the shape of a trap was to be had, except at fabulous prices. However, thanks to the efforts of an old acquaintance well up in these matters, we succeeded in getting something of the dog-cart kind, which answered our purpose, and we were soon on our way. The journey by rail would have been about five miles, but as we were compelled to travel the roads laid down by the wisdom of our ancestors, and as their views, on road making at least, were anything but straightforward, we had to travel 11 miles before we reached the scene of our destined labours. Our jehu enlivened the journey by some capital tales of the good old coach days, when the driver considered it a duty to endanger his own neck and those of all the pasengers, rather than let the rival coach pass him. One tale is worth repeating:—Once upon a time when he drove the Wells coach, they had a guard who could turn a tune on the key bugle most beautifully—he was especially celebrated for his playing of the "Old English Gentleman." One Sunday he had been playing this tune for the gratification of a passenger very near to Holkham Hall, for he thought the family from home. When he came in sight of the house, however, he was made very uncomfortable by the sight of the Earl of Leicester at one of the windows, and therefore tried to make amends by pulling up and playing the huudredth psalm very vigorously. A servant however came out with a request from the earl that he would repeat the "Old English Gentleman" which he did accordingly. During the performance some refreshments were sent out for the invigoration of the passengers. V. B.

# The International Exhibition.

## JURY AWARDS IN CLASS XIV.

MEDAL.

UNITED KINGDOM.

| *Name of Exhibitor.* | *Objects Awarded and Reasons for the Award.* |
|---|---|
| Amateur Photographic Association ... ... ... | For general photographic excellence. |
| Beckley ... ... ... | For a valuable series of photographs of spots on the sun, and for the application of photography to astronomical science. |
| Bedford, F. ... ... ... | Photographs. For landscapes and interiors of great excellence. |
| Breese, C. S. ... ... ... | For a series of instantaneous views on glass of clouds, waves, &c. |
| Colnaghi and Co. ... ... | For a valuable series of large photographs of antiquities, copies of cartoons, miniatures, &c. |
| Dallmeyer, T. H. .. .. | For excellence of lenses, and introduction of a new triplet lens free from distortion, with chemical and visual foci coincident. |
| De la Rue, W. ... ... | For the application of photography to astronomical science. |
| Fenton, R. ... ... ... | For great excellence in fruit and flower pieces and good general photography. |
| Frith ... ... ... ... | For views in Egypt taken by himself. |
| Heath, Vernon ... ... | For excellent landscape photography. |
| James, Col. Sir H., R.E. ... | For specimens of photography, photozincography, and photopapyrography. |
| London Stereoscopic Company ... ... ... ... | For great excellence of photographic views, and especially series of stereoscopic pictures of Paris. |
| Mayall, J. E. ... ... ... | For artistic excellence in photographic productions. |
| Mudd, J. ... ... ... | For very excellent landscapes produced by the collodio-albumen process. |
| Negretti and Zambra ... | Beauty and excellence of photographic transparencies and adaption of photography to book illustration, &c. |
| Piper, J. D. ... ... ... | For general excellence in the pictures exhibited, especially in landscape photography. |
| Ponting, T. C. ... ... | For the excellence of his iodized sensitive collodion. |
| Pretsch, P. ... ... ... | For a series of specimens of photographic printing by various means as improved and invented by himself. |
| Robinson, H. P. ... ... | For good photographic manipulation, and great artistic excellence in combined pictures, as well as in carte de visite portraits. |
| Ross, T. ... ... ... | For superiority of his photographic lenses. |
| Rouch, W. W. ... | For small photographs taken with his new binocular camera with Hardwich's bromo-iodized collodion. |
| Sidebotham, J. ... ... | For beautiful landscape photography by the collodio-albumen process. |
| Talbot, Fox W. H. ... | For photographic engravings on copper and steel produced by the action of light alone. |
| White, H. ... ... ... | For great artistic excellence in landscape photography. |
| Williams, T. R. ... ... | Photographs. For excellence in photographic portraiture, &c. |
| Wilson, G. W. ... ... | For the beauty of his small pictures of clouds, shipping, waves, &c., from nature. |
| | AUSTRALIA. |
| Osborne .. ... .. . | For the photolithographic process invented and patented by himself. |
| | CANADA. |
| Notman .. ... ... ... | For excellence in an extensive series of photographs. |
| | INDIA. |
| Simpson, Dr. ... ... .. | For a valuable series of portraits of the native tribes. |
| | JERSEY. |
| Mullins ... ... ... ... | For general photographic excellence. |
| | VICTORIA. |
| Daintree... ... ... ... | For an extensive series of photographs illustrative of the colony. |
| Haigh ... ... ... ... | For stereoscopic and other views in the colony, excellent in photographic treatment. |
| Nettleton ... ... ... | For excellence of photographic views in the colony. |
| | AUSTRIA. |
| Angerer, L. . ... ... | For general excellence and great definition of the photographs exhibited. |
| Dietzler, Ch. ... ... ... | For photographic lenses of excellence. |
| Ponti, Ch. ... ... ... | For the alethoscope, with the photographs exhibited therein. |
| Voigtlander and Son ... ... | For great excellence of photographic lenses. |
| | BADEN. |
| Lorent, Dr. ... ... ... | For a beautiful series of large pictures of great photographic excellence. |
| | BAVARIA. |
| Albert, T. ... ... ... | For a valuable series of reproductions of pictures and objects of art. |
| | BELGIUM. |
| Fierlants, Ed. ... ... ... | Photographs. For excellence in a series of photographs taken by the albumen process for the Government. |
| | FRANCE. |
| Aguado, Count O. .. | Enlarged photographs. For specimens of enlargements from small negatives. |
| Aguado, Viscount O. ... | Enlarged photographs. Pictures of shipping, &c., enlarged from small negatives. |
| Alophe, M. ... . | Photographs. For excellent photographs, especially as regards artistic arrangement. |
| Baldus, E. ... ... ... | Large photographs. For large views of monuments, views from nature, reproductions, &c. |
| Bayard and Bertall ... ... | Photographs. For excellence of photographic pictures. |
| Bertand ... ... ... ... | For excellence of lenses. |
| Bertsch, A. ... ... ... | For excellence of articles exhibited. |
| Bingham, R. ... ... ... | Photographs. For excellent reproduction of pictures and other objects of art. |
| Bisson, Brothers ... ... | Photographs. For panoramic views of Mont Blanc, pictures of monuments, &c. |
| Braun, A. ... ... ... | Photographs. For pictures of natural flowers, views, &c. |
| Cammas ... ... ... ... | Photographs. For large views, on waxed paper, of Egypt and its monuments. |
| Darlot ... ... ... ... | For excellence of articles exhibited. |
| Davanne and Girard ... ... | Photographs. For pictures of photographic excellence. |
| Delessert, E. ... ... ... | Large photographs. For large views of monuments in Paris, untouched. |
| Derogy ... ... ... ... | For an arrangement for altering the focus of a lens. |
| Disdéri ... ... ... ... | Photographs. For excellency of enlarged and other pictures. |
| Dubosq, L. J. ... ... ... | Photographic apparatus. For photographic appliances, lamp, &c. |
| Duvette and Romanet .. | Photographs. For excellent architectural views of Amiens cathedral. |
| Fargier ... ... ... ... | Photographs. For pictures done by the carbon process. |
| Ferrier ... ... ... ... | Large photographs on glass. For excellent pictures on glass, instantaneous views in Paris, &c. |
| Garnier and Salmon ... ... | For the carbon process invented by them. |
| Jeanrenaud ... ... ... | Photographs. For excellence of photographic views, &c. |
| Lafon, De Camarsac ... ... | For photographic reproductions in enamel. |
| Lyte, Maxwell ... ... ... | Views in the Pyrenees. For excellence of landscapes in the Pyrenees. |
| Marville ... ... ... ... | Photographs. For photographic pictures of objects of antiquity, landscapes, &c. |
| Muret ... ... ... ... | Views of the Isère. For good landscape photography. |

| Denier ... ... ... ... | For general photographic excellence. |
| | SAXONY. |
| Manecke, F. ... ... ... | For excellence of photographs. |
| | SWEDEN. |
| Manerke ... ... ... | For excellency of photographs exhibited. |

## HONOURABLE MENTION.

UNITED KINGDOM.

| *Name of Exhibitor.* | *Objects Awarded and Reasons for the Award.* |
|---|---|
| Austen, W. ... ... ... | For superior arrangement of head rests, and beauty of action of rolling press for photographs. |
| Barrable, J. G.... ... ... | For artistic excellence. |
| Beatty, F. S. ... ... ... | For heliographic surface and intaglio printing. |
| Bland and Co. ... ... ... | For very excellent workmanship and arrangement, especially adapted for India and foreign countries. |
| Bourquin and Co. ... ... | For general excellence of articles exhibited, especially for photographic albums, of his own manufacture. |
| Brothers, A. ... ... ... | For artistic excellence, and for a photographic group finished in water colours. |
| Bull, J. T., and G. ... ... | For photographic accessories and backgrounds. |
| Burnett, C. J.... ... ... | For experimental researches in photography, as exhibited in the specimens of printing by uranium, platinum, palladium, copper, &c. |
| Caithness, Earl of ... ... | For photographic landscape, especially the representation of hoar frost. |
| Cox, F. J. ... ... ... | For general excellence of articles exhibited. |
| Cramb, Brothers ... ... | For a series of views in Palestine. |
| Cundall, Downes, and Co. ... | For photographic reproductions. |
| Dancer, J. B. ... ... ... | For microscopic photographs, landscapes, and portraits. |
| Davies, T. S. ... ... ... | For excellent arrangement of his photographic manipulating camera for field purposes. |
| Gordon, R. ... ... ... | For excellent views in the Isle of Wight. |
| Green, B. R. ... ... ... | For artistic excellence in coloured photographs. |
| Hare, G. ... ... ... | For excellence in the manufacture of cameras. |
| Hemphill, Dr. W. D.... ... | For excellence of views of antiquities in Ireland. |
| Hennah, T. H... ... ... | For photographic portraits. |
| Hering, H. ... ... ... | For artistic excellence. |
| Highley, S. ... ... ... | For excellence of apparatus exhibited. |
| Hill, D. O. ... ... ... | For great artistic merit in photographs exhibited. |
| Hockin and Wilson ... ... | For excellence of articles exhibited. |
| Hopkin and Williams . ... | For excellence of photographic chemicals. |
| Horne and Thornthwaite ... | For general excellence in articles exhibited. |
| Jocelyn, Viscountess . ... | For artistic effect in landscape photography. |
| Kilburn, W. E. . ... ... | For artistic excellence in coloured photographs. |
| Lock and Whitfield ... ... | For artistic excellence in coloured photographs. |
| Maclean, Melhuish, and Co... | For general excellence of photographic apparatus, and artistic excellence in coloured photographs. |
| Mayland, W. ... ... ... | For good photography in views, &c. |
| Meagher... ... ... ... | For great excellence and cheapness in the apparatus exhibited. |
| Moule, T. ... ... ... | For his apparatus for taking portraits by night. |
| Murray and Heath ... ... | For superior arrangement and work in articles exhibited, and especially for usefulness of Smart's tent. |
| Olley, W. H. ... ... ... | For photographs from the microscope by the reflecting process |
| Ottewill, T., and Co. ... ... | For excellence in the manufacture of cameras. |
| Ramage, J. ... ... ... | For applications of photolithography. |
| Reeves, A. ... ... ... | For microscopic photographs. |
| Rejlander, O. G. ... ... | For artistic photographic effect. |
| Ross and Thompson ... ... | For artistic portraits. |
| Russell, J. ... ... ... | For views of the ruins of Chichester Cathedral after the fall of the spire. |
| Sedgefield ... ... ... | For good stereoscopic views. |
| Skaife, T. ... ... ... | For a pistolgraph and a series of productions called pistolgrams. |
| Smith, Lyndon ... ... | For landscapes, &c., artistically taken. |
| Smyth and Blanchard . ... | For a series of instantaneous views for the stereoscope. |
| Solomon, J. ... ... ... | For the introduction of many useful aids to photographic manipulation as exhibited. |
| Sutton, E. ... ... ... | For artistic excellence in coloured photographs. |
| Thompson, S. ... ... ... | For excellence in architectural photography, &c. |
| Tracr, J. R. ... ... ... | For excellence of photographs of microscopic objects, &c. |
| Wardley, G. ... ... ... | For excellent landscapes by the collodio-albumen process. |
| Warner, W. H... ... ... | For photography in a series of enlargements from small negatives. |
| Wortley-Stuart, A. H. P., Lieut.-Col. ... ... ... | For views of Vesuvious during the eruptions of 1861-62. |
| Wright, Dr. ... ... ... | Portable photographic apparatus for field purposes, combining tent, &c., adapted for railway travelling. |
| | BRITISH COLUMBIA. |
| Claudet, F. ... ... ... | For a series of views in New Westminster. |
| | BRITISH GUIANA. |
| Tucker ... ... ... ... | For photographic views in the colony. |
| | INDIA. |
| Sellon, Capt. ... ... ... | For a series of views in India. |
| | JAMAICA. |
| ——* ... ... ... ... | For a valuable series of photographs of the fish of the island. |
| | MELBOURNE. |
| Cox and Lukin ... ... | For photographic excellence. |
| | NEW BRUNSWICK. |
| Bowren and Cox ... ... | For photographic views, being the earliest taken in this colony. |
| | NEW ZEALAND. |
| Crombie, J. N.... ... ... | For views in the colony. |
| | QUEENSLAND. |
| Challingor, G. ... ... ... | For excellence of photographs. |
| Wilder, J. W. ... ... ... | For excellence of photographs. |
| | SOUTH AUSTRALIA. |
| Hall, Rev. ... ... ... | Ethnological studies of the aborigines. |
| | TASMANIA. |
| Allport, M. ... ... ... | For interesting pictures exhibited, including stereoscopic and other views. |
| | VICTORIA. |
| Bachelder and O'Neill . ... | For photographs of volunteers, &c. |
| Charlier... ... ... ... | For portraits of the aborigines of the colony. |
| Davis ... ... ... ... | For excellence of photographs in Melbourne and Fitzroy. |
| Johnston ... ... ... | For a collection of photographic views. |
| | AUSTRIA. |
| Lemann, C. ... ... ... | For excellent reproductions of objects of art and archæological subjects. |
| Leth ... ... ... ... | For a new carbon process, and copies of wood engraving accomplished by the same. |
| Melingo, A. ... ... ... | For general photographic excellence. |
| Oestermann, C... ... ... | For illustrations of Buda-Pesth, the metropolis of Hungary. |
| Rupp, W. ... ... ... | For his valuable application of photography. |
| Tiedge, T. ... ... ... | For a large collection of photographic pictures of peasantry, costumes, &., from South Hungary. |
| Widter, A. ... ... ... | For general excellence of pictures exhibited. |
| | BAVARIA. |
| Gypen and Frisch ... ... | For excellence of pictures exhibited. |
| | BELGIUM. |
| Ghémar, Brothers ... ... | For general excellence of photography. |
| Mascré, J. ... ... ... | For photographic copies of pictures, &c. |

* The name is blank in the official list of awards, and there is no mention of the contribution in question in the catalogue.

| *Name of Exhibitor.* | *Objects Awarded and Reasons for the Award.* |
|---|---|
| Michiels, J. J. ... ... ... | For general excellence of photographs. |
| Neyt, A. L. ... ... ... | For excellent specimens of photographic micography. |
| | DENMARK. |
| Hansen, G. E. ... ... ... | For excellence of photographs. |
| Lange, E. ... ... ... | For excelleuce of photographs. |
| Striegler, R. ... ... ... | For his portrait of the Princess of Denmark. |
| | FRANCE. |
| Albites, T. ... ... ... | For excellence of articles exhibited. |
| Aleo ... ... ... ... | For delicacy in landscape photography, &c. |
| Bérenger, Le Marquis de ... | For good landscape photography on wax paper, &c. |
| Berthier, P. ... ... ... | For excellent reproduction of works of art. |
| Blanc, N. ... ... ... | For good artistic arrangement in portraiture and excellent photography. |
| Bobin, A. ... ... ... | Photographic reproductions of maps and plans with great accuracy. |
| Breton, Madame ... ... | For archæological views, &c. |
| Briois, C. A. ... ... ... | For exce'lence of chemicals used in photography. |
| Carjat and Co. ... ... | For excellent photographic portraits. |
| Charnay, D. ... ... ... | For excellence of photographs exhibited. |
| Charavet ... ... ... | For his carbon pictures. |
| Collard ... ... ... ... | For excellence of photographic views. |
| Crémière ... ... ... | For instantaneous pictures of animals, &c. |
| Dagron, E. ... ... ... | For microscopic photography applied to bijouterie. |
| De Clercq, L. ... ... ... | For excellence of photographs exhibited. |
| Delondre, P. ... ... ... | For excellent views obtained by the wax-paper process. |
| Delton ... ... ... ... | For instantaneous pictures of animals. |
| De Champlouis ... ... | For views in Syria, obtained by his "wet-dry" process, as described by himself. |
| Garin ... ... ... ... | For excellence of photographic chemicals. |
| Gaumé ... ... ... ... | For reproductions of photographic pictures for glass in churches, &c. |
| Hermagis ... ... ... | For excellence of photographic lenses. |
| Jouet, E. ... ... ... | For landscape photography. |
| Ken, A. ... ... ... | For good photographic portraiture. |
| Koch ... ... ... ... | For excellence of articles exhibited. |
| Lackerbauer ... ... ... | For excellence in microscopic photography. |
| Laffon, J. C. ... ... ... | For studies of still life, photographs on silk. |
| Lecu, F. N. ... ... ... | For excellence of articles exhibited. |
| Lemercier ... ... ... | For specimens of photolithography, &c. |
| Mailand, E. ... ... ... | For excellent photographic landscapes by the wax-paper process. |
| Marion ... ... ... ... | For excellence of photographic paper. |
| Masson ... ... ... ... | For excellence of photographs exhibited. |
| Mayer and Pierson ... ... | For excellent photography. |
| Michelez, C. | For reproductions of works of design ancient and modern, &c. |
| Millett, A. ... ... ... | For excellence of photographic lenses. |
| Moulin, F. ... ... ... | For excellence of photographs exhibited. |
| Pesme ... ... ... ... | For excellence of photography. |
| Plessy, M. ... ... ... | For excellence of photographic chemicals. |
| Potteau ... ... ... ... | For excellence of photographs exhibited. |
| Puech, L. ... ... ... | For excellence of photographic chemicals. |
| Quinet, A. M. ... ... | For excellence of articles exhibited. |
| Richebourg ... ... ... | For good photography in portraiture and objects of art. |
| Rolloy, Fils ... ... ... | For excellence of articles exhibited, especially for his photographic varnish. |
| Roman, D. ... ... ... | For excellence of photographs exhibited. |
| Silvy ... ... ... ... | For good photographic pictures. |
| Tournachon, A., jun. ... | For instantaneous pictures of horses and other animals. |
| Villette, E. ... ... ... | For large photographic pictures obtained by Duboscq's electric light. |
| | FRANKFORT. |
| Hamacher ... ... ... | For excellence of articles exhibited. |
| | ITALY. |
| Roncalli, A. ... ... ... | For excellence of microscopic reproductions. |
| | MECKLENBURG-SCHWERIN. |
| Dethleff ... ... ... | For excellence of pictures exhibited. |
| | NETHERLANDS. |
| Eyck, Dr. J. A. van ... ... | For his photographic copies of etchings by Rembrandt, the size of the originals. |
| | NORWAY. |
| Selmer ... ... ... ... | For a series of pictures of the peasantry of the country. |
| | PERSIA. |
| Pesce, Luigi ... ... ... | Views of Teheran, Persepolis, and other localities in Persia. |
| | PORTUGAL. |
| Silveira, J. W. ... ... | For excellence of photographs. |
| | PRUSSIA. |
| Beyrich, F. ... ... ... | For photographic paper. |
| Kunzmann, H. ... ... | For photographic paper. |
| Minutoli, Von ... ... | For a valuable series of reproductions of objects of art. |
| Schauer, G. ... .. ... | For excellence of pictures exhibited. |
| | RUSSIA. |
| Mieczkowski, J. ... ... | For good portraiture and artistic effect. |

| *Name of Exhibitor.* | *Objects Awarded and Reasons for the Award.* |

| | WURTEMBURG. |
| Sprösser ... ... ... | For photographic excellence. |
| | ZOLLVEREIN. |
| Exhibitor not identified ... | For excellence of photographic impressions. |

## PHOTOGRAPHIC CHEMICALS.

The official report of the awards of the Juries is at length published. It will prove an apple of discord with a vengeance. Already complaints are reaching us from all sides, of the sins of commission and omission which characterise this ponderous volume. Confining ourselves in these articles to the chemical section, we must say that our feelings on examining the list of medals, and honorable mentions in Class II. is one of indignation, mingled perhaps with a very small proportion of gratification at finding, that the few firms whom we have especially noticed in these columns are, with scarcely an exception, rewarded by a prize medal.

For the rest, the Jury appear to have gone round with a yard measure in their hands, and to have bestowed prize medals upon those cases which were above a certain size; honorable mentions to those which did not quite come up to the mark of magnitude, and to have passed over most of the cases which did not expose an area of more than a few square feet.

Firms which have not the slightest pretensions to such distinction, have borne off the highest honours, whilst others, the gigantic scale of whose operations is known throughout Europe, are not considered worthy of mention. In answer to some indignant remonstrances which have been addressed to those in authority, it has been explained that there are *numerous errors* in the published awards, which will be shortly rectified when the agrieved individuals will of course find that they had a prize medal awarded them. The fact of having a medal bestowed in so ungracious and underhand a manner, being considered ample atonement for the unjust and public insult which has been thus indelibly inflicted upon some of the exhibitors by the slovenly way in which this most important official document has been revised and given to the world. Until the appearance of the amended list, it may be considered premature to make further comments on this subject.

To return to our notices of the photographically interesting products; we must not omit to mention the beautiful collection exhibited by Bolton and Barnett. A vast number of rare chemicals, together with most of those used in photography, are collected together in this case. To those of our readers who have not a very good acquaintance with the appearance and physical characteristics of those chemicals which are frequently mentioned in these pages, but seldom used except in experimental photography, an attentive examination of this case will prove very instructive.

Some good specimens of ether, hyposulphite of soda, acetic acid, &c. are shown by F. Allen, and some fine specimens of iodine and various metallic iodides, are exhibited by Messrs. Wright, Francis and Co. This firm also exhibits several varieties of collodion, including negative and positive for photographic purposes, and a non-contractile variety for use in surgery.

A most valuable and instructive series of artists' colours with the materials used in their manufacture, is shown by the well known firm of Newman. The student who is curious in such matters may see a piece of metallic cadmium and a lump of brimstone, as the component parts of the brilliant cadmium yellow. In like manner cobalt blue is seen to consist of phosphate of cobalt and alumina: vermilion is shown by the side of a bottle of caustic potash, some mercury and a piece of sulphur. Chrome yellow, has for its origin acetate of lead and chromate of potash; emerald green is formed from acetate of copper and arsenious acid and is therefore to be avoided by all those who object to the wholesale employment of this deadly poison in every-day life. Chinese white (oxide of zinc) is represented by a lump of the metal, the atmosphere in the case being, we suppose exhibited as the other component of this colour, it being prepared by burning zink in air. The manufacture of ultra-marine, both natural and artificial. is one of the specialities of this firm, and a magnificent collection is to be seen of this beautiful colour in all varieties of tint, together with the *lapis lazuli* from which the natural colour is obtained. and the quartz, carbonate of soda, sulphur and china-clay.

## THE PRINTING OF POSITIVES.

BY E. REYNAUD.

The influence on the beauty of positive pictures exercised by the circumstances in which the printing is performed, is well known to photographers generally. For instance, a negative, which on certain occasions yields but a poor and valueless print, would frequently, if obtained under better conditions, furnish a satisfactory production.

The importance, then, of an investigation leading to the determination of the best conditions, according to the nature of the negative, in order to obtain the best possible result, can easily be conceived.

I will briefly detail some hints, the result of my experience on the subject.

The chief points to be considered are:—

1. The intensity of the light.
2. The nature of the paper employed.*
3. The proportion of free nitrate of silver which it contains.

The intensity of the light, in which the operation of printing is performed, must always have a certain relation with the intensity of the negative. A negative that has been exposed too short a time in the camera presents, as is well known, large transparent portions without detail, which produce deep shades or masses of black in the positive prints, whilst the lights are opaque, and the middle tones are wanting. Printing from such a negative requires a bright light in order to be successful: in such a case the direct light of the sun is to be recommended. If, on the other hand, the negative has been exposed, contrast will be wanting in the light and shades, the delicate half tones about the lights being effaced, and those of the shades too far advanced. Such a negative exposed to an intense light will yield a grey and monotonous print; whilst on the other hand a weak light will produce more vigour. The following is an excellent means for obtaining a suitable degree of luminous intensity at a time when the rays of the sun are too brilliant:—it consists in placing between the glass of the printing-frame and the negatives, a sheet or two of white paper, quite homogeueous and more of less transparent. By this means the intensity of the glass becomes moderated, and arrives at the negative in a proper condition for the production of a good print.

I must here remark, that it is from the relation existing between the lights and shades of the negative, that we can deduce the proper degree of light to be employed, and not from the absolute opacity of the lights. For instance, certain parts of a negative may be extremely opaque, and yet, if the time has been too long, the whole of the negative will present but little contrast; in this a feeble light is indicated as the best for producing a good print.

Thus, then, to state the matter briefly, since a feeblo light, other things remaining the same, produces more contrast between the extreme tones of the prints, such a light is to be employed when the negatives are too weak or uniform; whilst an intense light, on the contrary, produces more monotonous images, this light is appropriate for harsh negatives, that is to say, for such in which the lights are too opaque and the shades too transparent.

But these phenomena are modified more or less by the nature of the positive paper; it is, therefore, necessary to study the properties of this substance, and to examine the influence of its elements on the beauty of its prints.

In the first place let me remark that a large proportion of free nitrate of silver acts like an increase in the intensity of the light. For instance, paper sensitized in a bath of twenty per cent. or 100 grains to the ounce, will produce, with the same negative, and the same light, a more monotonous or less contrasted print than if it were sensitized in a bath containing only fifteen per cent. of nitrate of silver.

Hence it may be deduced, that paper, sensitized in a bath rich in silver, is preferable for harshly contrasted negatives; whilst, on the contrary, paper sensitized in a weak solution is adapted to feeble and uniform negatives. Nevertheless, it must be observed that, since the vigour of tone depends also on the excess of nitrate of silver, the proportion of the latter cannot be diminished sensibly below fifteen per cent. if the toning and the fixing are to be properly effectuated.

I will now examine the influence of the first preparation of the paper.

Positive paper is divided into two distinct heads:—

Plain salted paper.

Albumenized paper.

Ordinary plain salted paper contains simply a certain proportion of some soluble chloride.

Albumenized paper contains, besides this chloride, organic matter—albumen.

After sensitizing, the former contains chloride of silver; and its surface is covered with a film of nitrate of silver.

The latter contains, besides these two salts, a large proportion of a peculiar body but little known; the same which is produced when a solution of nitrate of silver is poured into albumen. The fact is described and perfectly explained in an excellent article by Abbé Pujo.* Now this body, which the author denominates *albuminate of silver*, has the peculiarity of producing extremely vigorous or harsh images. It is to this salt that albumen paper owes the well known property of producing, with the same negative, prints endowed with much greater contrast than is found in those obtained on plain salted paper.

It is easy to comprehend, therefore, that the proportion existing between the albuminate and the chloride of silver, will exercise considerable influence on the prints. A large excess of the albuminate is adapted for gray or monotonous negatives, whilst negatives with great contrast require a large proportion of the chloride.

In short, the proportion between the albuminate of silver and the chloride of silver modifies the results, in the same manner as an excess of the nitrate, or the intensity of light; and it is on a correct relation between these four elements that positive printing depends for its success.

It is impossible to determine the proportion to be observed between these elements in accordance with the different degrees of intensity of the negatives; experience alone can teach the peculiar rules to be applied in each case.

I shall occupy myself further with the study of the influence which the above-mentioned elements exercise on the fixing and toning of prints, that is, the tone and vigour they assume in the gold bath and the fixing solution, hyposulphite of soda, and lay the particulars before the Society.—*Moniteur.*

* I understand here not the intimate nature of the paper, but that of the preparation which renders it appropriate for the purposes of photography, as salting and albumenizing.

* See pp. 291 and 302, Vol. v, Photographic News.

## Proceedings of Societies.

### Amateur Photographic Association.

A meeting of the Council of the Amateur Photographic Association was held on Monday the 7th instant, at 26, Haymarket. The Right Hon. the Earl of Caithness in the chair.

The minutes of the last meeting having been read and confirmed, the Secretary laid before the meeting the prizes of the Association, consisting of a highly ornamented claret jug, a plainer silver mounted ditto, three silver goblets, and two silver inkstands.

The Chairman having reported that His Royal Highness the Prince of Wales had graciously condescended to become the President of the Association, he was unanimously elected, and the Secretary was directed to address a letter to his Royal Highness, expressive of the great gratification experienced by the Council at his condescension. The following Vice-presidents were then elected :—

The Most Noble the Marquis of Drogheda.
Tho Right Hon. the Earl of Caithness.
The Right Hon. the Earl of Uxbridge.
The Right. Hon. the Viscount Ranelagh.

As also Lieut.-Col. Dudley Fitzgerald de Ros, and John Gooch Esq., Members of Council.

The Secretary then laid before the Council the names of the following members and subscribers who have joined the Association since the last meeting.

| | |
|---|---|
| Lord Carew. | S. J. Wethrell, Esq. |
| Lady Carew. | R. A. Cayley, Esq. |
| Dr. Diamond. | R. B. Bowman, Esq. |
| G. Wharton Simpson, Esq. | J. Burd, Esq. |
| The Hon. Nassau Joscelyn. | W. J. Owen, Esq. |
| Col. Challoner. | J. H. Page, Esq. |
| Major J. Wyngate. | A. Fentrill, Esq. |
| Capt. J. C. Bonamy. | W. L. Banks, Esq. |
| Capt. R. J. Henry. | Osmar King, Esq. |
| Capt. Burnaud. | F. Beasley, jun., Esq. |
| Capt. Fairlie. | C. Walters, Esq. |
| Rev. W. Law. | C. J. Tozer, Esq. |
| Rev. W. Eardley. | W. H. Harton, Esq. |
| Rev. H. Salnay. | C. Topham, Esq. |
| John Gooch, Esq. | Miss Clough. |
| W. W. King, Esq. | C. R. Jones, Esq. |
| F. Chambers, Esq. | A. Eichholtz, Esq. |
| W. M. Barnes, Esq. | C. F. Dickenson, Esq. |
| W. Jeffrey, Esq. | H. Boycott, Esq. |
| W. H. Bullock, Esq. | D. White, Esq. |
| Miss E. Scott. | W. Weare, Esq. |
| S. Hamilton, Esq. | J. W. Fall, Esq. |

The Right Hon. the Viscount Ranelagh having enquired whether professional photographers were eligible as members, was informed by the Secretary that amateur or non-professional photographers could alone become members of the Association. This having given rise to a discussion upon the mode of admitting members, it was decided that henceforth candidates for admission as members or subscribers must be proposed and seconded by existing members, and elected at a meeting of the Council.

The proceedings of the meeting then terminated.

A. J. Melhuish, Hon. Sec.

### The American Photographical Society.

The Society held a regular meeting at the University, on Monday evening, 9th ult., President Draper in the chair; C. Wager Hull, Secretary *pro tem.*

*Use of Sugar, &c., in the Tannin Process.*—Mr. Hull said he had been making trials of sugar, honey, &c., which had been recommended for the tannin process, and had found no advantage in them. If sometimes they gave a little gain in sensitiveness it was not sufficient to compensate for the extra trouble and risk. He preferred the tannin process in its simplest form.

Other members followed Mr. Hull to the same effect, fully endorsing his conclusions, and adding that plates which contained foreign matter would not be likely to keep so well.

*A New Photometer.*—The President said that he had recently modified one of the ordinary photometers so that it might be used for measuring the intensity of the chemical rays. The photometer in question is the one which is made of two cardboards united at one edge in the form of the letter V, and the lights to be tested being placed opposite the inclined surfaces, at points where the illumination on the surfaces would be equal, and then measuring the distances from the surfaces to the respective lights. The instrument thus far has been used only to measure the illuminating power of light, which is quite a different thing from the actinic power. The modification he had made was simply a contrivance for observing only the actinic rays, and consists of a blue medium through which the observation is to be made. He takes a piece of plate-glass, three inches square, and in the middle cuts out a hole one and a-half inches in diameter; this is laid on a second piece of plate-glass, also three inches square, and the cell thus formed is filled with a solution of the ammonia-sulphate of copper, and a third piece of plate-glass is laid on as a cover, and the fluid is closely sealed in, without danger of being disturbed. Through this solution only the actinic rays can pass, and if the operator makes his photometric observations through it, he measures the intensity of these rays.

Professor Seely.—This device for measuring actinic light is wonderfully simple, and there can be no doubt that it is accurate enough for all practical purposes. It costs only a little labour, cannot get out of order, and gives its indication almost as plainly as a thermometer. By a trifling modication, also, it may be used to measure daylight, so that a photographer may know, simply by looking, how much light he has.—*American Journal.*

## Correspondence.

### FOREIGN SCIENCE.

[From our Special Correspondent.]

*Paris, 16th July*, 1862.

The question is often asked, What connection exists between photography and the art of war? That there is a direct and natural connection, we think it will not be difficult to show.

An army has always had, and always will have, need of numerous auxiliaries; the mathematical, physical, and chemical sciences; the graphic and the mechanical arts form part of a course of military education: they afford a valuable and often indispensable aid to the combinations of war. Drawing, in its various branches, renders immense services; photography, which proceeds from all these scientific and artistic branches, and abridges their applications, has also an unquestionable affinity with military studies.

Regarded, at first, as a scientific curiosity and wonder, photography soon made rapid progress: it has advanced as a science, and, as a useful application of science, to the point of becoming a means, which, put into the hands of every one, has received its legitimate naturalization among the arts, sciences, and civilization.

Hitherto, however, photography has not fully co-operated with the art of war. Isolated applications have, it is true, been attempted for some time past; as, for example, in copies of plans, maps, and topographical drawings on an enlarged or reduced scale, have superseded the productions of the pantograph; views of plans of battles also; but these essays have been only individual and isolated, no general application of the photographic art has been made by the Government.

Only last year the State formed, under the direction of M. Disderi, a kind of school or class, of officers selected from various regiments, to whom he gave lessons in photography.

What, let us ask, is the value of this step? Will it have the utility claimed for it? We think not. For we must, in our opinion, view the application of photography to the art of war in a different light.

The officers who attend M. Disderi's lessons are, for the most part, merely amateurs, who only contemplate practising this art as an amusement; they are very far from suspecting that they are entering upon a very difficult career, the utility of which can hardly conceal its aridity: it requires, on the contrary, at the beginning especially, men endowed with much perseverance, and well convinced that a glorious future awaits them in this path, a well-earned reputation to be acquired, and a name to be made.

If photography, as seems manifest, is to render powerful aid to military operations, and if the Government is seriously disposed to attach photographers to land and sea expeditions, it is necessary that it should clearly comprehend the importance of such a decision.

Military photography, among other applications, may embrace perspective views of fortresses, military posts, redoubts, and general views, to accompany despatches, and furnish an explanation of the results obtained, and the means employed to obtain them. In other respects, this new art will give greater precision than any written documents. We obtain, instantaneously, *proportional and measured perspectives* of the *extent* and *distances* of forts, promontories, the distribution of groups in fleets and armies: we can obtain military positions, and an infinity of essential representations, without reckoning the application of the camera to topographical plans—a problem already partly resolved—and would have been completely so if men possessing competence and leisure had devoted themselves to the art under a military point of view, instead of making of it only an object of idle curiosity. The first proposals to the Minister of War to establish a class of photography among the military staff were rejected. But when Marshal Vaillant succeeded to that post, he gave it a more cordial reception. The terms of the proposal were mainly as follows:—

To introduce photography usefully into the army, it is first necessary to select officers devoted, apt, and especially with a decided talent for this kind of operations.

To establish in each military school a proper course of instruction in photography. Four or five lessons obligatory upon all, in order that every pupil may obtain a knowledge of the rudiments of the art; then, every year to make choice of a certain number of pupils, who, having already manipulated and shown a decided vocation for the art, and perfect them in a special establishment—the military depôt, for instance—and by these means obtain a result doubly advantageous; first, to endow all the young officers with a new art; and next, to excite in them a love for the physical and chemical sciences, which they are now very far from possessing.

To provide each regiment with the apparatus requisite for taking views, plans, &c.

It will be quite easy to stimulate and sustain the zeal of the officers by a daily application of the art to works of acknowledged utility, such as views, maps, uniforms, horses, the material of war, and in fact of everything interesting to the soldier.

It will be seen from the foregoing that all that is necessary in order to render photography as useful to the art of war as many arts and sciences already are, is, first, to recognize the great aid it is capable of rendering, and then to systematically organize a course of instruction among the young officers, and maintain their interest in the art by daily application to it.

## Photographic Notes and Queries.

### Intensifying Honey and Tannin Plates.

Dear Sir,—Perhaps it might be useful to some of your readers, who work the honey and tannin process, to know that those plates can be intensified to any extent by a solution of iodine, washed and then redeveloped; a good negative should not require this, but a plate over-exposed, and then too feeble to print, can be made a good printing negative in the manner above stated, and finally well washed.

I find a plate prepared with a mixture equal parts (say 15 grs. to the oz.) of caramel and tannin far more rapid than honey and tannin.—Yours truly, G.

### Fading Prints.

Dear Sir,—Your article on the fading of positive proofs in the last number of the News induces me to bring the subject forward again from circumstances of casual observation only.

My premises going under repair, and all useless lumber being turned out, amongst which were some old photographs printed in 1838–39–40, very few of which were faded; in referring to my Journal I find the method to vary little from that of the present time, the formula I give as follows:—Best drawing paper soaked in salting bath a few minutes composed of

| | |
|---|---|
| Water ... ... ... ... | 1 pint |
| Chloride of sodium ... ... | 400 grains |

Pin up to dry.

*Silver Bath.*

| | |
|---|---|
| Nitrate of silver ... ... ... ... | 8 drs. |
| Water ... ... ... ... ... ... | 8 ozs. |

one side of the paper to be brushed over or floated on the solution in a flat dish,* to be dried in the dark. When removed from the printing frame immersed in hyposulphite of soda, 4 oz., water, 4 oz., a few minutes; washed several times in boiling water, and dried between blotting paper. These photographs were all mounted on plate with gum water, which I used in mounting botanical specimens, animal preparations, &c., it contained—

| | |
|---|---|
| Turkey gum ... ... ... ... | 4 ozs. |
| Water ... ... ... ... ... | 2 „ |
| Saturated solution of bichloride of mercury | 2 „ |

I am inclined to think the bichloride of mercury assists the preservation of the prints, for of late years I have used other substances for mounting, and washed the prints with great care, and many have faded quite away.—Yours obediently,

H. R. Nichols.

[As the prints were on thick drawing paper, it may be that the bichloride of mercury never came into contact with the image; if it had done so it must inevitably have acted upon it, and probably in an injurious manner, as its usual effect upon a silver print is to bleach it. The perfect condition of the prints referred to, and indeed of very many old prints, which did not receive a tithe of the washing, &c., which prints now generally receive, is somewhat puzzling. The only suggestion we can make on the subject is, that at one time prints were washed individually, and that now they are washed in batches; a circumstance which materially alters the case. We shall have pleasure in receiving our correspondent's account of various waterproof compounds, as the hints of practical men on such subjects are always of value.—Ed.]

## Miscellaneous.

Physiognomy and Photography.—Looking over the portraits of men who have risen above their fellows, who have blessed, cursed, or influenced their race, we find no commonplace faces—none whose visages are beneath their greatness. Napoleon thought a large nose a mark of strength of character. So it is; but not alone the nose, but all the features are well developed in men of mark and vigour. A small and insignificant face is unknown to greatness. In saying so, we only claim, with the phrenologist, a large brain, which manifests itself in a corresponding countenance. None will deny that character is expressed in the face and body; the only doubt is as to the possibility of the skill that can read its complex and intertwined signs with any certainty. Lavater did not cultivate physiognomy in the specific spirit which alone can discover and secure truths for mankind. If any one would give to physiognomy the labour and genius Gall gave to the brain, and Professor Owen has given to comparative anatomy, there is little question but valuable results would be attained. He would have the world with him for sympathetic and admiring students, for we are all curious about one another, and ready to take stock of each others' attainments and possibilities. One of Lavater's constant difficulties was in careless and incorrect portraits. Now we have photography, we can not only study the living at our leisure as they are, but can obtain faithful transcripts of the best pictures of men famous and infamous who have passed from earth.—*Chambers's Journal.*

* I have now in use some of the wooden dishes used by me at that period; they are made of pine wood, lined with caoutchouc and Stockholm pitch, equal parts, melted together.

I can furnish you with many interesting compounds also of gutta-percha, having used the latter for various purposes for several years. I may say fully fifteen years. H. R. N.

## Talk in the Studio.

Copyright in Fine Arts.—The Copyright (Works of Art) Bill passed through committee, in the House of Lords, on Tuesday evening.

Royal Portraits.—We have pleasure in announcing that their Royal Highnesses the Princesses Helena and Louise honoured Mr. Jabez Hughes with sittings for portraits, at his studio, in the arcade, Ryde, by appointment, on Tuesday last. Several successful portraits, both single and grouped, were obtained. Their Royal Highnesses were accompanied by Major Elphinstone and Lady Caroline Barrington.

Large Angle.—We recently received from Major Gordon, of the Ilse of Wight, some 12 by 10 photographs, produced by a Voigtlander orthoscopic lens of 11½ in. focus. The pictures were very good indeed, and the definition pictorially sufficient to the edges. This, of course, includes a large angle, and with very satisfactory effect.

M. Claudet's Enlarged Drawings.—We received from Mr. Macandrew, a few weeks ago, a letter on M. Claudet's enlarged drawings, produced from a photographic negative by the aid of the solar camera, in which it was stated that a specimen exhibited at a meeting of the Photographic Society as produced in the manner described, was simply a painting, and whatever excellence it possessed was due only to the skill of the painter, who alleged that he had erased the slight traces on the canvas before commencing work, as being more hindrance than aid. We declined to insert the letter, as it simply involved a question of personal veracity in some of the parties concerned, and not of photographic possibility, as, if the pictures were not produced as described, they might have been; and we did not wish to give publicity to gossipping on the part of this painter, which, to speak mildly, was at least very imprudent. As the letter appears, however, in two of our contemporaries, in one of which it is accompanied by a letter from M. Claudet, who has been courteously permitted an opportunity of vindicating his veracity in the same page in which it is called in question, we now notice the matter to remark that M. Claudet distinctly describes every picture of this kind which he exhibits in the International Exhibition as having been traced by himself in the manner described in his paper, and painted under his own eyes. The only portrait not so painted was that of Professor Faraday, in relation to which the painter's assertion has been made. The true explanation of this matter is to be found, we fear, in a little of that jealousy in which so many artists indulge, and which induces them to seize every opportunity of decrying the merit of the photographic drawing, and alleging their independence of its aid. Not every painter who even now condescends to earn money by colouring photographs, is like our friend Wall, an ardent and enthusiastic lover of photography, as well as a skilled artist with the brush. Our opinion of M. Claudet's method was expressed last week. Its products are not photographs, but illustrations of a valuable application of photography to large portraiture, and as such worthy of much praise.

New Method to Amalgamate Zinc.—To amalgamate zinc of electric batteries, Mr. Berjot uses the following process:—Dissolve 7 ounces 375 grains of mercury in 3 pints 4 ounces of nitro muriatic acid (nitric acid 1 part, hydrochloric acid 3 parts). Heat the mixture a little, and add to it 2 pints 4 ounces hydrochloric acid. It is sufficient to put the zinc a few seconds in this mixture to have it amalgamated. The process is very simple and not costly. The above amount of mercury is enough to amalgamate 150 to 200 cylinders of zinc.

Gun-cotton as a Filter for Strong Acids.—Bottger recommends chemists to use gun-cotton as a filter for concentrated acids and liquids decomposable by organic matters. The author employs it with the greatest advantage for filtering concentrated nitric acid, fuming sulphuric acid, chromic acid, permanganate of potash, and even concentrated solutions of potash, and aqua regia. He says that properly prepared gun-cotton is only attacked at the ordinary temperature by acetic ether.

New Explosive Pyroxyline.—The latest explosive material consists of the flour of starch, which, boiled in a peculiar way with nitric acid, possesses a far greater projective force than the gunpowder in ordinary use. It also has the great advantage of not fouling the piece to any appreciable extent, and, from the nature of the materials used, is produced at a far cheaper rate. Another point in its composition which recommends it especially for fortresses and magazines, is the facility with which the ingredients are mixed together, thus rendering it possible to keep them separate until wanted for actual use. In this state the powder is non-explosive. The experiments now in course of progress in Vienna and Berlin are said to leave little doubt as to its general adoption in the Austrian and Prussian armies.

## To Correspondents.

Teesdale.—If you call upon us when you are in town we will advise you 2. The "halo" of which you speak is most probably a reflection from imperfect mounting of the lens. 3. Prints after washing are generally allowed to dry spontaneously. Many operators place them between leaves of blotting paper kept for the purpose, to remove excess of moisture, and then leave them to dry. Some operators make it a point to dry faint prints by the fire, under the impression that rapid drying gives a little more brilliancy.

"Mr. Warner, of Ross," presents his compliments to the editor of the Photographic News, and will thank him to state in his "Notices to Correspondents," that owing to the damp from the walls in the International "*Sky Parlour*," his specimens of enlarged photographs from small negatives (for which he has just obtained an "*Honourable Mention*" and Certificate of Merit) have been taken down; but that similar ones, with copies from the small negatives attached, may be seen at the exhibition of the *South London Photographic Society*, at the Crystal Palace, Sydenham.

C. A. R.—The deposit on the deep shadows of your negative, which obstruct the light in printing, and cause parts which should be black to be very pale, is really a form of fog. You do not describe the details of your manipulation; but it is probable that you develop with iron, and strengthen with pyrogallic acid and silver, and it is in the course of the latter operation that this deposit takes place. If so, you will probably find the use of citric acid in the pyro solution, instead of acetic acid, will aid in preventing this deposit. Pouring a weak solution of tincture of iodine over the plate, and then washing it off, prior to the application of pyro and silver, will also aid in preventing it. If these remedies do not apply, state your operations more clearly, and we will assist you further. Your other specimen has some good qualities, but it is a little hard, and the definition might be better.

A. B. C.—The general proportions of your proposed glass house appear to be very good. We should prefer nine feet dark over the head of the sitter to six, and about six feet at the sides, next the background, might be dark also. The amount of slope or "pitch" should be rather more than you propose, in order to prevent the slightest chance of water lodging and gradually soaking in. If the total height be 14 feet, let the sides be nine or ten feet, which will make the slope more steep than you propose, and will rapidly throw off water in very heavy showers. If your position will admit of placing the house so that the sitter will face the north, it will be an improvement. Except for ventilating purposes, we do not see the necessity of making any of the sashes to open.

W. Bartholomew.—A correspondent, who has not Mr. Bartholomew's address, asks us to put the following questions relative to the morphine dry process, and will be glad if Mr. Bartholomew will kindly help him with a few hints:—"Is old or new collodion the best? Must the plates be perfectly washed, or only with a limited quantity of water? My bath I have made at the rate of 1 grain muriate of morphine to 10 ounces of bath; is that enough or too much? The plates I have tried have been rather less sensitive at the corners and edges: should this be so? The bath deposits a dark looking film on the glass bottle in which I keep it; how can I prevent this?"

New Subscriber.—The specimens you enclose are very bad examples of mealiness, and we regret to say that we cannot give you a certain cure for the defect. It arises from a variety and combination of causes, primarily we believe the paper is at fault, but a variety of causes will bring it about when the predisposition is in the paper, and some modes of dealing will mitigate, if they do not cure. In the first place, the use of a thin, weak, or fogged negative will materially aid in producing the defect, whilst a clean, brilliant negative, which permits perfect reduction in printing will largely prevent it. In many cases we ascertain that the use of a neutral of alkaline silver bath, or of the ammonia nitrate silver bath for exciting the paper will prevent it. In some cases washing well with *distilled* water before toning will prevent it. In some cases the use of a bath of acetate of soda prior to toning will prevent it. It is a defect which has rarely if ever occurred in our own hands, and therefore we can only record the experience of others as to its cure or prevention. A very great deal has appeared in our pages on the subject during the last twelve months, but the chief remedies suggested are those we have just named. Good paper and good negatives are of the chief importance. The fifth print is altogether a puzzler, we cannot assign any certain cause for the effect. 2. The shadows turning red during intensifying is a circumstance we have met with. It will sometimes occur when intensifying, after fixing, in the light. When it occurs as you describe, after the fixed plate has stood a while in the light before intensifying, it may possibly, or may not, be due in some way to that cause; but we have seen it occur under these circumstances only when the plate has been imperfectly washed, and some traces of cyanide of potassium, and perhaps of cyanide of silver, have remained in the film. If the plate be thoroughly washed after fixing, and the intensifying be done in yellow or subdued light, this red deposit will not appear. The Almanac, "Manual of Colouring," and back numbers have been forwarded. Please state from whom your post-office order is made payable, whether with your full name or initials only.

J. Wilkinson.—The orange glass about which you enquire, regarding which we made a favourable report to Photos, was obtained, we are informed, of Messrs. Burfield and Rouch.

Chromo complains that he cannot learn colouring satisfactorily from a book. A good manual of instruction is an invaluable aid to the student, but how far it will be sufficient without the aid of a teacher, must largely depend upon natural capacity, &c. By all means, if you have opportunity, take lessons: you cannot have a more able or conscientious teacher than Mr. Wall. His own practice is chiefly in oil, but he is perfectly familiar with other methods. His address is 35, Westbourne Grove, Bayswater.

T. G. M.—You may add a bromide to your simply iodized collodion without difficulty. Bromide of cadmium, at the rate of from half a grain to a grain to each ounce. It may be either added to the collodion direct, or previously dissolved in a very small quantity of alcohol

Several Correspondents in our next.

Vol. VI. No. 203.—July 25, 1862.

## MODIFICATIONS IN THE TANNIN PROCESS.

The universal testimony to the excellence of the tannin process for dry plates, both in this country, on the Continent, and in the United States, seems to promise that if it be not in its original form *the* dry process which is required, at least some modification of it will be. We question whether, since its discovery, any other dry process has been half as much practised, or with half as much success.

We glean from time to time additional evidence as to the two modifications which have been recently brought prominently under public attention, the hot development, and the addition of honey or a similar substance to the tannin solution. Regarding both, the balance of evidence seems to be in their favour. Major Russell, the originator of the process, in a recent letter to us, says:—

"More than a year ago, however, I found out that tannin plates, unlike most other dry plates from which nitrate has been entirely removed, may be too dry; and in that case are less sensitive, less intense, and appear to solarize more readily. From this, I thought it probable that some substance which retained a moisture, might be advantageously mixed with the tannin, but tried no experiments in this direction, until I heard of Mr. England's use of honey, which I should think likely to answer well, if not used in sufficient quantity to render the surface sticky. I fancy, however, from theoretical considerations, that the same object may be obtained with still greater sensitiveness by other means, and several weeks ago prepared a number of plates to test the matter, but have not yet exposed them, on account of the unfavourable condition of the light, for it is quite useless to try experiments for sensitiveness in any but an uniform light; and this cannot be depended on, except when the sky is quite bright."

Lieut.-Col. Stuart Wortley, who has just returned from Italy, showed us the other day some very excellent pictures from tannin plates. He states, that he has found a similar advantage, as to sensitiveness, to that claimed for the addition of honey, when gum arabic has been added to the tannin solution. Some time ago the Rev. J Galloway Cowan related similar experience.

It is only right to add, however, that we have heard in some instances that these additions tended to destroy the keeping qualities of the plates. Mr. Hurst, an enthusiastic Yorkshire amateur, recently called upon and showed us some exceedingly fine tannin negatives. He stated that on the whole he preferred the original process to any of the modifications; as he was willing to give the long exposure, and obtained very perfect results. He had tried the honey and tannin with very satisfactory results. When the plates were freshly prepared they were decidedly considerably more sensitive than those with tannin alone. When they had been kept a few weeks however, this advantage was lost. At the end of a fortnight he found them no more sensitive than plain tannin plates, and he had a conviction that with longer keeping they would become even less so, as the film seemed to him to become, in the course of time, contrary to all expectations, even more completely hard than tannin alone. The fact, observed by all who have tried it, that honey and tannin give a hard dry film instead of a slightly sticky one, is somewhat unexpected; but that they should give a film which eventually becomes harder even than tannin alone, seems very singular, and deserves further examination, as does also the question of the keeping properties of honey and tannin plates generally.

The value of heat in developing, although still the subject of conflicting testimony, is obtaining increased recognition. Major Russell informs us that he has been experimenting in its use. He says—

"With regard to the use of heat in the development, my brother, Mr. Branfill, used it successfully; and I tried many experiments in that way long before hearing of Dr. Draper's experience. My experiments were not carried far enough to enable me to speak with much confidence, but the results were very promising, as I have succeeded by the aid of heat in bringing out a tolerably good picture after about $\frac{1}{25}$th of the exposure which would otherwise have been necessary. There are some difficulties in working in this way, which might probably be overcome; the picture is something like that brought out in the wet process by iron, and intensifies with difficulty. One circumstance, which I have not seen noticed is, that the image brought out by the aid of heat after very short exposure is quite superficial, and when dry can be entirely wiped off with the finger: this is probably the effect of the want of penetration of the light into the yellow iodide. After varnishing, however, the image would doubtless be firm enough to print from. Hot water is very apt to loosen the film, if on bare glass or on gelatine; but on a thin coating of india-rubber bears a boiling hot liquid with even less risk of moving than when a cold one is applied. I cannot as yet give any directions as to how the hot development should be managed; but it will probably be found that the heat should be proportioned to the length of the exposure, as the application of boiling water to a plate exposed about one quarter the usual time, will start the detail, but at the same time spoil the picture by fogging. The least trace of acid in the water destroys the invisible image. Pyrogallic solution is easily decomposed by heat, so it is better, if possible, to work with hot water, alternated with cool developer."

The thin feeble image, to which Major Russell here alludes as the frequent result of hot development, we have met with in our own experiments. The image is full of detail, but with no contrast, resembling in appearance the images produced by an over bromized collodion. The suggestion as to the relation between the amount of heat and the time of exposure, has, as Major Russell conjectures it would be, been found of the greatest importance. Some time ago Lieut.-Col. Stuart Wortley, in a communication which appeared in the News, pointed this out; and in a recent conversation he insisted strongly on the necessity of recognising this principle. The specimens he showed us of the results of hot development were exceedingly soft and full of detail.

Photographers on the Continent have recently been giving much attention to the tannin process, and Mr. Adolphe Martin, and M. Gaudin, endorse the value of hot development. We may mention that Mr. Sutton, who for some time maintained the pre-eminence of a simply iodized collodion for the tannin plates, has recently come to the conclusion that a bromide in dry plates materially accelerates; and with the honest straightforwardness which always distinguishes his writings, at once avows this change in his views on the subject, and explains the cause. We had hoped to relate the results of some further personal experience in this direction; but must delay it for the present. In the meantime, therefore, we lay before our readers these few brief notes on the subject. We shall be glad to learn from time to time the results of their experience.

## "OUR LIVERPOOL CONTEMPORARY."

We have to claim the indulgence of our readers for a few moments, whilst we make one or two explanations or comments upon a matter we should prefer to pass in silence, were it not for the fact, that silence would, probably, be misconstrued. We have been for some time past subjected, in the pages of a contemporary, to a series of petty innuendoes, and covert offensive allusions of various kinds. In accordance with a rule we had laid down for ourselves, we have steadily forborne to notice these puerilities. We now find a long leader making a general onslaught on the contemporary photographic press, in which onslaught, however, we are honoured with especial acrimony. As some of the statements made are false, as well as foolish, we feel it desirable to say one or two words on the subject. These few words of explanation over, we shall again resume our rule for unswerving observance.

Our primary offence appears to consist in the fact, that we sometimes refer to the journal in question as "Our Liverpool Contemporary," and, it is alleged, we quote its pages without due acknowledgment. In order to make clear the gravamen of this offence, it may be necessary, to some of our readers, to mention one or two facts. Some years ago, an enterprizing photographic society in a large provincial town established a journal to record its proceedings, and aid in the diffusion of photography. This happening at a period when the art was rapidly spreading and growing in importance, this little journal shortly afterwards became the organ of two or three other provincial societies. At this stage of affairs, the conductors of the journal in question, one fine morning, appropriated the title by which the organ of the London Photographic Society was best known to the world, and published their provincial paper as *The Photographic Journal.* Legal proceedings were at once initiated by the society to protect its property, and the issue was, that after the loss of a good round sum, it obtained again the sole use of the proper style and title of its journal.* The provincial journal in question did not, however, on being compelled to give up the title of *The Photographic Journal*, resume its old appellation, but, after some shuffling, dubbed itself, modestly, as *The British Journal of Photography.* Well, if it had assumed the title of "King of the Cannibal Islands," or "Brother to the Sun and Sister to the Moon," we don't know that any one had a right to find fault, beyond remarking, that the title was too long to be generally repeated. It has so happened, however, that those who have known the journal longest, and despise its frequent shortcomings in the matter of good taste, have respected it as, in its capacity of organ of the provincial societies, doing some good work, are now, as they have ever been, in the familiar habit of speaking of it as the *Liverpool Journal.* There is no disrespect in that title, but honour, as in using it they avoid recalling the act of "appropriation" to which we have referred. We are asked by our contemporary, however, in the article to which we have alluded, "Why Liverpool contemporary? Why not Manchester, or Birmingham, or Edinburgh, or, for that matter, London, unless it be to disguise the identity of the *British Journal of Photography*?" Why? Why for the commonsense reason that it *is* our Liverpool contemporary, that it was born in Liverpool, brought up in Liverpool, and is still printed and published, and, we hope, read there, and for the reason that being all this, there is nothing that we can conceive to be ashamed of in hailing from such a city.

We have used the phrase "Liverpool contemporary" amongst others, such as *Liverpool Journal, British Journal,* &c., whenever it happened to flow to our pen, to designate shortly the Journal in question, when we have chanced to refer to it, without the remotest thought of disrespect. As to disguising the identity of our contemporary, such an idea could never have given us a moment's concern. If that identity is so easily disguised, and our contemporary *must* know best, why we are sorry for it.

The especial article we are charged with quoting without due acknowledgement, was one by Mr. Dawson on bromides. Now weeks before that article was published our attention had been specially called to it in a private letter from Mr. Dawson, and we, in another letter, had promised to extract it when it appeared. We did so, as our readers will remember, distinctly accrediting Mr. Dawson as the writer, and our Liverpool contemporary as the Journal. This, then, stripped of its verbiage, and the "sound and fury signifying nothing" is the only special grievance our contemporary has to relate; the remainder of his allegations consist of vague generalities as false as this is foolish.

Our contemporary professes to be injured, and to apprehend loss of his identity, by our reference to him as "our Liverpool contemporary." As we have said, we have never dreamed of evasion, or meant anything like disrespect in the use of this term, although it may be, as he himself seems to think, that the photographic public are less familiar with his existence and history than we had even given him credit for. But had we intended anything offensive in this phrase, we must remind him that he initiated the practice of using an insulting alias some years ago. Before the advent to office of the present editor of the News, it used to be a favourite joke with our contemporary—and the pun was vastly funny!—to refer to this Journal as "our *weakly* contemporary!" We have never followed his bad example in the use of offensive epithets, and we can assure him that we should never dream of offence in his use of phrases to designate us analogous to those we use, such as "our London contemporary," or "our weekly contemporary," or any other reasonable variation he may choose.

Regarding the general charge of non-acknowledgment, we might with great propriety, if the allegations of our angry contemporary were correct, simply point to the well-known and universal practice in journalism by which any meeting held, speech made, paper read, &c., and appearing in the public prints, becomes, by universal agreement and understanding amongst journalists, common property. To illustrate: there are some hundreds of newspapers in Great Britain, who daily and weekly publish reports of the proceedings in parliament, &c. Of these hundreds there are not more than about half-a-dozen who send reporters to the house and obtain direct reports. The only advantage they secure over the press at large by this, is priority of publication. The custom to which we refer as recognized by common consent is further endorsed by law; the period of copyright permitted to newspapers, if we remember rightly, being just six hours! We could point, moreover, to the fact that our contemporary, when it suits his purpose, avails himself liberally of this custom without the slightest scruple!

But let us be understood, as regards our contemporary's alleged injury, we do not avail ourselves of the shelter of any such custom. We simply and entirely deny his charge. We know well the thin skinned irritability of our contemporary, we know well that during his career he has been a journalistic Ishmael, his hand, in turn, against every one of his *confrères*, and if every one's hand has not been against him, it has been simply due to forbearance or contempt. We resolved, when two years ago we assumed our duty as Editor of the News, we resolved then, if it were possible, to live at peace with him, and avoid deforming our pages with personal squabbles; and we are therefore most scrupulously in the habit of duly acknowledging any scrap of photographic information which in the interests of our readers we may quote from his pages. We do this with the utmost care: if it ever occur otherwise, and we think it does not, it is an accident. Very rarely, indeed, do we reprint at all from his journal; when we do so, it is, in the majority of instances, papers read at some provincial society of which he is the official organ. In such cases we always duly credit the writer of the paper, the society at which it is read, and the organ in which it appears.

We might add another reason for this care in acknowledgment, which is perhaps more important to our readers than our contemporary's feelings. It is this: that when a quotation is properly acknowledged, all responsibility for

* It may interest the members of the Photographic Society to know that this little experiment in "appropriation," "annexation," or whatever else it may be termed by the journal in question, cost the society nearly one hundred pounds!

its statements rests upon the original source; whilst quotation without acknowledgment transfers the responsibility to him who uses the quotation. Now we must confess we have no such profound faith in our contemporary as would lead us to accept the responsibility of affiliating his articles. If we had no other reason, we should refer to the source of such quotations, as indicative of the exact amount of authority they possess.

As we have said, we are attacked in a general onslaught, in which our American *confrères* come in for heavy punishments, and our contemporary the *Photographic Notes* for a timorous side-blow, which is, however, at the same time, accompanied by an impertinent and patronizing attempt to palliate its force or deprecate rejoinder, in which we detect some uneasy recollection of our friend Sutton's hard hitting on former occasions. Both he and our American friends can take care of themselves, and the bickerings of the Liverpool journal with them is no concern of ours. Nor have we ever meddled in the matter. Since, however, we are thus mixed up in the attack in question, we may make one or two remarks. The two American journals, in addition to the valuable original matter they publish, extract largely and with much discrimination from European journals. This is done, we have pleasure in adding, as a general rule, in a fair and honourable manner. with proper acknowledgment of the source. They have their own method of doing this, either at the beginning or end of a continued article, so as to avoid repetition. Inadvertent omission may also occur with them as with others. For some of these fancied or accidental omissions, these journals have been the object of of repeated querulous attacks in the pages of our contemporary. Our pages have been laid under contribution in American and other journals, to at least an equal extent; but it has never occurred to us to make this a grievance. Whether the source were acknowledged, or by inadvertence omitted, we have given our contemporaries credit for the best intentions, and have felt glad to know that information calculated to aid the progress of the art was obtaining wider circulation. In the very last number of one of our contemporaries in this country, an article is reproduced without acknowledgment, which had been contributed, to use our contemporary's phrase, "exclusively" to our pages; but we should feel somewhat ashamed of ourselves to cry out about it as an intentional evasion or slight. It is one of those cases in which "giving impoverishes not, neither does withholding enrich." If our contemporaries gather matter from us, we at times glean from them, and thus increased circulation is given to all photographic information of value, and the public are the gainers. We believe we are generally duly accredited, and we know we always aim at accrediting others; and if on either side it be at times omitted, it is probably through oversight, by which we do not know that anybody is much injured.

With our Liverpool contemporary all this is different. We rarely quote from his pages at all, and when we do so, as we have before said, we scrupulously acknowledge the source. But there is one other circumstance in connection with this, to which we must allude. It so happens that at one of the photographic societies the editor of our contemporary is the constant chairman: in this capacity he takes charge of, and systematically refuses to ourselves the permission to copy or make abstracts of the papers read at its meetings. It generally happens that we receive copies of such papers from the gentlemen who read them; it has occasionally happened, however, where we have not had opportunity of communication with the writers, that we have had to wait to reproduce them until our contemporary has published. If the paper has happened to be one of interest to our readers, we have then inserted it. In regard to such papers, which have been read to a society of which we are a member, and at a meeting at which we are present, which we forbear publishing from reporters' notes, simply to do the fullest justice to the writers and our readers; in regard to such papers our contemporary has the audacity to demand from us that we quote them as from his pages! This, in the one or two instances in which it has occurred, we have declined to do: this we shall decline to do, as by doing it, we should be but offering a premium for narrowness and discourtesy. We have had a tolerably lengthy experience in journalism: we had in early life a somewhat extended experience in reporting meetings of all kinds, and we can unhesitatingly aver that we never met with a similar discourtesy and similar claim to this on the part of our contemporary.

Let us add, that in cases where at any meeting the copy of a paper has first fallen into our hands, we have always hastened to furnish our contemporary with copy without any delay. Let us also state that our contemporary seeks and obtains, in common with ourselves, from the *Journal of the Photographic Society*, copy of the papers read at its meetings, for publication contemporaneously with that journal. The editor of the *Photographic Journal*, with unfailing courtesy, supplies to his contemporaries, copy of papers, to which he could assert a sole claim, his journal being the property of the Society; and our Liverpool contemporary eagerly profits by a courtesy which he is altogether unwilling to extend to others. We hold the conviction that photographic journals, as well as photographic societies, should exist for the advancement and diffusion of the art, and that so soon as they lose sight of that as their primary aim, so soon will they deserve to lose what should be their secondary object, individual advantage and trade profit; and, what is more, we believe *they will get what they deserve.*

To eke out his case, our contemporary talks about our quoting from foreign journals without permission or acknowledgment. To this, as we have before said, we might very properly answer with a *tu quoque.* We might also, for the satisfaction of our readers, if these explanations and denials had not extended to such a length, enter into more explanations or denials. But, so far as our contemporary is concerned, we simply bid him mind his own business. If he did that properly, he would probably have his hands full. Of our arrangements with our contemporaries, he simply knows nothing whatever, nor does the matter concern him.

We have already far exceeded the space of which the matter is worthy, simply because we wish to avoid the necessity of further reference to it. We must add one word, however, before we conclude. The question will naturally arise, What are our contemporary's motives for all this? It is difficult to determine. It may be from the preverted idea held by some that they raise themselves when they try to pull others down. It may be from motives which it might seem egotistic in us to express. It may be that our contemporary has eaten of the insane root, and believes in his own charges; it is possible to nurse a delusion until it seems true. It may be that a journal having, like a corporation, "neither a body to be kicked, nor a soul to be saved," will perpetrate things individuals would shrink from—for personally, and apart from journalistic rivalry, we have received many courtesies from all connected with the *British Journal.* However all this may be, we can simply assure our readers that we shall omit no opportunity of bringing under their notice everything, from every source, which can interest them and promote the art; and that in doing so we shall always endeavour to deserve, not their esteem only, but also to preserve our own self-respect and secure the goodwill of our fellow-labourers in photographic literature.

## MR. BEDFORD'S PHOTOGRAPHS OF THE EAST.

Mr. Francis Bedford invited his friends, on Tuesday last, to a private view, at the German Gallery, Bond Street, of his Photographs taken during the tour in the East, in which, by command, he accompanied His Royal Highness the Prince of Wales. These pictures are one hundred and seventy-two in number, chiefly on 12 by 10 plates. The entire series will be published in twenty-one parts, each containing eight or more pictures, the cost of the entire series being forty-three guineas. They will also be divided into sections, consisting severally of the Holy Land and Syria, of Egypt, and of Constantinople and the Mediterranean.

The occupation of a gallery, and formation of a complete exhibition with the works of one photographer, is a novel thing in this country, but we have rarely been more delighted by a visit to any exhibition than we were on Tuesday, and we left, after a few hours of close examination of these pictures, feeling very proud of photography; proud of its capabilities, of its progress, and of the recognition it was beginning to receive. If it had been necessary to offer any plea in mitigation of judgment, Mr. Bedford would have been furnished with the most cogent. A hasty summons, with little time for preparation; vicissitudes and transitions of climate the most unfavourable to photographic operations, rapid travel permitting no opportunity for the examination and selection of localities, points of view, or conditions of light. Mr. Bedford informs us that he never had a single opportunity of going twice to the same view, such selection as he could make at once, under such conditions of light as might then exist, was alone possible. Of the trials of climate, &c., some idea may be formed when it is stated that it was not unusual for swarms of small flies to fill the camera during exposure, and sometimes cover the plate! With all the drawbacks which existed, however, we have never seen a more magnificent collection of photographs, even of scenes and subjects affording the best facilities for successful operation. Apart from all other associations which give value and interest the photography is, in the majority of instances, perfect. Unlike so may eastern pictures, these are entirely free from hardness, and that spotty, cut-out effect and entire absence of atmosphere, which many have regarded us the inevitable characteristic of photographs taken under the glare of an eastern sun: these are full of gradation of tone, delicate, yet vigorous, and full of relief. There is no white-paper sky in the whole series, everywhere a satisfactory atmospheric tint is present, and in many instances exquisitely-managed clouds are introduced by skilful "dodging." We know this will be condemned by some photographic purists as not legitimate. We have ever held that success is the touchstone of legitimacy. These are so successful, in many instances, as to deceive even a technical eye into the conviction of their genuineness. The method employed is, we believe, simply painting on the back of the negative, in which the sky is in all cases sufficiently thin to print through; the old-fashioned sky, "as black as your hat," once regarded as such an excellence in a negative, has no existence here. Only the skilled artist could, however, produce such results by painting on the negative, as these; and this success will be no justification to the bungler who shall attempt a similar process. Mr. Bedford's object has been to make his photographs pictures, and he has succeeded to admiration.

This is, unquestionably, out of all proportion the finest series of eastern photographers which has ever been produced. Many new pictures not brought home by former operators are here; and subjects before done are here presented from new aspects. Notwithstanding the necessity of prompt action, and the lack of time for carefully studied choice of position and light, it is surprising in how many instances both seem all that could be desired, the practised eye of the artist having, almost intuitively, at once selected the position which would yield a picture.

Our space precludes the possibility of entering into detailed criticism or description of the pictures, otherwise, perhaps, no subjects could be more alluring. The scenes here depicted are fraught with associations of the deepest possible interest in relation to sacred or profane history; here are relics, indeed, of a period, in regard to which the most venerable antiquity of recorded facts are but as yesterday. Here, amongst the ruins of Baalbec, are still standing, notwithstanding the ravages of time, and the still more ruthless ravages of man, titanic columns, in regard to which much of the architecture of modern days seems child's play. These were ruins even before the dawn of history, and are monuments of the state of the arts at a period we are in the habit of regarding as the night of time! Here, too, are the scenes so sacred to the student of Biblical history; Bethlehem, Bethany, and Jerusalem; here is the Mount of Olives, and the Garden of Gethsamene; and here the Lake of Gennesareth, whose face seems to wear an eternal calm in memory of the feet which once trod it. But the series abounds with associations of every kind which are full of interest, to which we have not space even to refer.

We merely call the attention of our readers to the photographic interest of the series, and earnestly recommend all who can to visit the German Gallery where they are now exhibited. To photographers they are full of value in an educational point of view, as illustrating the result of excellent judgment, fine taste, and unsurpassed photographic skill when working under difficulties. Notwithstanding the picturesque nature of the subjects and the associations by which they are surrounded, we have seen many views of eastern scenes, which from their hard, dry, spotty character, even these associations have failed to make interesting. These photographs are, however, valuable as pictures: some few are a trifle under-exposed, one or two may not be well lighted, and in one or two more the architecture may be a trifle distorted, but, as a whole, they are perfectly harmonious, with a singular uniformity of excellence, well worthy of study and imitation.

As we have before stated, those pictures were produced by the wet collodion process, the operator working in a tent. In the majority a bromo-iodized collodion and pyrogallic acid development were used. The lenses were single landscape lenses, about thirty seconds being an average exposure. Development was in all cases stopped before entire density of the sky was obtained, a circumstance to which much of the harmonious and atmospheric character of the pictures is doubtless due.

## THE INUNDATIONS IN THE FENS FROM A PHOTOGRAPHIC POINT OF VIEW.*

In a short time we reached the broken sluice, the sad cause of all the dire mishaps which had visited this unfortunate district; and certainly a most melancholy spectacle presented itself to the eye. Only one arch of this magnificent structure remained in anything like a state of completeness, but it had a zigzag fissure descending to the keystone of the arch. Of the other buttresses all had disappeared but one, and it had laid itself over as though resting a moment before taking the final plunge into the eager water.

The day was now gloriously fine; compact masses of cumulous clouds were driving rapidly across the sky. With eager hands, therefore, we prepared to make our first venture, We had scarcely got our dark box into workable trim, before a native, who had been watching our movements with an astonished expression very visibly apparent on his face, and who had hitherto kept at a safe distance, now cautiously approached, and after walking all round, ventured to look through the yellow glass. The moment he found he was enabled to see through it, he rushed to a group of companions at a distance, and presently I was surrounded. They were, however, doomed to disappointment, for my black hood was now over all, and nothing was to be seen. The fortunate beholder, however, tried to lessen their disappointment by a vivid description, and certainly his inventive faculties were of no mean order, for in a few minutes he had completely crammed them with an account very considerably removed from the truth. Lots of wonderful moving figures were to be seen inside the box, all *wonderfully* magnified. "It was a more wonderfuller *penny rummer* than he had ever see'd at a fair."

We exposed two plates, and both were tolerably successful.

* Continued from p. 342.

Indeed, they proved more interesting, as pictures, than we had hoped originally to secure, for the tide was rushing through the unguarded portal of the Middle Level with resistless impetuosity, and as the exposure of the plate was instantaneous, all this was crisply rendered in the picture. We therefore contentedly packed up, and moved on to a spot about a quarter of a mile distant on the banks of the drain, which was now the centre of attraction for all the surrounding county.

As we walked on the banks, we saw sad traces of the eager useless efforts first made to prevent the calamity. Here, heaps of chalk, thrown in to prevent the banks from falling further into the stream; a little further on, and hundreds of sacks filled with clay, thrown in for the same purpose; but in vain. A few steps brought us to the site of St. Mary's Bridge, and here we found a more determined stand had been made against the intrusion of the victorious waters; but made, alas! too late. Lighters had here been sunk, weighted with clay and gravel; but the water, like an infuriated bull let loose, had tossed them up, bottom upward, and emptied and sent them spinning along quite giddy, and they in turn became unmanageable, and knocked down several bridges in their mad career. One of them lay bottom upward on the muddy shore, and close to it a lot of basket-work, made by some of the Dutchmen engaged in shutting out the sea in the estuary near Lyme. This kind of defence, so successfully employed in Holland, was quite useless here. The sea was in no mood to be *cradled*, and washed it indignantly away. In a few minutes, we came to a scene of the most animated description, and we saw at once that at least something was being done, that in the end promised to be successful. Hundreds of navvies were here busily employed in all kinds of labour; some filling sacks with clay, others bracing together large masses of timber, another gang was directing the efforts of a dozen pile-driving engines, whilst an immense number were filling railway trucks with gravel. A tramway had been laid down on either side to facilitate operations, and it was clear that in spite of the hubbub and noise attendant upon the efforts of a thousand men, all was so admirably arranged, and there was so little of confusion, that things were progressing as rapidly as possible towards a successful conclusion.

At this point our progress was barred by a strange looking being, whom at a distance we had taken for a rat-catcher, for he had a paper band round his hat, and also a belt of the same material. These badges informed us, however, on a nearer inspection, that he was a police assistant. He informed us we could proceed no further; but on informing him that we wished to see the contractor, we were conducted to his office. We found in him an old friend, who was an enthusiastic photographic amateur, as well as an accomplished musician, and with whom we had spent many pleasant hours. After the first congratulations, scarcely a moment's breathing time was allowed, for our unexpected arrival was most opportune, a number of pictures being particularly wanted, to show the works in various stages of progress. It is true that the tall gaunt-looking pile-engines were rather unmanageable objects in the picture; but still, the ceaseless activity of the workers, and above all the furious roar of the waters against the piles, which would so soon bar their further progress, furnished materials which, if caught instantaneously, would be interesting to all who had witnessed the strange scene; we were, therefore, soon earnestly at work. Unfortunately, however, it had now gathered up dark overhead, and the general aspect of the sky led us to expect a tempest. A smart shower now followed; but as we had a plate ready, we determined to use it. It turned out to be an amusing picture, but was useless from under-exposure. All the overlookers in various parts of the works were to be seen with umbrellas over their heads. After waiting patiently until the shower was passed, we ventured another plate, which proved tolerably successful. The picture was a singular one. The sky at the back of the picture was very dark, broken only by one or two small openings of a lighter colour; all the busy foreground was, in consequence, thrown into very prominent relief, which appeared very strange and unusual, and the foaming water, though full of detail, appeared of unusual whiteness. Two more pictures, and we had done all that was necessary for that day; and as we were anxious to still go further, for the wide waste of waters had still to be visited, we were soon packed, and were once more on our way.

The prospect of a fine evening was not a bright one, for though by this time the wind had freshened into a stiff breeze, the clouds were low and heavy, and were coursing each other at a rapid rate; but *nil desperandum* is pre-eminently the photographer's motto, and we determined to go to the end.

Our journey lay through country the exact counterpart of that now inundated, and separated from it only by the banks of the Middle Level drain. It is a district of singular fertility, and there is something of solemn grandeur about its vast monotony, that in some measure compensates for the want of variety so abundant in hilly districts. As far as the eye can reach, the view is unbroken, and the sky line is as straight as at sea. Field after field meets the eye, separated from its neighbour by a deep dyke filled with water. The effect is not unlike a vast chess-board; the cultivated squares are laid out with such regularity, and at this season the alteration of colour is so marked. Now a field of wheat with its intense green, and now one of mustard or coll seed, with its brilliant yellow, shines out with dazzling brightness. The hawthorn hedge is scarcely to be seen in this part. The willow pollard may be regarded the king of the fens, for his reign is undisputed here.

V. B.

## Scientific Gossip.

There are few words which are capable of giving rise to more thought and abstruse enquiry than "force." The subject is one which cannot fail to be of interest to the photographic experimentalist, working, as he does, with tangible and ponderable effects, produced apparently without adequate material cause. The present state of our knowledge, or rather, of our ideas in respect to this subject, has been recently summarised by Professor Tyndall in a lecture before the Royal Institution, and as some attention has been excited by the ideas therein propounded, we give our readers an abstract of it. As giving a general idea of the meaning of the word force, a pound weight of lead was allowed to fall on to the floor of the theatre, from a height of sixteen feet. It required exactly a second to fall, and the instant before it touched the earth it had acquired a velocity sufficient to carry it forward at the uniform rate of thirty-two feet a second, if the attraction of the earth could have been annihilated at that instant. If the pound weight had then to be thrown upwards in opposition to gravity, the velocity with which it must start from the earth's surface in order to reach a height of sixteen feet, would have to be thirty-two feet a second. If double this speed were imparted to it, it would not only rise to twice the height, but to four times the height. The mechanical effect, or, in other words, the work done by a projectile increases as the square of the velocity, and this holds good whether the weight be cast upwards in opposition to the resistance of gravity, or if the projectile be sent into water, mud, earth, timber, or other resisting material. When the pound weight falls to the earth from a height of sixteen feet the motion is suddenly arrested on contact with the ground, and the mechanical force changes into heat, the exact amount due to its suddenly arrested motion being sufficient to raise the temperature of it own mass three-fifths of a degree Fahrenheit. This heat increases according to a remarkable law. If we double the mass which falls, other things being equal, we double the amount of heat;

but if we double the velocity, we quadruple the heat. The heat developed, therefore, is exactly in proportion to the mechanical effect, or the mass of the body multiplied by the square of its velocity. In the experiments at Shoeburyness it is a common thing to see a flash of light even in broad daylight when the ball strikes the target; and a rifle bullet developes an amount of heat on collision with the target, sufficient, if wholly concentrated in the lead, to raise its temperature 960°, or above its melting point. But we can convert heat back again into mechanical motion, and it has been found both by theory and experiment that an amount of heat equal to three-fifths of a degree Fahrenheit may be so expended as to raise a pound weight to the height of sixteen feet. The combustion of coal is a familiar instance of the production of mechanical effect by the expenditure of heat, and in this agent we possess an enormous store of mechanical power. A pound weight of coal produces when burnt an amount of heat sufficient to raise a weight of one hundred pounds to a height of twenty miles above the earth's surface, and conversely 100 lbs. falling from a height of twenty miles would generate, on striking against the earth an amount of heat equal to that developed by the combustion of a pound of coal. Wherever work is done by heat, heat disappears. A gun which fires a ball gets less heated than one which fires blank cartridge. Although the amount of heat developed by ordinary gravity appears insignificant in comparison to that developed by combustion, if we permit gravity to act throughout its entire range the disproportion ceases. Place a pound weight at such a distance from the earth that the attraction of gravitation is barely sensible, and let it fall to the earth from this distance. It would reach the earth with a final velocity of 86,747 feet in a second, and on collision with the earth the body would generate twice the amount of heat evolved by the combustion its own weight of coal.

Turning our attention from the earth to the sun, it has been found that the whole heat emitted by this orb in a minute is competent to boil 12,000 millions of cubic miles of ice cold water. Whence then, is the sun's heat derived, and by what means is it maintained? No combustion, with which we are acquainted, would be able to produce a temperature like this; besides which, even supposing the sun to be a solid globe of coal, it would burn itself out in 4,600 years. What agency can then produce the temperature and maintain the outlay? We must seek for such a cause in the heat which is developed by mechanical motion. We have seen that a body falling from space into the earth, would generate twice the amount of heat evolved by the combustion of its own weight of coal. The maximum velocity with which such a body could strike the earth, is about seven miles in a second; whilst the maximum velocity with which it could strike the sun, is 390 miles in a second, when it would generate 10,000 times the heat of combustion of an equal weight of coal. It is almost certain that an infinite number of small bodies—planetary dust—exist in space; the showers of meteoric stones so common on different parts of the earth's surface, are part of these. The zodiacal light has been almost proved to consist of an assemblage of asteroids revolving round the sun; and moving as they do in a resisting medium, they continually approach the sun and fall into it, producing the heat observed and constituting a source from which the annual loss of heat would be made good. The sun according to this hypothesis would be continually growing larger; but how much larger? Were our moon to fall into the sun it would develope an amount of heat sufficient to cover one or two years' loss; and were our earth to fall into the sun a century's loss would be made good. Still, our moon and our earth, if distributed over the surface of the sun, would utterly vanish from perception. Indeed the quantity of matter competent to produce the necessary effect would, during the range of history, produce no appreciable augmentation in the sun's magnitude. The augmentation of the sun's attractive force would be more appreciable. However this hypothesis may fare as a representant of what is going on in nature, it certainly shows how a sun might be formed and maintained by the application of known thermo-dynamic principles.

## TANNIN AND HONEY PROCESS.

After sensitizing the plate, attach the holder, and pour over the film a solution of one part honey to three parts water; let it flow three times round the surface, and then off. Place on a levelling stand, or level board, till next plate has been similarly treated, or until half a dozen or more have been thus prepared. Wash off the honey solution thoroughly under a tap, or with water from a jug. Stand to drain for one minute, then apply the tannin solution (5, 8, or 10 grains to the ounce), and dry.

This plan of applying the diluted honey before washing off the free nitrate, is applicable to all dry processes. Caramel may answer as well. In this process, it is preferable to mixing the honey with the tannin, as you get a cleaner plate, with less liability to stains, if the washing have been properly performed.

In preparing dry plates, it is a matter of great importance to use soft water for washing them. Hard water coagulates the pyroxyline, and produces mottled films. Spring or pump water may often be soft enough, but where that is not the case, boiled and filtered rain water should be used.

R.

# The International Exhibition.

## BRITISH PHOTOGRAPHIC DEPARTMENT.

The landscape photographs in the British Department is, as we have before intimated, out of all proportion the best in the Exhibition. It is not, however, illustrated by many novelties, the majority of the pictures having been exhibited before. The exquisite examples of Bedford, and Heath, and Mudd, have all before come under our notice. Wilson's charming little views, 7 by 4 in., including a wide angle, by the triple lens, are novelties, and are universally admired. Here are Sidebotham's "Chepstow Castle" and "Tintern Abbey," by the collodio-albumen process, which we have noticed on a former occasion, and which we now think, notwithstanding the extensive collection in which they appear, are as fine pictures as ever have been produced by the art. Dixon Piper's "Old Curiosity Shop," "Lock Gates," &c., have before been seen and admired; a large instantaneous picture entitled, "Early Morning," is, we think, new; it contains a magnificent study of clouds. The photographs of Sir A. K. Macdonald, Bart., we have already noticed at the Crystal Palace: all the specimens we have seen, both in the Exhibition and elsewhere, are among the finest examples of picturesque photography we have seen.

Mr. Rouch exhibits a frame of the small landscapes of the same sort and style as those to which we have referred of Wilson's. The subjects, which are all in the Isle of Wight, and include some instantaneous pictures, are well chosen and picturesque, and the photography delicate and brilliant, and the pictures altogether exceedingly good. Lieut.-Col. S. Wortley exhibits a series of views of Vesuvius in a state of eruption. These are, in our estimation, amongst the most charming photographs in the Exhibition: each picture includes some view of the noble Bay of Naples, with Vesuvius belching forth smoke in volumes; this, together with the exquisite natural clouds, are most perfectly rendered, indicating that the exposure has been instantaneous. There are some interesting views of the effects of the earthquake in the town of Torre del Greco. The majority of the pictures are on 12 by 10 plates, and were taken, we are informed, with the 8½ by 6½ triple lens. We regret that these prints were amongst the severe sufferers by the damp walls, and are at present removed for the purpose of being replaced by fresh prints. Mr. Henry White exhibits a series of very beautiful and well-selected views in North Wales, in which the photography and the art are alike good. The contributions from the Amateur Photographic Association include many specimens of great excellence. Mr. Lynden Smyth exhibits several of his most artistic pictures. Mr. D. Campbell sends his fine picture, the "Auld Brig o' Doon," and several others. Dr. Hemphill's photographs of Irish antiquities attract attention, not only from the interest of the subjects, but the excellence of the photography. W. L. Noverre's photographs of Indian subjects are full of interest. Mr. W. J. C. Moens sends a capital series of fine pictures taken at various places full of classic memories, during a yacht voyage up the Mediterranean. Roger Fenton sends many of his old favourites. Mr. Wardley contributes a number of his very excellent pictures by the collodio-albumen process. Mr. R. Keene contributes a good number of very fine specimens. B. B. Turner sends some of his fine calotypes. Amongst other very meritorious contributors of landscapes we find the names of John Burton, and Robert Pateson, T. Carr, W. Mayland, Baynham Jones, Stoven and Co., Major Russell Mauners Gordon, Major R. Gordon, J. Cade, Stephen Thompson, Dr. Holden, J. Spode, S. Bourne, F. Frith, Lord Caithness, and some others. As we have before said, however, so many of the landscape photographs have been exhibited before that they do not call for lengthened notice here.

The *Daily Telegraph* has the following remarks on the display of British photography :—

"The stairs that lead from the middle vestibule of the picture galleries to the photographic department are three score and ten. Sated and dazed. With acres of glowing colour, the visitor to the Louvre of Old Brompton will hesitate about ascending to that height where sun-pictures are displayed in their uniform sameness of hue, relieved here and there by tinted specimens. Truth to tell, the photographs have proved the least attractive branch of the show; and the contributors of these productions must now perceive that they gained little by refusing to be classed with exhibitors of machinery. Still, for those who take any interest in an art which is one of the poetical commonplaces of our day, and whose history is quite a fairy tale of science, the 'sky-chamber' in the south central tower of the Exhibition Building will, assuredly, have charms enough. We ask our readers to accompany us thither in our notice to-day. The first thing to strike them is the ominous fact, that many frames are being removed, leaving great blank gaps on the bare walls. Damp is the unfortunate cause of this proceeding. Signs of warping, and of mildew, are apparent on many of the photographs which remain. Another very striking peculiarity about some of these works—we will not say of all, or half, or a quarter of the number exhibited, but certainly of a large proportion—is their faded appearance. Evidently there has been haste on the part of several photographers; and if their pictures continue this growth of indistinctness, they will, before the close of the Exhibition, be little else than strips of yellow paper. It is not a pleasant indication of the quality of photographs, on the permanence of which we depend for reminiscences in future years of scenes and faces which are present, and which are dear to us. Every practitioner should be able to assure his patrons that each portrait is sufficiently washed to stand exposure to light for any duration of time. That this precaution is efficacious, we may see in the pictures taken of the 1851 Exhibition by Mr. Mayall. The date of these works is established beyond dispute. We know that they were produced exactly eleven years since, and they are as clear and deep in tone as if they had been printed yesterday. The fact speaks for itself, and must prove an additional recommendation of Mr. Mayall to the confidence of the public. Of his portraits we need only say that they are worthy his reputation."

Without any wish whatever to lessen the weight of this recommendation, we must point out the absurdity of the deduction. The pictures of the Exhibition of 1851, here referred to, are very fine Daguerreotypes, worthy of all praise, but their permanency and that of paper pictures have nothing in common, the causes of permanency in the former having no analogy or relation to the amount or mode of washing employed in the latter. The writer proceeds :—

"Others who follow in the same beaten track of portrait-photography deserve praise as great for the good focussing and tone of their specimens. Messrs. John and Charles Watkins are specially to be commended; and Mr. H. N. King has a great variety of likenesses, which readily strike the beholder. In coloured photographs—a very nice and somewhat dangerous ground—we see nothing to rival the pure, though rich and brilliant, miniatures of Messrs. Loch and Whitfield. Their table includes quite a little gallery of aristocratic beauty. Mr. A. Claudet, who takes a bold stand as a life-size delineator, has a portrait of a lady which might almost pass for an original painting from the walls of the Royal Academy; and his likeness of Sir Charles Wentworth Dilke, taken by the enlarged solar camera, is a most characteristic and vivid piece of portraiture.

"The branches into which the practice of photography has lately struck are fairly, though not abundantly, illustrated in this collection. The photo-galvanographic process, which is a species of engraving by the combined aid of photography and the electrotype, is exemplified by Mr. Paul Pretsch. The kindred method of phototyping in carbon, claimed as a French invention, is also shown in the fac-similes of old prints and title-pages exhibited by Mr. John Pouncy. Another system of reproduction by photographic agency, is that of Col. Sir Henry James, director of the Ordnance Survey, whose plan of photozincography has the credit of saving the country many thousands a year. For maps, engravings, and printed objects, this method is eminently efficient and serviceable. We must conclude our present remarks with a reference to the transparent albuminous pictures for the stereoscope, and other interesting productions shown by Messrs. Negretti and Zambra. In these stereoscopic views, principally from Siam, Java, Sumatra, China, and Japan, the only specimens of albumen transparencies to cope with the works of M. Ferrier of Paris, are here afforded. There is in the stand of the above-named firm a work of high merit and interest. It is in the form of a printed volume, published by Messrs. Smith and Elder, but chiefly noticeable as a wonder of photography. The book is a recollection of Egypt, Nubia, and Ethiopia, principally from the pen of Mr. Joseph Bonomi, the great Eastern traveller, with controversial notes by Mr. Sharpe, of Egyptian celebrity. It is illustrated with stereoscopic scenes; and a folding instrument accompanies the work, to enable the reader, as he proceeds, to realise each description.

"The London Stereoscopic Company, as may be supposed, is not behindhand in contributing to the display. Among their noteworthy objects are some American views, including an excellent photograph of the Virginia Falls, and several good examples of the instantaneous process. Messrs. Cundall and Downes have a show of unexceptionable specimens. They manifest quite a speciality for picture copying—another and a far more difficult operation than photographing a print in black and white. Mr. L. Caldesi reproduces cartoons and other works of art with wonderful skill, and also displays great capability in rendering all the fine qualities of highly-finished and delicate miniatures. The albumen photographs from Palestine, by Messrs. Cramb Brothers, are praiseworthy for their clearness and precision; but, as pictures, they are deficient in half-tones and nice gradations. That deservedly-famed artist, Mr. James Mudd, adheres principally to the collodio-albumen process, and wite a result which justifies his preference. Indeed, we are of opinion that this is the only known operation of photography by which justice can ever be done to scenes of external nature. Ordinary collodion photographs are best for portraiture, simply because they do not require so much time; but for landscapes, despite the almost perfect works of such experienced and able men as Mr. Bedford and Mr. Wilson, the true method of bringing out every *nuance*, and of assimilating shadows with high lights, seems to involve the slower operations of collodio-albumen."

Photographers will smile to learn that the exquisite delicacy, softness, atmosphere, half-tone, and gradation of Mr. Mudd's pictures are due to his use of a dry process, and that in regard to such qualities wet collodion is inferior!

"We have mentioned Mr. Bedford, and it would be a difficult task to do him full justice, were this column free for a descriptive account of his labours at the International Exhibition. We need scarcely say that they do not comprise the pictures taken by him in the Holy Land, while accompanying the Prince of Wales, inasmuch as the return of his Royal Highness and suite took place after the Exhibition had long been open.

They are, in fact, mostly English and Welsh scenes. "Cheddar Cliffs" and a "Study of Nature" are gems which no visitors to the gallery should miss. The simple truthfulness of these and kindred works is worth a hundred feats of artistic arrangement, such as photography, undervaluing its true mission, sometimes aspires to. A very ingenious manufacturer of subjects is Mr. Robinson, whose "Holiday in the Woods" made quite a sensation at one of the annual shows of the Photographic Society. Almost as much trouble must have been expended on the building up of this scene, and on the bringing together of all its constituent parts, on the drilling its actors, on the subordination of its accessories, and on the careful eliminating of all petty "accidentals," which, though likely to pass unobserved in a *tableau vivant*, are apt to grow painfully obtrusive in a permanent picture—almost as much trouble, we say, is apparent in the mere posing and scene-setting, and arrangement of properties, in this composition, as a practised draughtsman would have found in placing the whole group on paper or canvas. There is something almost absurd in all this preparation for a mechanical and instantaneous operation. It is an anti-climax —a reversal of the order of things. Mr. Robinson's subject-photograph, "The Lady of Shalott," is quite an artistic *bouleversement*. We not learn from Mr. Tennyson that this interesting damsel, before she floated down to Camelot, had her hair nicely crimped and spread out as we see it in the picture; but this may or may not have been the case. What we would specially remark is the disproportion in this work between the model's part and the artist's. The whole merit lies in the cleverness of a *pose plastique*. The printing from several negatives may be adduced as a feat of photographic skill, but such a system of legerdemain is radically vicious, and cannot help photography on to higher things."

It is somewhat amusing to remember that the "set scenes" and "properties" which the critic declaims against in the "Holiday in the Woods" are simply the noble woods of Kenilworth. His other strictures here are of equal worth. For instance, the real beauty of the "Lady of Shalott" consists far more in the mystic twilight effect which pervades the meadow trees overhanging the river, than in anything else; the faults chiefly belong to the boat and figure; and yet we are told the "whole merit lies in the clearness of a *pose plastique!*" The question of composition printing is one upon which competent authorities differ; but the mode in which the critic discusses the matter shows that he understands nothing whatever about it, either as regards its failings, difficulties, or merits.

"Mr. Frith exhibits some of those wonderfully sunny Eastern views for which he is celebrated; and Messrs. Dolamore and Bullock have some neatly vignetted landscapes. The *cartes de visite* of Mr. Kilburn must not be passed over; they are very sharp and well defined. Colonel Verschoyle contributes several valuable illustrations of different processes. His favourite method seems to be the employment of collodio-albumen, but he is also very successful with tannin. We spoke yesterday of the effective results of printing in carbon, instead of nitrate of silver; and we may refer to the specimens exhibited by Messrs. C. Walker and Son as admirably demonstrating the immediately good results of the operation. Its lasting qualities, however, are its great speciality. The prints may be submitted to acid, which will destroy the paper, but leave the carbon uninjured. The perishable nature of photography is the worst charge that can be brought against it. Let this character of evanescence and frailty be removed, and photographic portraits will be preferred to all others. We have had to speak of the faded appearance of many pictures in the present exhibition, and we have ventured to attribute the defect to want of care in fixing the image. It is urged as a plea in extenuation that the damp on the walls has partly caused the blemish; but this excuse will only serve the photographs on the walls, not those on either of the screens."

And we may add, although the critic implies the contrary, that it is on the walls alone, and not on the screens that the palpably fading pictures are found. Some few old pictures on the screens, have a somewhat yellow tinge; but it is unquestionably the damp walls which has proved the grand *crux* of exhibitors. We trust, as we have before said, that the annoyance will be turned to good account.

## PHOTOGRAPHIC CHEMICALS.

Considering the immense development of the trade in photographic chemicals which has taken place of late years, and the number of articles which have to be specially prepared or purified for photographic purposes, it seems strange that we have so few exhibitors of photographic chemicals in the department set aside for this art. There is, indeed, only one case exhibited containing chemicals alone, and not more than two or three other cases in which the chemical agents are shown in conjunction with apparatus. This seems the more remarkable, as there are few photographic dealers of any eminence who do not, at all events, profess to prepare some chemicals in a state of photographic purity. Amateurs have thus got into the habit of considering that certain houses make a speciality of certain photographic chemicals, so that if a complete chemical outfit were required, in order to obtain the various materials in the greatest state of purity, they must be purchased at half-a-dozen different establishments. We do not know whether we are justified in assuming that there are really very few special manufacturers of photographic chemicals, but an observer would be warranted in drawing this inference by an inspection of the very limited display of chemicals in Class XIV. The solitary case of chemicals alluded to above is contributed by Messrs. Hopkin and Williams (3,099). Although some of the articles exhibited have been injured by the intense light and heat to which they have been subjected during the last two months, the whole collection is, perhaps, unsurpassed in the whole building for completeness and beauty. Some of their exhibits have been alluded to before, as they are shown in duplicate in the Eastern Annexe, but the greater number are only exhibited here. The beauty of their bromide of cadmium has already been spoken of. Near this is a very fine sample of recrystallized nitrate of silver, which, judging from the excellent manner in which it has kept its colour, must be, at all events, free from that bug-bear of photographers—organic matter. A sample of iodide of ammonium has not stood the searching ordeal of light and heat so well as its neighbour; the crystals are very fine, and when they were first exposed were quite white, but they have now assumed that orange brown colour, from the separation of iodine, so well known to all who make their own collodion. Of course, we need hardly say, that this colouration says nothing against its original purity, but is a natural consequence of its exposed position. A tray full of very white pyrogallic acid deserves notice, and also some fine crystals of hyposulphite of soda. These are of some interest, as they show photographers what the pure salt is like, it being by no means so easy to obtain in commerce as is sometimes imagined. A specimen of pure tannin is especially worthy of notice at the present time, owing to the beautiful dry process which owes its name to this organic body. A few words on the chemistry of this body may be acceptable to our readers. There are several varieties of tannin, or tannic acid, as it is also called. They are astringent principles, very extensively diffused throughout the vegetable kingdom. The bark and leaves of most forest trees, such as the oak, the elm, the willow, the horse-chesnut, and the pine; and many fruit trees, such as the pear and plum, contain tannin in notable quantity. The wood, bark, and roots of many shrubs also contain one of the forms of tannin. These varieties are named according to the source from which they are derived; thus, tannin from the gall nut is called gallo-tannic acid, that of the oak is called querci-tannic acid, that of the fustic, mori-tannic acid; the tannin of the cinchona is called quino-tannic acid, whilst the name, mimo-tannic acid is applied to the tannin of the catechu. Besides these, there are several other distinct varieties of tannin which are yet unnamed. We may remark, in parentheses, what a fine field is here open for new process-mongers; there is very little doubt that any of these varieties of tannin will answer the desired photographic end, so an ingenious experimentalist has only to make use of a hitherto unused variety of tannin, when he can appear in print as the discoverer of a new dry process. We may, perhaps, save much future discussion as to priority of discovery, if we state that the tannin in general use is derived from the gall-nut, and is, therefore, known as gallo-tannic acid. It is a pale, yellow crystalline body, soluble in water and dilute alcohol, but sparingly so in ether, it has decided acid reactions, reddening litmus paper, and dissolving carbonates with effervescence. Its diluted aqueous solution slowly absorbs oxygen from the air, and is converted into gallic acid. Many salts, such as chloride of potassium and others, coagulate an aqueous solution of tannic acid. When subjected to a temperature of about 620°, it is decomposed into pyrogallic acid. The remaining chemicals in this case do not need detailed notice. They include a very nice sample of gallic acid, some sodio-chloride of platinum, ammonio-nitrate of silver in crystals, which have a suspiciously dark and fulminating appearance, the rather rare salt—chloride of lithium, and numerous other ordinary photographic chemicals.

## AWARDS OF JURORS IN CLASS XIII.

[WE here merely make such a selection of names in the class devoted to philosophical instruments as we think may be interesting to photographers, from having some connection, intimate or remote, with photography.]

MEDAL.

UNITED KINGDOM.

| *Name of Exhibitor.* | *Objects Awarded and Reasons for the Award.* |
|---|---|
| Beckly ... ... ... ... | For his registering anemometer; and for the skilful execution of his photographs of the sun. |
| Butters, T. E. ... ... ... | For great excellence of workmanship of parallel glass for optical instruments. |
| Casella, L. P. | For his mercurial minimum thermometer and accuracy and excellence of construction of thermometers, &c. |
| Chance, Brothers ... ... | For improvements in dioptric lights and great excellence in optical glass. |
| Dallmeyer, J. H. ... ... | Equatorial telescopes. For his excellent object glasses and equatorial mountings. |
| Dancer, J. B. ... ... ... | For the general excellence of his microscopes and microscopic photographs. |
| De la Rue, W. ... ... ... | For the general excellence of his astronomical photographs. |
| Grubb, T. ... ... ... | Large equatorial telescope. For general excellence; with regard to his object glass no means of testing it has been afforded to the Jury. |
| Highley, S. ... ... ... | For students' microscopes, combining cheapness and good workmanship, and for excellence in other optical instruments. |
| Horne and Thornthwaite ... | Herapathites, and polarising apparatus. For general excellence. |
| Negretti and Zambra ... | Meteorological instruments. For many important inventions and improvements, together with accuracy and excellence in objects exhibited. |
| Ross, T.... ... ... ... | Microscopes and hand telescopes of large aperture. For great excellence of construction. |
| Silver, S. W., and Co. ... | Conductors insulated with caoutchouc. For general excellence of manufacture. |
| Smith, Beck, and Beck ... | Microscopes and other optical instruments. For economy in the production of students' binocular microscopes, and the excellence of their instruments generally. |
| Wenham, F. H. ... ... | For improvements in his binocular microscope. |
| | AUSTRIA. |
| Voigtländer and Son ... ... | For general excellence in optical instruments. |
| | FRANCE. |
| Duboscq, L. J. ... ... | Optical instruments for scientific researches. For great excellence. |
| Serrin, V. ... ... ... | Self-regulating electric light. For novelty of construction and general excellence. |
| | PRUSSIA. |
| Nobert, F. ... ... ... | For the great skill displayed in the execution of his microscopic test lines. |

HONOURABLE MENTION.

UNITED KINGDOM.

| *Name of Exhibitor.* | *Objects Awarded and Reasons for the Award.* |
|---|---|
| Ackland, W. ... ... | For the accurate construction of his straight line dividing engine. |
| Buss, T. O. ... ... ... | For the accurate construction of his hydrometers. |
| Murray and Heath ... ... | For good workmanship in his philosophical instruments. |
| Reade, Rev. J. B. ... ... | For novelty of construction in his hemispherical condenser for microscopes.. |

## STUDY OF THE WET COLLODION PROCESS.

BY E. REYNAUD.*

I NOW proceed to study the cause of the failures that most frequently occur to the inexperienced operator, and by analyzing each in succession, determine their source, and the means of avoiding them. These failures may be classed as follows:—

1. Non-adherence of the collodion film, and cracking and scaling off while drying.
2. The formation of streaks, specks, &c.
3. Spots in the film produced during sensitizing.
4. The negative riddled with small holes produced during development, and also after intensifying and fixing.
5. A complete fogging of the picture.

I will now proceed to examine each of these failures in succession, and determine as completely as possible their causes and remedy.

### 1. *Non-adherence of the collodion film, and cracking and scaling off while drying.*

These two accidents often occur together, and are generally caused by imperfect cleaning of the glass plate; but they may be produced by another cause. Too large a proportion of iodine, for example, will destroy the adherence of a collodion film. Examination of the negative will show whether it is to this excess of iodine, or to a bad cleaning of the plate, that this accident must be attributed. For, if the reverse of the image, that is, the side touching the glass plate is spotted with brilliant reductions of metallic silver, visible after the negative is fixed, we must attribute it to imperfect cleaning of the plate.

The complete absence of these reductions, and the transparency of the darkest portion of the picture viewed *positively*, indicate, on the contrary, sufficient cleanliness in the glass, and if, notwithstanding, the film does not adhere, if it allows the solutions to penetrate through it to the glass, this non-adherence must be attributed to the proportion of iodine in the collodion being too strong.

It must be remarked in this place, that the quantity of iodine which the latter can contain with impunity depends on the thickness of the film, and, consequently, on the proportion of pyroxyline: the thinner the film, the less quantity of iodine: it must be kept within the following limits:—

| | |
|---|---|
| Pyroxyline ... ... ... | 1·5 to 2 grains. |
| Iodine... ... ... ... | 1·0 to 1·5 „ |
| Mixture of ether and alcohol ... | 100 „ |

The iodide of ammonium being that which, in equal weight, contains most iodine, must be employed in less proportion.—1 grain to 100 of collodion is quite sufficient.

The rapidity with which the collodion plate becomes tinted at the moment of immersion in the sensitizing bath, and the degree of opacity the film exhibits when the sensitizing reaction is completed, appears, *à priori*, a certain means of recognizing the greater or lesser proportion of iodides contained in the collodion; but these different phenomena being intimately allied to the state of the silver bath, and the nature of the iodides, we must examine these several questions, in order to arrive at a rational conclusion.

The degree of concentration of the bath has a considerable influence upon the phenomenon of double decomposition, which, as we know, forms iodide of silver in the film; thus, at the moment of the immersion of the plate, a certain

* From the *Moniteur*. Continued from p. 332.

quantity of iodide is dissolved by the water of the bath, before the nitrate has decomposed any: thus, we may understand, that the proportion of iodide remaining in the film becomes changed more or less; now, when a weak bath is employed, this solution subtracts a larger proportion of iodide. If the strength of the bath be 4 per 100 only, the water would have the effect of dissolving out almost all the iodide contained in the film, before the latter became attacked by the nitrate, which would cause the production of a layer of iodide of silver superimposed on the collodion film, and so little adherent that it would become detached under the slightest motion of the liquid. We perceive, therefore, that the same proportion of liquid may give very different results, according to the strength of the silver bath.

The use that has already been made of this is now to be considered: we know that the iodide of silver, being soluble in the nitrate of that metal, the first plates sensitized in the bath furnish it with a certain quantity of this substance, and that, consequently, the proportion remaining is diminished. But when a certain number of plates have been sensitized, the nitrate of silver becomes saturated with iodide, and can no longer dissolve any of the latter, as it is formed upon the plates subsequently immersed. From all that has been said, it is clear that, in order to operate under constantly identical conditions, the collodion must always be iodized in the same proportions, the sensitizing bath maintained at the same degree of concentration, and saturated at first with iodide of silver, in order that it may never dissolve that on the sensitized plates.

In operating under these conditions, we may always avoid the accidents now under consideration, and the non-adherence of the film can be due only to the bad quality of the pyroxyline, or to imperfect cleaning of the glass plate.

(*To be continued.*)

## ABOUT TONING BATHS.

BY J. MILTON SANDERS, LL.D.*

In the fourth volume of the *American Journal of Photography*, p. 457, there is an able article from the pen of Mr. Sutton, on the "Alkaline Toning Bath." Mr. Sutton has no doubt given us the rationale by which "mealiness" is produced, and he has, doubtless, indicated the chemical changes involved in the reaction. Mr. Sutton has arrived at the conclusion that soda must be used, in combination with gold, there being not the least doubt but that there exists in the toning bath a double chloride of gold and sodium, whether we make use of the acetate, phosphate, or carbonate, of that base. Thereupon Mr. Sutton concludes that it is "better to use carbonate of soda at once, than to proceed to the inelegant and roundabout way of substituting phosphate, or acetate of soda, for it." Now, it is politic, before we shall have arrived at a conclusion, that we should take rigid cognizance of all the phenomena observable in the reaction investigated.

We all know that the toning bath made with the carbonate of soda is very unstable. With each new batch of prints the bath requires to be made anew, otherwise mealiness, and other disasters, will occur. If the toning bath, according to Mr. Sutton, requires simply a soda salt, no matter what kind it may be, in order that the requisite amount of this base shall be furnished to form a double salt with the gold, does it mean whether we use either the phosphate, acetic, or carbonate, indiscriminately? Mr. Sutton, it would appear, thinks not. Then, wherefore, does the bath made of the phosphate of soda possess such stable qualities, while that made of the carbonate of this base is so prone to decomposition? yet such is the case. A bath made of the phosphate of soda, by the formula given below, will never deteriorate, but really appears to improve with age. We have tried pretty much all the recipes given in the journals devoted to photography (at least a score of them), but have found none of them to surpass the phosphate bath in depth, clearness, and beauty of tone. With this bath you can tone from a light brown, or chocolate, through all the intermediate shades to a deep, rich brown, to blue-black, without incurring the risk of mealiness, or failure of any kind. The merest tyro can prepare and use this bath for months, nay, indefinitely, without the fear of its deterioration, only observing to replace with fresh fluid that obstructed by use and evaporation. In this bath we have for the last ten months toned indiscriminately ammonia-nitrate and albumen prints, and we have found the result in every case perfectly satisfactory. The formula for this bath has, if we are not mistaken, been published in this journal. It is the discovery of Mr. Maxwell Lyte. We have tried several variations from it, but with no better results. It is prepared as follows:—In sixteen ounces of pure water, dissolve three drachms of phosphate of soda, and then add one fluid ounce of solution of gold, made by dissolving fifteen grains of that salt in one pint (sixteen ounces) of pure water, and neutralizing with carbonate of soda, if it is required. Perhaps the addition of a little sesqui-nitrate of uranium might improve the tone, if that be possible. At all events it might modify it, but whether there would result an improvement is only to be determined by experiment.

In our daily working of this bath, we proceed as follows:—We first make the bath, according to the formula above; we keep by the bath a bottle of solution of phosphate of soda, three drachms to the pint, and by the side of this another bottle containing the gold solution, made as given above. To keep up the stock of fluid we occasionally add a little of the phosphate fluid, and if the toning proceeds too slowly, we add a little of the gold solution. Our prints, or *cartes de visite*, we are willing to compare with the best taken in New York, or elsewhere, for upon their appearance we are willing to rest the virtues of Mr. Maxwell Lyte's toning bath.

Now, there has been an immense amount of twaddle written about toning albumen prints. Every photographer who can write a lucid sentence, has inflicted upon the public his essay upon this subject, but nowhere have we found any of these gladiatorial gentlemen advocating a toning bath that performs equally as well as the best carbonate of soda ones, and which never requires to be made anew, nor deteriorates with age. Will not some of these chivalrous gentlemen take up the lance in defence of the poor old neglected hyposulphite bath, and shiver it against the shaft of those who are so loud in praise of the carbonate of soda bath? With all due deference then, to so mighty an authority as Mr. Sutton, we must dissent from his views regarding the indiscriminate use of the soda salts, but place our favour decidedly in favour of that made exclusively of the *phosphate* of soda.

We should state in conclusion, that it is absolutely necessary that the prints should be thoroughly washed before and after toning. We do not use chloride of sodium previous to toning, as has been recommended by some, for the reason that we have imagined it interfered with the clearness of the prints; but we soak the prints an hour in the first water (which of course we save for the silver it contains), when we transfer them into fresh running water and give them another hour's soaking there. We then turn them and soak them again for another hour, previous to fixing them in hypo.

The albumen paper we use in combination with this bath we make ourself. It is made as follows:—Pour the whites of six large hen's eggs into a bottle holding at least a quart, having previously taken out the germs. Add to this six ounces of water, in which is dissolved two drachms of chloride of ammonium. Shake the bottle vigourously for about ten minutes, or until the fluid flows out devoid of glutinosity, when it is ready. The paper is laid upon this albumen, taking the usual precaution to prevent the adherence of air-bubbles, and allowed to remain in it not over one minute and a-half. It is then hung up and dried.

The silver solution on which this paper is laid consists of one ounce of pure nitrate of silver dissolved in six ounces of distilled water, to which add a few drops of aqua ammonia. The paper is allowed to remain on this solution from four to five minutes, and then hung up and dried.

* From the *American Journal of Photography*.

## Correspondence.

### PHOTOGRAPHY IN AMERICA.

Dear Sir,—I owe you, as well as numerous friends, a sincere apology for my neglect of duty in the photographic world. I have only to inform you of my various occupations for you to excuse me willingly. In this country a man must turn is hand to everything, so I am a banker from necessity, a soldier from duty, and a photographer from pleasure.

Holding a captaincy, I was called suddenly to the wars, and am in New York on furlough, at present to look to business. I returned a few days since, and found a stack of "News" in the office for me. Accept my thanks for the copies you send me by mail, I receive them ahead of your agent here, who supplies me with my subscription copy.

During the war my letters may be interrupted very frequently, in which case please pardon short-comings, for I have discovered lately that war and photography are not akin, that collodion and gunpowder will not mix, that nitrate of silver and blood make different colored stains, and that the photographic tent and the mess tent are, *in fact*, as different as black is from white.

Now for a short talk on peaceful subjects. You see by the last number of the *American Journal*, that the dry process has come out ahead, in a trial between Mr. Coleman Sellers and myself. But Mr. Sellers was not well that day, and his pictures were far from his usual excellence, so the "duel" was hardly a fair one, for I never was in finer trim in my life. A word about tannin plates. Some correspondent of yours says the picture fades out after exposure and before development. He bases this assertion only on his own experience. If he fails to get good pictures on a plate exposed two weeks or so before development, he says it cannot be done. I have been in the habit of taking trips of several weeks in the country, carrying my camera, plate box, and plates only, developing the negatives after my return home. My pictures suit my friends pretty well, and therefore I am satisfied. I enclose two prints from different negatives of the same subject. You will see by the labels, that both were exposed the same timo and place; but only one was developed the same day, while the other (No. 307) laid two weeks before development. It is very difficult to tell which is the best. I have some negatives equally well developed three weeks after exposure, and I see no reason to expect failures under six weeks keeping. I wash my plates *thoroughly*, by using six vertical baths of water, and changing the plate from the silver bath to each one in succession, and finally immersing in a vertical bath of tannin solution, to which at least 5 per cent. of alcohol has been added. In this way I can prepare twelve to fifteen plates per hour with ease, and in case of hurry, more than that number. I cannot explain your correspondent's failure, except on the ground of lack of uniformity in preparing the surface of the plate.

I suppose you know our Photographical Society has adjourned its meetings to the second Monday in September. This was principally on account of the absence of some of its prominent members, and its secretary, in the army. This will explain the absence of your copy of the proceedings; but I hope in a few weeks we will be "right side up with care" on this side of the ocean. In the meantime, I will write as often as I can.—Yours repectfully,

F. F. Thompson.

2, *Wall Street, New York, July* 7, 1862.

[The specimens enclosed are two views of exactly the same spot, in the Central Park, New York, the only difference being that one negative was developed within 12 hours and the other in 15 days. They are both excellent photographs, and charming pictures, and there is scarcely the slightest perceptible difference between the two: perhaps that developed within 12 hours is a little more transparent and detailed in the shadows. The experience of different persons as to the result of keeping before development is conflicting. The subject certainly requires further investigation, so as to determine, if possible, the causes which at any time cause deterioration; the correspondent, who wrote to us as to his experience in the evils of keeping after exposure, was Mr. Penny, of Cheltenham, unquestionably one of the most able dry plate amateur photographers in the country. We hope this sad war will soon be over, and enable our correspondent to lay aside the sword and resume the camera, and shall be glad in the mean time to receive such hasty notes as he can find time to send us.—Ed.]

## INSTANTANEOUS PICTURES IN AUSTRALIA.

Sir,—I have been engaged for some time past in a series of experimental researches in photography, having the object in view of discovering some certain process by which the clouds could be photographed in landscapes; and I think I have succeeded in a great measure in solving that difficult problem (*vide* enclosed stereograms). According to my experience, the most beautiful photographic clouds are to be obtained towards the sun, and by selecting some light coloured object for the foreground (the church for instance), such clouds as you see in specimens marked (1) can be easily obtained by the process I adopt. I cannot manage to get satisfactory pictures with foliage in the foreground, when pointing my camera towards the sun.

The enclosed specimens I obtained with Ross's View Lenses —exposure from 30 to 40 seconds in a bright light. My process is therefore applicable to plates of any size, and differs very considerably from any of the processes now used by photographers, and which I hope considerably to improve upon in time.

Will you please to acknowledge the receipt of this in your Journal?—Your obedient servant, Jenner Plomley.

*River View, Hunter's Hill, Sydney, New South Wales, May* 20*th*, 1862.

[The letter is accompanied by a series of interesting stereoscopic pictures of Australian scenery, many of which possess very fine clouds. We insert this letter as an interesting illustration of what is going on, in this direction, at the antipodes. We shall have pleasure in hearing further from our correspondent.—Ed.]

## THE MISSING NAME IN THE JURY AWARDS.

Dear Sir,—I was sorry to see a blank in the list of Jury Awards published in your last, where should have been the name of my talented friend, Mr. John Savage, of Kingston, Jamaica, the photographer of the series of fish of that island. He is an old-established artist, and an excellent portraitist. I cannot imagine how his name was omitted, as he informed me in January what he intended to do.

Begging the insertion of this note in your valuable space, I am, dear sir, yours, &c., J. Davis Burton.

*Harborne, Birmingham, July* 19, 1862.

## MORPHINE DRY PROCESS.

Dear Sir,—In reply to your correspondent's questions on the morphine process, I believe the particular age of the collodion (provided it is a good sample and bromo-iodized) to be of small consequence, and its age may probably range from a few days to a year or two. The plates must be perfectly washed, too much water cannot be applied.

I have adopted the proportion of 1 grain of muriate morphine in 8 ounces of bath, but see no reason why 1 grain in 10 ounces should not be equally effective.

The edges and corners of the plates have never shown a diminution in sensitiveness in my hands, unless one has inadvertently become too dry before immersion.

The bath deposits a minute quantity of matter, but as every manipulator filters his bath before preparing a batch of dry plates, and the bath remaining perfectly unimpaired, I look on this as of little moment. Nitric acid, in the place of acetic acid in the bath, will exert a more decided action in preventing this, but I prefer acetic acid and filtering a little oftener; in procuring muriate of morphine it is within the bounds of possibility that you may receive acetate of morphine, and this will much increase the deposit in rapidity and quantity.

There appears to me to be a deep-rooted feeling against the use of organic matter in the bath, whether it is introduced in the collodion or applied directly to the silver solution, and if the organic matter referred to for such uses in photographic works is meant, why, the objection is well founded, for such substances as rosin, gum guaiacum, amber, oil of cloves, glycyrrhizin, &c., quickly disorders a bath; but morphine being what is styled an alkaloid, *i.e.*, a substance derived from organic matter (opium), and possessing very similar properties to an alkali, combining with, and neutralizing strong acids; forming crystallizable salts, with muriatic acid, a muriate; and with nitric acid, a nitrate of morphine; I think that there is a wide distinction to be drawn between this organic matter, and the term as usually applied in such cases. The bath I have now I prepared in January or February last, and it is in no way deteriorated, certain evidence of the harmless nature of nitrate of morphine in the silver solution.—I am, dear sir, yours faithfully,

Wm. Bartholomew.

## Talk in the Studio.

Copyright (Works of Art) Bill.—We have pleasure in announcing that this Bill, after some further amendment, has been read a third time, and passed the House of Lords. It now only waits the royal assent before it passes into law. We shall shortly lay such of the provisions as relate to photography before our readers in their present form.

The Glasgow Photographic Society.—We have pleasure in stating that there is every probability of this society being re-constituted under better auspices than it has existed for the last year or two. Indeed, it was dissolved for the purpose of getting rid of a small dictatorship under which it had for some time languished.

Mr. Bedford's Tour.—History informs us that in all memorable journeys the functions of the secretary have not been least important. Even the Japanese, on their late entrance into society, were everywhere accompanied by this indispensable functionary. The works of Mr. Bedford go far to prove that another state officer must shortly be created. While Court dignitaries in different countries are defining the duties of the Court photographer, the public at large cannot do better than admire the very admirable memoranda of the latest Royal progress which have been penned by the industry and skill of the artist who took part in it.—*The Times.*

Jury Awards.—The *Telegraph* says:—"It now appears to be more than likely that there will be some revision of the jurors' awards. The difficulty is not a slight one; for, in the first place, the value of the honour consists greatly in its being final and without appeal; while there is already a pretty general impression that medals, having been nearly as plentiful as blackberries, are not as precious as pearls, and the giving more will cheapen these distinctions yet farther. As for taking any away that have already been given, that is out of the question; so that the amendment, if any be attempted, can only amount to an imperfect patching-up of an unsatisfactory business. The discontent of exhibitors is by no means confined to those who have missed their expected award. Some are heard to protest against the loose and incorrect terms in which their articles are described; and others deem that they have been slighted by the reticence or the lukewarmness of the praise. Others, again, declare that they set no store whatever by a prize which few could manage to miss. It is a fact that, in one of the classes, out of the small number of six different forms of a useful domestic apparatus, four are rewarded with medals, while the other two are honourably mentioned. The distinction here would be in getting left out. However, it seems exceedingly probable that there will be an overhauling of the decisions, and that at least some disappointed inventors and manufacturers have yet a chance of obtaining a recognition commensurate with the value they place upon their works." Should any such revision take place in the photographic department, we would venture to suggest this question in addition to what we have before said: Is it not by some oversight that a man who has done so much to advance the artistic character of photography as Rejlander, has not got a medal?

## To Correspondents.

E. C. L.—Your question as to the best mode of developing negatives is a somewhat vague one, and cannot be answered in a short and decisive manner. The best developer depends much upon the collodion employed. Some good operators still prefer pyrogallic acid; but, in portraiture at least, iron is now almost universally used. If your collodion be strongly bromized you may use a very strong solution of iron, if slightly a weak solution. A good average formula is 15 grains of iron, and 15 minims of glacial acetic acid to an ounce of water. Some operators, as you will have seen, if you read our pages regularly, recommend various additions, such as formic acid, acetate of soda, &c. Whatever iron solution you may use it will often happen that you require, after continuing the iron as long as any additional detail is to be obtained, some additional density. This may be secured before or after fixing. A simple plan is to wash the film well after the iron has done its work, and apply a two-grain solution of pyrogallic acid, with citric acid one grain, and a few drops of 20-grain solution of silver until the right intensity is obtained, and then fix. Mr. Mudd's dry process is described on page 386 of our fifth volume, No. 154. You will find an epitome of the dry processes in the Photographic News Almanac for 1862.

J. H. C.—Samples of tannin vary somewhat. In mixing 15 grains of tannin and 15 grains of honey in one ounce of distilled water, we have not experienced much difficulty, nearly the whole dissolving, and leaving a very slight filtrate. We have heard, however, of cases similar to that you describe, in which a large undissolved residue remained. One correspondent stated that with a sample of tannin which dissolved readily alone, he had a large residue the moment he added honey, as though some insoluble compound were formed by the combination. We see no reason why this should be so: if it occur we can only recommend you to filter it carefully to get rid of insoluble particles. It should be ready for use as soon as it is mixed. 2. The majority of the back numbers of the News can be had, a few are out of print.

M. B. Y.—Both the prints enclosed are examples of virulent measles, arising from imperfect fixation. The hypo was too weak, it had been too long used, the prints had been immersed for too short a period, or they had been stuck together, so that the solution never acted properly upon them. Whichever of these causes has been in operation, the yellowness and spots arise from decomposed hyposulphite of silver, which having been formed in the print, was never dissolved, as it should have been, by strong hyposulphite of soda. We have heard many complaints of late of bad hyposulphite of soda, and from the large number of imperfectly fixed prints we receive, we conceive this complaint must be only too well grounded.

Photos.—We have no certain information, but we conceive that it is very likely the usual Exhibition of the Photographic Society will be held in the coming winter as usual; and we should imagine that any novelty in chemicals or apparatus would be admissible. 2. Your question as to the construction of "a glass-house to produce perfect pictures" is somewhat too general for a very definite answer; much depends on circumstances. Sufficient top and side light are required, but the top light should not be vertical, but should fall upon the model at an angle of about 45°. A convenient arrangement of blinds is desirable, so as to be able readily to get any amount of shadow. 3. In a short room the camera may be moved outside as you suggest, but it will be necessary to have around the lens a box or black cone, to cut off the mass of diffused light which will surround it. Diffused light entering through the lens is a fertile source of flat, feeble, imperfectly defined pictures.

W. W.—It is somewhat difficult to name any single book which will "post you up" in all that has been done in photography for the past five years. The more recent instruction books will help you, such as Hardwich's last edition and Mr. Hughes' Manual, as they contain processes as now practised. For a complete and progressive view of all that has been done in the art recently, you cannot do better than refer to our pages. The present and the last volume of the Photographic News contain an immense mass of information as to every detail of the present practice of the art, practical as well as theoretical. You will find an excellent epitome of progress in the last two Photographic News Almanacs issued.

Formic.—Your suggestion received attention.

Cassandra.—The white spot in the print now enclosed arises from the removal of the albumen from some cause. As you state that it appeared immediately after toning, it may arise from the toning bath being too alkaline. Thank you for the description of a plate holder. We shall have pleasure in receiving your further communication.

F. Vincent.—You do not state whether it is in intensifying before or after fixing that the deposit on the shadows to which you refer occurs. In hot weather it is apt to occur in both cases, but the remedy is different in each. Please state which, definitely. In any case, the use of silver from the bath is very apt to cause it. Use fresh silver solution made for the purpose. See answers to C. A. R. and New Subscriber in our last. Where the defect exists, the best remedy is to give the negative a hasty wash with a solution of bichloride of mercury, which will change the red deposit to a bluish white, which, in printing, will scarcely be observed.

Phos.—The difficulty in getting the developer to flow evenly over the plate, to which you refer, and describe it as running off "like water off a duck's back," will arise from several causes, and sometimes from a combination of them. A great accumulation of ether and alcohol in the bath, from immersion of many plates in succession, will cause it, and it may in a few days, as you describe, disappear, simply from some evaporation of the ether and alcohol from the bath. A very common and little suspected cause exists in some collodion. If the pyroxyline give a tough skinny film, and if there be a large proportion of alcohol in the collodion, it will yield this repellant film, which it seems almost impossible to wet evenly. This will sometimes disappear in a few days of damp weather, the collodion having absorbed moisture from the atmosphere, which has slightly altered its physical properties. When this is the cause, and it is most frequently so, a drop or two of distilled water to each ounce of collodion will cure it. In such a case adding alcohol to the developer is quite useless.

G. W. Hale.—The card portraits had been omitted from your envelope, as they have not come to hand. We shall be glad to give you our opinion when we receive them, and also to receive your further communication of particulars.

Received, and will be noticed shortly: A series of cabinet pictures, by G. W. Wilson; a series of instantaneous stereographs, by Mr. Alfred Harman; a composition group from Mr. Brothers, and card pictures from several correspondents.

P. Henderson.—Mr. Fitzgerald's description of a powerful and economical battery has been in type some weeks, but has been omitted through the pressure on our pages. It will appear in a week or two.

Several correspondents in our next.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 204.—*August* 1, 1862.

## RED DEPOSIT ON SHADOWS FROM INTENSIFYING.

The elevation of temperature during summer is very frequently accompanied by the presence, in the dark room, of one very annoying evil, amongst other minor troubles. From a number of communications recently received, we suspect the evil to be very rife at the present time. We refer to the prevalence of a form of fogging, or abnormal reduction, on the shadows of the negative. Everything appears to be working satisfactorily up to a certain point; the image develops perfectly, and is brilliant and clean: during the process of intensifying, however, the deepest shadows suddenly show some signs of deposit, and before it is possible to stop operations, and wash the plate, a decided deposit of a red or coppery hue has taken place.

This occurs chiefly when developing with iron and strengthening by means of pyrogallic acid and silver. It occurs both when the process of intensifying is applied before fixing, and after fixing. It differs from general or universal fog in occurring, not all over the plate, but in patches, on the deepest shadows first. We are not now about to inquire into the theory of the matter, which is somewhat perplexing, but rather to point to some of the causes which induce the trouble, and to suggest some remedies which we have found generally efficient for preventing the recurrence of the evil.

We may observe at the outset, that the occurrence of this deposit is generally much more common with a collodion giving a somewhat spongy or absorbent film, than with one giving a horny film, and that the deposit appears to be caused by the spongy film retaining, whilst intensifying, some traces of the preceding solutions which had been applied.

It occurs, as we have said, not unfrequently after development with iron, whilst intensifying before fixing. We are uncertain of all the causes which produce this; but we can mention some of them, and we can point out a remedy. Great heat is a common cause, and it is for that, as well as other reasons, desirable to keep the dark room as cool as possible during hot weather. The use of an old bath, or one containing organic matter, aids in causing this trouble. It is sometimes induced by the film having been imperfectly washed after developing with iron, before applying the pyro and silver: the remedy in that case is simple and obvious—a more thorough washing before commencing to intensify. It is very often caused by the use of the bath solution for the purpose of adding to the pyro. This, especially when the bath is an old one, is a very common cause. We have always found that a twenty-grain solution of the purest nitrate of silver was the best for intensifying, and gave much more satisfactory results than when a few drops from the bath were added. Prolonged application of the pyro and silver, when density appears tardily, especially if there be any trace of chemical light in the room, will also cause this trouble.

Besides the remedies suggested in this brief enumeration of causes, there are one or two more. The first is not a universal remedy, but is, nevertheless, often largely preventive; it consists in the free use of citric acid in the intensifying solution of pyro and silver, instead of acetic acid. The usual proportion of citric acid used, is one grain to two of pyro. For this purpose the proportion may, in hot weather, be largely increased with advantage, in some cases to equal proportions of each. This will frequently remove or reduce the tendency to this copper-coloured deposit. The remedy which has in our hands, however, been unfailing, consists in the application to the film, after developing with iron and washing, of a solution of iodine. This may consist of an alcoholic tincture of iodine added to water, until it is the colour of brown sherry, or iodine with an equal proportion of iodide of potassium dissolved in water, say one grain of each to an ounce of water. This solution is poured over the film, and in a few seconds washed off; the solution of pyro and silver is then applied, and in our hands, and in the hands of all whom we know to have tried the plan, it is found that the intensification proceeds satisfactorily without any tendency to the red deposit on the shadows, or any other form of fogging. The exact theory of this remedy we do not undertake to determine: we might hazard some conjectures, but we content ourselves at present by stating the fact.

This red deposit on the shadows also occurs whilst intensifying after fixing, and here we believe we can point more definitely to the cause. The evil occurs, as we have already stated, most frequently with a spongy and absorbent film, and we may add that when it occurs after fixing, it is generally, if not universally, when cyanide of potassium has been used for that purpose. It also generally happens when the intensifying is conducted in the light, or when the plate has stood in the light after fixing and before intensifying. From a careful consideration of our own experience, and the records of that of many others, we are convinced that this deposit, in many cases, arises from the retention in the absorbent film of some unsuspected traces of cyanide of potassium holding in solution cyanide of silver, which have been acted upon by light, and form the nuclei for reduction of what Mr. Malone would call "ruby silver," when the intensifying solution of pyro and silver is applied. We know that it will be urged by some that all their plates have been well washed, and yet this deposit has occurred; but the amount of washing required by an absorbent porous film may be very easily under-estimated. We have known a negative which had been apparently thoroughly washed, after fixing, with cyanide, manifest the presence of the latter salt in a curious and annoying manner. A solution of iodine has been applied as a preparatory step to intensifying with pyro and silver, and in a short time the half tones of the image have disappeared, indicating that the image was being gradually dissolved. Some traces of cyanide had remained in the film, but not sufficiently energetic to act upon the image of reduced silver, but so soon as any portion of it was converted into iodide of silver, the cyanide manifested its presence by dissolving the iodide so formed.

Cyanide of silver is very readily acted upon by light, and any traces remaining in the porous film, as we have described, and being acted upon by light, will readily become a source upon which abnormal reduction readily takes place. The preventive in this case, in addition to other precautions already named, is a very perfect washing after fixing, before applying the intensifying solution. An additional aid will be found, when this thorough washing has been given, in an application to the film, before intensifying, of the solution of iodine we have already referred to.

When the first trace of this deposit appears, the plate should be quickly washed, and by the judicious use of cyanide the deposit may be removed. If it be necessary to proceed further with the intensifying, it is important that a most thorough rinsing, and sometimes an application of the iodine solution, should be given before proceeding further with the pyro and silver, as the tendency, once evinced, is very persistent, and will probably occur again at once on attempting to intensify further.

Perhaps the best remedy which can be applied, when once the evil is in existence, and cannot be removed by cyanide without endangering the picture, is to treat the plate with a dilute solution of bichloride of mercury, which will not affect, in any appreciable degree, the general image, but will convert the red deposit, which is very non-actinic, and a serious detriment in printing, into a thin one of bluish white, through which the light can easily pass, and will therefore render the defect of comparatively small importance in printing. Prevention is best; but when the time for prevention is past, this remedy will be found valuable.

## PHOTOGRAPHIC CHEMICALS:

### Their Manufacture, Adulteration, and Analysis.

*Potassium Salts.—Permanganate of Potash* (continued).—Mr. Robert Hunt, to whom photography owes so much, has shown that the metallic acid contained in this salt is possessed of photographic properties; for instance, if two bottles are filled with this solution, and one of them be placed in the sunshine, whilst the other is carefully preserved in darkness, it will be found that the solution exposed to the sun will very rapidly throw down a deep brown precipitate, whereas the one in the dark remains for some time quite clear. This experiment, if cautiously made in weak diffused daylight, will exhibit the same change, although more slowly; showing in a very remarkable manner the influence of the solar rays in determining the tendency to precipitation. If a dilute solution of permanganate of potash is washed over paper, it imparts to it a brown colour, owing to the reduction of the acid by the organic matter, and precipitation of binoxide of manganese. The sun's rays have a tendency to discharge this colour, and thus give a positive image. The addition of a small quantity of nitrate of silver to paper prepared with this salt of manganese renders it brown, and causes it to assume a very intense black colour upon exposure to light.

*Arseniate of Potash.*—Arsenic and arsenious acids have frequently been employed in photography; and, indeed, some experimenters have succeeded in obtaining very excellent photographic pictures by using the *liquor arsenicalis* of the pharmacœpia. Mr. Hunt says that paper washed with this solution, and then with nitrate of silver, changes with tolerable readiness, and darkens to a perfectly jet black: the photographs resulting from this process are very decided in their contrasts of black and white. The salt may be formed by powdering together equal weights of arsenious acid and nitre, and throwing the mixture gradually into a red-hot crucible, the mass is then allowed to cool, when it is dissolved in water, the solution filtered and left to crystallize. It may also be formed by mixing carbonate of potash and arsenic acid together in proper proportion, and evaporating, the mono-salt crystallizes out. The crystals are permanent in the air, and taste somewhat like nitre; this experiment, however, is very dangerous, as the salt is terribly poisonous. It dissolves in about five parts of water, at the ordinary temperature, and in a much smaller quantity of hot water; it is insoluble in alcohol. The crystals are exactly similar in appearance and crystalline form as the monophosphate of potash.

*Arsenite of Potash.*—This combination is not known in very definite form. Three salts are supposed to exist, but they are difficult to crystallize. Pasteur succeeded in obtaining a compound in the crystalline form, by digesting arsenious acid in excess in a cold solution of potash; upon adding alcohol to the resulting oily, alkaline, liquid, it became thick and turbid, and after a few days deposited beautiful crystals on the sides of the vessel, having the form of rectangular prisms. When nitrate of silver is added to this solution, the yellow neutral arsenite of silver is precipitated, mixed with free arsenious acid, while the supernatant liquid acquires an acid reaction. In some photographic experiments it may be advisable to avoid this acidity. This may be effected by digesting the crystallized salt with excess of potash, and precipitating with alcohol. In this manner a salt is formed which gives, with nitrate of silver, a yellow precipitate, containing no free arsenious acid, whilst the supernatant solution becomes neutral.

*Carbazotate of Potash.*—Carbazotic acid is so frequently used as a test for potash, and is now becoming an article of such importance, that a short notice of this salt may not be out of place here. Carbazotic acid is prepared by acting upon numerous complex organic substances with fuming nitric acid. At present it is made in enormous quantities from some of the products of the distillation of coal, the hot solution obtained by acting upon this mixture with nitric acid must be decanted from the undissolved portion, when the carbazotic acid will be deposited as the liquid cools; it may be purified by washing with cold water, and converting it into the potash salt. Carbazotate of potash forms orange yellow, needle-shaped crystals, freely soluble in boiling water, but requiring 260 parts of cold water for solution. By dissolving it in boiling water, and adding dilute nitric acid, it is decomposed, and crystals of carbazotic acid will be deposited as the liquid cools, nitrate of potash remaining in solution. This acid crystallizes in long pale yellow brilliant rectangular plates which are readily soluble in alcohol and ether. It requires between 80 and 90 parts of cold water for its solution, forming a liquid of a bright yellow colour, and stains the skin yellow. It has an intensely bitter taste, on which account it is reported to be used by some persons as a fraudulent substitute for a portion of the hops in beer. The great use of carbazotic acid is, however, for dyeing purposes, as it communicates to silk and wool a brilliant yellow colour. Cloth dyed in this manner might be advantageously employed as an adjunct to the yellow glass in photographic laboratories.

*Silico-fluoride of Potassium.*—Another useful test for potash is the hydro-fluo-silicic acid. This is formed by a rather difficult process, by the decomposition of fluoride of silicium by water, or by dissolving silica in dilute hydrofluoric acid. When the acid is added to a soluble potash salt silico-fluoride of potassium is thrown down; the precipitate forms in a very characteristic manner, at first it separates very slowly and is scarcely visible, afterwards it produces prismatic colours in the liquid, and is finally deposited as a transparent gelatinous iridescent mass, which dries upon the filter to a soft white powder. It is very sparingly soluble in water, but more freely so when the water is hot.

*Sulpho-cyanide of Potassium.*—This is rather an important salt, and is much used as a test for iron. It is prepared on the large scale by mixing 46 parts of dried ferrocyanide of potassium, 17 parts of carbonate of potash, and 32 parts of sulphur, powdering them well together, and heating until the mixture attains a state of clear and tranquil fusion; the heat is then raised to low redness to decompose the hyposulphite of potash; it is afterwards left to cool, boiled with alcohol, and filtered. On the filter there remain bisulphide of iron and sulphate of potash, whilst the transparent and colourless filtrate yields crystals of pure sulpho-cyanide of potassium. This is a very advantageous process devised by Liebig, the product is yielded in large quantity and very pure. The salt forms long, transparent, colourless striated prisms and needles; at a temperature considerably below redness they fuse to a transparent and colourless liquid, which solidifies to a crystalline mass on cooling. It deliquesces in the air and dissolves abundantly in water, producing a considerable degree of cold. It likewise dissolves in alcohol, especially when hot, it has a saline and cooling taste like nitre, and is a narcotic poison like hydrocyanic acid. When in aqueous solution it suffers gradual decomposition, even when kept in a well-stoppered bottle, attended with formation of ammonia. Its alcoholic solution is much more stable.

*Nitro-prusside of Potassium.*—This salt is prepared by acting upon ferro-cyanide of potassium with dilute nitric acid. The mixture first assumes a milky appearance, but after a little while the salt dissolves, forming a coffee-coloured solution, with evolution of various gases such as cyanogen, hydro-cyanic acid, &c. When the salt is completely dissolved, the solution is to be decanted into a large flask, and heated over the water bath. After a while it is removed and left to crystallize, a large quantity of nitre separates at first; the decanted liquid is neutralized with carbonate of potash, and the solution is boiled, whereupon it gradually deposits a green or brown precipitate, which must be separated by filtration. The liquid then contains nothing but nitro-prusside of potassium and nitrate of potash. The latter being the least soluble crystallizes out first, and the remaining liquid, on further evaporation, yields crystals of nitro-prusside of potassium: it may be purified by recrystallization. The crystals form ruby-coloured prisms very soluble in water. The great use of nitro-prusside of potassium (or of sodium) is as a test for sulphur; an addition of a soluble sulphide to its solution, in even very small quantity, immediately produces a magnificent blue or purple colour, affording a highly characteristic test for the least trace of a soluble sulphide. It is of the greatest importance that many salts used by photographers should be absolutely free from a sulphide; hence, the value of so delicate a test for this impurity will be readily appreciated.

## The International Exhibition.

### BRITISH PHOTOGRAPHIC DEPARTMENT.

Reproduction is not largely represented in the British Photographic Department of the Exhibition, but there are, nevertheless, some very fine examples. Amongst the most prominent are the large copies of Raffaelle's cartoons; both Signor Caldesi and Mr. Thurston Thompson exhibit very fine specimens of these noble reproductions. Both these gentlemen, also, exhibit other excellent reproductions. The Elgin marbles by the former—which, although not strictly reproductions, are analagous in their character and purpose—are magnificent specimens, very valuable as works of art, and possessing importance in an educational point of view not easily to be overrated. Mr. Thompson's reproductions from Turner's paintings have before been noticed in our pages; we regard them as decided triumphs in this line. Very few paintings could be found presenting greater difficulties to the photographer, from the prevalence of the most brilliant and anti-photogenic colours on the pallette of the painter; yet few paintings that we have seen have received fuller justice from the photographer.

Dollamore and Bullock have several fine reproductions. Here is one of that much-abused-by-artists, but much-admired-by-the-public painting, "The Blind Beggar," left a few years ago to the National Gallery by a milliner. Perhaps few reproductions of paintings have had a greater sale than this, and as photographs of the pictures in the National Gallery are not permitted to be taken, it may be interesting to refer to the method by which rumour states this copy was obtained, without, however, vouching for the truth of the statement. We have been informed that a very skilful artist was employed to make a copy of the painting in monochrome, from which might be produced with ease an excellent photograph. This done, and several negatives obtained, the artist's copy, it is said, sold for more than it originally cost. Whether the story be true or not, it is well found, and the photograph referred to is an excellent copy of a very popular picture.

Mr. J. B. Pyne has some very fine copies of paintings and carvings. We may call especial attention to an exquisite photograph of a *bas relief*, entitled, "The Tomb Revisited," sculptured by Foley, the delicacy, softness, and roundness, and the low tone in keeping with the sentiment of the subject, are all worthy of high praise. Messrs. Cundall and Downes have also some very fine reproductions from paintings and sculpture; a copy of a *bas relief* in bronze, a material presenting serious difficulties, is admirably executed, doing full justice to the metallic texture of surface. Specimens are exhibited by the same firm of their fine copies of Raffaelle's drawings, executed for the late Prince Consort. Some good copies of engravings are contributed by the Amateur Photographic Association. Mr. Stephen Thompson also sends some fine reproductions. Mr. Ramage's reproductions of engravings, by means of photography, are as perfect as anything of the kind exhibited. Mr. Victor Prout has some very fine reproductions. Mr. Ponting has some good copies of pictures: "Making a Hayrick," an enlargement from a small negative of an engraving, is a very successful picture indeed. It is, we presume, a developed print, and the peculiar tone and extreme softness give it much the effect of a chalk drawing. The reference to development printing reminds us, that we omitted before to notice some prints by Mr. Lamb, of Aberdeen, which we had marked for mention. Some of these are developed prints, and are well worthy of the attention of visitors, as illustrating the softness, vigour, and excellence of tone which may be obtained by that method of printing.

A stand of stereoscopes with M. Claudet's exquisite coloured Daguerreotypes, receives much attention. Mr. Breese's two tables of stereoscopes with instantaneous and other transparencies, as we have before stated, monopolize a large share of the attention and interest of visitors. Apart from the curiosity excited by the moon-light pictures, it is impossible to conceive anything more beautiful than the mass of these slides even as ordinary illustrations of photography; the rare and poetic beauty of many of the cloud and atmospheric effects and breaking water, the fine composition as pictures, the perfect instantaneity, and the wonderful rendering of difficult texture, all combine to complete the charms of these pictures. Many of them are printed from several negatives, although they present no suggestion of such a process. An effect is produced in two or three of the specimens which is very beautiful and appears very marvellous: we refer to the flood of red or golden light which streams from behind masses of cloud, irradiating the horizon and sea with the glowing hues of sunset. This effect is not produced by the hand of the painter, but is due to the skilful adaptation of photographic appliances. We hope at some time to have Mr. Breese's permission to explain the *modus operandi*. We may add here, for the information of various enquirers, that Mr. Breese has been induced to publish some of his slides, and is now completing arrangements for the purpose. Amongst other stereoscopic contributions are Negretti and Zambra's very fine transparencies; Mr. England's instantaneous pictures, chiefly of street scenes; Mr. Blanchard's instantaneous marine pictures; and a few others.

Mr. Swan's novel form of stereoscope is worthy of examination. The novelty consists in exhibiting a single photograph about 12 by 10 in such a manner as to render it stereoscopic. This is effected by placing in the right position a small box, containing a small photograph, forming the stereoscopic complement of the large one, and an eye-piece, which shall magnify this small picture to the size of the large one: when one eye is placed to the eye-piece the large picture is opposite the other eye, and the two images combining produce a large stereoscopic picture.

We may here call the attention of those interested in enlarging, to one of the pictures exhibited by Mr. Swan "The First Cradle," as from an enlarged negative by Mr. Samuel Fry, produced by the same method described recently by Mr. Vernon Heath; some excellent specimens by the same process are also exhibited by Mr. Warner in this department.

M. Joubert exhibits some fine specimens, in colours and in monochrome, of his fine photographic enamels on glass: also of his phototype printing process, both of which have been so strangely overlooked by the Jurors. M. Joubert blames himself, and with apparent good reason, that he did not exhibit in his own national department, where recognition of all kinds of claims appears to have been much more generously accorded. But is it not a circumstance for deep regret, or something more, that a gentleman having resided long in this country, and merging his nationality to do the English Department such honour as he could, should in doing so become an absolute sufferer in the matter of awards? We trust, as we have before said, that this with some others have been the result of some oversight, yet to be remedied in the promised revision of awards.

Mr. Skaife has a handsome revolving stand, for the purpose of exhibiting his minature camera, or "pistolgraph," and its varied products. These consist of a very charming selection of the minute glass positives, suitable for lockets, brooches, &c., hermetically sealed, and backed up with coloured glass. They are chiefly of portraits of babies; the exuberance of infantine mirth, which is stamped on many of the faces, showing the facility and rapidity of the process. There are also some enlarged copies on paper from similar pictures. The whole are very pleasing and satisfactory.

We have now noticed the chief pictorial contributions to this department. We shall shortly refer to the apparatus, and also to the photographs and apparatus from other countries.

## PHOTOGRAPHIC CHEMICALS.

The remaining exhibitors of chemical products in the Photographic Department are very few. Mr. Rouch (3150) has some good specimens of all the chemical agents in general use, the series being very complete and well arranged. Gun-cotton seems to be a branch of manufacture to which Mr. Rouch has devoted special attention, a beautifully clean specimen of purified cotton forms the starting point, and near this is shown a nice sample of pyroxyline, of the ordinary variety, we suppose, and another specimen of powdery pyroxyline of special value for dry processes.

Messrs. Horne and Thornthwaite (3100) also exhibit chemicals in connection with apparatus. Their chloride of gold is in magnificent crystals, and is, without exception, the finest specimen of the salt we have ever seen. They also exhibit nitrate of silver, a salt which this firm professes to manufacture specially for photographic purposes. The fused cakes which they show are, however, not quite so white as they might be.

Messrs. Hockin and Wilson (3097) exhibit a contrivance for preserving collodion, ether, and other volatile liquids from change. A glass tube is hermetically sealed up at one end, the other extremity being drawn out to a fine point; it is then filled with the liquid by drawing some of the air out by heat, and then dipping the beak under the surface of the liquid. The contraction on cooling sucks some of this up into the tube, and by a repetition of this process the latter is at length filled. The flame of a blowpipe is now applied to the capillary point with the proper precautions adopted in chemical laboratories, and the opening is instantly closed. In this way no atmospheric agency can affect the contents of the tube in the slightest degree. If they are carefully packed in bran or saw dust they may be exported to any part of the world, and be subjected to the greatest natural extremes of heat and cold, without undergoing loss from evaporation, or deterioration from the absorption of oxygen. There may, possibly, be room for deterioration in the case of collodion, even when isolated in this perfect manner from all external agencies, as this highly complicated organic mixture is prone to undergo molecular change upon keeping; but we think it most probable, that even this unstable liquid would be found to preserve its qualities pretty well; with the other chemicals employed by the photographer, alcohol, acetic acid, ether, nitrate of silver, as well as the other less changeable materials, we think the plan is admirable, and should be invariably adapted when chemicals have to be exported. A few chemicals are likewise exhibited by Mr. Solomon (3158), these appear to be of good quality, but do not demand a more special notice.

There is one article exhibited in the chemical department to which we have not yet drawn the attention it deserves, this is the purified wood naphtha exhibited by Mr. Eschwege (513). This article is likely to become of considerable use in photography. Wood naphtha, chemically known as methylic alcohol, is at present only used for the purpose of mixing with ordinary alcohol to prevent its being used as an intoxicating beverage. The unpleasant taste and smell which is thereby communicated to the spirit, being inseparable by distillation or other ready means. Mr. Eschwege has now shown that this smell and taste are not due to the wood spirit, but to impurities which he has succeeded in separating. The specimens of purified methylic alcohol here exhibited have scarcely any of the ordinary taste and flavour which have hitherto characterized this body. The taste is almost identical with that of pure alcohol, and leaves none of the disagreeable flavour in the mouth given by methylated spirit, the smell is also strongly alcoholic, whilst it is much more volatile (boiling at 151°, alcohol boiling at 173° F.) Although methylated spirit is generally banished from photographic laboratories, we see no reason why this purified wood spirit should not be applied to a variety of useful purposes.

## ON THE PRODUCTION OF THE ELECTRIC LIGHT FOR PHOTOGRAPHIC PURPOSES.

Sir,—A few details relating to the conditions for producing an artificial sunlight, which may occasionally replace the agency by which the heliograph is usually obtained, will perhaps be of interest to many of your readers, in whom are combined the acquirements both of the artist and the chemist. The question—"which is the best form of battery for our use in producing the electric light?"—has doubtless often been put by the photographer, but would appear hitherto not to have received a definite and satisfactory answer. Nor is it a question that can be readily met; for the advantages and disadvantages of different battery arrangements are so various, that it is only recently that telegraphists in Europe have arrived at unanimity in the adoption of the Daniell's battery, or in some few cases that of Marié-Davy, which is based upon the same principles, for their particular purposes. For the economic production of a constant and continuous supply of electricity, the Daniell battery, requiring but little attention for a period of many weeks or months, is possessed of great advantages. But by other arrangements, a powerful current, lasting for a comparatively short period, is far more readily obtained. Before attempting to answer the above question, I should therefore require to know whether a battery, cheap in construction and working, occupying but little space, easily charged, emptied, and taken to pieces, and maintaining during *several hours* the necessary power for the production of the electric light, would generally answer the purposes of the photographer.

The fact of this battery requiring attention in the renewal of the existing fluid every few hours, is sufficient to unfit it for use in telegraphy, or in the electro-deposition of metals, but even when constructed of very moderate dimensions, it is capable of furnishing a *quantity* of electricity far greater than would be required for the transmission of telegraphic signals, and therefore appears particularly adapted for the production of the electric light, in which great quantity has to be combined with considerable force or *intensity* in the current—in cases where the light is not required uninterruptedly for a lengthened period of time.

The elements in the batteries I would propose for use by photographers, are the same as those employed by Callan in his single fluid arrangement—viz: amalgamated zinc for the positive, and cast iron for the negative elements. The exciting fluid is a mixture of sulphuric acid with a solution of common salt, to which I add a small quantity of the black oxide of manganese or of the chlorate of potash, for the purpose of absorbing the hydrogen generated on the negative plate; the oxide of manganese evolving chlorine in presence of the salt and sulphuric acid, and the chlorate acting, like the chlorine, as an oxydizing agent. The mechanical arrangement of the battery in a very convenient form, has been contrived by Mr. John Cliff of Lambeth, and will be described on a future occasion.

The following brief comparison of the various forms of battery, will enable many of your readers to arrive at some conclusions respecting their adaptability, on economical grounds, for the purpose now in view. Equal surfaces are taken in each case; and it should be borne in mind that increased quantity may be obtained by augmenting these surfaces, and increased intensity by augmenting the number of cells arranged in series.

*Groves's Battery.*—Positive element, amalgamated zinc in dilute sulphuric acid; negative element, platinum in pure nitric acid. A porous cell is necessary to separate the two exciting fluids. *Quantity* high. *Intensity* high. Duration of action moderate.

*Bunsen's Battery.*—The same as that of Grove, with the exception of a negative element of graphite or gas carbon. Quantity and intensity the same as in Grove's arrangement.

N.B.—The employment of nitric acid is objectionable on the grounds of expense and the liberation of nitrous fumes.

*Daniell's Battery arranged for Quantity.*—Positive element, amalgamated zinc in dilute sulphuric acid; negative element, copper in sulphate of copper. A porous vessel is necessary, and requires to be occasionally renewed. *Quantity* moderate. *Intensity* moderate. Duration of action moderate as regards the continuance of the quantity effects. Very constant, *i.e.*, little or no variation in the current while the exciting fluids are maintained of normal strength, or nearly so.

*Daniell's Battery as arranged for Line Batteries in Telegraphic Service.*—The same as the preceding, with the exception of the exciting fluid for the positive element, which may be pure water, or a solution of the sulphate of zinc. The positive element may also be used without amalgamation. Quantity very small, intensity moderate, duration of action very great. Constancy of action very great.

N.B.—Surfaces of enormous extent would be required in producing the electric light.

*Double Fluid Cast-iron Battery.*—Positive element, amalgamated zinc; negative, cast-iron. Exciting fluid for zinc, dilute sulphuric acid; for iron, pure nitric acid. *Quantity* very great, *intensity* low. Duration of action comparatively small. A porous vessel is necessary to preserve the solutions separate.

N.B.—This battery was supplied by the Electric Light Company, the cost of 48 cells being, if I remember rightly, £20. Besides the original expense, the cost of working was very great, owing to the use of the nitric acid, which moreover possessed the disadvantage of liberating nitrous fumes when the battery was in action.

*Single-fluid Cast-iron Battery as now Proposed.*—Positive element amalgamated zinc; negative element a plate of cast iron. One exciting fluid. *Quantity* very great, *intensity* low.

N.B.—In the absence of the porous cells or partitions, 60 couples may be arranged in much less space than would be occupied by 48 of the preceding.

To those of your readers who may be interested in the present question, I shall be happy to afford any further details which may be required; and I hope shortly to be able to give full data as to the original cost and expense in working of the battery arrangement I suggest for the production of the electric light for photographic purposes. I may also, perhaps, at some future time, have an opportunity of showing to you the battery in action when producing the splendid arc of light between charcoal points. —I am, &c.,

Desmond G. Fitzgerald.

## RAPID DRY PROCESS, WITH BROMO-IODIZED COLLODION, AND WITHOUT FREE NITRATE.

BY THOMAS SUTTON.

We have now been engaged for some months in experiments on the action of a bromide in wet collodion, and also on its effect in the dry processes. Our results have been stated from time to time in this journal, as the experiments proceeded, and we have now arrived at definite conclusions on the subject, and have constructed a theory of the action of light on the sensitive salts of silver, which appears to explain satisfactorily all the known phenomena of photography, and to establish the true proportions which should exist between the iodine and bromine in the various processes, so as to obtain the most exalted sensitiveness and the best results. This theory we will, in the next number, lay fully before our readers, and submit to their approval, and in the meantime will describe an application of it which yields rapid dry plates.

There are two methods of preparing rapid dry plates; one with iodide and free nitrate of silver, the other with iodide and bromide of silver. It is needless to observe that with iodide or bromide of silver alone, it is impossible to make a plate highly sensitive, either wet or dry. The secret of sensitiveness consists in the presence of iodide of silver, along with some other sensitive salt of silver; and our theory is, that the iodide of silver is not itself sensitive to light, but acts by its presence in exalting the sensitiveness of the other silver salt which is exposed in contact with it; and that by an action which is called in chemistry "Catalysis," and of which numerous examples might be cited, but the following will suffice:—

Put chlorate of potass into a retort, and heat it, and you evolve slowly oxygen gas. But add black oxide of manganese to the chlorate of potass, and mix them well together, and the heat will drive off the oxygen much more abundantly than before. Now, on examining the contents of the retort it is found that the black oxide of manganese remains unchanged, so that it has acted by its mere presence in assisting the liberation of oxygen from the other salt. In a similar way iodide of silver acts by its mere presence in assisting the decomposition by light of the other silver salt which is placed in contact with it. Moreover, in order that this action may be the most complete, and the combination the most sensitive possible, it is necessary that there should be in the film an atom of iodide of silver for every atom of the other salt of silver, so that the two may be distributed together in pairs throughout the film; for it is evident that if either salt be in excess, the sensitiveness of the film must be impaired.

This is our new theory of the action of light upon iodide of silver, and we can explain by means of it all the known phenomena of the Daguerreotype, Calotype, and collodion processes, and deduce from it some important practical results, which are true as far as they have been tried. And now, after this brief hint as to the nature of the theory, and with a promise to return to the subject and discuss it more fully in the next number, and show how it can be made to explain all known facts in photography, from the insensitiveness of calotype papers and Taupenot plates, to the exalted sensitiveness of dry bromo-iodized collodion films, we will return to the particulars of the rapid dry process.

The first method consists in preparing an iodized plate with free nitrate in excess. This can best be done by the Taupenot process, in which the plate, after its excitation in the bath of aceto-nitrate is not thoroughly washed, but ex-

* From *Photographic Notes.*

posed with some free nitrate in it. Plates prepared in this way are not quite so rapid as those with bromo-iodized collodion, and no plates which contain free nitrate in combination with organic matter can be relied on for good keeping properties.

The second method consists in preparing the plates with bromo-iodized collodion, in the way which we will now minutely describe—the process appearing to be the same, in all essential particulars, as that which Dr. Hill Norris employs.

Clean the plate in the usual way, and coat it with gelatine, about two grains to the ounce of water. The object of this gelatine coating is to prevent the film from blistering, or leaving the glass in the after operations.

Use collodion of a rather powdery kind, and made according to such proportions that the film shall contain, when excited, an equal number of atoms of iodide and bromide of silver. It seems to be an advantage to use a small quantity of free iodine in the collodion, and when this is done, you may make an iodizing solution, containing equal parts of iodide and bromide of cadmium, and about the one-eighth part of the whole of free iodine. This iodizer will impart a dark colour to the collodion. Its effects are these: it gives a very even, clear, and perfect film, and by liberating a small quantity of free nitric acid, it keeps the picture clean, without affecting the sensitiveness, because a trace of nitric acid is not a retarding cause when bromide is used. In other ways, the effect of free iodine in the collodion is remarkable. It seems to render the film harder and more contractile, and also to diminish its creamy appearance on leaving the nitrate bath; but it greatly facilitates the decomposition of the bromide of cadmium. When collodion contains free iodine, it should not be left so long as usual in the nitrate bath, because the bath then more freely reduces the creamy appearance of the film. On the whole, it seems that the addition of a small quantity of free iodine is advantageous.

The nitrate bath should be about 35 grains to the ounce. It should be slightly acid when there is no free iodine in the collodion.

On removal from the nitrate bath, wash the plate thoroughly in distilled, or clean rain water, and then pour over it a preservative, consisting of about 6 grains of gum arabic dissolved in an ounce of water. Set it up to dry. When dry it is ready for use, and may be developed in the usual way with cold pyro and silver, after receiving about the same exposure as a wet collodion plate. The principal object of the preservative is to give density to the thin and delicate image which would be obtained without it. If a slight trace of nitrate of silver is added to the solution of gum, the sensitiveness is increased, but the plates are rendered liable to fog. If meta-gelatine is used instead of gum, the image has a redder tint.

If, instead of using gum as a preservative, you pour over the plate the ordinary solution of tannin, viz., 15 grains to the ounce, the films are nearly as sensitive as before, and we have obtained excellent tannin negatives with an exposure very little more than was required for wet collodion.

The films prepared in the manner described have a deep greenish-yellow tinge, and they become more creamy when wetted, having in these respects exactly the same appearance as Dr. Norris's rapid dry plates.

The grand secret in the process described lies in the exact determination of the proportions between the iodide and bromide in the film. Mr. Heisch has said that the proportions should be two of iodide to one of bromide, while others have recommended equal parts. It is generally agreed that the extra sensitiveness produced by adding bromide increases up to a certain point, and then diminishes, and the difficulty has hitherto been to fix that particular point. This we have now done, by laying down the new principle of the equal number of atoms of iodine and bromine in the iodizer. Suppose, for instance, that the iodide and bromide of cadmium were used, then the ratio of the quantity of that iodide to that bromide would be by weight as 182 : 134, or nearly as three of the iodide to two of the bromide.

Of all the salts of silver which have been examined singly under exposure to light, that which darkens the most rapidly is the bromide. It has been impossible hitherto to obtain pure iodide of silver uncontaminated either with nitrate or oxide of silver on the one hand, or with an alkaline or other metallic iodide on the other hand, but it is found that the nearer we can arrive at a pure sample of iodide of silver the less sensitive it becomes—and it is altogether insensitive when there is the smallest trace of iodide of potassium or cadmium in excess. We may reasonably conclude, therefore, that pure iodide of silver is of itself perfectly insensitive to light. Whenever the contrary is stated it is assumed that some other salt of silver is in contact with it. In the Daguerreotype process the iodized film contains oxide of silver in excess, and it is this oxide which is reduced under the action of light. The surface of the plate is oxydized in the operation of polishing. Bromide of silver (as well as chloride) retains its sensitiveness under a weak solution of iodide of potassium, and those who prepare Taupenot plates should never use bromo-iodized collodion, but add the bromide to the albumen.

It is only since we have used bromide in the right proportion in the Tannin process, that we have discovered its accelerating action, and it is with pleasure that we can now endorse Major Russell's remarks, and admit our former error.

In saying that free nitrate is an essential element of rapidity with iodized collodion, we were perfectly correct.

Most of the discrepancies which occur in the results published by various experimentalists proceed from their not carefully noting the composition of their collodion, and the state of their nitrate bath.

In order to meet the wishes of those who may like to try this very simple and elegant dry process, we have arranged with Mr. Bailey to sell the proper collodion, with the iodizer, made according to our proportions.

## TRANSPARENT GLASS POSITIVES ON COLLODION.

BY DR. SABATIER.

Towards the end of the year 1860, I published in various journals a photographic process, by the aid of which it is possible, after exposure in the camera, to obtain a direct positive without quitting the operating room. It was not by the aid of black varnish, coloured paper, &c., that a negative was backed up into a positive; on the contrary, it was to replace pseudo-positives by true positives; that is, those obtained wholly by heliographic means. It also enabled, I do not say professional photographers, but mere amateurs, who are inexperienced in the albumen process, to produce stereoscopic views on collodion, which they had been compelled to take upon paper, and then impart to them that transparency which constitutes their principal charm.

But, notwithstanding its unquestionable utility, the process I described met with no favour, at least, so far as I can ascertain, it is not much practised: transparent pictures are still produced by tedious and very difficult manipulations upon albumen, and no attempt is made to produce them upon collodion, which would be so much more expeditious. Thus a source of profit is allowed to pass by unheeded. Amateurs deprive themselves of the most vivid pleasure photography can afford them. And for what reason?

If I am not mistaken, the reason lies in a very serious and almost insurmountable practical difficulty, in the process I published.

When only a negative is sought to be produced, and the exposure has been too long or too short, the negative is spoiled, it is necessarily imperfect, for to produce a good negative it is necessary to hit the exact moment in covering up the lens. Still a little more or a little less exposure than that exactly required, gives negatives which, if not exactly perfect, are at least still tolerable.

But it is quite different when we seek to obtain a direct or transparent positive. Beside the constant uncertainty in the time of exposure, we have to contend with a still greater difficulty, that of hitting the exact moment when we must stop the formation of the negative to convert it into a positive. If we stop too soon, the fine details are checked, and disappear in the shadows; if we stop too late they pass immediately under the influence of the pyrogallic acid to the state of perfect negatives, and then it is impossible to convert them into positives. The "too much" and the "too little" are equally formidable, and Scylla and Charybdis are so near to each other, that it is almost impossible to sail between them without incurring shipwreck.

I have thought that I could render a service to photography if I smoothed this difficulty, or if I caused this double peril to vanish. I have attempted it, and I think succeeded. By means of a very simple modification in the composition of my collodion, I believe I have arrived as near to it as possible, and it is to make known this modification to photographers that I now recur to publication. Before, however, showing what this modification consists of, and stating in what manner it removes all difficulty, I will, for the benefit of those readers who have not perused my former account, give a clear and succinct description of what the process itself consists of.

In the first place, let me remark, that those who say and believe, they have made a direct or latent positive, in the operating-room, after exposure in the camera, that they deceived themselves, and involuntarily deceived others. Apart from all experience, reasoning alone demonstrates, that without a previous latent or apparent sketch of the negative, the positive is absolutely impossible. To be convinced of this, it is sufficient to consider that the positive must be most intense in colour in the very places where the light has acted the least, and weaker, on the contrary, in the places where its action has been most marked. To produce a direct positive at once, we must, then, find a substance acting exactly contrary to the luminous principle which acts upon it, a substance of the existence of which we at present know nothing.

But if it be impossible after exposure to produce a direct positive, it becomes, on the contrary, easy to produce it when the development of the negative has begun, and while it remains in a latent state upon the plate. It is sufficient to that end—

1st. To stop the formation of the negative at a given moment, so as to have, instead of a perfect negative, only a simple sketch of one.

2nd. To form, with all the iodide acted upon by light—which has been employed in the formation of the sketch, and with the latter only—a combination of uniform colour, but which will be more intense in the places where the impressed and free iodide exists in the greatest quantity.

Now, to stop the formation of the negative after developing the sketch, it suffices to wash the plate with distilled water, or simply, with rain-water, before the negative becomes completely developed. When no more pyrogallic acid remains on the plate the formation of the negative must necessarily be interrupted, and to form a colour different from the first with the exposed iodide which has not yet been employed, it suffices to substitute for the electric current which prevailed at the first combination, an electric current of the opposite nature.

Many substances poured in solution upon a negative, the formation of which has been interrupted, possess the power of inverting the electric current previously developed, and causing the positive combination to succeed the negative. Such are most of the alkalies, lime-water, ammoniacal solution, and especially nitrate of silver, which alone will be regarded in this place, because it is always at hand in every photographic operating-room, and as its manipulation is the easiest. M. l'Abbé Despratz has proved, by experiment, that nitrate of silver solution, poured upon iodide of potassium, causes the production of an electro-positive current. So also do gallic acid, pyrogallic acid, perfectly neutral protosulphate of iron, poured upon nitrate of silver in presence of the iodide of that metal, and with nitrate of silver, poured upon developing solutions in presence of exposed iodide of silver. Not only is the electric current inverted, but the chemical combination at which it presides also changes in aspect. It is this change of current and of combination which explains why it is not a matter of indifference whether to pour solution of chloride of gold into hyposulphite of soda, or the hyposulphite into the solution of chloride of gold; it is this change of current which explains why some nitrate of silver poured upon a sketch of a negative is powerless to strengthen it, and that the negative is transformed into a positive when pyrogallic acid is superadded to it.

This phenomenon of change in the electric current, or rather, this transformation of negative into positive, manifests itself invariably with all kinds of developing agents, on the sole condition that none of the substances employed contain an energetic acid in a free state, and by energetic acid I understand particularly sulphuric, nitric, and even citric acid. I have not experimented with tartaric and formic acids, which are, however, much used, nor can I offer any opinion with regard to them; but what I can affirm is that acetic acid does not oppose the transformation in question. Those who wish to try the process I describe, should, therefore, first satisfy themselves that their sensitizing bath is perfectly neutral; and as we seldom or never meet with commercial sulphate of iron which does not contain free sulphuric acid, and as this salt, even when it is neutral, turns litmus paper red, which renders it difficult to ascertain its quality, preference should be given to pyrogallic acid as a developing agent, and that no acid beside acetic acid should be mixed with it, for experiment has shown me that upon the addition of another acid it is no longer anti-positive.

I cannot claim the merit of this discovery of the transformation of a negative into a positive. In most countries, long ago, photographers desiring, by the aid of pyrogallic acid, to strengthen a negative before it was completely developed, have seen, with great surprise, an imperfect positive appear in the place of the faint negative, and this fact would have been much more general if the sulphate of iron employed had contained no traces of free sulphuric acid. But a fact so general ought not merely to excite surprise; it should fix the attention, and stimulate enquiry. I have thought it would not be an idle task to study these circumstances, and trace their causes, and I shall have good reason to congratulate myself, if I perceive the process resulting from my researches become generally practised.

It is based upon this fact, henceforth indisputable, that a solution of nitrate of silver of 3 or 4 per cent., poured upon a weak negative previously washed with distilled water, or with rain-water merely, inverts the electric current previously developed, and causes the positive combination to succeed the negative as soon as pyrogallic acid is added. All the exposed iodide of silver remaining out of the first combination, enters into the second, and when the various manipulations are well performed, the two combinations unite so as to form a perfect whole.

Nothing, therefore, can be simpler than to make a perfect positive, and nothing easier when we have the means of knowing the precise moment when to stop the further progress of the sketch negative. But in following my process, a few seconds more or less may in the hands of the most skilful operator, render the result imperfect; the image is either too positive or too negative; it is composed of two unequal parts, when it ought to have been the combination of two similar and exact halves. In the impossibility of actually surmounting this difficulty, I have done my best to avert it, and by introducing a new element into the collodion I make use of, I have succeeded so well, that I venture to say, that the precise moment for stopping the progress of development involves no greater uncertainty than that of replacing the cap on the lens of the camera in exposure, and a few hours of experiment will suffice, henceforth, to place the merest amateur in a position to obtain transparent positives, both portraits and stereoscopic views of every description, at pleasure.

Formerly I added only one iodide to my collodion—the iodide of cadmium. At present I add two, those of cadmium and potassium. Taken singly, the iodide of cadmium is the most rapid, and the iodide of potassium the slowest of the iodides used in photography. Exposure in the camera, and development proceed quickly with the cadmium, but slowly with the potassium. With the first alone, the development proceeds so rapidly that the negative has to be stopped almost as soon as it becomes visible. The addition of iodide of potassium has caused this source of innumerable failures to disappear. If it does not check the luminous action during exposure, or if, on the contrary, it appears to accelerate it, it at least gives to the development an entirely different character. Under the influence of pyrogallic acid, the negative continues to develop rapidly; it appears in all its most delicate details almost immediately; but there is no necessity for hurrying the manipulation, there is time to look at it well, to examine it, and when the negative appears to have arrived at the culminating point of perfection, there still remains in the collodion film sufficient excited iodide to form an excellent positive. This idea also presents itself forcibly to the mind—that the negative, the development of which is so rapid, is formed at the expense of the iodide of cadmium only, and the positive at the expense of the iodide of potassium.

These preliminary and theoretical considerations certainly admit of further very important development; but they appear to me sufficient to render comprehensible the manipulations I now proceed to give in detail.—*Moniteur.*

(*To be continued.*)

## ENGRAVING BY PHOTOGRAPHY.

[We have pleasure in making the following extract from an article headed "Engraving by Photography," in the *Gentleman's Magazine*, as illustrating that the oldest of the monthlies, and devoted chiefly to matters antiquarian, as Sylvanus Urban generally has been, takes a foremost position in recognizing the value and progress of a new and wonderful art.]

Comparing tho productions of the present International Exhibition with those of its predecessor, the progress is most strikingly visible in photography; in fact, in 1851 photography not being sufficiently advanced to be placed in a separate class, it was, with the apparatus used, included among philosophical instruments; now, however, it has a class of itself, namely Class XIV.

Many people interested in photography may recollect having seen some photographs, done from paper negatives, obtained by the ordinary wet process, and exhibited in 1851, under the head of tho Imperial Printing Office at Vienna, executed by the manager of it, Mr. Paul Pretsch, for which he was rewarded with tho prize medal. But they may have asked themselves, What has the the printer to do with photography?

In the present year we have received an answer to such questions. There aro to be seen in Class XIV. of the English Department eighteen frames, filled with impressions, printed with ordinary printing-ink by the ordinary printing-presses, from plates and blocks engraved by nature's mysterious hand only, viz.. by photography and electro-metallurgy. Photography and its sister art are made subject to the printing-press, and for this reason the manager of tho Vienna Printing Office became a photographer.

These frames are headed by printed inscriptions, "Engraving by Photography." The blocks, from which these copies have been printed with tho ordinary press, are all absolutely untouched by the graver; and the plates, whose printed copies exhibited in a considerablo number, are of various descriptions. Some of them are, like the blocks, absolutely untouched by the graver, but some have been assisted, cleaned, and improved by the engraver, and a few show tho process of naturo in combination with the work of the human hand, producing a result not attainablo by the latter alone. In many instances this capability proves to be of great advantage. They are distinguished by printed labels on the specimens, and two frames of them contain the photographed original sido by side with tho printed copy.

But not satisfied with this clear definition, Mr. Pretsch has exhibited on a counter in glass cases the plates and blocks themselves for examination by connoisseurs. There aro to bo seen seven blocks entirely untouched with tho graver; tho photographic originals of them being partly taken from naturo and partly from works of art. There is also a large engraved printing-plate of copper, absolutely untouched, and a second plate, which has been assisted by the graver, and afterwards coated with a very thin film of steel, by which means the copper-plates have been made almost as durablo as engraved steel-plates.

Therefore we see here the specimens of two processes, viz.,—

1. Producing engraved printing-plates of copper, coated with steel, for the copper-plate printing-press.

2. Producing engraved printing blocks (surface copper, backed with typo metal, mounted on wood, like the cast of a wood engraving), to bo printed by tho ordinary printing-press, with or without types; and by this last process the specimen before our readers is executed.

Both processes preserve the true finger of nature, or the real touch of the artist. Tho first process is for the best works of the fine arts, and for hundreds of people; the second process, however, is for the million. Photographs in our present time are still perishable, but printer's-ink and paper stand the test of centuries. The influence of light is used in theso two processes only for the production of the first engraved surface; having obtained tho engraving in the desired effect, the subsequent portion of the processes is mere mechanical skill, however great tho number of copies. Our ancestors had only written books, but sinco the invention of typography, religion, wisdom, and knowledge became universal goods of mankind. Tho rapidity and cheapness of production by the ordinary printing-press, aro as well known as the spread of its productions over the whole globe. And what typography has been for the spread of thought, that is photography for the reproduction of authentic illustrations, if they can be printed with ordinary printer's-ink, and by the common cheap process.

To enablo our readers to obtain a correct idea of these processes, we introduce a brief explanation of them. An ordinary glass plate is coated with a certain mixture sensitive to the influence of light, and this coating is dried. The photographic *negative* is placed on the surface of the coated glass plate, both of them are fixed in an ordinary photographic copying frame, and exposed to the influence of light. After sufficient exposuro they are taken out of the frame, separated, and the picture now appears in a faint coloured copy on tho flat surface of the coated glass plate, which is to be immersed in a bath of powerful chemical action. By this treatment some portions of the picture become more or less raised, and some remain sunk, according to the previous action of light, and exactly corresponding to the lights and shadows of the picture. In fact, this picturo is the main portion of the process; it forms the engraved surface, and therefore must be obtained so as to answer the requirements of the printing-press. A picture can bo obtained without much difficulty, but not so easily tho picture which will suit a certain purpose. It is marvellous how nature can accomplish this result, but it does so only under certain conditions; she demands great attention, experience, and study of her laws, because they are not easily discovered.

Having obtained in this manner the engraving as it ought to be, though tho material is perishable and transient, a cast or mould is made from it; the coating of the glass plate, having served its purpose, is removed, the plate cleaned, and may be used over and over again. The above-mentioned mould, having been made conductive, is used for tho purpose of inducing, by means of voltaic electricity, a deposit of copper thereon, forming the matrix from which the printing surface of copper is obtained by repeating tho process of electrotyping.

## PHOTOGRAPHIC STUDIES.

BY DR. SCHNAUSS.

*Examination of various formulæ.*

There is a general complaint, and a just one, that the photographic journals overwhelm us with numerous formulæ and recipes, which frequently contradict each other. "We cannot," say the photographers, "try all these methods; our time is too limited, and yet there is no other way of separating the good from the bad." This is very true, and greatly to be regretted; and is the cause of many valuable formulæ being neglected, or rejected among others of no value.

*Experientia est mater studiorum*, say the Latins, and we photographers know very well that knowledge can only be bought by experience. But a sure guide is always valuable, and on this account we employ a portion of our leisure in carefully testing the formulæ recommended in different journals, and communicate the results to our readers.

There are three principal points which most of the formulæ published now-a-days tend to improve.

1st.—The process for taking permanent pictures without the salts of gold or of silver.

2nd.—A good dry process.

3rd.—The improvement of present processes with collodion, and in toning chloride of silver, either to render the collodion more sensitive, or better tone proofs upon albumenized paper.

The last processes are doubtless the most important in practical photography; for during the fashion for *carte de visite* portraits, a very sensitive collodion and a good toning bath for proofs upon albumenized paper, are valuable to know. We therefore commence with a study of them.

We know that in a good collodion process, it is the silver bath and the iron developing agent that are of the first consideration. As to the first, the suggestion of M. Laborde, to add free iodine, has been found a very good one; only a certain limit must not be surpassed, so as not to liberate too much nitric acid, which would injure the dark portions of the negative. In this case, the addition of a few drops of acetate of ammonia, or of a solution of soda, may be recommended, because, by their aid the free nitric acid is retained, and a little acetic acid (which by its organic constitution favours the vigour of the dark portions) is set at liberty. If we add much of these salts, some acetate of silver is formed, which must be removed from the bath by careful filtration, because it tends to separate in microscopic crystals, and spot the negative. To avoid an excess of iodine, I like better to add some drops of tincture of iodine to the recently prepared silver bath, with some nitrate of silver which has an alkaline reaction, and with the necessary quantity of iodide of silver, known to every photographer. It is essential to prepare the silver bath in the *daylight*, in the sunshine if possible. It seems to me that by these means the principle of the formation of veils, or fogging, may be removed. The iodo-nitrate of silver which is formed, and which is extremely sensitive, is partially decomposed, and a little iodine and nitric acid disengaged. And also all useless matters present, and which may cause fogging, are decomposed, and put out of the way of causing injury. We immediately perceive that the iodide of silver (which at first must be in excess in the bath) blackens, which it never does so energetically or so rapidly if it is not in contact with nitrate of silver.

The addition of formic acid to the silver bath is of no value, as the negatives are completely fogged by it. We can always add this acid to the iron developing solution, taking care to add also some acetic acid.—*Moniteur.*

(*To be continued.*)

## DRY COLLODION.

BY M. L'ABBE' DELEAGE.

Collodion prepared with iodide and bromide of cadmium may be employed in the dry state. It gives results identically the same as those given by wet collodion. We can even employ it for portraiture: it will keep in good condition for at least a week, and even longer. This fact anyone may easily verify for himself. I shall, however, add some details which may serve to guard the photographer from the errors and failures into which I was led by prejudice, and the general directions given in most photographic treatises.

The necessity I have been under of operating quickly had always led me to avoid the tedious manipulations and slow development indicated for working with dry collodion; for this reason, when some months ago I read Mr. Saunders Van Loo's communication on dry collodion, I hastened to try afresh the resin formulæ of M. l'Abbé Despratz, which I had previously tried without success. I also employed collodion without resin, and the satisfactory results I obtained on many occasions satisfied me that even with ordinary collodion we may obtain successful results.

But I was ignorant of the composition of the collodion I employed: it was a mixture of all the residues of previous operations with collodions of different formulæ. This was the first point to be elucidated.

I tried various formulæ in succession; collodion with excess of alcohol; collodion with excess of ether; excess of iodide of cadmium; excess of bromide; various quantities of pyroxyline; alcohol more or less anhydrous, &c. Finally, I became convinced that the best collodion to operate with in the dry state, was also the best for the wet. How is it then that every photographic treatise has gone on repeating that ordinary collodion does not give good results in the dry state. (I speak of such treatises as I have studied). And why have amateurs taken so much trouble to modify it. I believe that I have discovered the reason in the fact that there are certain difficulties peculiar to dry collodion, and which I have often encountered.

Numerous transparent round spots, having a black point in the centre, often cover the finest negatives at the moment of development. These spots have been described in treatises on wet collodion; they are easily avoided by careful filtering. But it is not the same with dry collodion. These spots are produced whenever the sensitizing is performed in a shallow dish. As we are consequently compelled to agitate the dish to make the liquid cover the plate, particles in the atmosphere, deposited on the surface of the bath, are brought into contact with the humid collodion, and adhere to it. If we operate with wet collodion these particles have not time to decompose the iodide of the collodion film; but with dry collodion this effect is invariably produced. It is therefore necessary to sensitize in an ample bath. I use a bath containing 16 or 18 ounces of nitrate solution for half plate negatives, and I never am troubled with these spots.

On the other hand, a black veil generally covers at least one of the corners of the plate, and sometimes spreads very far into the film. These changes in the sensitive film, which become manifest only at the time of developing, can very easily be avoided by concluding the washings of the sensitized plates by a last washing with water, to which acetic acid has been added, in quantity that will be greater in proportion as the temperature is high, and when we desire to keep the dry plates a long time.

Still I have obtained the best results by adding acetic acid to the silver bath itself. The sensitized collodion keeps better. And while plates prepared with a neutral bath give bad negatives at the end of four or five days, I have succeeded in keeping them good eight days, after sensitizing them in an acid bath. To sum up:—

1. Employ ordinary collodion, with iodide and bromide of cadmium.

2. Sensitize in the ordinary nitrate of silver bath 7 per cent., which may be modified with 5 per cent. of acetic acid.

3. Wash freely under a fine stream of rain or river water, and conclude with a washing with distilled water, to which from 1 to 5 per cent. of acetic acid has been added. This washing with acidulated water is strictly necessary only when the nitrate bath is not acid.

These washings can be performed in successive dishes, by which the operation is accelerated.

I employ water for washing as pure as it can possibly be obtained.

4. Leave the plate to dry in the dark. Besides, the plates while wet, after being washed, yield the same results, and per-

haps more rapidly. And the drying taking place slowly, the operator can take his time, arrange his model, wait the favourable moment, &c., without having to fear any change in the condition of the sensitive film. But the plates must not be exposed while half dry, else the result will be inequalities in the tone of the picture and other defects.

5. The exposure need not be much longer than with wet collodion. I have obtained *cartes de visite* half-plate in 15 to 20 seconds; views in 1 to 2 seconds. For landscapes taken with a landscape lens, and with a diaphragm of 4-10ths of an inch, in fine weather a very good picture was obtained in a minute and a half.

6. Immerse the plate in the sensitizing bath immediately before developing, which may be postponed some hours after exposure. I have not yet ascertained if the development can be postponed until the following day. Instead of immersing the plate in the silver bath, we may content ourselves with moistening its surface with plain water, but in that case some silver solution must be added to the developing agent.

7. Lastly, develop with iron or pyrogallic acid. The developing takes place rather slowly, but effectually.

The success which for at least two months I have constantly obtained by the method indicated above, leads me to suppose that in more experienced hands dry collodion will give excellent results.—*Cosmos.*

## ON THE LIGHTING AND MANAGEMENT OF LIGHT IN PHOTOGRAPHIC GALLERIES.

BY LACHLAN MC'LACHLAN.*

The construction of galleries for the taking of portraits has never, in my humble opinion, received that attention which its great importance demands. Their present construction is to a great extent wrong, inasmuch as they do not answer the purpose for which they were originally intended, namely, the production of vigorous and truthful portraits, copies of statuary, &c., &c., at any hour of the day when there is sufficient light.

I may ask in what respect are galleries superior to the open air for the taking of portraits? They are superior in two respects:—First, they are not subservient to the weather; and, secondly, they give the light a certain direction, according to the slope of the roof. But in every other respect they are much inferior to the open air. Why? Because we have to deal with the refraction caused by the glass and the reflection from everything in the room, which makes it very painful to the sitter, who is placed in the midst of a blaze of light. Yet there are many worse evils than these to contend with. The reflected light is scattered in every nook and crevice in the room. It enters the lens, pervading every shadow, reflecting from the background upon the sitter, and quite overpowering all that beautiful gradation of light that gives rotundity to the figure. The picture depends more upon the combination of light than it does upon the manipulation or chemicals; in fact, the light with ordinary care makes the picture, and good chemicals, lenses, &c., are nearly valueless unless the sitter be properly *illuminated.*

We have searched into the chemistry of photography, and we have greatly improved the apparatus used in the art; but it is a notable fact that the portrait gallery remains stationary, no improvement whatever having been effected in it. I have most unceasingly endeavoured to point out to many of my professional friends the great defects of most of the present structures.

The great error in their present construction is, that the balance of side and top light is seldom, if ever, taken into consideration. In the majority of galleries which I have seen, whatever amount of side or front light there was, the roofs had nearly the same inclination, just as if there were no side light. This I have proved to be a great error, and a greater detriment than may at first appear; for if we do not screen off a large portion of our side light, the picture is sure to be flat; for it is only by a certain amount of top and side light that we round the figure. It is a nice calculation to balance the one against the other: and if we have too much of one or the other it is so much light thrown away.

I am willing to admit that under peculiar circumstances of light, chemicals, &c., results sometimes are obtained which seem to us nearly perfect; but how rarely is this the case! The exception is only found amongst a few professionals who have made the management of light their particular study. Under the present general system, a perfect combination of light will perhaps be lost in an hour, or less. We have done nothing special to bring about this unity, and, as a consequence, we can do nothing to retain it—to avail ourselves of its effect. This should not be so.

I will now endeavour to describe the means which I employ to relieve myself and the sitter, at once, of the intolerable nuisance of an oppressive and unmanageable light. We will suppose a gallery faces the south. The plan I adopt to keep out the sun's rays, and to govern the light at pleasure, is this:—I take pieces of thin wood: place them hanging from the roof, in a south-west direction; but, before doing so I obtain the highest altitude of the sun, and calculate the rake of roof, to ascertain the due distances to place them apart. Yet there is a simpler plan which can be adopted. First of all, decide how deep you would like these pieces or strips; then fix two or three of them in their places, and as near as you think will do; then watch if they arrest the rays of the sun; if they do not, place them nearer together till the sun is excluded (I allude to the direct rays). Do the same to the front or side light, provided you have sun there; you will then find that this method far surpasses the use of white blinds, brown paper, or other numerous contrivances—in fact, you will feel conscious of having overcome one of the greatest difficulties in your profession. If the sun cannot introduce itself directly, it will do so indirectly, and, consequently, scatter its rays in every direction. This is undesirable; certainly it is an improvement, but not a remedy.

What we want is a concentration of light, with power to give it any direction at will. I have accomplished this by means of placing pieces of thin wood fixed in grooved rods, which rods are placed across the long blinds, so as to form compartments. These divisions are made to move at pleasure, which is easily done by connecting rods that may be made to move in sections, and to any required angle: by this method I have absolute control over the light.

The plan is the result of many years' constant study and observation; and, from the practical application of it, I am enabled to say that I can accomplish the results here stated. Of course judgment must guide us in the particular application of it, as well as in the working. For instance: when the light is focussed upon the sitter on a very bright day, all the high lights are exaggerated. But the remedy is easy: by reversing the light the image will gradually change, and you may do so until you obtain an excess of half tone if desired.

It is absolutely essential that we should have perfect command over the light in our art—as much, at least, as the painter possesses over his brilliant and well-mixed colours; and before we can rival the painter in perspective, we must be able to delineate or paint with the light, exactly as a studious and artistic painter does with his brush.

In order to claim for the photograph a place amongst works of art, we must be able to command at will as complete control over the background, as we now can over the figure. Ask an artist to give you a delicate drawing of a statue upon a piece of soiled or smoked paper: he would naturally consider you a fool! And yet that is precisely what the photographer does. His back light is the smoke, and, until he can get rid of it, his pictures will appear as if

* Read at a meeting of the Manchester Photographic Society, May 7th, 1862, and reported in the organ of the Society.

they were sunk into what ought to be a background. In effect it is a palpable misnomer. Besides, it is lamentably deficient of the requisite light and shade which all artistic backgrounds ought to possess. Sometimes we see the light and shade (when there are any) quite reversed, thus clearly proving that the light is not under our control.

I will now endeavour to describe my plan of a background, which enables me to obtain any effect of light and shade I please, much easier than the painter can with his brush. I have four frames, made exactly as the one you stretch your present material upon, with which you require two other frames, about twenty inches wide. These must each have a piece framed in the middle, with a slot about half an inch wide. Take and secure firmly two of your large frames to the edges of your two smaller ones, and you will have a skeleton box; place the third and fourth frames inside, allowing them to be moveable, with a handle or knob, which works in the slot of the narrow frames, by which means you will be able to fix the moveable frames in any position or angle you please between the others; cover the back fixed frame with black velvet, and also the sides and top with the same material, to prevent the light entering from any source but the front. The two inner moveable frames must be covered with very open gauze or net. When you want to use this background, draw up and fix the front moveable frame forward to its full extent, and secure it there. The principle involved in the arrangement is this:—the background is partially transparent, and allows the light striking upon it to pass through its meshes, so as to become absorbed by the black velvet at the back, and thus that halo is avoided which is so often seen around the margin of the figure, and which, perhaps, as much as anything else, tends to flatten the picture, and give it the appearance of having been taken separately and placed upon the background. The object of the front moveable frame is to allow us to remove it out of harm's way when done with. The front or outer frame might have been used for the front gauze screen, but it would continually be liable to injury. This skeleton box also serves to hold a series of landscape and interior backgrounds for *cartes de visite:* of course it must be understood that these views roll up to admit of the other frames passing. I may state that this *box* moves on castors.

With regard to the amateur's gallery, it is made exactly on the same plan, and at a great saving in cost, besides effecting portability and greater efficiency than if glass were used. Calico can be adopted with strings, which are made to answer the place of rods. The whole may be fixed on four horizontal rods, and supported by four others fixed in the ground. The strips of calico can be made with eyelet holes in one end; the other end may have a piece of elastic webbing, so as to stretch and keep it tight. The top ends must be fixed on hooks placed at the proper distances; the lower ends must be left loose, and a piece of tape or cord sewed to every one, so that when we pull the one end of the cords we can give the pieces of calico any angle we please. The same process can be applied to the sides or front. Now you have only to attach a piece of calico on one side of your tent, which is intended to shade the face of the sitter on one side. Without it the face would be quite flat. If the amateur select some shady nook for a background he will have a *gallery* very much superior to that of the professional.

In conclusion, I may state that, having spent a considerable amount of time and money on this subject, I have thought it due to myself to patent the invention with a view to mere reimbursement; but I freely give it to all amateurs, and shall be happy to afford them any assistance they may require.

## Correspondence.

### M. CLAUDET'S ENLARGED PICTURES.

Sir,—My attention has been drawn to a paragraph in the Photographic News of the 18th inst., in which you make some remarks about me as the artist who painted Professor Faraday's portrait, which I feel bound to answer, and which has become necessary in consequence of the controversy between Mr. Macandrew and M. Claudet.

I regret the occurrence, though I have not been the cause of it, as the following plain facts will show.

When M. Claudet, for whom I must say, *en passant*, I entertain the greatest esteem, delivered to me the canvas, the drawing upon it was in a very unfinished state, the place for the hands, &c., being scarcely indicated; but even had the drawing been complete, it would have been of no use to me, as it was smaller than nature, the size M. Claudet wished the portrait painted; and every person knows that it is much more *difficult* to enlarge or lessen a drawing than to re-draw it entirely.

The controversy must have arisen through some parties who were present in my studio and saw me drawing the outlines on the canvas from a small photograph, and were very naturally surprised to see it exhibited and described as the drawing having been done by M. Claudet's apparatus.

You have stated that I have been imprudent in this matter, but I trust the foregoing is sufficient explanation; and as regards jealousy, I feel your remarks are made without knowing me, for no person can appreciate photography more than I do; and although I but seldom paint with its aid, the *Spanish Girl*, in the Crystal Palace Exhibition, of which you spoke in such eulogistic terms a few weeks ago, will prove the great benefit I have already derived from it; and, as a further proof, if you will favour me with your photograph and a *clean canvas* I shall be most happy to execute your portrait the same as Professor Faraday's, and assure you that there is not in my studio any magnifying apparatus.—Yours, &c., A. de Lafollie.

[We have pleasure in giving publicity to the explanation of M. de Lafollie, from which it appears that the controversy in question has arisen simply from a misconception. M. Claudet having furnished the artist with a canvas, upon which was traced an outline of the portrait required, very naturally regarded the exquisite painting he received from the artist as produced upon the drawing he had furnished, and exhibited it as an illustration of the process. The applicability of the method did not, however, in any way depend upon the picture in question, as M. Claudet practically demonstrated the facility and worth of his plan to the meeting, when he read his paper. We are glad to find that our suggestion as to artistic jealousy of photography was, in this instance, misplaced, and to learn that a painter of such great ability entertains the respect for our art of which it is worthy.—Ed.]

---

Sir,—I have had my attention drawn to a paper read by M. Claudet at a meeting of the London Photographic Society on the 3rd of June.

In this paper is described a method of producing enlarged drawings, by means of reflecting the negative through a lens, by the agency of gas-light, and traced by hand upon canvas or paper.

I fully agree with all M. Claudet says of the value of this process, and of its being one likely to rise in estimation as it becomes more generally known.

When applied to portraiture, architectural subjects, and maps, where correct distance and dimensions are of so great importance. From a small negative very large reproductions can be faithfully traced.

Its utility is not in any degree a matter of doubt, and this I am justified in asserting, from my experience of the last three years, during which time I have been professionally engaged in applying the method, both publicly and privately, with considerable success.

In the greater portion, too, of this period, portraits enlarged in the manner described, and coloured in crayon, have been exhibited in my rooms, and given much satisfaction.—I am, Sir, yours obediently, W. Hall.

## Talk in the Studio.

South London Photographic Society.—The third outdoor meeting of this society takes place on Saturday, August 2, at Charlton Station, on the North Kent Railway, reached by train from London Bridge at one o'clock. The weather for the two previous appointments has proved very unpropitious; there is, however, now a fair prospect of fine weather, and we trust the meeting will be a large and pleasant one. Just on going to press we have received a note from Mr. Wall to say that the meeting will take place, by permission, in the private grounds of Sir T. Wilson, at Charlton. A dark room, for those who practise the wet process, will be kindly provided by Mr. Davis of Woolwich.

Royal Portraits.—We have just seen some of Mr. Jabez Hughes' charming portraits of their Royal Highnesses the Princesses Helena and Louise, which Her Majesty has graciously accorded permission to be published. The groups especially please us; they are amongst the most graceful and artistic photographs which have hitherto been published of the Royal Family.

The Royal Academy.—Lord Elcho has applied for a Commission to inquire into the present position of the Royal Academy in relation to the Fine Arts, and into the circumstances and conditions under which it occupies a portion of the National Gallery, and to suggest such measures as may be required to render it more useful in promoting art and in improving and developing public taste. There has been talk for some time of such an institution as a Ministry of Art, and it appears Lord Elcho recommends that some dictatorial power be vested in the Academy. Of this *The Times* says:—The remedy, so far as we could understand it, would be to give the Academy the direction of our public works, or at least a veto on the designs. If anything of the kind be contemplated by artistic reformers, we would say, 'Leave us the old Academy with all its defects—its exclusiveness, its alleged favouritism, its staff of sinecure professors, its inefficient schooling, its dinners, and all that move the indignation of the outsiders. Leave us with the Havelock and the Jenner of Trafalgar Square; leave us with the National Gallery and the International Exhibition, and the equestrian Wellington, and every other monstrosity of this capital, rather than turn King Log into King Stork, and subject the art of the country to the dictation of an Academy. However eminent and illustrious the members of such a body may be, the power it possesses is sure in the end to repress genius and originality. Such as we are in literature, art, and science, we have become without the aid of academies, and no intellectual evil could be greater than the foundation of these exotic institutions among us.

## To Correspondents.

Photographic News Almanac.—We have to inform several applicants that the Photographic News Almanacs for every year are now out of print. Agents having any clean copies on hand of the present year will oblige by communicating with the publisher. Agents will oblige also by notifying any stock of back numbers of the Photographic News for the present year, as several recent numbers are out of print.

Subscriber inquires, "If such articles as cloud plates exist, or in what manner clouds are introduced into views?" We presume, by "cloud plates," our correspondent means negatives of clouds. These certainly exist, and aid in one of the methods of introducing clouds into photographic landscapes; we are not aware that they exist at all as articles of commerce, each photographer who uses them producing his own, and getting such a selection, under such circumstances, as will best suit his pictures. Mr. Maxwell Lyte adopts this method; Mr. Annan, of Glasgow, and Mr. Samuel Fry, both, at times, adopt the same method. The latter gentleman described his plan of operating in our last volume. There are other methods of introducing clouds, either by using a very rapid process, or shading the sky so as to secure them on the same negative. This method is used by Mr. Wilson and others. Some secure cloud effects by painting carefully on the back of the negative; these effects may be seen in some of the pictures of Mudd, Bedford, and others. Whichever plan be used, taste, judgment, and care are imperatively necessary.

R. A. R.—The spots on your prints appear to be due to the albumenized paper, which is probably old, or the albumen possibly stale. Your prints would be improved by more judicious lighting, and a little longer exposure, as they are a little hard. The definition might also be improved. A little care in these respects, and your pictures will be better. 2. The best thing to prepare albumenized paper for water colours is a preparation sold for the purpose by Newman, of Soho Square. Some persons colour on the albumenized surface without preparation, merely using a little ox gall with the colours. But the article we have named answers admirably.

R. W. Jacob.—Photographic slides for the magic lantern are transparent positives, produced in printing from a negative on to a collodion film, either by super-position, as by printing on paper, or by what is termed camera printing. Various articles descriptive of the process of producing them have appeared in our pages; we may refer you especially to pp. 208, 220, 257, and 280 of our fifth volume; the numbers containing these pages are: Nos. 139, 140, 143, and 145. In these articles you will find full instructions on the manipulatory details.

D. W. T.—Your difficulty, most probably, arises from excess of iodide of silver in the bath, than from deficiency. Try the addition of a few ounces of fresh silver solution, without any iodide, to the bath, and the sandy effect after development, which results in pinholes after fixing the picture, will disappear. The white spots to which you refer, as occurring on glass positives, may arise from turbid collodion, or from using glass with a rough, imperfect surface. Using a thick collodion with more body will sometimes prove a remedy. A very thin collodion is always troublesome for working the positive process.

L. E W.—Similar spots to that you enclose will sometimes arise from some defect, or decomposition, in the albumen. They also arise from hypo touching the unfixed print, or nitrate of silver touching the fixed, but unwashed, print. We cannot say, certainly, the cause of this especial one.

Young Photo.—We have repeatedly stated that there is no method of turning a good positive into a good negative; for if it have been rightly exposed for the former, it will be under exposed for the latter. It is possible, however, to produce a moderate negative from some positives. The best plan is to wet the film thoroughly, and then apply a solution consisting of iodine one grain, and iodide of potassium two grains, in an ounce of water. After this has remained on for a few minutes, wash and apply a solution of pyrogallic acid two grains, and citric acid one grain, in an ounce of distilled water, adding a few drops of a 20-grain solution of silver. Continue this until the proper printing density is obtained.

Operator.—The stain of reduced silver to which you refer, if we rightly understand you, is the irregular line of white surface reduction which sometimes occurs. It generally arises from the free silver coming in contact with some organic matter at the corners of the inner frame of the dark slide. Having these well varnished, and frequently well washed and dried, will prevent the evil; or letting the plate rest on pieces of clean blotting-paper will often answer the same purpose. If these do not meet your case, write again explaining more fully.

John Beck.—The stain on the mounted print enclosed evidently proceeds from the back of the card-board, for, on examining, we find it larger there, passing through and slightly staining the surface of the print. There are several similar, but smaller, stains at the back of the card, which have not passed through. Whether it is from some impurity in the card-board, or accidental contact with some chemical, we cannot say.

No. 35.—We prefer the lenses of the best English makers at all times to French ones. The No. 1 of the maker you name first would most probably answer your purpose best. Those of the two French makers you name are, probably, pretty good, but we have no personal knowledge of their qualities. They will, probably, be of too long focus for stereoscopic work, giving you very little subject, except at a great distance. Amongst French makers, both the names stand well.

B. G. P.—The pinholes are, probably, caused by excess of iodide of silver in the bath. See answer to D. W. T., above. 2. A changing box is the neatest and simplest means of changing sensitive dry plates without a tent. You can get them made for any-size plates. It consists of a plate-box with facility for attaching the dark slide, and allowing the exposed plate to drop into its groove in the box, and then placing another in the slide, without admitting any light.

Actinic.—The report on your coloured glass in our next. 2. By all means the first mentioned maker. The superiority in quality is quite equal to the difference in price.

J. C. L.—The dirty brown tone which you describe is very difficult to avoid with some samples of paper, especially in printing weak thin negatives. The best mode of dealing with such a sample of paper, is to use it with vigorous negatives, use a neutral silver bath, and tone considerably deeper than seems necessary, to allow for the loss in the hypo. It is impossible to get fine prints on such a paper, but this treatment will make the best of it. The sour smell is doubtless due to the addition of acetic acid to the albumen, a custom practised by some manufacturers. It seems to be of doubtful utility, as we hear many complaints of its results, the paper generally discolouring rapidly after sensitizing.

T. N. W.—Negatives cannot be satisfactorily intensified after varnishing, except by first removing the varnish, a process which we have sometimes effected for the purpose of intensifying. Amber varnish, or crystal varnish, may be removed by benzole or chloroform. Spirit varnish is more difficult to remove; strong alcohol will sometimes do it. A negative varnished with spirit varnish may be intensified by using an alcoholic solution of bichloride of mercury, followed by a dilute tincture of iodine, but there is great risk of the intensity being irregular and unsatisfactory.

R. H.—A background to roll up may be made of a piece of unbleached sheeting calico, 6 or 7 feet wide, and about 8 feet high. This should be stretched on a frame, or against a wall for painting, and when dry may be attached to suitable rollers. The calico shou d be sized first with a good glue size, and may then be painted grey in oil flatting, or in distemper. If the latter be chosen, the method described by Mr. Gulliver on p. 165, Vol. V., Photographic News, should be used. For some purposes a cheap grey broadcloth, or merino may be obtained wide enough. A blanket if kept well out of focus makes a good background; and we have seen a good one improvised for occasional use out of the wide brown paper sold by upholsterers for under-lining carpets.

M. J.—It is somewhat difficult to advise you from the data given, as much will depend upon the actual condition of light, &c., at the time of operating. So far as we can judge, from your description, we should say place the camera in the corner, in preference to directly in front. If you require further aid please send a sample of the evil produced, or the difficulty to be overcome.

Honesty Good Policy.—The circumstance you mention, if it be as you describe, is somewhat inexplicable. We will enquire into the matter, and endeavour to obtain an explanation.

Dages.—The stereographs will be duly noticed as the productions of Dages and Harman. The reference in this column to one name only, arose out of a private note on other business arriving at the same time, and incidentally mentioning the slides.

F. Vincent.—We are glad you have overcome the difficulty. See first article in the present number.

Several correspondents in our next.

Vol. VI. No. 205.—August 8, 1862.

## REVISION OF AWARDS IN CLASS XIV.

We have pleasure in announcing that the revision of awards in Class XIV. of the International Exhibition, for which we have more than once expressed a hope, will absolutely be made. We are not at present in possession of the corrected list; but have reason to believe that the name of M. Joubert will be found in it, and we hope with a medal attached. Another revision, in reference to which we have received one or two letters, will be the withdrawal from the list of honourable mentions of the name of Mr. Beatty, whose products, we believe, never arrived at the Exhibition, and in his place the name of Sir A. K. Macdonald will be inserted. We have pleasure in expressing the conviction that his pictures well merit such a distinction. It would be premature to enter into further detail at present, but we hope to be able to publish full particulars in our next.

## OUR LIVERPOOL CONTEMPORARY ONCE MORE.

As past experience might have led us to anticipate, our Liverpool Contemporary, *more suo*, returns to the charge, and, like one of old, "breathing out threatenings." He now marshals all his forces for the assault—editor, publisher, and staff, down to the funny contributor, each making a separate attack. Even were we disposed to indulge our contemporary, who, like the traditional Irishman, seems to be "blue moulding for a bating," by entering into the arena with him, we should find very little to answer. "Tall talk," in Ercles' vein, and dreary facetiæ; reckless assertion and mis-assertion, and equally reckless denial; much angry epithet; insinuations as to the feebleness of an antagonist he brings out his whole forces to attack; wilful misrepresentation and sophistication—these are the weapons of his warfare. What good end is to be gained, then, by any one in such a contest? We may deny his mis-statements, and refute his calumnies, but that does not prevent his re-asserting them or framing fresh ones—

> "Destroy the web of sophistry in vain!
> The creature's at his dirty work again."

We do not, therefore, care to answer him in detail, nor to deface our pages further with a squabble which is, we believe, offensive to our readers, is distasteful to ourselves, and disgraceful to scientific journalism.

## COPYRIGHT IN PHOTOGRAPHS.

We congratulate our readers on the fact that an Act securing to photographers a property in the production of their skill and enterprize, their brains, hands, and capital, has now become law. On another page we reprint the Act *in extenso*, and shall here only refer briefly to one or two of its salient points. It will be seen from the Act that photographs are classed with paintings and drawings, neither of which, in common with photography, it is declared in the preamble, have hitherto had the protection of any copyright law. The Act now passed includes all three in a common protection. Many of our readers will be interested in this measure of justice to fine arts generally; but it is with that part of it especially relating to photographs that we are more immediately concerned.

We could have wished that the general wording of the Act in several places had been less obscure; but we are glad to observe that especial attention has given to the distinction between a photograph, or print, and the negative from which it has been produced—a point of technical importance which might easily have been overlooked in the framing of such a law. The first section of the Act gives to the photographer the exclusive right to reproduce, or permit to be reproduced, his own works, not simply by photography, but by engraving, or "by any means whatsoever and of any size." It is then provided, however, that an artist selling his productions, or executing them to order, shall not retain a copyright therein, except by especial agreement in writing, signed by the vendee, or person for whom the commission is executed. This, at first glance, would appear to involve a photographer taking portraits of public characters, with a view to publication, in the necessity for making a definite agreement in writing with each person so taken, securing to the photographer the copyright in the portrait, which would otherwise belong solely to the person for whom such portrait was taken. It might seem only strictly just to the public, that anyone sitting for a portrait and paying the charge made, should secure a copyright in his own likeness. Just as this may seem, it would have involved the portraitist in a great deal of trouble, in rendering necessary an agreement in writing in all cases, before he could sell a single copy of his pictures to any one but the person originally ordering the portrait. So far as we understand the Act, however, this arrangement is not intended, and it is avoided by referring in the clause in question, to the negative and not to the print. A person commissioning the production of a *negative* would, we apprehend, unless a written agreement existed to the contrary, become the owner of the copyright in such negative; but in simply ordering a portrait, he unquestionably means a print from a negative, and the copyright in the negative, it seems to us, remains in the hands of the artist. The wording of the Act is a little obscure, but we apprehend that this is meant, and that it is, moreover, a reasonable and legitimate conclusion; nor do we see any reason to fear that when the photographer has an absolute property in the copyright of the negative, he is any more likely than he has been hitherto, to publish and sell copies of portraits against the wish of the sitters. The public is saved from any risk of suffering annoyance in this way, by the simple fact that it is never the interest of the photographer to affront his patrons by selling their portraits without permission. The photographer is protected, by the possession of a copyright, in every negative he takes, unless the negative itself be ordered, and not simply prints from it, or unless he sells the negative without reserving any copyright in it. If it had been necessary to obtain an agreement in writing in order to secure a copyright in each negative taken, the issue would have been, that the trouble would have been generally neglected, and the mass of photographs would have still remained without any copyright.

It is important to remember, that no copyright is secured under this Act, until registration shall be made in the proper manner at Stationers' Hall. The provisions of a former Bill which rendered necessary a signature, or trade mark, or monogram, upon each picture, are not included in the present Act; the only step necessary is the registration prescribed. This, in the case of photographs, will be a simple transaction, inasmuch as a copy of the photograph, with the name of the artist, and date of production are all that will be necessary. In the case of valuable paintings a "sketch, outline, or photograph" is recommended, for entry in the register, as well as a description. The copyright to be acquired under this Act will be deemed personal estate; and any sale must be the subject of a written memorandum, written licences to use such copyright may be also given; but it is necessary that sale made, or license allowed, shall be duly registered at Stationers' Hall. For the various conditions governing the examination of such registry, of securing certified copies for reception in evidence, &c. &c., reference is made to the existing Act on literary copyright, which enacts that the register shall be, at all convenient times, open for inspection on payment of one shilling for every entry searched for; and that a stamped and certified copy of such entry, which shall be received as evidence in all courts, in case of legal proceedings, shall be furnished by the proper officer for the sum of five shillings.

As regards the penalties by which the protection is enforced, there is not much aubiguity. For every offence the pirate is liable to a penalty of ten pounds, and all "copies, repetitions, and imitations," and all negatives are to be forfeited and, together with the penalties, given up to the proprietor of the copyright. In England and Ireland the penalties are to be recovered by summary proceedings before two justices of the peace, having jurisdiction where the offending party resides. In Scotland they are to be recovered by action before the Court of Session, or by summary action before the sheriff of the county.

Provision is also made for seizing importations of piracies, and also for including in this Act, in relation to paintings, drawings, and photographs, the provisions of the International Copyright Act.

We again congratulate photographers that they have, though tardily, obtained this measure of justice, which will do much, we believe, to improve the productions of the art, by giving the artist exclusive property in the excellence of his works, and will contribute towards raising photography in the eyes of the public, by removing from the market the vile copies with which it has been recently increasingly inundated.

## Scientific Gossip.

Separation of Silver from its Alloys—New Iron Developing Salts—O'Neil's Dictionary, Advice to young Experimentalists—New and important Property of Carbolic Acid.

An improved method of separating pure silver from an alloy of silver and copper, has just come before our notice; it has been proposed by Berlandt. He dissolves the mixed metals in nitric acid, and evaporates the solution to dryness to get rid of excess of acid. He then dissolves an ounce of the salts in five ounces of water, filters the solution, adds fourteen ounces of a solution of protosulphate of iron (five and a half parts sulphate to eight and a half parts water), mixes and stirs well. The greyish white deposit, washed with very dilute sulphuric acid, and afterwards with water, is found to be pure silver. By dissolving this in nitric acid, taking the precautions mentioned in one of our early chapters on photographic chemicals, the photographer will be in possession of nitrate of silver pure enough for all ordinary purposes.

The employment of protosulphate of iron in developing solutions is becoming so general, that our readers may be glad to know an easy method of preventing the peroxidation of this salt in the atmosphere. The value of protosulphate of iron as a developing agent depends upon its rapid absorption of oxygen, and conversion into a per-salt of iron. If, however, this oxidation has partially taken place before it is used—if part of its reducing propensities have been gratified before it comes in contact with the latent negative image—it is evident that its action will be much weaker. Instead of using sulphate of iron alone we would suggest a trial of the double sulphate of iron and ammonia, $FeO.SO_3+NH_4O.SO_3+6HO$. This salt is easily obtained in crystals from a solution in which 139 parts of green vitriol, and 66 parts of sulphate of ammonia have been dissolved. The liquid is to be evaporated down, by preference over a water bath until it begins to show signs of crystallization; it is then allowed to remain at rest until it is perfectly cold, when the double salt will be found to have separated in the form of hard crystals: they preserve their transparency perfectly, even when kept in an imperfectly stoppered bottle, thereby showing that no alteration has taken place in their constitution. In using this salt, it must be remembered that its equivalent is greater than that of sulphate of iron, by the amount of sulphate of ammonia which it contains. On this account 196 parts, by weight, of the double sulphate will be required to effect the same amount of reduction as 139 parts of sulphate of iron. Whilst writing on this subject, it may not be out of place to mention a method frequently employed in chemical laboratories for preparing sulphate of iron in a form in which it does not readily peroxidize. A saturated aqueous solution of protosulphate of iron is prepared, and then mixed with twice its bulk of alcohol. The salt is immediately precipitated in a partially dehydrated form as a white powder; this is filtered off and drained from the adhering liquid (no washing is needed). When dry, it may be preserved for use in a stoppered bottle. Owing to its being in a fine state of division it is very convenient for weighing out definite quantities, and it also has the advantage of dissolving with great rapidity in water. Owing to its having lost part of the water of crystallization, it is slightly stronger in its reducing or developing powers, weight for weight, than the crystallized sulphate. We are not aware that either of these forms of sulphate of iron have been used, but from our own experiments, as well as from their more obvious valuable properties, we do not hesitate to recommend our readers to make trial of them as developing agents. We shall be glad to hear of their success.

A Dictionary of Dyeing and Calico Printing, by Charles O'Neill,* can scarce be expected to contain much that is of interest to photographers, although it is a work which will not fail to prove of the greatest value to those for whom it is specially written. Some of the author's remarks in the introduction are, however, so excellent, and are of such universal application, that, for the benefit of our younger readers, we transcribe a portion of them, which will apply quite as forcibly to photographers as to dyers. He writes:—"It is not necessary to say to practical and experienced colour-mixers and dyers what amateurs must be strongly reminded of, that receipts, in themselves, are valueless without preliminary experience. The failure of a receipt, in nine cases out of ten, is not necessarily a condemnation of its correctness, but is frequently a reflection upon the skill of the operator. The real use of receipts in a work of this nature, is to show how things have been done by some one in some particular circumstances, and with certain materials; and to suggest to another person in another place, with materials of a similar nature, but not exactly the same, how he may hope to obtain equal results. Receipts should be looked upon rather as valuable hints than as arbitrary prescriptions."

A very important property of carbolic acid has recently been described by Mr. J. E. Ashby. Our readers may, perhaps, be aware, that this is one of the products of the distillation of coal, and is now made in somewhat large quantities, on account of its most energetic deodorizing and disinfecting properties. When perfectly pure, it is a white crystalline solid, which by absorbing moisture soon changes into a colourless, refractive liquid having a faint odour of roses and tar. It is not an acid in the popular sense, not being either sour or corrosive, and should, therefore, perhaps, be generally designated by its other title of phenol. Crude carbolic acid may be now obtained in bulk for about a shilling per gallon; it is a dark, tarry liquid, containing, perhaps, from ten to twenty different substances in a state of mechanical admixture. This

* Part I., price 1s. London: Simpkin, Marshall, and Co.

crude acid is available for the purposes to which attention is now directed. Just as oil is an anti-frictional liquid, so is phenol pro-frictional: or, to state it more correctly, as oil appears to keep surfaces in motion asunder by interposing a thin film between them, so phenol appears to make them bite and bind by bringing them into absolute contact (after a manner of speaking) and removing even the finest film from between them. Mr. Ashby states that any one may convince himself of this by placing a little upon a perfectly clean and dry oil-stone, and then rubbing up the face of a broad chisel upon it. The sensation of the bite is very curious, and renders any further explanation unnecessary; it seems as if the stone and the steel had absolutely nothing between them, or even as if they were brought together by some attractive force. This property of carbolic acid has been applied to the operations of grinding, filing, boring, and sawing in metal with great apparent advantage. When dissolved in fifteen parts, by measure, of methylated alcohol, it forms a milk-white emulsion if poured into water, and it would be worth while to ascertain whether such carbolated water would facilitate the ordinary work of the grindstone. a point on which Mr. Ashby is not able to speak with certainty. This property of carbolic acid reminds us of an artifice which is of frequent employment in chemical, and, we presume, in other laboratories, where common spirits of turpentine are used for a somewhat similar purpose. A hole may readily be bored through a plate of glass with a common bradawl, if it is kept plentifully moistened with turpentine. The point must be sharp, and the movement must be somewhat similar to that adopted in boring a hole through hard wood, considerably less force being, however, used. With ordinary care there is no danger of cracking the glass, and the hole will be drilled through very neat and smooth. This plan of drilling glass is also of great use in extracting stoppers from bottles when the former are broken off short. By a judicious employment of the bradawl and turpentine, the broken stopper may be drilled through and through until it is readily removable from the neck, when the bottle may either have a fresh stopper ground into it, or be closed with a cork. From the above experiments of Mr. Ashby there is every reason to suppose that carbolic acid would answer this purpose very much better than turpentine.

Neither of the pieces of glass forwarded by "Actinic" are sufficiently opaque to the chemical rays to be of much value. The darkest of them, No. 2, admits some of the blue rays; whilst No. 1, is transparent even to the higher green. No. 2 might be used if no bromides were present, but we do not recommend it.

## Critical Notices.

A SERIES OF CABINET VIEWS, Size 6¾ by 4½. Photographed by G. W. Wilson. London: Marion & Co.

Mr. Wilson is not only one of the ablest artists in the profession, but he is in a pre-eminent sense an originator of certain styles in which he will find many, we will scarcely say imitators, but at least followers. Instantaneous stereographs had been taken for years, but it was not until Mr. Wilson issued a series of his exquisite sea and cloud pieces, in many of which he set the daring example of pointing his camera in the face of the sun, that such pictures began to have a recognized position amongst the staple productions of the art: and now several able artists are running a close race with the originator in the competition for excellence. We venture to intimate that the class of pictures Mr. Wilson has recently issued, as Cabinet Views, will become largely popular with the public, and with photographers, both professional and amateur, and that this series will, in fact, originate a style which will have many followers. It is quite certain that one barrier to the extensive circulation of photographs, as works of art, has arisen from a certain difficulty as to the proper mode of keeping them; they are scarcely well suited for framing, at any rate they have not a certainly recognized position in interior decoration; and an extensive collection, especially if the pictures be large, demands serious portfolio accommodation. Photographs of a size, then, capable of preservation in albums, especially if suitable albums be manufactured, are likely to become favorites with the public, and hence we conceive that Mr. Wilson in issuing this series will originate a style. Most of our readers know that these pictures are produced with the triple lens, and include a somewhat larger angle of view than is common with landscape photographs, thus often obtaining much in pictorial effect: the size, about 7 by 4½, is, moreover, exceedingly convenient for handling, and is not so small as to render objects insignificantly diminutive. We believe it is the intention of Messrs. Marion to prepare albums of a similar kind to those used for card portraits, especially suited to the reception of this size of photographs.

These views are characterized by the qualities which have hitherto distinguished Mr. Wilson's pictures: judicious and artistic selection of position and light, softness and brilliancy combined, and above all, the unmistakable presence of atmosphere. In many, which are not, however, instantaneous pictures, there are very fine natural clouds, and in others, the sky possesses a graduated or flat tint, but in no instance is it represented by a mass of white paper. Amongst the finest specimens of skies in the non-instantaneous pictures, we may mention that in a view of Aberdeen, with the Union Bridge in the foreground, which contains an exquisitely round yet soft and atmospheric bank of clouds. Two or three of the views of Balmoral Castle are charming pictures, and also contain fine clouds. Aberdeen University, and Castle Street, Aberdeen, are both very fine architectural pictures, and excellent illustrations of the value of a graduated atmospheric tint over the sky in making a picture, and preserving breadth. Braemar Castle, Mill on the Cluny, and Bridge on the Cluny, are three of the most charming pictures of the series, admirable examples of the soft rendering of running and broken water; foliage and rocks in the foreground do not lose their slightest detail, and distant hills are perfectly defined without, however, the cutting hardness which ignores aërial perspective. There are also some fine instantaneous pictures in the series, including shipping, water, and clouds We have not space to notice in detail every picture in the series, nor have we alluded to all their merits, our object being chiefly to draw attention to such points as possess technical interest in the eyes of our readers, to many of whom a selection from such a series will possess high educational value, as illustrating how the overcoming of merely technical and photographic difficulties becomes conducive to the attainment of pictorial excellence. As a whole we have rarely seen a series of photographs more pleasing; combining more of the artistic and photographic beauties necessary to a perfect result.

A PHOTOGRAPH OF SOME OF THE MEMBERS OF THE BRITISH ASSOCIATION. Designed and Photographed by A. Brothers. London: Day & Son; Manchester: A. Brothers.

Mr. Brothers has, on former occasions, earned high praise for the skill and taste with which he has designed and photographed composition portrait groups. The picture before us, however, is unquestionably one of the very best grouped pictures we have seen. The original photograph was a commission for Mr. Fairbairn, President of the British Association for the Advancement of Science last year, when the meetings were held at Manchester, and was intended to commemorate the occasion. The picture consists of twenty-two persons, assembled in Mr. Fairbairn's drawing-room; the assembly comprises some of the most eminent savans who took part in the proceedings of the Association, amongst whom we may name, in addition to the President himself, the Astronomer Royal, Sir Roderick Murchison, General Sabine, Sir David Brewster, Lord Wrottesley, Professor

Miller, and others. The figures are arranged in minor groups around three tables, but these three minor groups are united by standing figures so as to constitute one complete and admirably composed group, the individual positions being all so arranged as to aid in producing unity of idea and design, the whole being easy, natural, artistic, and harmonious.

The original photograph was about 33 inches by 20 inches. The number of negatives was thirty-two, twenty for the figures, and twelve for the background and accessories; the total number of printings was thirty-seven. The mere enumeration of these facts is suggestive enough of the care and skill required, and the difficulties to be overcome in producing a satisfactory result; but a little reflection suggests, how much greater are the difficulties than at first sight might appear. In a recent conversation we had with Mr. Brothers, he mentioned some of these difficulties. A painter in producing such a group, or even a photographer in producing a fancy composition group, has the whole of his material before him, and more or less under control. He can conceive his idea, arrange his composition, make his sketch beforehand, and work out his ideas in his own way; but the professional portraitist, when called upon to produce a composition like the one before us, rarely possesses any of these facilities: he has to form his design on the spur of the moment, in the absence of the component parts; often in ignorance even of their personal appearance, and sometimes in doubt as to the exact number to be included. The sittings are to be secured at such different times, and in such conditions of light, &c., as may suit the sitter, however ill it may suit the photographer. With all this, it is necessary to secure such accuracy of proportion, and such positions and relations of light and shade as shall constitute a satisfactory and harmonious completed picture. With such artistic difficulties, in addition to all the technical troubles which will at once flash to the mind of the reader, many shortcomings in the result, if they existed, might be pardoned. No such plea is, however, required by the group before us. The likenesses are striking; the positions easy, characteristic, and natural; the composition, grouping, and arrangement of accessories excellent.

The print now published is from one negative 16 by 10, taken from the original picture. In this copy, the photography is very excellent, round, vigorous, and brilliant, and speaking very highly for the perfect photography of the original picture. We have before us also a card picture, containing a copy of the same group, which is an admirable example of photographic reproduction.

---

INSTANTANEOUS VIEWS OF THE INUNDATIONS IN THE FENS. Photographed by V. Blanchard. London: C. E. Elliot.

Few of our, readers before reading Mr. Blanchard's graphic description of a photographic trip to the recently inundated and desolated fen country, would be likely to conceive that anything interesting or picturesque for the camera could be found in such a scene—a dreary waste of waters, and "stretched wide and wild the waste enormous marsh." Mr. Blanchard has here proved, however, what painters have often proved, but what photographers have found much more difficult, that the trained eye and hand of the artist will secure a picture out of the most unpromising materials; and apart from their deep interest as an unerring record of a great calamity, this series contains many slides of very great pictorial excellence.

"Sunset after a Storm," No. 150, is an exceedingly charming picture, with fine clouds and sky; the light on the troubled water is very beautiful; a piece of partially submerged railing in the foreground, and a boat in the middle distance, give force and value to the picture. Another sunset view (No. 156) is also a very fine composition: the sun and clouds are calmly reflected in the water, which apparently covers a meadow, the taller grass of which occasionally merges beyond the surface. A forcible picture of the desolation is suggested by a boat with canvas set, sailing past a partially submerged haystack. In another slide, a boat, the same apparently, is approaching one of the drowned farm-houses, and is just passing over or through a hedgerow, the pliant top twigs of which just emerge from the surface of the water.

A view from the Middle Level Bank (No. 151) and one from the Gravel Bank, near Marshland Fen engine (157), are two very good slides, admirably illustrative of the subject, and presenting some fine pictorial effects besides. Here also are views of the broken sluice, and of the coffer dam, with a group of celebrated engineers present, and other views possessing historic interest, as illustrating different phases of, the inundation and the works connected therewith. The photography is in all instances good, the negatives manifestly being very perfect, and the printing excellent.

We may here take occasion to allude to a happy knack Mr. Blanchard possesses, of giving increased interest to his slides by excellent description and apt quotation. The inundation series are made valuable by having printed on the back a brief but very clear and succinct description of the position of the land now from the sea, of the draining embankments, and recent inundations. An admirable quotation from Tennyson beneath the title of the slide wonderfully helps the imagination whilst examining its subject. It runs—

> " ———— we see
> Stretched wide and wild the waste enormous marsh,
> Where from the frequent bridge,
> Like emblems of infinity,
> The trenched waters run from sky to sky."

This is as apt as the quotation from Cowper on Mr. Blanchard's instantaneous views of Loudon; running thus:

> " 'Tis pleasant, through the loopholes of retreat,
> To peep at such a world; to see the stir
> Of the great Babel, and not feel the crowd."

Surely Cowper must have had a stereoscope and a pile of instantaneous street scenes before him when he wrote this! Never mind the anachronism!

---

INSTANTANEOUS MARINE VIEWS for the Stereoscope. By Dages and Harman.

Another series of instantaneous pictures of maritime subjects, chiefly sea, and shipping, and clouds, and comprising some very beautiful atmospheric effects indeed. Messrs. Dages and Harman have visited the east and south coast, and the views are chiefly off Yarmouth or Portland, those of the former place abounding with incident, the latter being chiefly confined to effects of water and cloud, some of which are, however, very fine. No. 197, "Sunset," and 199, "A Stormy Day," have magnificent clouds, but require some foreground object to give solidity and force to the whole; the finest atmospheric effect loses much of its value if there be not some fore-ground object, however simple. The Yarmouth views are not wanting in this respect, and some of them are very beautiful indeed. No. 229, A "Fishing Lugger just coming in to the Pier," is very fine. and sufficiently sharp for the figures, indicating the number of the vessel, to be read perfectly. No. 220, "A Steamer bringing in a Disabled Vessel," is also very fine, perfectly exposed, and yet with every line of cordage, both in the steamer and ship, perfectly defined. There are a great many other admirably selected views, full of incident, and many of them excellent photographs. Some of them are, however, slightly under-exposed, and some of them a little over-intensified, which gives some tendency to coarseness and hardness. They are all so nearly good, and many of them quite so, that we feel sure that, with a little more care in manipulating, Messrs. Dages and Harman will produce uniformly very perfect results.

---

THE BRITISH HOUSES OF PARLIAMENT. London: Ashford, Brothers.

This will necessarily be a popular series of slides, as few subjects could well be more interesting for the stereoscope, than the interiors of the Upper and Lower senate houses of the British Empire. Those who are familiar with the buildings will know that they present greater difficulties to the photographer than many interiors; remembering these difficulties, it will be seen that many of these pictures are well done. We trust their circulation will be as large as they deserve.

## The International Exhibition.

### PHOTOGRAPHIC CHEMICALS.

The display of photographic chemicals in the Foreign Department of the Exhibition is not large. The French is particularly meagre in this respect. The firm of Rolloy exhibit some very nicely crystallized, and apparently pure, specimens of the chemicals in general use. M. Plessy also has a good show of chemicals; and a few manufacturers of apparatus and paper also display chemical products, but these, as a rule, are inferior to the English, and call for no special comment. Turning to Class II. in the French Department, we may notice, as specially worthy of remark, the beautiful salts of cadmium exhibited by A. Desespringalle, and the acetic acid shown by Raques and Bourgeois. Lefèvre exhibits a substance, which, although not, strictly speaking, photographic, is nevertheless of great interest at the present time, and is likely, before long, to be used in photography; we allude to the new alkali, fubidia.

Austria is well represented by Dr. John Lamatsch, who exhibits all the ordinary photographic chemicals, iodides, bromides, fluorides, &c., together with different kinds of collodion and gun-cotton. Classed with the photographic chemicals exhibited by this chemist is a specimen of "transmaticine," respecting the photographic qualifications of which we confess our utter ignorance. Some nice specimens of chloride and sulphate of rubidium are also exhibited along with the pure chemicals.

The Zollverein Department makes a very creditable show. The specimen of pyrogallic acid exhibited by E. Schering, of Berlin, is unrivalled in the whole building. It forms a mass of beautifully white feathery crystals, filling a bottle a yard high by a foot in diameter, which well merits the eulogium bestowed upon it by the manufacturer, "au acid pyrogallic, so fine as none of my competitors may equal it in any way." This exhibitor has a very admirable show of iodide of potassium, cyanide of potassium, and various bromides and iodides, to again quote the description given by M. Schering, "all other photographic preparations, such as cotton of collodion, lithion, gold, and argent salts, all fluors, &c., were brought forth with the greatest conscientiousness, in an equally pure and superior quality, so that, whenever indirectly, my preparations gained credit, not only throughout Germany, but also in all European, and a great deal of transatlantic countries; the demand of these articles being actually great, and, I dare say, daily increasing, I am obliged to think repeatedly of an adequate extent of my laboratories." In justice to this exhibitor we may state, that his products well deserve the good opinion with which he evidently regards them. The same exhibitor also shows photographic papers, prepared in various ways. With characteristic modesty, M. Schering suggests, that these papers would be useful to *grocers*; we, however, have no hesitation in strongly recommending them to photographers.

The manufacture of collodion has been entered into on a considerable scale by Hermann Kuntzmann. He employs the iodides and bromides of cadmium, lithium, sodium, and potassium, and by using several of these in various combinations, he has succeeded in producing about a dozen different collodions, varying considerably in name, and, possibly, having some slight differences of quality. Among the euphonious combinations, which the exhibitor offers for the delectation of photographers, we find cadmio-lithio-bromato-iodatum, cadmio-natrio-bromato-iodatum, cadmio-kalio-bromato-iodatum, cadmio-ammonio-bromato-iodatum, *et hoc genus omne*. There *may* be some occult properties in these various salts, which render such permutations advisable, but as chemists they seem to us simply ridiculous. This exhibitor fares better when he dismisses such permetative pen-and-ink photography, and becomes more practical; the papers which he exhibits, salted and otherwise prepared, for positive printing, are excellent, although the desire to embrace every possible compound in their preparation is evident here also.

G. F. Toussaint, of Fürth, in Bavaria, has some good cyanide of potassium in tubes, and also cast in sticks, similar to lunar caustic; this is a very convenient form, and we wish some English manufacturer would adopt this plan, for with the large hard lumps, in which it is at present met, there is great difficulty in using small portions without great waste.

We ought not to pass over without mentioning the magnificent show of shellac, exhibited by C. Mellinger and M. Abrecht, the latter also exhibits different kinds of varnish, some of which is well adapted for photographic purposes.

In concluding these brief notices of the photographic chemicals exhibited in the International Exhibition, we would by no means have it understood that we have exhausted the subject. Whilst we feel that we have left unnoticed many exhibitors of merit, we have endeavoured to give our readers a fair idea of the position occupied by photographic chemistry at home and abroad. Those who remember the almost unknown position of photography in 1851, and the meagre display which it made in that Exhibition, cannot but be struck with the vast importance which it has attained during the last decade. From a mere curiosity of applied chemistry it has become an important branch of science, and the arts and manufactures directly or indirectly connected with it now form no insignificant portion of the world's industry.

### PHOTOGRAPHY IN AMERICA.

2, *Wall Street, New York, July 15th*, 1862.

Dear Sir,—You have noticed by *Seeley's Journal*, that Coleman Sellers, the champion of wet photography in America, has gracefully "dried up," and ordered a dry-plate box on the same principle as my own. We have now but one "fossil" left in the club, Mr. Robert Shriver, and a very good "fossil" he is, too. Even he, however, is experimenting on dry plates, and sent me, the other day, a very good print, labelled "Tannin." Thus we are converting all to the pleasures of photography, with five pounds weight only. I say "we;" but I suspect the hot weather has done most of the converting, for the mercury has been like good alcohol for two weeks (*i.e.* 95°); and any amateur with a tent this weather, would also resemble the alcohol as far as evaporation. About dry plates generally, the tannin process is the favourite; but all are used among us. Mr. E. Borda has taken excellent pictures by the resin process, and expresses great faith in it. He uses but one quarter of a grain of resin to the ounce of collodion, and *dries* his plates spontaneously in a *damp cellar*. Curious way to prepare *dry* plates.

The problem of instantaneous dry plates is about solved, by H. T. Anthony, Esq., of this city. His discovery consists in subjecting a tannin dry plate to the fumes of weak ammonia for a few seconds, and exposing it within one day after fuming. These plates are exceedingly sensitive, two seconds exposure being sufficient with small diaphragm, and instantaneous with full opening of Harrison's stereo portrait lens. The development is conducted cold in the ordinary manner. Mr. Anthony is an irrepressible experimentalist, and the father of many discoveries not yet made public. The finest dry process I know of is due to his ideas and my manipulation: I refer to the "milk process," which I have used a year past, and always succeeded. In my hands it fully equals the wet in all respects, as you may see by some prints I will enclose in this letter. The plates are prepared with the usual collodion, and sensitized and washed thoroughly, after which they are flowed with a solution of "American solidified milk" (5 per cent. in bulk, dissolved in warm water); they are then thoroughly washed, and dried in a hot box. This milk powder is made by boiling down milk and sugar to dryness, and when packed in tin boxes, will keep for years in good condition: probably it can be procured in London. The trace of albumen in the milk acts in the film in such a way as to soften the whole picture. Negatives by this process are *yellow*, and so thin you can easily read through them. The skies look like church window glass. The plates keep equally well with tannin, as I have tested them on a two months' trip "out west," and developed my negatives after coming home with perfect success. They cannot be prepared so fast as tannin plates, hence lack of time compels me to work the latter the most, but when business allows me leisure to work, I infinitely prefer the "milk plates," or, as I labelled my first pictures before I told the secret, "modified albumen." I took the first picture by this method, and it is now confined to Mr. Anthony and myself. I would be pleased to have the opinion of yourself on the *comparative* merits of the too most perfect dry processes—"tannin," and "milk"—as shown by the enclosed prints. I hope some of your workers will take this up, for they cannot fail to like it. I would mention, in closing, that Professor Edwin Emerson, of the University of Troy, will visit Europe on pleasure in a few weeks, and besides being a thorough photographer, he is a *savant* of the first proof, and the scientific men of the mother-land will like him. He will tell you much about our blood-stained country at the present time.—Yours respectfully, F. F. Thompson.

[The prints enclosed are all admirable specimens of photography, as well as interesting pictures; we think, however, that in making a choice, we should give those by the milk process the preference. They have all the delicacy and softness of very fine pictures by the wet process, and are, withal, very brilliant. The foliage is full of detail, without any black patches of under-exposure, the distance well preserved, and a pleasant atmospheric tint on the sky. The exposure appears to be shorter with the milk plates than with the tannin; the former averaging one minute with a Ross's single stereo lens, $\frac{3}{16}$ stop, whilst the latter required nearly double that time. We shall look forward with pleasure to a call from Professor Emerson, with whose name photographers in this country are not unfamiliar.—Ed.]

## TRANSPARENT GLASS POSITIVES ON COLLODION.*

BY DR. SABATIER.

### Lighting the Operating-Room.

The formation of the negative will support an intensity of light quite inconsistent with the formation of a positive. My operating-room receives light from an adjoining room, through four panes of glass covered with yellow paper. To obtain a positive I have been obliged to suppress two of these panes, and to place a black curtain before the other two, by means of which I can diminish the quantity of light when it is too strong. When the yellow rays are too strong the entire plate becomes blackened, and the negative itself completely disappears upon the second addition of pyrogallic acid.

### Collodion.

My collodion, modified as above described, is composed as follows:—

| | | |
|---|---|---|
| Plain collodion ... ... ... | 120 | parts |
| Iodide of cadmium ... ... | 1 | part |
| Iodide of potassium ... ... | 0·50 | " |
| Bromide of cadmium ... ... | 0·40 | " |
| Bromide of potassium ... ... | 0·20 | " |
| Iodine ... ... ... ... | 0·05 | " |

* From *Moniteur de la Photographie*. Continued from p. 358.

The glass plate, when coated with collodion, is sensitized in the following

### Sensitizing Bath.

But as the slightest traces of nitric acid prevent the formation of the positive, I have been careful to replace crystallized nitrate of silver by fused nitrate—

| | | |
|---|---|---|
| Distilled water ... ... ... | 100 | parts |
| Fused nitrate of silver ... ... | 6 | " |

### Exposure in the Camera.

After draining the sensitized plate, and placing it in the slide, I expose it in the camera; this exposure, in consequence of the addition of iodide of potassium to the collodion, need be neither more nor less than the time required to take a good negative; only, it is necessary, as always, to take into consideration the intensity of the light and heat, as well as the colours of the object.

### Developing Solution.

My developing solution consists of—

| | | |
|---|---|---|
| Distilled water ... ... ... | 100 | parts |
| Pyrogallic acid ... ... ... | 0·1 | part |
| Crystallizable acetic acid ... | 1·0 | " |

When the atmospheric temperature is below 60° F., I increase the proportion of pyrogallic acid a little, in order to hasten the development.

As soon as the negative appears in its minuter details, without hurrying or delaying, I pour on the pyrogallic developer, and then immerse the plate in a dish of rain-water, less than half an inch in depth—this water must be employed for one plate only; then I give the dish a gentle rocking motion, so as to wash off all the acid collected upon it. After one or two minutes washing, I lift out the plate by means of a silver hook, drain it, and wipe the back, and holding it by one corner, cover it with a small quantity of a solution of nitrate of silver, of the strength of 4 per cent., and cause it to flow over the whole surface with the least possible delay. To this solution I have given the name of *substituting bath*, because it determines the substitution of the electric currents, and, consequently, the change of photographic combination. In general, the longer the substituting solution remains upon the collodion film, the sooner the positive appears when the pyrogallic acid is applied for the second time. Before proceeding to this second application of pyrogallic acid, I pour off by a corner, into a bottle, the nitrate solution with which the plate is covered; for this solution may be employed indefinitely, and it even improves by use.

It is the second application of pyrogallic acid, made subsequent to the substituting bath, that develops the positive. As I have stated, it is developed suddenly, if the substituting bath be prolonged; but slowly on the contrary, if it has been in it a quarter or half a minute only; still slower if the substituting bath is weaker than 4 per cent. It now only remains to fix the image in the usual manner, either with cyanide of potassium or hyposulphite of soda, and proceed to toning, if the colour of the positive be not agreeable. The usual colour of the positive is a chocolate, more or less intense; this is not an agreeable colour, but it is easy to tint them differently. This I effect without the aid of salt of gold, and by means of a method quite opposed to generally received notions on this subject. After the fixing I wash the glass plate thoroughly, then cover it with a solution of sulphide of potassium, of the strength of one-half per cent. My positive immediately assumes the most beautiful black tone imaginable. I quickly wash it, dry it, and varnish with picture varnish, diluted with five times its volume of spirits of turpentine.

What takes place in toning by sulphide of potassium? Is not the sulphuration of the positive image increased? I believe it to be possible, but up to the present time, although I have submitted my positives to many causes of destruction, I cannot perceive that they have lost anything of their original hue, and I continue to tone with sulphide of potassium without any fear of the consequences.

## THE INUNDATION IN THE FENS FROM A PHOTOGRAPHIC POINT OF VIEW.*

I learned from this old man, who informed me that he had been one of the anxious watchers for the breaking of the bank, that every precaution had been taken at all the weak points along the bank, but that it was evident to every one, long before the actual arrival of the catastrophe, that nothing short of a miracle could save the fens from inundation after the breaking of the sluice. It appears that the water found its way through, some feet below the top of the bank; and spurted out on the other side, like the stream from the hose of a fire engine, but that in almost less time than it takes to tell, there was an aperture, 20 feet across, which continues to widen at an alarming rate, the earth crumbling away on each side and disappearing in the most extraordinary manner. Various attempts to stop it were made, but all in vain. Barges were knocked to pieces by the force of the waters, and the fragments were carried miles away.

I did not attempt to unpack, for the weather unmistakably said, no photography to-day. As, however, much could be done in selecting spots for future operations, I left my companion in charge, and strolled on along the bank towards an unfortunate house, which the hanger-on informed me was an inn. A brisk walk of some ten minutes duration brought me to it, and truly it was a melancholy picture to look at. The house stood about 100 yards from the bank on which I stood, and was surrounded by several outbuildings, and the water was nearly up to the roof of some of them. A little nearer a gate peeped out just above the water, and evidently stood upon a higher piece of ground. The sign of the house had evidently been removed, for its announcement—"good entertainment for man and beast"—would have indeed been a bitter jest at the present moment. The waters were sullenly dashing against the closed door, as though angrily asserting that a public house should be open to all comers.

About a mile further on the bank I saw a large farm, with many outbuildings, and several cottages at a short distance from it, and therefore went still on. A strange feeling took possession of me as I wandered on alone. I looked out on the vast waste, and, far as the eye could reach, not a trace of human existence was visible—nothing but ruin and desolation. No sound came upon the ear but the howl of the wind, and the angry response of the waves. The clouds were wild and strong, and were coursing after each other rapidly, as though eager to get away from so dismal a spot. It seemed no great stretch of the imagination to fancy the deluge once more here, and I the last man left.

When I came up to the farm I found that it would be the best point for photographic operations. I therefore determined that on the following day, weather permitting, it should be my first point, for without carrying the camera far several very interesting pictures could be made.

## WATER-PROOF VARNISHES AND CEMENTS FOR PHOTOGRAPHIC PURPOSES.

BY H. R. NICHOLLS.

Dear Sir,—The wants of the ardent student of photography being many, I forward you, as a contribution to the supply of some of them, the quantities for the compounds, to which I referred in a recent communication, of caoutchouc and gutta-percha with pitch, their uses and application. They are great favourites with me, as I have used them successfully for photographic purposes now twenty-four years, and for some four or five years previously for chemical, domestic, and building purposes. The first purpose to which I applied such a compound was for lining a tank to supply my laboratory with water. Being at the time a very bad plumber, necessity compelled me to resort to other means than the soldering irons. I then used :—

| | |
|---|---|
| Caoutchouc ... ... ... ... | $1\frac{3}{4}$ pound |
| Stockholm pitch ... ... ... | 1 " |

Cut the caoutchouc in small pieces, and melt in an iron ladle, stirring with an iron rod, add the pitch in small portions at a time, stirring it until the compound is perfectly smooth. For convenience in use, mould it in the form of a stick, in a stout paper tray. This compound is adapted for metal joints of tanks or pipes, above or below ground.

To apply it, scrape the parts clean and apply the compound with a hot iron, smoothing it well over the edges of the joint or fracture. For stone, slate, or glass, add to every four ounces of the compound a quarter of an ounce of *glass flour*. Care must be taken that no fatty substance comes in contact with the compounds, or their destruction will soon follow.

For wood-work sunk in the ground, use :—

| | |
|---|---|
| Caoutchouc ... ... ... ... ... | $1\frac{1}{2}$ lb. |
| Pitch ... ... .. ... ... ... | $\frac{1}{2}$ " |

Melted as before, apply in the same way.

Gutta-percha may be used for these two compounds, but its results will be bad, I have found them so in my experience. In my next communication gutta-percha will be treated for its photographic uses, as I have found them in practice.

## PHOTOGRAPHIC STUDIES.

BY DR. SCHNAUSS.

*Examination of various Formulæ.**

The fact observed by M. Krüger is very curious; namely that a solution of sulphate of iron, more concentrated than employed at present, gives greater sensitiveness and purer proofs than more diluted solutions, and does not require so much acetic acid. The addition of alcohol is superfluous. I have tried this formula, and find it excellent. As the solution is stronger than ordinary, the plates may be immersed in it. M. Krüger recommends the following formula :—

| | |
|---|---|
| Sulphate of iron ... ... ... | 2 parts. |
| Distilled water ... ... ... | 8 " |
| Acetic acid ... ... ... ... | 1 " |

It is better not to add sulphuric acid ; the solution may be employed immediately. But I advise the addition of the acetic acid *before* filtering the solution, if operating with a sensitizing bath and a collodion recently prepared; or of adding it only *after* the filtering, if the collodion and the bath are old. An aqueous solution of sulphate of iron always contains a little basic salt in suspension, which produces an opaline aspect, or a yellow precipitate, which is formed upon the addition of the acetic acid. This salt is dissolved, and it produces a little acetate of iron in solution. But if filtered beforehand, the basic salt remains upon the filter. The presence of a small quantity of acetate of iron in the bath, favours the vigour of the dark portions of the negative.

We know, at the present day, how very essential it is to satisfy ourselves what proportion the iodides bear to the bromides, and if free iodine be present in the collodion ; the nature of the iodides is of less importance. Frequently, a special iodide influences the properties of a collodion according as it allows the iodine to evaporate or not. It is now settled that no collodion should be employed until it has been some time prepared ; the ether, even when neutral, will separate a little free iodine from every iodide. Now, free iodine is indispensable to the collodion, if we wish to obtain intensity and transparent shadows. This also responds to the theory of free iodine in the sensitizing bath. If free iodine be not developed spontaneously in the collodion, some drops of tincture of iodine must be added to it,

* Continued from page 369.

until it acquires the colour of amber. If bromides are present, we can greatly augment the proportion of iodine, without injury to the sensitiveness. Naturally, every substance which sets iodine at liberty, acts like iodine itself; we can, then, for example, add acetic acid to recently prepared collodion, as recommended.

Many formulæ for rapid collodion possess no value. M. Engène Sahler recommends a collodion prepared with iodide of iron; according to his formula, the collodion gives very good results during a few hours; but its sensitiveness is not so great as that of a good bromo-iodized collodion, and in the course of a few days the liquid becomes brown black, opaque, and gelatinous. It seems as if the pyroxyline lost its sensibility through the iodide of iron. We must make the collodion as thick as possible, else it will give an unequal film, which succeeds better with an alcoholic collodion than with an etherial collodion. The ether disengages the iodine in the collodion, and the collodion gives more vigorous negatives, while alcoholic collodion gives more harmonious pictures, and keeps good much longer. For card portraits, I prefer etherial collodion.

In my next article, I shall speak of the application of the chloric acid to the negative silver bath.—*Moniteur.*

(*To be continued.*)

## NEW COPYRIGHT ACT.

*An Act for Amending the Law Relating to Copyright in Works of the Fine Arts, and for Repressing the Commission of Fraud in the Production and Sale of such Works.*

Whereas by law, as now established, the authors of paintings, drawings, and photographs, have no copyright in such their works, and it is expedient that the law should in that respect be amended: be it, therefore, enacted by the Queen's most Excellent Majesty, by and with the advice and consent of the Lords Spiritual and Temporal, and Commons, in this present Parliament assembled, and by the authority of the same, as follows:—

1. The author, being a British subject, or resident within the dominions of the crown, of every original painting, drawing, and photograph which shall be, or shall have been, made, either in the British dominions or elsewhere, and which shall not have been sold or disposed of before the commencement of this Act, and his assigns, shall have the sole and exclusive right of copying, engraving, reproducing, and multiplying such painting or drawing, and the design thereof, or such photograph, and the negative thereof, by any means and of any size, for the term of the natural life of such author, and seven years after his death; provided that when any painting or drawing, or the negative of any photograph, shall for the first time after the passing of this Act be sold or disposed of, or shall be made or executed for, or on behalf of, any other person for a good or a valuable consideration, the person so selling or disposing of, or making or executing the same, shall not retain the copyright thereof, unless it be expressly reserved to him by agreement in writing, signed, at or before the time of such sale or disposition, by the vendee or assignee of such painting or drawing, or of such negative of a photograph, or by the person for or on whose behalf the same shall be so made or executed, but the copyright shall belong to the vendee or assignee of such painting or drawing, or of such negative of a photograph, or to the person for or on whose behalf the same shall have been made or executed; nor shall the vendee or assignee thereof be entitled to any such copyright, unless, at or before the time of such sale or disposition, an agreement in writing, signed by the person so selling or disposing of the same, or by his agent duly authorized, shall have been made to that effect.

2. Nothing herein contained shall prejudice the right of any person to copy or use any work in which there shall be no copyright, or to represent any scene or object, notwithstanding that there might be copyright in some representation of such scene or object.

3. All copyright under this act shall be deemed personal or moveable estate, and shall be assignable at law, and every assignment thereof, and every licence to use or copy by any means or process the design or work which shall be the subject of such copyright, shall be made by some note of memorandum in writing, to be signed by the proprietor of the copyright, or by his agent appointed for that purpose in writing.

4. There shall be kept at the Hall of the Stationers Company, by the officer appointed by the said company for the purposes of the Act passed in the sixth year of her present Majesty intituled, 'An Act to Amend the Law of Copyright,' a book or books, entitled, 'The Register of Proprietors of Copyright in Paintings, Drawings, and Photographs,' wherein shall be entered a memorandum of every copyright to which any person shall be entitled under this Act, and also of every subsequent assignment of any such copyright; and such memorandum shall contain a statement of the date of such agreement or assignment, and of the names of the parties thereto, and of the name and place of abode of the persons in whom such copyright shall be vested by virtue thereof, and of the name and place of abode of the author of the work in which there shall be such copyright, together with a short description of the nature and subject of such work, and in addition thereto, if the person registering shall so desire, a sketch, outline, or photograph of the said work, and no proprietor of any such copyright shall be entitled to the benefit of this Act until such registration, and no action shall be sustainable, nor any penalty be recoverable in respect of anything done before registration.

5. The several enactments in the said Act of the sixth year of her present Majesty contained, with relation to keeping the register book thereby required, and the inspection thereof, the searches therein, and the delivery of certified and stamped copies thereof, the reception of such copies in evidence, the making of false entries in the said book, and the production in evidence of papers falsely purporting to be copies of entries in the said book, the application to the courts and judges by persons aggrieved by entries in the said book, and the expunging and varying such entries, shall apply to the book or books to be kept by virtue of this Act, and to the entries and assignments of copyright and proprietorship therein under this act, in such and the same manner as if such enactments were here expressly enacted in relation thereto, save and except that the forms of entry prescribed by the said Act of the sixth year of her present Majesty, may be varied to meet the circumstances of the case, and that the sum to be demanded by the officer of the said Company of Stationers for making any entry required by this Act shall be one shilling only.

6. If the author of any painting, drawing, or photograph in which there shall be subsisting copyright, after having sold or disposed of such copyright, or if any other person, not being the proprietor for the time being of copyright in any painting, drawing, or photograph, shall, without the consent of such proprietor, repeat, copy, colourably imitate, or otherwise multiply for sale, hire, exhibition, or distribution, or cause or procure to be repeated, copied, colourably imitated, or otherwise multiplied for sale, hire, exhibition, or distribution, any such work or the design thereof, or, knowing that any such repetition, copy, or other imitation has been unlawfully made, shall import into any part of the United Kingdom, or sell, publish, let to hire, exhibit, or distribute, or offer for sale, hire, exhibition, or distribution, or cause or procure to be imported, sold, published let to hire, distributed, or offered for sale, hire, exhibition, or distribution, any repetition, copy, or imitation of the said work, or of the design thereof, made without such consent as aforesaid, such person for every such offence shall forfeit to the proprietor of the copyright for the time being a sum not exceeding ten pounds; and all such repetitions, copies, and imitations made without such consent as aforesaid, and all negatives of photographs made for the purpose of obtaining such copies, shall be forfeited to the proprietor of the copyright.

7. No person shall do or cause to be done any or either of the following acts; that is to say:—First, no person shall fraudulently sign or otherwise affix, or fraudulently cause to be signed or otherwise affixed, to or upon any painting, drawing, or photograph, or the negative thereof, any name, initials, or monogram. Secondly, no person shall fraudulently sell, publish, exhibit, or dispose of, or offer for sale, exhibition, or distribution, any painting, drawing, or photograph, or negative of a photograph, having thereon the name, initials, or monogram of a person who did not execute or make such work. Thirdly, no person shall fraudulently utter, dispose of, or put off, or cause to be uttered or disposed of, any copy or colourable imitation of any painting, drawing, or photograph, or negative of a photograph, whether there shall be subsisting copyright therein

or not, as having been made or executed by the author or maker of the original work from which such copy or imitation shall have been taken. Fourthly, where the author or maker of any painting, drawing, or photograph, or negative of a photograph, made either before or after the passing of this Act, shall have sold or otherwise parted with the possession of such work, if any alteration shall afterwards be made therein by any other person, by addition or otherwise, no person shall be at liberty during the life of the author or maker of such work, without his consent, to make or knowingly to sell or publish, or offer for sale, such work or any copies of such work so altered as aforesaid, or of any part thereof, as or for the unaltered work of such author or maker. Every offender under this section shall, upon conviction, forfeit to the person aggrieved a sum not exceeding ten pounds, or not exceeding double the full price, if any, at which all such copies, engravings, imitations, or altered works shall have been sold or offered for sale; and all such copies, engravings, imitations, or altered works shall be forfeited to the person, or the assigns or legal representatives of the person, whose name, initials, or monogram shall be so fraudulently signed or affixed thereto, or to whom such spurious or altered work shall be so fraudulently or falsely ascribed as aforesaid: provided always, that the penalties imposed by this section shall not be incurred unless the person whose name, initials, or monogram shall be so fraudulently signed or affixed, or to whom such spurious or altered work shall be so fraudulently or falsely ascribed as aforesaid, shall have been living at or within twenty years next before the time when the offence may have been committed.

8. All pecuniary penalties which shall be incurred, and all such unlawful copies, imitations, and all other effects and things as shall have been forfeited by offenders, pursuant to this Act, and pursuant to any Act for the protection of copyright engravings, may be recovered by the person herein-before, and in any such Act as aforesaid, empowered to recover the same respectively, and herein-after called the complainant or the complainer, as follows: In England or Ireland, either by action against the party offending, or by summary proceeding before any two Justices having jurisdiction where the party offending resides: In Scotland, by action before the Court of Session in ordinary form, or by summary action before the sheriff of the county where the offence may be committed, or the offender resides, who, upon proof of the offence or offences, either by confession of the party offending, or by the oath or affirmation of one or more credible witnesses, shall convict the offender, and find him liable to the penalty or penalties aforesaid, as also in expenses; and it shall be lawful for the Sheriff, in pronouncing such judgment for the penalty or penalties and costs, to insert in such judgment a warrant, in the event of such penalty or penalties and costs not being paid, to levy and recover the amount of the same by poinding: provided always, that it shall be lawful to the Sheriff, in the event of his dismissing the action and assoilzieing the defender, to find the complainer liable in expenses, and any judgment so to be pronounced by the Sheriff in such summary application shall be final and conclusive, and not subject to review by advocation, suspension, reduction, or otherwise.

9. In any action in any of Her Majesty's Superior Courts of Record at Westminster and in Dublin, for the infringement of any such copyright as aforesaid, it shall be lawful for the court in which such action is pending, if the court be then sitting, or if the court be not sitting, then for a Judge of such court, on the application of the plaintiff or defendant respectively, to make such order for an injuction, inspection, or account, and to give such direction respecting such action, injunction, inspection, and account, and the proceedings therein respectively, as to such court or Judge may seem fit.

10. All repetitions, copies, or imitations of paintings, drawings, or photographs, wherein, or in the design whereof, there shall be subsisting copyright under this Act, and all repetitions, copies and imitations of the design of any such painting or drawing, or of the negative of any such photograph, which, contrary to the provisions of this Act, shall have been made in any Foreign State, or in any part of the British Dominions, are hereby absolutely prohibited to be imported into any part of the United Kingdom, except by or with the consent of the proprietor of the copyright thereof, or his agent, authorized in writing; and if the proprietor of any such copyright, or his agent, shall declare that any goods imported are repetitions, copies, or imitations of any such painting, drawing, or photograph, or of the negative of any such photograph, and so prohibited as aforesaid, then such goods may be detained by the officers of Her Majesty's Customs.

11. If the author of any painting, drawing, or photograph, in which there shall be subsisting copyright, after having sold, or otherwise disposed of such copyright, or if any other person, not being the proprietor for the time being of such copyright, shall, without the consent of such proprietor, repeat, copy, colourably imitate, or otherwise multiply, or cause or procure to be repeated, copied, colourably imitated, or otherwise multiplied, for sale, hire, exhibition, or distribution, any such work, or the design thereof, or the negative of any such photograph, or shall import or cause to be imported into any part of the United Kingdom, or sell, publish, let to hire, exhibit, or distribute, or offer for sale, hire, exhibition, or distribution, or cause or procure to be sold, published, let to hire, exhibited, or distributed, or offered for sale, hire, exhibition, or distribution, any repetition, copy, or imitation of such work, or the design thereof, or the negative of any such photograph, made without such consent as aforesaid, then every such proprietor, in addition to the remedies hereby given for the recovery of any such penalties, and forfeiture of any such things as aforesaid, may recover damages by and in a special action on the case, to be brought against the person so offending, and may in such action recover and enforce the delivery to him of all unlawful repetitions, copies, and imitations, and negatives of photographs, or may recover damages for the retention or conversion thereof: provided that nothing herein contained, nor any proceeding, conviction, or judgment, for any act hereby forbidden, shall affect any remedy which any person aggrieved by such act may be entitled to either at law or in equity.

12. This Act shall be considered as including the provisions of the Act passed in the session of Parliament held in the seventh and eighth years of her present Majesty, intituled, "An Act to amend the Law relating to the International Copyright," in the same manner as if such provisions were part of this Act.

## CEMENT FOR GLASS, CHINA, AND EARTHENWARE.

Order and economy are both necessary properties in the routine of any business or art, and more especially so where operations are performed by seconds, or marred in the same short time. The photographer must, of all men, be disciplined to order, if success in the art, or in a financial point of view, be his aim; he must also be economical in all his operations, because he manipulates with materials of the most costly nature—more costly than gold or silver; and also because competition has reduced the honourable profits of the art lower than those of the lowest artizan. It will be the aim, therefore of this Journal to embrace every opportunity of introducing into its pages whatever may tend to economise.

It is very disagreeable to break any of your dishes or baths; but then, it is very gratifying to know how to repair them, and to repair them effectually; moreover, to have a recipe for a cement for glass or earthenware equal to the best in the market, by the aid of which, when all other things fail, you may enrich yourselves as *pedlars*. Pardon the insinuation—and now to the point.

Take one ounce of isinglass, such as is used for clearing wines, that is to say of the best quality, and steep it in rain-water until it is thoroughly expanded; after this point has been arrived at, the water is poured off, and then a sufficient quantity of alcohol is added so as just to cover the isinglass, which, by the application of a gentle warmth, is by degrees dissolved. In another vessel take three ounces of alcohol, and, by a similar application of heat, dissolve therein one ounce of powdered gum mastic. The two solutions are then mixed together, and to these add one ounce of gum ammoniac already reduced into small particles, either by the knife or the mortar. By heat and frequent shaking this gum also dissolves; the solution or mixture is then evaporated to the consistency of ordinary glue, which is used for veneering, or similar purposes. It is then poured into small bottles for future use.

When about to use this cement, the bottle containing it is placed in warm water, or on a thin layer of wood or cardboard on the stove, by which means the cement becomes fluid. The fractured surfaces, if not thoroughly clean, must be well washed, first with soap and water, and afterwards with alcohol, but if the vessel has been newly broken it is not necessary to take this precaution. The edges of the broken parts are next warmed, and then the glue is applied; the pieces are now brought into apposition and kept there until the glue has thoroughly concreted, which will take place in a few days. All the articles used in this cement have to be the purest and best of their kind in order to succeed in its preparation satisfactorily; but it can certainly be relied upon when so prepared.—*Humphrey's Journal*,

## A NEW RAPID DRY PROCESS.

BY E. BORDA.*

Mr. Editor.—As you no doubt inferred from my last comunication to you, I was far from satisfied with the instantaneity of the tannin plate, developed after soaking it in warm water. It was a great step forward, rendering the tannin plate as quick as the generality of wet plates, and its usefulness must have been felt by many in more than one respect: to me it was an auxiliary in one way, of a stimulant, in another; an auxiliary by enabling me to bring out of a tannin plate, not sufficiently exposed for ordinary development, more details in the shadows, avoiding at the same time the solarization near the high lights, which takes place in a view offering great contrasts, when the exposure is sufficiently prolonged to secure details in the shadows; a stimulant, by leading to the supposition that during the shortest exposure, the light had likely performed its share on any sensitive film, and that to render the film sufficiently penetrable to the developer was the true way to obtain a quick dry plate. My last experiments seem to confirm this hypothesis, although contrary to the conclusion of Mr. Sutton, that free nitrate of silver in the pores of the collodion was necessary; Mr. Sutton may be correct that far, that such condition may lead to an instantaneous dry plate, but I do not believe it to be a *sine qua non.*

I am indebted to Mr. H. T. Anthony for a suggestion which has given me results in rapid dry plates, far beyond what I have been able to obtain with warm water. Mr. Anthony, amongst numerous valuable hints which he has freely and generously given to me, stated that some years ago he had submitted a dry plate to the action of ammonia, and obtained with it a good negative with very short exposure. It was shortly after the warm water process was made public that Mr. Anthony suggested to me to try the warm water, and fuming by ammonia combined.

I first tried the fuming alone, and on a tannin plate; the acceleration was remarkable. I obtained with it, at the start, quicker plates than with warm water, by fully one-third. I soon ascertained also that it was not necessary to fume the plate before exposure, but merely before development; rendering the process more valuable for fieldwork, as it is doubtful whether a plate fumed with ammonia would keep; but when I proceeded to add the acceleration by warm water to the fuming, I was disappointed. Both had an accelerating effect, separately, but the result of their combined actions was not the same of the two; nor indeed could I detect any acceleration on the fumed plate, by developing it warm. The film covered with tannin became very tender, and had a tendency to fog, which any amount of acid did not appear to check, and as far as my own work was concerned, I substituted the fuming to the warm water development, when I desired to accelerate a plate, as more controllable, simpler, and requiring less exposure. I merely speak of results in my hands, and would much rejoice to know that others are trying it thoroughly. While making the experiments above mentioned, it happened several times that a tannin plate, from which the free nitrate could not have been washed off thoroughly, gave me a faint image of the high lights, when soaked in warm water, after fuming with ammonia, and before any developer was used. The quantity of free nitrate must have been excessively small, for I wash my plates very carefully, and am not troubled with the spots arising from an imperfectly washed plate. I would have been tempted to attribute it to some other cause, if it had invariably occurred; but it was only occasionally, some of the plates not giving the slightest trace of an image before the developer with silver was poured on. Nor could it be caused by over-exposure, the same plates failing from under-exposure, as I was trying to obtain negatives by very short exposure, and with a supposed combined acceleration, resulting from joined actions of water and ammonia on the film. This fact might confirm Mr. Sutton's theory, when removing from it its objectionable conclusion, that the free nitrate of silver in the film is the only mode of securing the quick dry plate. Is it not possible that, by leaving in the film a certain proportion of free nitrate of silver, such as is left on a Fothergill plate, an image can be obtained sufficiently intense, with the addition of fuming with ammonia and warm water, with very little development, or no development at all?

The fuming with ammonia, like the warm water, is to be regulated by experience, and it is impossible to give any more than general rules. Every operator must depend a good deal on his own judgment. The strength of the ammoniacal solution itself varies very much, as well as the size of the box in which the fuming takes place. For a tannin plate, exposed fifteen to twenty seconds, with one-eighth inch diaphragm, by a clear day (I allude to landscape photography), I fume the plate from five to six minutes, in a box about two cubic feet in capacity; using one ounce of concentrated solution of ammonia, placed in a flat dish in the bottom of the box. By a little fan at the top, moved by a crank at the outside, I equallize the amount of ammonia through the box. The more the plate is fumed, the more citric acid must be used in the developer, to prevent the formation of a deposit which ruins the negative. I even fume plates exposed two, three, and occasionally five minutes, with the view of bringing out details in the shadows. When the plate is almost sufficiently exposed for ordinary development, I regulate the fuming accordingly. I sometimes confine it to one minute, using one ounce of the concentrated solution, diluted with two or three times its volume of water, or some ammonia solution which has already been used for the same purpose, and has lost much of its strength. When the plate has been but shortly exposed and fully fumed, it develops blue black, and the more it has been exposed the more purple it gets; when very purple, care must be used to not over-develop. With distant hills a couple of minutes exposure, and pretty good fuming, is preferable, in order to secure good clear distances. If there is no great distance, and no bright sky likely to solarize the top of trees, &c., more exposure and less fuming is preferable; the older the collodion the less solarization is to fear. When I wish to secure clouds, I reduce the exposure to a few seconds, and rely on plenty of fuming and a good dose of citric acid. I never begin to develop a plate (seven by four) with more than one drop of a ten-grain solution of nitrate of silver, and to each drop of silver I use one drop of a sixty-grain solution of citric acid, for a plate fully exposed and not fumed; if fumed slightly, two drops of citric acid; if shortly exposed and fumed fully, five to six drops, and a proportionate quantity of citric acid for intermediate exposures and fumings.

My experiments with fuming did not stop with the tannin plate. I thought it too valuable not to apply it to other processes, and it naturally occurred to me to try some dry process quicker than the tannin: I tried the resin process, and first on its own merits; I succeeded with it beyond all my expectations, and by a ramble in our mountains, in which I filled every one of my double dry plate holders with a tannin plate and a resin plate, duplicating each view; I ascertained beyond a doubt, that the resin plate was at least twice as quick as the tannin plate; the collodion was the same: the resin plate, with half the exposure, gave more softness and more details in the shadows. The fuming by ammonia accelerated the resin plate fully in proportion, and six to eight seconds gave me a good negative, where fully fifteen were required with the tannin. With a quarter tube of no diaphragm, I obtained with the resin plate, in one second, a negative full of details in the shadows. I tried the iron developer with the very short exposure, but it gave only a faint image, while, with pyrogallic acid, a sufficient intensity was easily attained. If I had the proper apparatus, I would try fuming by the gas ammonia as soon as it is prepared, in which state I imagine that its action is more energetic.

I have cautioned your readers against jumping too quick at conclusions and indulging too readily in the imaginary possession of a truly instantaneous dry process; to be consistent, I cannot give the resin plate fumed by gas ammonia as such, but that it is another great step towards it, I can state positively; my confidence arises from a series of progressive and systematic trials conscientiously done. I long to give the information through your paper, with the hope that others will take it up

* From the *American Journal of Photography*

and improve on my results. To Mr. H. T. Anthony all the credit is due for this simple and valuable discovery.

I will not close without adding a few words about the resin process. It has every possible quality, and but one fault, and that fault, I hope, can be removed. The plates are often filled with small round spots which do not develop, and cause black spots on the positive. As the plates I obtained from the collodion, but one day after the resin had been added, did not possess that fault to the same extent as those prepared with the same collodion a few days after, I am inclined to believe that there is a period, and a short one, during which the resinified collodion is just suited for the purpose. I only used one-quarter grain of common resin to ounce of collodion, and that such a small quantity should render an ordinary bromo-iodized collodion very sensitive dry, indicates that the action of resin is powerful, likely constant, and probably unfitting the collodion for use after a certain time. I do not hesitate to say that if this objection is removed, it will render that process the most valuable of dry processes so far known. The film possesses a remarkable toughness, which I cannot better illustrate than by stating that while wet, before fixing, and after development, it can be rubbed gently with the fingers with impunity. The plates are merely washed thoroughly, after being sensitized, and let dry spontaneously. I have not tested their keeping qualities beyond ten days. The silver bath used is the acidified forty-grain bath I use for tannin plates, the result everything that can be desired in softness, details, &c.—all, but the provoking little round transparent spots. Who will come to the rescue, and give us the resin process perfect? I have not given it up, but the more at it, the sooner it will be conquered.

*Woodside, July 8th*, 1862.

## Correspondence.

### OUR LIVERPOOL CONTEMPORARY.

[We must apologise to our readers and correspondents, for troubling them with a long letter from one of "the staff" of our contemporary, on a subject in reference to which we have declined to publish complimentary letters from our own friends. In such a case we prefer to strain courtesy a little, and allow Mr. Dawson to make his explanation, although he accompanies it by comments and opinions which we feel sure our readers neither endorse nor care about. We print his letter, however, and subjoin one or two remarks illustrative of its value.]

"Sir,—In your last week's article on 'Our Liverpool Contemporary' you have, I think, in your zeal to retaliate and attack, gone somewhat beyond the bounds of ordinary courtesy and discretion. Leaving the Editor of the *British Journal of Photography* to digest the rest of your article, I notice two passages affecting myself, which I cannot let pass without a word or two of explanation. You say 'The especial article we are charged with quoting, without due acknowledgment, was one by Mr. Dawson on Bromides. Now, weeks before that article was published our attention had been specially called to it in a private letter from Mr. Dawson, and we, in another letter, had promised to extract it when it appeared.' This statement would seem to imply an intention and object on my part, which I am sure I was far from entertaining. If my memory serves me right, these are the simple facts of the case. *After* my paper was in the publisher's hands, I, in replying to an urgent note of yours on another subject, incidentally mentioned that I had prepared for publication in the *British Journal of Photography*, an article on the bromides, in which my conclusions materially differed from yours. This is all I stated, and that, too incidentally, as I have said; and if you, in reply, which I do not recollect, threatened or *promised*, as you call it, to extract my article, that was no business of mine, for it had ceased to be my property the moment it passed into the hands of the publisher. Whether it was extracted with a proper recognition is also no business of mine.

"The other passage more indirectly referring to me, to which, in justice to myself, I am bound to allude, is this statement:—'It so happens, that at one of the photographic societies, the editor of our contemporary is the constant chairman: in this capacity he takes charge of, and systematically refuses to ourselves the permission to copy or make abstracts of the papers read at its meetings. It generally happens that we receive copies of such papers from the gentlemen who read them, &c.' Now, as I have occasion sometimes to read papers and act as chairman at the society referred to, and have constantly declined furnishing copies to any but the *British Journal of Photography*, I do not consider myself guilty of discourtesy, but am simply doing my duty to the society, in declining to furnish to others what is specially meant for publication in our own journal. In truth, the papers read at the meetings are the property of the society, and it has made arrangements with the proprietor of that journal, in consideration of certain advantages, of which its members all reap the benefit, to give him the right of prior publication. Reporters are allowed to be present, and are offered every facility for their work, as you must admit. They may record and publish as much or as little of the paper read as they please; but the *bona fide* copy is, as I have said, to be disposed of as the society sees fit. Any member, therefore, of the North London Photographic Society, who forwards a paper read there, to any other than the *British Journal of Photography*, may be doing a courteous act to that other journal, but certainly a very dishonest one to his own, in deliberately breaking a compact to which he is himself a party.

"My esteem for yourself personally, and a desire to set the matter in its true light, have prompted these short explanations in reply to a most sweeping charge of discourtesy, applicable to me as well as to others, and which I am sure your sense of justice must now at once admit, could only have been made through a misapprehension of the facts of the case.—Your, &c.,

"*Bath, July 28th*, 1862. George Dawson.

"Vice-President of the North London Photographic Society."

[To enable our readers to attach its right value to this letter, we print *the* letter to which reference has been made, and in doing so we appeal from Mr. Dawson with a purpose to serve, to Mr. Dawson free from such influence. Our "urgent letter" to which he refers was one making application for copy of a paper he had read at the North London Society. Here is his reply, which being a private letter we do not publish without his permission:—

"*King's College, Tuesday.*

"My dear Simpson,—I have not got any copy of the paper I read at the North London last Wednesday, but I daresay since you don't anticipate the journal, Mr. Shadbolt will have no objections to send you a proof. I have none.—Very truly yours,

"Geo. Dawson.

"P.S.—I have sent him also a short paper on the bromide question, on which I have formed opinions rather different from those usually entertained. I also attack ——* rather mildly.

"G. D."

We leave our readers to form their own opinion as to the intention of the postscript of this letter, calling our attention to the fact that the writer was about to take part in a friendly controversy then existing between the editor of the *Photographic Notes* and ourselves. As a fresh comer into the controversy we gave his remarks with every possible acknowledgment before we commented upon them. The quibble as to "threatening" or "promising" is unworthy of Mr. Dawson, as a promise could only be regarded as a threat if he felt his article unworthy of increased publicity.

Mr. Dawson drags in the North London Society and his position as chairman. We carefully avoided mentioning the name of any society in the matter, and should have preferred to continue doing so; and, we take leave now to doubt his right to enter without authority into this matter officially. We remember Mr. Dawson once to have been chairman at one of these meetings, in which capacity he neither granted nor refused us the paper, since he was never asked; he could not, then, by any possibility construe our remarks as referring to himself. As to his real opinion of our right to copies of papers, we refer to this note, in which it will be seen that there is not one word denying it, but an evident conviction that a proof should be furnished. We have never asked to anticipate the *Journal*, but simply to have facilities for coincident, or early subsequent publication. It is unnecessary here to enter further into the question of how far societies subserve the object of their existence, by becoming parties to narrowness and exclusiveness. We are happy to know that few of their members endorse such opinions, much less enter into a "compact" to aid and abet such a course.—Ed.]

* We suppress the name of the gentleman here mentioned, as it is unnecessary to drag him into the controversy.

## To Correspondents.

Old Photo., Liverpool, Vindex, B. L. G., H., W. H. W., and other correspondents incidentally alluding to the same subject, are thanked for their letters; but we are sure they will not take it amiss that they are not inserted. We are gratified by the expressions of interest and approval; and the desire to vindicate and praise the News; but the insertion of all the letters would nearly fill our pages, and would be only prolonging a squabble which we prefer to exclude from our pages. We make room for one or two extracts. Old Photo says: "Imitation is the sincerest flattery, and in this respect the *Liverpool Journal* is perpetually paying you practical compliments. There is scarcely an 'original' feature in your contemporary which is not an imitation of the News. When the News was first published it appeared in a quarto form, and straightway the *Liverpool Journal* merged from its octavo and expanded into quarto. The News commenced a series of articles on Colouring Photographs, and was followed by the *Liverpool Journal* with a similar series. The News issued a series of articles entitled 'The Amateur Mechanic,' and the *Liverpool Journal* followed with 'Photographers their own Artificers;' The News commenced a series of articles entitled the 'Dictionary of Photography,' the *Liverpool Journal* followed with the 'Photographic Glossary;' the News originated a column of gossiping fragments as 'Talk in the Studio,' and straightway the *British* was inundated with 'Scraps and Fragments,' '*Olla Podrida*,' '*Entremets*,' &c., &c.; the News commenced a series of articles on 'Photographic Chemicals,' and was followed in the *Liverpool Journal* by 'Notes on Photographic Chemicals.' I might extend the list, but I think this is sufficient to suggest to your readers and those of your contemporary, the value of his boasted originality." Quite enough we should think!

Fairplay says:—"I have just, by accident, come across a copy of the *British Journal of Photography*, in which I find a supposed dialogue between *Mr. Journal* and *Mrs. News*, stated to have been sent to the Editor of the *British* by one of their witty (Heaven save the mark) correspondents! Allow me to question the truth of that statement, and, at the same time, to protest against such a prostitution of the purposes of scientific journalism, as the insertion of such very unworthy productions. If a journal has to resort to the *Eatanswille Gazette* style of Billingsgate, in reviling a contemporary, it always appears to me as though there was something wrong in the financial department, and that these stale subterfuges are resorted to to raise the circulation. That the article has emanated from the pen of one whose "fine Roman hand" it is not hard to trace, and whose elephantine playfulness is unmistakable, there can be no doubt. I would just remark that the tone attributed to the News is but too surely the natural manner of expressing opinion, by the writer of the dialogue and his colleagues. There is, too certainly, the remains of that wooden dogmatism, which so often disfigures other columns in the *British*. 'Ourself' is, in fact, a personage who cannot so easily transform himself so entirely as to be taken for any one else. As to the charge brought against the News of copying, the less said the better. As an investigation as to the extent of cribbing generally, might turn out not to be quite so favourable to those who are so profuse in their charges, as would be desirable." As regards "cribbing," our Liverpool contemporary in his last number, in which he so loudly declaims against this practice, himself appropriates part of an article from the News without one word as to the source from which he "conveys" it. But we should fill our pages if we took the trouble to point out all his shortcomings.

F. M. S.—Mere fudge, as you suspect The act defines a newspaper as "any paper containing any public news, intelligence, or occurrences, or any remarks or observations thereon, printed in any part of the kingdom for sale, and published periodically, or in any parts or numbers, at intervals not exceeding twenty-six days between the publication of any two such papers, parts, or numbers." 2. We know nothing of any such phrase in the letter of a correspondent, nor do we care to seek it; the epithet in the case to which we referred was from the pen of the editor. 3. Your other conjectures are probably right, but it is really not worth while to go into the matter.

J. A. R.—We have not had much personal experience in travelling with photographic apparatus on the continent, but in such opportunities as we have had, no difficulty has arisen. We have just consulted a friend who has frequently visited the continent with photographic intent, who informs us that in Switzerland there is no trouble whatever; and very little anywhere if proper tact be used. It is advisable to have dry plates so packed that they may be slung over the shoulder, and at all times to push forward the camera under the attention of custom house officers first, as the object of that instrument is now pretty well understood by every one; other matters connected with photography will then be better explained and understood. It is advisable to have an inner cover of non-actinic glass to the box of prepared plates, in order to be able on emergency to verify your statement, without injuring the plates. Have also a full description of the object of the apparatus, on each article, in the language of the country.

Nil Desperandum.—A bath of protosulphate of iron may be used for developing negatives, but we prefer to pour on the solution, because in immersing the plate a certain proportion of the free nitrate on the plate is reduced *in* the solution instead of *on* the plate, and the image loses in density. If you prefer dipping, however, let the solution be a strong one, so that the development may be rapid. The use of a weak solution under such circumstances would be almost equivalent to washing the plate before developing. The strength should not be less than from 30 to 40 grains to the ounce, with an equal number of minims of acetic acid. The same solution may be used for positives, but it will not be good as a developer made expressly for positives, and containing a little protonitrate of iron, or a trace of nitric acid. A good developer for negatives, if you pour it on, is as follows:—

| | |
|---|---|
| Protosulphate of iron ... ... ... ... ... | 15 grains |
| Glacial acetic acid ... ... ... ... ... | 15 minims |
| Water (distilled) ... ... ... ... ... | 1 ounce. |

For positives, the same with one drop of nitric acid to each ounce may be used. Alcohol sufficient to make the solution flow properly, as a general rule 20 minims in each ounce. Wash away the iron thoroughly, and intensify with pyro 3 grains, citric acid 2 grains, water 1 ounce, and a few drops of a 20 grain solution of silver.

A. B. C.—The Photographic News Almanac is, we regret to say, out of print. Gold toning solution, made with acetate of soda and chloride of gold should not turn dark coloured, unless some decomposition have taken place, which might be produced by a variety of causes, but we cannot tell which, in your case. 2. Toning and fixing should be conducted in the dark-room. 3. For brushing silver solutions over paper, use a glass rod, or Buckle's brush. 4. In using a solution of iodine before pyrogallic acid and silver, for intensifying after fixing, it may be poured on the plate and left in the light a few minutes prior to washing off. 5. Disderi's "Art of Photography" is published in Paris at ten francs, by Leiber, 13, Rue de Seine. 6. Our pages abound with articles on intensifying, printing, toning, fixing, &c., but we cannot undertake to point out any one as absolutely "best," as each one given succeeds best in some hands, and different methods are best under different circumstances. Should we be able to procure a copy of the Almanac we will forward it: you will there find a complete and satisfactory epitome of those processes.

J. Lewis.—We do not know of any place where you can procure Poitevin's recent treatise in this country, but you can obtain it by ordering it through a foreign bookseller. We do not at this moment remember the price.

Doubtful.—If you use common water to make your developer, a turbidity from the formation of chloride of silver, might occur when the solution is poured on the plate. In that case the remedy would be to use distilled water. We suspect, however, that the white, floating particles to which you refer are not chloride of silver but white, sparkling particles of metallic silver, which in certain conditions of the bath, and in very hot weather, are apt to be reduced the moment the solution comes in contact with the plate. 2. The edge of your plate rapidly drying, arises probably from the use of a repellant, horny collodion. A drop of distilled water to each ounce of collodion will often prove a remedy. 3. We have rarely used any alcohol in the developer for years, either for positives or negatives, but methylated spirit. It answers perfectly, and in no way injures the tone of either. There is an objection felt by many to the use of methylated spirit for making collodion; but many commercial samples are made with it, and in one of the most popular positive collodions in the market nothing else is employed.

Pemberton.—The construction of photographic lenses is not a subject which can be treated popularly, nor would be of much use to photographers if it could. There is no work devoted to the subject; the principles involved are treated of in most works on optics, and in some works on natural philosophy, such as that of Dr. Golding Bird, Dicks' "Practical Astronomer," &c. Some popular information on the optics of photography would be very useful to many photographers, but the subject is difficult to popularize. For price, &c., of M. Disderi's work, see answer to A. B. C.

Honesty Good Policy.—See announcement on first page of the present number.

J. H. S.—We are not in possession of any further particulars beyond what Mr. McLachlan gives. A letter addressed to him at the Manchester Photographic Society, 36, George Street, Manchester, would reach him. The subject is, as you state, one of the most important in connection with the art, and Mr. McLachlan treats it as one who has considered it very intelligently. Your specimen enclosed is in many respects very pleasing.

Phos.—Your collodion or bath were probably turbid: the streaks have probably been caused by the silver solution, running in separate streams down the plate during exposure. The plate has not been exposed long enough. You appear to be using a simply iodized collodion; a bromo-iodized collodion, in inexperienced hands, will give much cleaner and better results.

W. J. C.—A good negative iodizer, for iron development, may be made as follows:—for each ounce of collodion 2½ grains iodide of cadmium, 2 grains iodide of ammonia, and from half a grain to a grain of bromide of cadmium, according to the character of the pyroxyline. If the latter be made at a high temperature, and with weak acids, a grain of bromide may be used with advantage. The collodion thus iodized will give harmonious negatives and keep well.

Fred. Power.—The tendency to reticulation in your negatives may be favoured by the character of the pyroxyline; but it probably chiefly arises from the presence of too much water in the solvents. The tendency existing, however, the best mode of getting rid of it will be found in using especial care to let the film set well always before immersion in the bath. If this fail the only plan will be to mix off the collodion with another sample having no such tendency. The picture is otherwise very good, and the tone fine.

C. E. L.—If you carefully observe *all* the precautions suggested in our last, you will not, we think, be troubled with the red deposit; but as it may proceed from different causes, all the precautions should be observed. We have not tried the keeping properties of honey and tannin, but have several times heard that they do not keep well. We shall be glad to hear the result of your morphine plates.

B. T. V.—We see no objection to the dimensions of your dark room, nor to the paper for it, of which sample was enclosed. Blue is not a good colour for the roof. The design of your glass room appears to be similar to that of Mr. Fitch's, described some months ago. As a matter of choice we prefer some side light, and no front light. Tiffany is scarcely a suitable material for blinds, as it will not keep out direct sunlight. We were not aware of the price of the prepared silk. It does seem rather high; but we cannot tell whether it is possible to make it cheaper.

No. 35.—Stereo lenses on the triple construction will doubtless be valuable as regards extent of angle. The compound stereo lenses in existence, however, include a wide angle; it is only when using portrait lenses of seven or eight inches focus, such as you mentioned, that you need to retire so far back. To include much subject in stereo pictures you must use lenses of somewhat short focus; and such lenses are scarcely well suited for *cartes de visite*.

W. W.—There is a little looseness of statement in the remarks you quote from the writer in our contemporary. A print is scarcely likely to contain much free nitrate of silver after toning in an alkaline gold solution.

Actinic.—You will find a report upon your glass in another column. The mode of ventilating a dark room must depend largely upon its construction, but our plan is simply to leave door and window open between the intervals of manipulation.

G. W. Hill.—Thank you for the description of your method of producing transparencies, which shall appear shortly. The card portraits are brilliant, vigorous, round, and well modelled.

Several Correspondents in our next.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 206.—*August* 15, 1862.

## A FEW WORDS ABOUT TONING.

Notwithstanding all that has been written about toning during the last few years, much uncertainty both in theory and practice still prevails; and notwithstanding all the remedies which have been suggested, slaty tones, irregular tones, and the difficulty of getting any tones at all, at times continue to perplex both amateur and professional photographers. There can be no doubt that the various remedies proposed, such as the ammonia-nitrate silver bath, the bath of acetate of soda, &c., have proved beneficial in many instances, and have mitigated, if they have not entirely removed the evils they were intended to cure. Still the subject is of so much importance, and beset with so much uncertainty, that every practical suggestion in connection with it is eagerly sought after. We are not now about to enter into any fresh discussion of the theory of alkaline gold toning, but to lay before our readers a few hints which will prove interesting even if they fail to be instructive.

It may be within the knowledge of some of our readers, that many of the prints of the late Mr. Lacy of Ryde, were distinguished by a rich black tone, and freedom from mealiness, and that this tone was said to be due to the use of a toning process the formula of which was a secret. This was indeed the fact. Mr. Lacy, when in Paris at the beginning of last summer, being greatly struck with the rich tones of the pictures issued by M. Ken, made overtures to him or his printer, for information as to the method of producing them. The tones were said to be due to a secret process, and a sum of one thousand francs (£40) was demanded for the recipe. Finally Mr. Lacy agreed to give five hundred francs (£20) for the information, and received it. A formula for which he paid thus heavily, he very naturally wished to preserve for his own especial benefit, and he did so. During the first few weeks of trying it, he found much difficulty in obtaining anything like perfect results. He persevered, however, and finally succeeded to his complete satisfaction. The prints of which we have some before us, were certainly very fine; the tones of a rich deep neutral tint, or warm black, altogether free from redness or inkiness, and there was, for the most part, an entire immunity from mealiness.

Knowing that Mr. Lacy had paid thus highly for the formula, we did not ask any questions as to its composition. A very superficial examination, however, of a bottle of the solution placed in our hands, convinced us there was not much novelty in the matter, that the solution was, in fact, prepared by some modification of a well-known formula, which, by a singular inadvertence in a highly intelligent photographer and a careful reader of the journals, had escaped his attention. Mr. Lacy subsequently detailed the particulars to us, with a promise to communicate them at some time, together with the result of his experience in the matter, for the benefit of our readers. His untimely death prevented the possibility of this promise being performed, and at the same time exonerates us from any necessity of preserving the secret of which we were the repository. We are now, therefore, at liberty to state what we know on the subject. As our readers will have gleaned, so far as the formula is concerned, we have no great secret to communicate; but there are, nevertheless, a few hints in connection with it, which may be instructive as well as interesting.

The formula was substantially that of Legray, with chloride of lime added to chloride of gold. It may be stated simply thus:

| | | |
|---|---|---|
| Chloride of gold ... | ... | 2 grains |
| Chloride of lime, from | 2 to 4 | „ |
| Water ... ... | ... | 1 pint |

The exact proportion of water was not always strictly regarded. The usual method adopted was to dissolve the bottle of gold, containing fifteen grains, in a pint of water, and add twenty grains of chloride of lime. The solution was kept in this state, and subsequently diluted for use by placing in a bottle which was filled up with water: the bottle was stated to hold a gallon, but, from our own observation, we should conceive it did not hold more than six pints. This was the toning solution for use.

So far the process is nearly identical with that originally proposed by M. Legray, which will be found on p. 213 of our first volume, and repeatedly given with modifications since. The essentially valuable part of the instructions consisted in defining the age at which the solution was to be used. This bath used immediately, or soon after its mixture, gave the worst possible results. The prints were always impoverished; if they remained long in the bath they became slaty and grey, if a short time, they were brown and red, and in each case were mealy and flat. The great secret of success consisted in keeping the solution a proper time, after mixing, before using it for toning purposes. The shortest time in which it acquired the proper qualities was eight days, and it was stated to go on improving for a month longer. It might be used, however, with advantage, at any age, from eight days to five weeks. The prints were excited in a strong silver bath, a little over-printed, washed, but not with any especial care, toned in the solution just given, washed again, and fixed in fresh hypo. The results were generally as we have already stated—fine, black, vigorous prints.

A few words may be said regarding the keeping of alkaline gold solutions. The result of adding carbonate of soda to a solution of chloride of gold is a double decomposition, in which a peroxide of gold or auric acid is formed, which, Hardwich states, is capable of uniting with excess of alkali, forming a colourless solution. The same reaction takes place when several other of the soda salts are added. This colourless solution, although it is usually found to be comparatively inert in toning, yet generally gives the best results if the toning action be once set up. A solution of chloride of gold, with carbonate of soda added, will often refuse to tone if it have been mixed a few hours; but if a trace of fresh chloride of gold be added, the toning will go on rapidly and satisfactorily. The solutions of gold with the acetate and phosphate of soda generally work better after having been made a few days, a much greater immunity from the tendency to mealiness being the general result. It is somewhat singular that, with the addition of chloride of lime, which is more strongly alkaline than either of these, which generally have a feebly alkaline reaction, the toning properties of the solution should continue for several weeks unimpaired. The change which takes place is difficult to determine, but it is probable that the effect of age on toning solutions is a question which would repay further experiment.

Mr. Lacy was satisfied that the improvement in tone, and freedom from mealiness which he obtained, were worth the twenty pounds he had expended; but it is only fair to state that one or two who have tried the formula have not found any especial advantage in it. Whether the unquestionably good tone he obtained were due to the method, or to the perseverance with which he worked it out, we cannot undertake to state. But to whichever cause it was due, the twenty pound recipe is now the property of our readers. We do not generally attribute much importance to secret nostrums, although we do not doubt for one moment the right of an investigator to be paid for his trouble. As a commentary, however, upon the practice of buying and selling secrets, we may mention one anecdote which recently came under our notice. A certain printer boasted that the good qualities of a batch of prints, which turned out unusually fine and brilliant, were due to a little discovery of his own, which he would reveal for a consideration. His employer, willing to remunerate him for his discovery, gave him a guinea to disclose it. The revelation was made: a pin had accidentally dropped into the silver bath and turned it green: all the prints turned out fine; the operation was repeated with like success. And the pin was the cause of it all! That was the secret. We have heard the addition, to the silver bath, of nitrate of copper recommended as an aid to toning, but only in this instance the addition of the compounds of tin, copper, &c., which are found in a pin. Still some photographers are fond of the use of empirical nostrums; those who like may try this one.

## PHOTOGRAPHIC CHEMICALS:

### Their Manufacture, Adulteration, and Analysis.

*Potassium Salts* (continued).—*Lactate of Potash.*—This salt is formed by the direct union of lactic acid with either caustic, or carbonate of potash. Compounds of this acid have, on several occasions, been employed in photography, and, owing to the silver salt being soluble in water as well as sensitive to light, there is little doubt that future experimenters will derive considerable benefit from a more thorough examination of the photographic value of the salts of this acid. Lactic acid is a very common product of vegetable, or animal decomposition; it is contained in sour milk, and is formed by inducing a particular kind of fermentation in solutions of glucose, or common sugar. The processes of preparing lactic acid are rather complicated, and to persons unaccustomed to organic chemistry, somewhat repulsive. One of the easiest processes for preparing it is to keep milk until it has became sour; the whey is then separated from the curd by filtration, and the clear liquid evaporated down over the water bath, until it is reduced to about one-eighth of its original bulk. If any more curd be separated during the evaporation, it must be filtered off a second time. Lime water must now be added, until the phosphoric acid is all precipitated; the base being introduced in slight excess. The precipitated phosphate of lime is now to be filtered off, and the filtrate diluted with three times its bulk of water. A solution of oxalic acid is now to be added, a few drops at a time, until the lime is all precipitated, avoiding excess of the acid; the oxalate of lime is filtered off, and the aqueous solution evaporated to the consistency of honey. The viscid mass is next mixed with four times its bulk of alcohol, and heated: the lactic acid will be taken up by the spirit, leaving most of the impurities behind. Filter from the insoluble portion, and mix the filtrate with water; upon evaporating this over a water bath lactic acid will be left behind. Another process, which is better when preparing the acid in quantity, is to mix together in a gallon stoneware jar two hundred and fifty grammes of milk sugar, two hundred grammes of powdered chalk, one quart of skimmed milk, and sufficient water to fill the jar. The mixture is then placed on a sand bath, or in some warm place where it can be kept at a uniform temperature of between 25° and 30° C. It must be frequently stirred, and fresh water added to it, to supply that lost by evaporation. Fermentation will take place with evolution of carbonic acid. In about twelve days the evolution of gas ceases, a sour and cheese-like odour will be perceptible, and the chalk powder will have become granular. When this point has arrived, the contents of the jar are emptied out into an enamelled saucepan, and boiled for a quarter of an hour. It must then be strained through flannel, and the residue well washed with boiling water. The whole of the liquid must be filtered through paper until it is quite clear, and then evaporated at a gentle heat over a water bath. When it has become reduced to a fraction of its original bulk, allow it to cool, and set it on one side for twenty-four hours. At the end of that time a considerable quantity of lactate of lime will have crystallized out, and upon separating this from the mother liquor, and evaporating the latter to a still smaller bulk, a fresh quantity of lactate of lime separates. The whole of these deposits are then to be strongly pressed between canvass. If the operation has been conducted properly, the product will amount to 350 grammes. The separation of lactic acid from the lime salt has now to be effected; for this purpose, oil of vitriol is diluted with six times its bulk of water, and the lactate of lime decomposed by a slight excess of this diluted acid; alcohol is added to the mixture, and the precipitated sulphate of lime filtered off; the clear liquid now contains a mixture of lactic acid with a little sulphuric acid; in order to separate the sulphuric acid, a little previously prepared lactate of lead is to be added, and boiled with it. The sulphate of lead is separated by filtration, and the trace of lead in excess removed by sulphuretted hydrogen. Upon evaporating the clear solution over the water bath, lactic acid will be left behind. It forms a colourless syrup, inodorous and of an intolerably biting pure acid taste; it decomposes when heated. Upon adding to the diluted acid carbonate of potash, and evaporating, a very difficultly crystallizable salt is obtained, which is soluble in water and in alcohol. This is the potash salt, which may be used to prepare the other less soluble salts of this acid.

*Ferro-cyanide of Potassium.*—The photographic value of this salt has been investigated by Mr. Robert Hunt, who, as early as the year 1841, described a photographic process in which it was used in conjunction with iodide of silver. In a communication which he made to the Chemical Section of the British Association, at Plymouth, in that year, he stated that when paper, prepared with the iodide of silver, as in the ordinary Talbotype process, was washed over with a solution of ferro-cyanide of potassium, it blackened instantly on being exposed to the sun's rays. This effect, Mr. Hunt proceeds, will take place with the greatest rapidity when the iodide of silver on the paper is as free from admixture as possible. Perfectly pure iodide of silver, it is well known, does not appear to undergo any change by exposure to light, but if, upon some pure iodide of silver, spread out on glass and exposed to sunshine, a little solution of ferro-cyanide of potassium is dropped, an instantaneous darkening will take place, which extends in different degrees over the whole space moistened by that salt.

The preparation of ferro-cyanide of potassium illustrates, in a remarkable manner, the wonderful powers which modern chemistry possesses, of transmuting substances, apparently the most worthless and repulsive, into products of the utmost purity and beauty. For its manufacture scarcely anything is used except substances which are too waste and too refuse to be employed for any other purpose; for instance, the horns and hoofs of cattle, clippings of leather, the cast off woollen garments of the inhabitants of the sister isle, blood and offal, and similar kinds of refuse are mixed up with crude pearl ash obtained from the combustion of wood, and with scraps of iron, hoops from beer barrels, old iron horse shoes, or any other old iron that can be obtained; the whole is then fused together in an iron pot until the nitrogen and carbon, potash and iron, have rearranged themselves in a different manner; the mixture is then lixiviated with hot water, and metallic iron or sulphide of iron added to the mass. After standing some time at the boiling temperature, it is filtered and evaporated to the crystallizing point. The ferro-cyanide will separate upon cooling. Commercial ferro-cyanide of potassium is often contaminated with carbonate and sulphate of potash. It may be purified by dissolving it in the smallest possible quantity of hot water, filtering and allowing the liquid to cool; sulphate of potash, with part of the ferro-cyanide crystallizes out, the mother liquor is decanted and mixed with its own bulk of alcohol; ferro-cyanide of potassium will be precipitated in the form of a white powder, this must be filtered, washed with alcohol, and then crystallized from water. It forms brilliant lemon-yellow crystals, belonging to the prismatic system, they are soft, and somewhat flexible, and quite permanent in the air. When finely powdered and heated for some time to the boiling point of water, it loses three equivalents of water and becomes converted to a white powder or friable mass, inodorous, and having a sweetish, saline, somewhat bitter taste. It fuses at a heat a little below redness, giving off nitrogen gas, and leaving a mixture of cyanide of potassium and bi-carbide of iron. On this account ferro-cyanide of potassium is a very excellent reducing agent, and would serve well for the reduction of silver residues to the metallic state. When dissolved in water and exposed to the light, it is decomposed with separation of prussian blue: it is owing to this reaction that the reagent bottles, containing ferro-cyanide of potassium, in chemical laboratories, are generally discoloured blue. Ferro-cyanide of potassium dissolves readily in water, forming a pale yellow solution, and is more soluble in hot than cold water.

## The International Exhibition.

### BRITISH PHOTOGRAPHIC DEPARTMENT.—APPARATUS.

The display of photographic apparatus in Class XIV., at the International Exhibition, comprises some of the very best mechanical appliances for the practice of the art which can be conceived, and we question very much, if, for ingenuity of design, quality of material, and excellence of workmanship, it could be, as a whole, equalled in the world. The fact that cabinet work, much of it hastily prepared at the last moment, should have stood uninjured the heat of an apartment, equalling, at times, the temperature of the tropics, the direct rays of the sun for some weeks, until an awning was provided, being superadded, speaks in the strongest terms for the thorough seasoning, and careful workmanship, especially when it is remembered that not all the objects exhibited could have been prepared for use in a tropical climate. There are not, however, many special novelties with which the public were not previously acquainted; nor, indeed, is every branch of the art represented, as we do not remember to have seen a single solar camera.

There are about five-and-twenty exhibitors of apparatus: the catalogue contains a few more names and numbers, for which no corresponding contributions are to be found. The articles exhibited are cameras of all kinds, lenses, camera stands, baths, &c.; dark tents, and manipulation chambers; rolling presses, head-rests, and a few other small articles. The majority of the contributions are in enclosed glass cases; some having descriptive cards attached, a plan we should commend to all exhibitors. It would be manifestly out of place here to enter into any detailed criticism of articles which can only be generally examined, and not tested; we shall briefly refer to the general characteristics of the contributions, only entering, where the novelty or importance of the article demands it, into more detailed description.

Mr. Austen (3,033) exhibits the contributions of a machinist to photographic apparatus, in the shape of rolling presses, camera stands, and head-rests of metal. A rolling press for cards consists of two rollers, without any plate: we have not tried this form of press, but it is maintained by some that a more perfect pressure is obtained when the card passes between two polished rollers, than where a burnished plate is interposed. A larger rolling press, by Mr. Austen, is chiefly distinguished by the fact, that, instead of having a steel plate resting on a bed of wood, the plate itself consists of a thick, solid piece of cast metal. A very ingenious and solid-looking camera stand, made entirely of metal, with every form of motion, is also exhibited. There are some metal head-rests for standing figures, which look firm and steady. One of these, however, strikes us as very bad in principle: instead of depending for its firmness, as a support to the head, upon the weight and breadth of its base, it is screwed down to the ground. This, of course, keeps it always in one place, and it inevitably follows that the head must be "backed" into the rest, instead of the rest being placed so as to gently support the head, after it has assumed an easy and natural position. One of the causes of the appearance of constraint in many photographic portraits arises from the injudicious management of the head-rest, even where it is moveable; but if the rest be immoveable, this constraint must be an inevitable result. The object in the present instance is, we presume, to facilitate the concealing of the head-rest, the base of which often awkwardly obtrudes in standing figures of gentlemen; but there are better modes of meeting the difficulty than this, which is entirely inadmissible.

Messrs. Bland and Co. have a good display of apparatus, one of the noticeable circumstances in connection with which is the fact, that a large portion of the articles are intended for use in India, and tropical climates generally. These include every form of camera, both for the operating-room and the field, and comprise every modern improvement in design and workmanship. A "new universal camera" is arranged for stereoscopic and *carte de visite* pictures, with wet or dry plates, facilities for carrying half-a-dozen of the latter being provided. Amongst other conveniences which this camera possesses, is an arrangement for sliding the lenses into the body of the camera, which then packs up into a compact square parcel. A small chemical chest with a selection of bottles, developing cups, dishes, &c., is provided to accompany this camera, which is invented by Mr. C. D. Smith. Some water-tight baths have a convenient arrangement in the form of a door near the bottom of the outer case of mahogany, which enables the operator to examine the condition of the solution in the glass bath, when turbidity or deposit is suspected. Some flat baths for exciting plates with a small quantity of solution; a collodion filter, Keene's metal boxes, with gutta-percha grooves for dry plates; and samples of Keene's and Ponting's collodion, complete the equipment of Messrs. Bland and Co's. well-arranged case. In referring to the collodion by Mr. Ponting, for which a medal was awarded, we may remark that we have recently tried a sample of his new bromo-iodized collodion, and are much pleased with its qualities, instantaneous exposure with a portrait lens giving a good negative, in which sufficient density was obtained by iron development only.

Messrs. Bull, Brothers (3053), exhibit a variety of photographic profile accessories, and pictorial backgrounds. The legitimacy of these accessories has been the subject of some little discussion. A practical answer might be given to those who challenge them, by stating that the immense demand for them proved that they were what photographers wanted. Whilst there can be no doubt, however, that they can be misused, such misuse is no argument against their proper use. They require using with judgment and taste, and in their proper place can be made very effective. The designs are in many instances good: perhaps both in some of the profiles and the backgrounds, if the lines were softer and the contrasts a little less definitely pronounced, the result would be better. Messrs. Bull very naturally tell us, however, in reply to any such suggestion, that they are quite ready to adopt it for those who desire it, but that the mass of those who use them demand sharply cut outlines, and vigorously marked lights and shadows. Some of the highest art authorities amongst photographers, such as Mr. Rejlander, for instance, entirely condemn the painted background, as an illegitimate mingling of the unrealities of conventional art with the truth of photography, which must ever result in incongruity. So long, however, as the demand exists among the public for photographs with pictorial backgrounds, so long will professional photographers necessarily produce them, and so long will scenic artists paint just the designs which are required by photographers. Messrs. Bull display an immense variety of designs both in backgrounds and accessories.

## BRITISH PHOTOGRAPHIC DEPARTMENT.

The *Times* has an excellent article on British Photography, speaking of this and the Educational Department contiguous, it says:—"Both these classes are far better worth a visit than many others which receive more notice. The visitor will find the staircase which gives access to them in the centre tower, between the picture galleries over the entrance from the Cromwell-road. Photography may be said to be an entirely new class since 1851; indeed, the art itself can scarcely be said to have existed at that time, if we compare it with its now universal spread. It is true we had then the Daguerreotype and the Talbotype, the former the only process sufficiently rapid to take portraits, and the latter only suited to views and objects admitting of long exposure to the camera. We all remember the very beautiful specimens of both these processes exhibited in the building in Hyde Park. They were, however, few in number, and exhibited as mere adjuncts of the philosophical instruments. In 1851 Archer invented the collodion process, and this has given rise to the marvellous development of the art of late years. The Daguerreotype, however exquisite in its details (probably even now unsurpassed by any process), had an unpleasant leaden hue, and gave a ghastly appearance to the picture. The Talbotype, owing to the negative being on paper, was subject to all the imperfections of texture; and though, when great care was bestowed on the manipulation, charming pictures were produced, the art had no commercial value, and it remained in the hands of a very few amateurs. The Exhibition of 1851 showed what was doing, for hitherto the workers had carried on their labours without knowing what others were employed upon, and this, combined with Archer's invention, gave a great impulse to the art. The Society of Arts established and held in the Adelphi the first photographic exhibition, and this led to the formation of the Photographic Society of London, the parent of the innumerable photographic societies existing all over the Kingdom. By the collodion process the extremest rapidity was obtained, the imperfection of the texture of the paper got rid of, and the power of multiplying copies to any extent, at a cheap rate, was achieved. Hence photography at once took a commercial standing, and photographers multiplied in all directions. With this the adaptation of the art to an infinite variety of purpose rose up in all directions. Mr. Charles Vignoles was, it is believed, the first to turn it to account for engineering purposes. Having large works in Russia, he had photographs sent him periodically of their progress, and copies were also sent to the Emperor Nicholas. Such reports could not be "cooked," and the Emperor saw literally with his own eyes what was doing. Astronomers have turned the art to account, and Mr. Warren De la Rue this year has received the gold medal of the Royal Astronomical Society—the highest honour it can bestow—for the perfection to which he has brought the art in this direction, and for the valuable addition to science which he has made by its aid.

"The Commissioners for the present Exhibition seemed to have been puzzled in what class to place it, and at last decided to give it a class to itself, and, fearing to give it a position in Section IV. (Fine Arts), placed it in Section II., as a sort of branch of philosophical instruments. This gave great offence to the lovers of the art, and the Council of the Photographic Society of London, whose assistance had been invoked by the Commissioners, after a long correspondence, flatly refused to give, as a body, any aid whatever in the matter. Some few persons, having at heart the interest of the Exhibition and of their art, and not wishing that English photography should be imperfectly shown, took the matter up, and a committee was formed. The result will show, notwithstanding the very inadequate space which the Commissioners have been able to allot for the display of the art, that British photography need fear no comparison with its Continental rivals. The landscapes of Bedford, Mudd, Robinson, the Earl of Caithness, Vernon Heath, Lady Jocelyn, Cundall and Downes, and a host of others, attest a supremacy in the art which, we venture to assert, very few, if any, Continental rivals will dispute. C. Thurston Thompson and Caldesi show gigantic photographs of the cartoons of Raffaelle, which are wonderful as masterpieces of manipulation. In portraits, the well-known names of Williams, Claudet, Mayall, Lock and Whitfield, Mayer, Dolamore and Bullock, Maull and Polyblank, &c., as exhibitors, give assurance of that branch of the art being well represented. Their coloured photographs are in reality miniatures, being so worked by hand as to leave no trace of the photograph. Doubts at one time existed as to whether these should be admitted in this class, but, inasmuch as they are founded on the photograph, it was thought desirable to allow their introduction. Photography has completely destroyed miniature painting proper; hence it was but fair that the new art of converting photographs into miniatures should be represented. Very charming and artistic are some of the specimens shown, but photographs these are not. One of the great drawbacks in photography has been the liability of the specimens to fade or change colour, and sometimes absolutely disappear: hence great efforts have been made by chemists and photographers to get some process in manipulation which should defeat this enemy of the art. The result has been that photographs, when carefully and honestly prepared, and preserved with ordinary care, are now very fairly permanent—probably as permanent as a water-colour drawing. Many trials have been made to produce in printers' ink or carbon a print from a photograph, which would thus have all the permanency of an engraving, and some very charming results have been produced; but hitherto—probably from expense, uncertainty, or difficulty in manipulation—none have come into general use. Negretti and Zambra exhibit transparent photographs on glass, similar to those well-known productions of Ferrier of Paris, than which none were thought finer till Negretti and Zambra entered the field against them. Enlarged photographs are shown by Claudet and others, which are life-sized, and some of them coloured; the latter, however, can scarcely be called photographs—they are simply a result of photography. Paul Pretsch, Pouncey, John Field, and F. Joubert, contribute specimens of this class.

"Colonel Sir Henry James, director of the Ordnance Survey, shows specimens of a very valuable adaptation of the art, by which the Government saves many thousands a year in the operations of his department, in the reduction, enlarging, and printing of maps and plans. It is termed "photozincography," and the results are extremely beautiful and interesting. Sir Henry shows adaptations of it to the production of fac-similes of ancient MS., and one of a page of Domesday Book is shown. The photograph, by a simple and cheap process, is transferred to a zinc plate, whence any number of copies can be taken off by the ordinary plate-printing press.

"F. Joubert exhibits a series of very beautiful pictures burnt in on glass, a marvellous adaptation of the photographic art in an absolutely new direction; and here perfect permanency is obtained, at least so long as the glass will last. By a pure photographic process he produces on the glass, in ceramic colours, a picture, which by exposure to heat in the furnace becomes burnt in like any other picture on glass or china. By a careful and artistic manipulation he has been able to produce effects in several colours. The process has been perfected, and a cheap and artistic ornamentation of our windows, whether in portraits of our friends, landscapes of familiar scenes, architectural objects, or statuary, is brought within the means of the many.

"Mingled with the photographs, and closely packed on the small floor space allotted for their display, are the instruments and appliances used in the art. In lenses, on which the artist is so greatly dependent, there has been great progress made since 1851. Ross and Dallmeyer show some very fine specimens—marvellous proofs of a combination of methematical theory with the skilful development of the practical optician; Horne and Thornethwaite, veterans in the field of photography; Murray and Heath, Bland and Co., attest what the English can do as makers of apparatus. All sides show a host of contrivances thoroughly unintelligible to the uninitiated, but seemingly contrived with great ingenuity for extemporizing a laboratory, workshop, and dark room, wherever the labours of the photographer may carry him. One firm shows specimens of albumenized paper, an article much in use by the photographer, and it is said that this firm alone (and it is only one of a legion of others) uses for this purpose annually half a million of hen's eggs.

"Class 14 has a high position in the building, and, though only to be reached by overcoming the labour of a long staircase, will, we venture to say, well repay the toil of the undertaking."

## DIRECT COLLODION POSITIVES UPON GLASS.

BY DR. SABATIER.

Writing preceded typography: painting preceded engraving and lithography. In photography, writing and painting do not even exist. Objects are not copied directly; we have to proceed through the *cliché*, or negative; and to arrive at the result achieved by the scribe in an instant, the long and delicate operation of printing must be undertaken. Writing, that cursive heliography, will it then become useless; or, rather, have we hitherto dreamed of seeking it? I believed and foresaw the possibility of it, when, a year ago, I published my process for obtaining directly, and in the course of a few minutes, direct collodion positives upon glass.

Notwithstanding the modification I have introduced and indicated in my last communication, this process leaves much to be desired, and cannot become popular; but the new improvements I have recently made reduces the manipulation so much, renders its production so rapid and easy, that the least experienced photographer may easily become familiar with it, and its adoption will, I hope, afford a pastime and pleasure to all who undertake it.

My direct positives upon glass were not very visible, and could only be properly appreciated when viewed as transparencies. I now make them visible at pleasure, by transparency or by reflection, like photographs upon paper. These two kinds of positives require different manipulations. I shall now describe the method of obtaining them.

### *Direct Positives by Reflected Light.*

This kind of positive, I must first premise, in order to prevent misunderstandings, does not completely respond to the exigencies of photography. It is in order to excite the improvements of which it is susceptible, that I proceed to describe the manipulations by which they can be produced; and also, because these manipulations, well understood, assist in the comprehension of the production of transparent positives.

When the development of the negative picture is completed in the laboratory, there remains in the collodion film a certain quantity of uncombined iodide of silver, either because it has not been acted upon by light, or because it has not been sufficiently so to be influenced by pyrogallic acid. Finding a substance which, in acting upon this iodide, forms a colour approaching that of a negative, and then we have the means of producing a collodion positive upon glass, by reflection: for, necessarily, the new colour will be more abundant and more intense where the non-reduced iodide is most abundant; for the diffusion of the iodide in the collodion film is such, that the new colour necessarily places itself in perfect harmony with that of the negative.

Now, in the absence of more suitable materials, which yet remain to be found—pyrogallic acid, which has already given the colour of the negative by acting upon the iodide impressed in the camera—can also furnish another colour by combining with the iodide unacted upon by light, provided, that, before putting one into contact with the other, the plate be exposed to diffused light for a few seconds.

Doubtless, it is an extraordinary fact, that pyrogallic acid reduces the iodide impressed in the camera, while it also combines with it, when it is impressed by diffused light, which seems to prove that the action of the light is not the same in both cases; but, although extraordinary, the fact is none the less true. These two reactions of pyrogallic acid may also manifest themselves under the influence of other causes quite as mysterious.

To be convinced of this, take two test-tubes; pour into the one four or five c. centimetres of a solution of nitrate of silver, and into the other an equal quantity of solution of pyrogallic acid; the strength of the solutions is unimportant; then, drop three minims (or drops) of pyrogallic acid into the test-tube containing the nitrate of silver, and into the test-tube containing pyrogallic acid pour three drops of the solution of nitrate of silver; in each test-tube a different colour and combination will be evident.

The pyrogallic acid poured upon the nitrate of silver does not appear to combine with it immediately; the liquid remains for a few moments colourless, then the upper stratum commences to blacken. The black descends down the tube, communicating gradually with the lower strata, and after four-and-twenty hours' repose, a precipitate will be found at the bottom of the tube, exactly similar to the reduced silver of which a negative is composed. The liquid, now become limpid, has only a very light tinge of green.

The nitrate of silver poured into the pyrogallic acid behaves quite differently. The liquid mass immediately becomes thick, and of a dull yellow colour; a rusty-coloured precipitate gradually falls to the bottom of the test-tubes, and twenty-four hours after the experiment, the liquid becomes limpid, and assumes the yellow colour it presented at the commencement. The image has all the appearance of the combination which constitutes the positive image.

To what is this difference in the mode of acting due? Is it to the respective quantity of the elements put into contact, or rather to the manner in which that contact is made? Will it be with the nitrate of silver and the pyrogallic acid as with the letters A and B, which form a different syllable according as the first of these letters is placed before or after the other? M. l'Abbé Despratz, in proving that the nitrate of silver poured upon the iodide of potassium gives rise to an electro-positive current, while iodide of potassium poured upon nitrate of silver gives rise to an electro-negative current, has rendered this hypothesis very probable.

What confirms also the fact that the colour of the positive, and that of the negative are due to different combinations, is, that in leaving a transparent positive in a solution of hyposulphite, the positive portion of the picture disappears even before the negative portion is attacked, and that the sulphide of potassium, which lines the positive remains without influence upon the negative.

Pyrogallic acid, which forms two combinations, two different colours, and which has already served to develop the negative, serves also to develop the positive, I proceed as follows:—

When the negative appears to have attained its highest perfection, I pour off the acid, and wash the plate in rain or distilled water, and drain it with one corner resting on blotting paper. It is next moistened with a solution of nitrate of silver, strength 5 to 6 per cent. in order to render sensitive all the iodide which has not contributed to the formation of the negative, and then exposed for a few seconds to diffused light, and not to the direct rays of the sun, o which I have not yet studied the action. After the exposure, I return to the operating room, and give it a second bath of pyrogallic acid, this time pure, that is, without the addition of any other acid, and the positive is instantly developed.

It is very superior to the negative, and much more strongly defined. To give it more vigour, the exposure must not however be prolonged until certain portions become solarized, for in such parts, the negative, instead of defining it, is confounded with it.

This first kind of direct positives, as I have already stated, does not sufficiently respond to the exigencies of photography: the two colours differ, but are not sufficiently opposed: the gradations of tone also, are not very distinct, and the finer details are lost in the shadows. But if one among the numerous searchers into the mysteries of the philosophy of photography will undertake to improve this defect, it will not be long before he furnishes us with excellent results.—*Moniteur.*

(*To be continued.*)

## THEORY OF THE ACTION OF LIGHT UPON IODIDE OF SILVER, IN COMBINATION OR CONTACT WITH OTHER SILVER SALTS.

BY THOMAS SUTTON.*

In our last number we promised to discuss more fully in the present a new theory of the action of light upon iodide of silver, by means of which all the known phenomena of photography in the various processes in which that silver salt is employed, may be satisfactorily explained.

According to this theory pure iodide of silver is itself insensitive to light, but when placed in combination or contact with some other salts of silver, it has the effect of greatly exalting their sensitiveness to light, and of hastening their decomposition by light, in consequence of its mere presence in the film; its action being what is called in chemistry "catalytic."

Since our first brief allusion to this theory in the last number, we have seen an article by M. Van Monckhoven, in the News, from which it appears that he is also tending towards similar views.†

Our object will now be to show that the theory stated at the commencement of this article is strictly in accordance with fact, and that it is capable of affording a satisfactory explanation of all the phenomena in photography in which the iodide of silver occurs.

We have to prove in the first place that pure iodide of silver is insensitive to light; it being understood that a salt is said to be insensitive to light in photography, when it neither exhibits visible evidence of reduction on exposure to light, or yields an image, after exposure under a negative, by any after process of development.

Although we cannot obtain iodide of silver in a state of absolute purity, yet we can obtain it in a state bordering very closely upon perfect purity. For instance, if you add a solution of nitrate of silver to a solution of iodide of potassium, the latter salt being in excess, and then wash the precipitated iodide of silver very thoroughly in numerous changes of water, you find the iodide of silver thus obtained perfectly insensitive to light. And again, if you coat a sheet of paper with a solution of iodide of silver in iodide of potassium (as in the calotype process), and then precipitate the iodide of silver in the paper, by thoroughly washing out the iodide of potassium, you find the paper perfectly insensitive to light; that is, you can neither obtain visible reduction, nor develop an image upon it after exposure to light.

In both these cases there is, no doubt, present with the iodide of silver a slight trace of iodide of potassium; but if the iodide of silver were itself sensitive to light, and capable of reduction like the bromide, chloride, and other salts of silver, it is inconceivable that so slight a trace of iodide of potassium should prevent the reduction of so comparatively large a quantity of iodide of silver, especially as we find that it cannot do so in the case of any of the other really sensitive silver salts, for both the chloride and bromide of silver can be darkened by light under a weak solution of iodide of potassium.

Another instance of insensitive iodide of silver occurs in the Taupenot process, in which, after the excited plate has been thoroughly washed, iodized albumen is poured over it, which converts the last trace of free nitrate which remains in the film into iodide of silver, after which the plate becomes insensitive to light.

Let us next consider some of the facts which seem at first to be inconsistent with the idea that pure iodide of silver is insensitive to light.

However thoroughly you may wash with water an excited iodized collodion plate, you can never entirely destroy its sensitiveness. The reason is, not that the iodide of silver is sensitive to light, but that the film of collodion retains some free nitrate, which no amount of washing will remove, and it is this collodio-nitrate of silver which is sensitive to light. The more thoroughly you wash such a plate the less sensitive it becomes, and this shows that the free nitrate is the true cause of its sensitiveness. Dip it into a solution of iodide of potassium and you convert this free nitrate into iodide of silver, and then the sensitiveness is entirely destroyed.

But Dr. Hill Norris some years ago denied the truth of the latter statement, and asserted that he had taken negatives upon plates which had been washed with iodide of potassium, and not excited again in a nitrate bath. This we explain by supposing that he had used bromo-iodized collodion; for it is perfectly true that bromide of silvor is sensitive after being washed with iodide of potassium. The collodion which Dr. Norris used, probably, contained a bromide, and was *not* simply iodized collodion. A Taupenot plate prepared with bromo-iodized collodion does not lose all its sensitiveness by having iodized albumen poured over it.

Another fact, apparently adverse to our theory, is that an iodized Daguerreotype plate (without bromine), is sensitive to light, although very feebly so. This we explain by supposing that the surface of the plate becomes slightly oxidized in the operations of polishing, and the film which is exposed to light then consists of iodide of silver plus oxyde of silver, and it is the oxyde which is reduced when the plate is exposed to light. Pure silver is white, but a polished Daguerreotype plate is black.

Such are the reasons for concluding that pure iodide of silver is not sensitive to light. If this be true, its effect in accelerating the action of light upon other salts of silver, placed in contact with it, must be due to a molecular disturbance produced by light among the particles of iodide, and not to its reduction by light, and the liberation of iodine. If this be true, the iodide of silver forms a remarkable exception to the law which governs most of the other silver salts when exposed to light. For instance, when chloride of silver is exposed to light in presence of moisture, or hydrogen, the chlorine unites with the hydrogen and forms hydrochloric acid, and the silver is reduced. When bromide of silver is similarly exposed, bromine is liberated, hydro-bromic acid formed, and silver reduced. When organic silver salts or compounds, such as the citrate of silver, are exposed to light, sub-salts of silver are formed; and so on. But when any of these salts of silver are exposed to light in presence of iodide of silver, the reduction proceeds much more rapidly than before, upon the particles which are actually in contact with the iodide of silver. And the law which determines the most exalted sensitiveness of the combination, seems to be this, viz., that every atom of the reducible silver salt should have an atom of iodide of silver in contact with it, and no more. Should there be an excess of the reducible salt present on the one hand, or of iodide of silver on the other, then the slowly reducible salt in the first case, or the insensitive iodide in the second case, would interfere mechanically by its presence with the action of light upon the pairs of atoms of iodide and the other salt which were distributed through the film. Thus, in the Daguerreotype process the iodized plate has but slight sensibility, but when it is put over the bromine, its sensitiveness continues to increase up to a certain point, and then diminishes, the most exalted sensitiveness being probably that in which an atom of bromide exists side by side with an atom of iodide throughout the film.

Those salts of silver which are most sensitive alone, appear, with the exception of the nitrate of silver, to be the most sensitive in presence of the iodide. Thus, iodo-bromide of silver is

* From *Photographic Notes.*

† See Photographic News, p. 279, present volume.

more sensitive than iodo-lactate of silver, and the presence of such salts as the lactate, oxalate, and acetate of silver reduces the sensitiveness of the collodion film, but gives greater density to the image, because those parts which *are* reduced by prolonged exposure to a strong light are very easily intensified by the developer.

Of all known silver salts those which are reduced most rapidly by exposure to light are the bromide and chloride, the former of which assumes a blue, and the latter a grey tint under the action of light. It would appear, therefore, that the most sensitive film would be produced by a bromo-iodized or chloro-iodized collodion. We cannot, however, assert that such is the case, because, singularly enough, the nitrate of silver in combination with the iodide forms a highly sensitive compound; so sensitive that when all the materials are pure, and the nitrate neutral, you can take instantaneous views as readily with this combination as with a bromo-iodized film.

Bromo-iodide of silver appears to be sensitive without free nitrate in excess, and this fact lies at the foundation of the rapid dry processes.

There is a curious circumstance which occurs in the Daguerreotype process, and requires explanation in this place, as it appears at first sight to be irreconcilable with our theory. It is this: If you happen accidentally to expose to light a bromo-iodized silver plate, you can restore its good qualities by putting it once more over the iodine for a few seconds. The explanation is, that the iodine converts into iodide of silver the whole of the silver which has been reduced by the action of light upon the bromide, and leaves the plate nearly in the same condition as before, the difference being that there is now a rather larger proportion of iodide to bromide of silver upon the plate.

We have now endeavoured to explain the leading phenomena which attend the action of light upon iodized films, plates, and papers. The theory now advanced is different from that which we have hitherto held, and which has been explained in an article by Mr. Worden, in our *Dictionary of Photography*. As that work has been for some years out of print, it may be interesting to many of our readers to reproduce that article, so that they may be able to compare both theories, and decide for themselves.

We need hardly say that it is of the utmost practical importance to be able to give a sound explanation of what one is about, and that theories are only despised by ignorant and uneducated people who work by rule of thumb.

## WATERPROOF VARNISHES AND CEMENTS.—GUTTA-PERCHA COMPOUNDS.

BY H. R. NICHOLLS.

To resume my communication on the wants of photography, I shall describe the waterproof compounds of gutta-percha with pitch, and how to construct the various apparatus to which it is applied, in order that the amateur or professional photographer, at home or abroad, may not be brought to a stand still when "on the tramp," at all events for the want of a water-tight vessel.

The dark room I shall make the base of operations, the tanks, sinks, trays, and waterways may be lined with this compound, which is easily applied or repaired when fractured.

Take of gutta-percha, cut in small pieces, one pound, put it into pipkin, and melt it over a clear fire, keeping it well stirred with a *wooden spatula*, adding gradually three pounds of Stockholm pitch. When thoroughly incorporated it is fit for use.

The surfaces of either wood, metal, or stone, to which this compound is to be applied, must be well dried, and all being in readiness, pour sufficient of the melted cement into the sink, or whatever vessel is to be coated, at the same time spreading it with a piece of flat wood, to about 1-16th of an inch in thickness; then smooth it down with a hot iron, similar to that used by laundresses, working well into the corners and joints. In case of curves, or angular parts, a piece of stout iron rod, bent in the form of the letter J, will be found useful. When fractures occur, or joints require to be made, the application of a hot iron rubbed over the parts at once remedies the defects; observing carefully first to dry the parts where such fractures appear.

This compound mixed with one twentieth of fine dry silver sand, or one fiftieth of vegetable charcoal, forms an excellent material for coating damp floors or bad roofs, and may be applied in the same manner as before mentioned.

The next compound requires great purity, as it may come in contact with the various chemical solutions. The gutta-percha must be well cleansed, and dried in the following manner: cut any quantity of gutta-percha into fine shreds, wash in several changes of cold water, or until the water come away quite colourless, it is then to be well kneaded in hot water, with a clean *wooden spatula*, and well pulled out and dried for further use. The pitch requires to be kept in a melted state for an hour or more, that any earthy particles may subside, the upper stratum alone is then to be used; it may be broken away as soon as cold, and kept in well corked bottles for use. A well glazed earthenware pipkin should be used, and kept for this compound only. Equal parts by weight of the purified gutta-percha and pitch are to be melted together as before. This compound also forms an excellent covering for bottles, protecting them from injury when travelling. The method I adopt is, fit a piece of wood into the neck of the bottle long enough to hold conveniently in the hand, clean the outside of the bottle well, then make it gradually hot, and dip it into the pot of melted compound up to the stick, holding it by the handle; when withdrawn, hold it vertically, bottom up, that the superfluous cement may run off at the neck, which may then be stopped upon the stick with a pasteboard collar placed about an inch from the bottle neck upon the stick. To perform this job nicely requires a little dexterity, at the same time it will repay the trouble.

I will send you next a few hints upon the construction of baths, dishes, trays, &c.

2, *St. Jude Street, August 9th*, 1862.

## A SHORT LESSON IN PHOTOGRAPHY—No. 1.

BY J. TOWLER.*

Take a grain of nitrate of silver and a grain of common salt (chloride of sodium). Dissolve each in a separate two-drachm vial, filling each about half-full with rain water. Now light a candle with a very fine wick, or a fluid lamp with a very small wick, and follow me into a darkened room, as, for instance, under the stair-case, if no better can be found. Bring with you a pitcher containing rain water, a slop-pail, an empty vial, and two tea-cups. Shut the door after you. Now pour the solution of nitrate of silver into the solution of chloride of sodium; you observe a dense white precipitate is formed in the chloride salt. This is an example of what we call double decomposition in chemistry. Thus we have nitrate of silver, which consists of the *oxide of silver*, combined with *nitric acid* in such a way that neither acid, nor silver, nor oxygen, is manifest in the combination. This nitrate is dissolved in a neutral solvent—water—which dissolves also the chloride of sodium, consisting of *chlorine* and the metal *sodium*, in such a way also that neither the metal nor chlorine can be recognized by the senses. In this solvent—water—you must then understand that we now have these four substances in intimate contact, namely, oxide of silver, nitric acid, chlorine, and sodium. Now, all chemical bodies have their likes and dislikes, that is, their predilections, affinities, or attractions, on one side, and their repulsions on the other; we cannot as yet, *a priori*, account for such tastes and distastes; they exist, and are invariable when once found out. Well, what is the result? Chlorine leaves Sodium the moment she sees Oxide of Silver; but you observe that the silver compound has already got a companion, Miss Oxygen; she, however, wisely decamps at the sight of so powerful a rival, and runs and allies herself with the poor Mr. Sodium,

* From *Humphrey's Journal*.

in order to sooth him in his desolate condition; Nitric acid follows her example, whereby they form a new and compact trio—the nitrate of the oxide of sodium; but the oxide of sodium is denominated soda, therefore the name of this new compound is generally called nitrate of soda: that of the other new compound is chloride of silver.

This decomposition takes place as soon as contact is effected, and is, therefore, almost instantaneous. But observe well the difference in one of the new compounds; it is insoluble in water, and is therefore precipitated, or falls to the bottom of the vial. The supernatant liquid is the water holding in solution the nitrate of soda, which can now be decanted from the residue; after this we can drive off the water from the nitrate of soda by boiling, when we shall have the nitrate of soda alone, tasting and acting very much like saltpetre. The residue, after decantation, we will wash several times, pouring off the water at each time after the white precipitate has settled. Now take two teacups and pour into the bottom of either half of this white chloride; leave one cup in the dark room: I will take the other into the light, in fact, allow the sun to shine upon it; you observe how quickly the colour is changing into a beautiful violet; the colour, however, is only on the surface; for by stirring the precipitate you perceive it is still white beneath. This change of colour has been effected by the light, and it is in proportion to the intensity of the light; and where the light is obstructed the change is not produced; so that if I were to place a ten-cent piece on a portion of the chloride before exposition to the light, the chloride beneath the coin would remain white.

Let us now return to the dark room, and see if the other half has changed in the meanwhile. No alteration is visible. And none will take place, as we know by experience, if light is excluded. But what you have seen is not all the change that has been effected in the chloride; for if we convert all the white chloride into the violet chloride, by exposing it some time to the sun, and by continually stirring it all the while, it will undergo another very important change, as I will show you.

I have here a solution of another salt called hyposulphite of soda; in this solution the white chloride is quite soluble, so that now not a single particle is visible; on the other hand, the violet chloride is insoluble in a similar solution in this other vessel. On these two changes, produced by light, depends, in a great measure, the science of photography; the light *produces colour* according to its intensity, and *renders this colour insoluble* in the same proportion.

Repeat these experiments at home until you are quite expert in their manipulation. Your next lesson I will give you in about two weeks from now.

## PHOTOGRAPHIC STUDIES.

BY DR. SCHNAUSS.

*Examination of Various Formulæ.*

We know that the collodion and the silver bath must contain a slight excess of acid, or of the element *iodine* which supplies the acid. M. Gaudin recommends *chloric* acid for acidifying the silver bath; but, in fact, this acid has the instability and volatility of those heretofore employed for the same purpose, namely nitric and acetic acid. Doubtless we should add to the silver bath only an acid whose salts are soluble in water, for upon adding an acid which forms an insoluble combination with silver, we set at liberty an equivalent of nitric acid. In this particular, chloric acid, $Cl\,O^5$, must not be confounded with hydrochloric acid, $Cl\,H$, which produces a precipitate of chloride of silver in the bath:—it is well suited for this purpose, for all its salts are very soluble in water. But it is different with regard to its instability, for chloric acid and its salts form some of the most unstable chemical combinations known. Strong friction, or the presence of an incandescent body, is sufficient to decompose the chlorates, and cause a terrible explosion. Chlorate of pottassa, one of the most familiar salts of this acid, is used in the manufacture of "lucifer" matches. Chloric acid itself is very easily decomposed into chloric acid and oxygen. If a piece of paper be moistened with the concentrated acid, it ignites spontaneously on drying. The facility with which chloric acid gives up its oxygen greatly surpasses that which characterizes nitric acid. In this respect, the employment of the new acidifier will not be an improvement. But we perceive from this example, that a greater or lesser instability in these bodies, which are added to the silver bath in very small quantities, must not be regarded as important, for the action of chloric acid is the same as that of acetic acid or of free iodine. For those of our readers who desire to repeat the experiment, we give the preparation of chlorate of baryta (which is not nearly so dear as stated by M. Gaudin), and of chloric acid.

Chlorate of baryta is prepared by dissolving 7½ parts of crystallized carbonate of soda in 24 parts of boiling water. As the carbonic acid is given off, a large vessel must be employed for making the solution in, 6 parts of chlorate of potassa are dissolved in 16 parts of boiling water, and added to the solution of soda, well stirred, and left to subside; tartar is deposited, and chlorate of soda remains in solution, which is filtered, evaporated, and 14 parts dissolved in 27 parts of cold water. On the other hand, 19 parts of vinic acid are dissolved in 19 parts of cold water, and the solution added to the solution of chlorate of soda, and also double its volume of alcoholized spirits of wine is added. After 24 hours a precipitate is deposited, and the liquid, which is a dilute solution of chloric acid, is filtered. It is then saturated with carbonate of baryta, and filtered. The filtered liquid contains chlorate of baryta; we then add to it, cautiously, some diluted sulphuric acid, until a precipitate of sulphate of baryta is formed. The filtered liquid is chloric acid.—*Le Moniteur de la Photographie.*

* Continued from p. 380.

## THE STEREOGRAPH AND THE STEREOSCOPE.

The stereograph, as its name implies, is a solid picture, or a picture whose different parts retain their distances apart in space proportionately to those in the objects of which it is a picture. Such a picture naturally can never be printed, because it then would be on the same plane, and hence not solid; but it can be produced by two pictures of the same objects, these pictures being on the same plane, and endowed with the *requisite conditions.* A combination of two such pictures, mounted side by side, receives the appellation of that which they produce—the stereograph.

The conditions thus required are, in the first place, a regular difference in the distances between the corresponding points on the two photographs, or pictures, increasing or decreasing according to a certain law from the front objects to those in the back ground; secondly, that, theoretically, the maximum distance shall not be less* than that between the centres of the two eyes, whose average is about two inches and a half, nor the maximum greater than the sum of the distance between the centres of the two eyes and twice the tangent of the parallactic angle to be described hereafter; and, thirdly, that an equal number of objects shall be contained in either photograph or picture.

The pictures of near objects in a landscape projected on the retina of either eye, that is, as seen by the two eyes separately and independently, possess, when mounted on the same cardboard side by side, the above conditions: that is, if the picture, as seen by the right eye, be mounted on the right side, and the other on the left side, then the distances between the corresponding points of the two pictures will de-

* Practically, these maxima and minima distances admit of a considerable range of variability, arising from the expansive capability of the eye (if I may so express myself) under difficult conditions.

crease from the foreground to the background; if the photographs, &c., be mounted in the reverse order, the distances will likewise be inverted, and will increase backwards.*

The photographs, therefore, of near objects taken by a pair of corrected lenses, whose distance apart is equal to that between the centres of the eyes, will possess the requisite conditions for producing a stereograph. Without the conditions of difference, no stereoscopic effect can be produced; and since these differences for distant objects are so slight as scarcely to be appreciable, binocular photographs without a foreground produce only *plane* not *solid* pictures.

The angle subtended by the axes of the two eyes converging to a point at a given object, is the parallax of that object; this parallax becomes zero at an infinite distance, in which case the axis of the eyes become parallel: as far as optical accuracy has attained, however, this parallelism supervenes within a mile or so; and, for practical photographic purposes, objects at a few hundred feet distance cease to give any stereographic effect. But the parallax of an object can always be maintained at a given quantity by increasing the base line, that is, by increasing the distance apart of the two lenses. By this expedient, the photographs of distant objects, as, for instance, of the moon, can be endowed with the requisite conditions for stereoscopic effect; and this expedient must never be omitted in practical stereography. It is a common error to regard perspective as stereoscopic effect. Most of the stereoscopic views of streets, avenues, bays, mountains, &c., for sale, are totally devoid of true relief; all that is produced by the stereoscope with such views is the superimposition of two similar photographs in true perspective producing a perfectly flat picture. For instance, with a pair of one-quarter tubes, let two binocular views be taken of a house having trees in front, of which the nearest is distant 200 feet from the observer; in one case let the lenses be 2½ inches apart, in the other 7 feet apart, and then mount the views respectively for lenticular observation in the stereoscope. The result will be as follows: in both cases we have perspective; but in the former case the picture is nearly flat, the trees being projected on the building, with but very little relief; whilst in the latter case the relief is much more marked, so that the picture *may be* a fac-simile of the reality condensed into a small space, in fact, a *stereograph;* or it may exhibit a decided distortion of relief, according to circumstances, which I hope to be able thoroughly to designate.

As a general occurrence, large objects, as, for instance, human beings, are seldom photographed at a less distance from the lenses than six feet; smaller objects frequently require a much shorter distance. Assuming, then, this distance as a starting point, and 2½ inches for the average distance between the eyes, the parallax for this distance is obtained as follows:—Let A and B represent the two eyes, and C the object, distant from A and B, six feet; then we have the propostion; as 72 inches : R : : 1¼ inch : Sine : parallax = 1 deg. nearly. In this way was obtained the following table:—

| Distance. | Parallax (doubled). Degrees. | | | Distance. | Parallax (doubled). Degrees. | | |
|---|---|---|---|---|---|---|---|
| feet. | deg. | min. | sec. | feet. | deg. | sec. | nearly. |
| ½ | 24 | 2 | 58 | 12 | 1 | 0 | ,, |
| 1 | 11 | 57 | 30 | 15 | 0 | 48 | ,, |
| 1½ | 7 | 39 | 0 | 18 | 0 | 40 | ,, |
| 2 | 5 | 58 | 12 | 21 | 0 | 35 | ,, |
| 2½ | 4 | 46 | 34 | 24 | 0 | 30 | ,, |
| 3 | 3 | 58 | 46 | 27 | 0 | 27 | ,, |
| 3½ | 3 | 24 | 40 | 30 | 0 | 24 | ,, |
| 4 | 2 | 59 | 4 | 33 | 0 | 22 | ,, |
| 4½ | 2 | 39 | 12 | 36 | 0 | 20 | ,, |
| 5 | 2 | 23 | 14 | ¼ mile | 0 | 0 | 32¼ sec. |
| 5½ | 2 | 10 | 14 | ½ mile | 0 | 0 | 16¼ ,, |
| 6 | 1 | 59 | 24 | 1 mile | 0 | 0 | 0 ,, |
| 9 | 1 | 20 | nearly. | | | | |

* This fact can be verified by taking a pair of compasses and expanding them so that the foot of either rests upon what you suppose to be the nearest point in each photograph, as for instance upon the nose of the nearest individual; lay off this distance on a piece of paper, or measure it on a scale. Then place the points of the dividers on the points you suppose the most distant in the landscape behind, and lay off as before; this latter distance will be less than the preceding. If there be no difference, the photographs are not stereographic.

From the preceding table it is evident that the axes of the eyes fixed upon an object at the distance of one mile have nearly half the same parallax as that of the sun; but to obtain this latter parallax was a practical problem of considerable difficulty, by reason of the approximate parallelism of the rays subtending this angle; we may hence regard all objects beyond the distance of a mile devoid of all practical parallax, and consequently *incapable of producing stereographic effect* at this angle.

But with a given parallax it is easy to derive the amount of displacement which must take place between the cameras in order that an object at any given distance may be photographed as if seen at the distance corresponding with the said parallax, when 2½ inches is the width between the cameras, and consequently that the photographs just taken shall produce the same stereographic effect as a similar proportionately diminished object placed at this nearer distance. For instance, it is required to find the distance between the cameras, so that an object situated one quarter of a mile off shall be represented as if seen at the distance of 6 feet.

Now the parallax for 6 feet is 2° nearly; therefore, taking the line C A in the preceding figure equal to one quarter of a mile or 1,320 feet, we proceed as follows:—

As R : 1320 feet : : sine 1 deg. : 53 feet = A D.

But the distance A D is only half the amount of displacement; hence the two cameras have to be separated 46 feet if an object is to be represented stereographically at the distance of one quarter of a mile. The following table was derived in accordance with the above formula:—

Table exhibiting the distances between the two lenses, in order that objects may appear stereoscopically as if photographed at the distance of six feet from the observer.

| Distance of the object from the observer. | Distance of the lenses apart. | |
|---|---|---|
| 25 feet ... ... | 0 feet | 10·49 inches. |
| 30 ,, ... ... | 1 ,, | 0·56 ,, |
| 50 ,, ... ... | 1 ,, | 8·95 ,, |
| 60 ,, ... ... | 2 ,, | 1·13 ,, |
| 75 ,, ... ... | 2 ,, | 7·41 ,, |
| 90 ,, ... ... | 2 ,, | 11·18 ,, |
| 100 ,, ... ... | 3 ,, | 5·88 ,, |
| 120 ,, ... ... | 4 ,, | 2·26 ,, |
| 125 ,, ... ... | 4 ,, | 4·36 ,, |
| 150 ,, ... ... | 5 ,, | 2·82 ,, |
| 175 ,, ... ... | 6 ,, | 1·30 ,, |
| 200 ,, ... ... | 6 ,, | 11·77 ,, |
| 225 ,, ... ... | 7 ,, | 10·24 ,, |
| 250 ,, ... ... | 8 ,, | 8·08 ,, |
| 275 ,, ... ... | 9 ,, | 7·02 ,, |
| 300 ,, ... ... | 10 ,, | 5·07 ,, |
| 325 ,, ... ... | 11 ,, | 3 07 ,, |
| 350 ,, ... ... | 12 ,, | 2·06 ,, |
| 375 ,, ... ... | 13 ,, | 1·01 ,, |
| 400 ,, ... ... | 13 ,, | 11·05 ,, |
| 425 ,, ... ... | 14 ,, | 9·96 ,, |
| 450 ,, ... ... | 15 ,, | 8·50 ,, |
| 475 ,, ... ... | 16 ,, | 6·96 ,, |
| 500 ,, ... ... | 17 ,, | 5·04 ,, |
| 600 ,, ... ... | 20 ,, | 11·68 ,, |
| 700 ,, ... ... | 24 ,, | 5·16 ,, |
| 800 ,, ... ... | 29 ,, | 6·84 ,, |
| 900 ,, ... ... | 31 ,, | 4·92 ,, |
| 1000 ,, ... ... | 34 ,, | 10·08 ,, |
| 1100 ,, ... ... | 38 ,, | 4·68 ,, |
| 1200 ,, ... ... | 41 ,, | 10·26 ,, |
| 1300 ,, ... ... | 45 ,, | 4·44 ,, |
| 1320 ,, or ¼ of a mile | 46 ,, | 0·84 ,, |
| 2640 ,, or ½ of a mile | 92 ,, | 1·08 ,, |
| 5280 ,, or 1 mile ... | 202 ,, | 1·02 ,, |

*Application of the preceding Table.*—Any object, or assemblage of objects, that might be comprehended on the stereographic glass plate at the distance of six feet, or at any other given distance from the camera, may be photographed at any other distance, and still retain the stereographic effect as if photographed at the given distances, as follows :—

*Example* 1.—At the distance of fifty feet there is a pic-nic party ; if the camera could be planted close by, or at six feet distance from the first object, it is known that the whole party would be taken in by a one-fourth tube on an ordinary stereographic plate ; but a small pool of water intervenes, what is to be done ? Look in the table for fifty feet ; opposite this number stands one foot nine inches nearly ; take, therefore, two camera stands, and place them each at fifty feet, or as near this distance as may be from the nearest central object in the view, and at the tabular distance apart, that is, one foot nine inches, and at the same elevation. If you are furnished with two separate cameras, focus either of them as an independent instrument ; if, on the other hand, you have a pair of tubes on the same camera, focus with the right tube from the left camera stand, and with the left from the right camera stand, taking strict care to mark the position of the camera on either camera stand.

As soon as this part of the operation is performed, take the view in the same order as you focussed, which is done of course by transferring the camera from one position to the other. In such cases it is always advisable to use longer focussed tubes, as, for instance, half view tubes, or whole view tubes, or even still longer ones, to compensate for the diminution of the size of the figures at the increased distances. By this allowance of distance between the camera, the proper relief is obtained when the two photographs are superimposed ; and by focussing as recommended in the latter case, where only a single camera is used, the prints do not require to be separated when mounted.—*Humphrey's Journal.*

(*To be continued.*)

## THE GREAT PHOTOGRAPHIC DUELLO.

[We subjoin an extract from the *American Journal*, in which Mr. Coleman Sellers describes the contest of Wet *v.* Dry Collodion, to which our American correspondent, Mr. Thompson, referred in a recent letter. It will be seen, as before intimated, that Dry came off victorious.]

The excursion was planned, on my arrival in New York, by Messrs. Thompson and Anthony, and was looked forward to with pleasure by me. The day came, and with it a bad headache. Thompson called for us at Anthony's store, in Broadway, and we were soon enjoying a ride through Central Park (seen by me for the first time), towards the High Bridge. The park had been well represented in my collection of stereographs, thanks to many kind friends, and it was with pleasure I saw and recognized the views I had admired so much on paper. The ride and fresh air relieved my aching head, but the pain came back with redoubled violence when we reached our destination, and the boxes and traps for wet collodion were to be carried. Thompson, the representative of Siccus, started off with five or six pounds under his arm, while Humidus trudged on, aided by his kind friend Anthony, who relieved him of half his load.

On the edge of the river bluff we pitched the tent, or rather developing box, and soon a plate was ready for the camera. But now the trouble began. The plates were fogged and useless, four were spoiled in succession, until my kind companion found a yellow envelope in his pocket, this he opened with care and fastened over the yellow glass window : this cured the evil, and I had the pleasure of making four or five good negatives (two being of the same view), and adding to my headache, until it seemed unbearable. In the meantime Siccus had scrambled over the rocks, and visited all manner of (to me) inaccessible localities, and exposed seven dry plates. Mr. Anthony stood by me in all my trouble, and added to my stock of knowledge many choice items of information.

The ride home and rest from the exertion of "wet photography" cured my headache ; I say the ride and rest, but perhaps more was due to the curative influence of my companions' wit and humour. It was a delightful merry ride. One little scintillation from their brains shall find a record here. We were talking about the "troubles of an amateur photographer in portraiture," and giving our experience as to the assurance of some folks in their demand for gratuitous work. One of my companions said, "Why, the other day quite a stranger sent me a polite request *to take his aged parent.*" "You did not see it, did you ?" exclaimed his companion. "No, I did not ; it was not apparent (*a parent*) to me."

I'll not take up your valuable space by telling all that I saw, in our secretary's sanctum ; enough, I took some lessons in dry photography. The end of the matter is, that I have barely four (one of these nothing to brag of) prints to send my friends, while Thompson incloses me in a recent letter seven prints, one from each of his seven dry plates, ALL *very good indeed.*

I have given a faithful history of my friend's success and my own failures. Some days afterwards, at Springfield, Mass., I did better. Starting from the hotel at 9 a.m., I rode to the country, then to the pine woods back of the lower water shops, making five stoppages. I secured fourteen negatives, twelve of which were good, the other two spoiled by the horse moving, that animal being the conspicuous object in the view ; we returned to the hotel in time for dinner, 2 p.m., having been gone five hours.

Mr. Thompson's box for dry plates is the best I have seen, and one is being arranged for me, by my carpenter, on the same plan. It will soon be done, and in my plate-box stand a goodly row of tannin plates awaiting exposure.

Having by the above "exposed myself," I am with due regard, Coleman Sellers.

## FATAL EXPLOSION OF GUN-COTTON.

The *American Journal of Photography* records the death, by an explosion of gun-cotton, of Mr. L. M. Dornbach, a photographic chemist of considerable ability, with whose name some of our readers may be familiar, through occasional extracts in our pages from American journals, to which he was a frequent contributor. We quote the details :—

"The death of Mr. Dornbach was, in consequence of injuries received by an explosion of gun-cotton, which occurred at one o'clock p.m., on the 21st inst. Mr. Dornbach, for the past six months, has been engaged in the manufacture of gun-cotton for use in the preparation of waterproof cartridges. The business was conducted on a much larger scale than was ever before attempted, the explosive material being manufactured a part of the time at the rate of hundreds of pounds daily. The peril of the business was fully appreciated by his friends, and Mr. Dornbach adopted many expedients to ensure safety, which his experience and his scientific judgment approved. Before he received the mortal injuries several accidents had occurred in his factory, in one case three hundred pounds of gun-cotton being exploded at once, demolishing a large three-storey brick building ; but in the accidents heretofore, fortunately no one received any personal injury. For the past two months the manufacture was carried on in a secluded part of Williamsburgh, and so far away from other buildings, that no danger could occur from it, outside the premises. On the fatal Saturday, two persons only were engaged in the factory, Mr. Dornbach, and his brother-in-law, Mr. George E. Hall, of Cambridge, Mass. At the time of the explosion Mr. Dornbach was engaged in packing the gun-cotton for shipment to Connecticut, in stout oaken casks of twenty gallons capacity, and intended for thirty-eight pounds of the cotton. A cask was nearly filled, and Mr. Dornbach was pressing down the cotton with a heavy stick, when a thrust, probably heavier than usual, ignited the mass. His hands, arms, and face were severely burned, and his clothes were set on fire ; but these injuries did not disable him, and he ran towards a small building which contained the hydrant, and where Mr. Hall was employed. Mr. Hall witnessed the explosion, and, with commendable presence of mind, at once directed a stream of water upon his friend. But this thoughtfulness of both at the terrible moment was of little avail, for another more fearful explosion took place, completing the destruction which the first began. Mr. Hall was much injured, but will recover. Mr. Dornbach's case from the first was almost hopeless : death relieved him from all suffering at one a.m. of the 23rd. His widow and child, his venerable parents, and many friends will never cease to lament his untimely removal from among them.

"Mr. Dornbach had by nature an inclination for the study of the physical sciences which could not be restrained. While a farmer's boy (in a district of Pennsylvania where science is little thought of), with nothing but his tastes to encourage him, he became an accomplished chemist. Afterwards, he entered the Scientific School of Harvard University, and graduated with distinction, securing the approbation of his instructors, and his classmates; there he systematized and made compact the knowledge which he had acquired in his earlier voluntary studies. While at the college, he translated from the German a profound treatise on crystalography, and performed other similar tasks, which entitle him to the grateful remembrance of men of science. He was a man of extraordinary vigour of mind and body, and, had he been spared, would have made his mark in the progress of science. He was well known to the photographers of New York, and to many in the country, as a manufacturer of photographic chemicals, and as a writer on photographic subjects."

## PHOTOGRAPHS OF THE EXHIBITION.

Photography in 1851 was a scientific curiosity. In the interval that has elapsed it has risen and spread from a chemical wonder into a commercial branch of art, that increases in value every day. In our first Exhibition there were not more than a dozen or so of Daguerreotypes and Talbotypes shown, and we believe there is not a single one of these sun-pictures in existence which records the interior of the beautiful old building in Hyde Park, with the truth and accuracy which belong to photography alone. Since that time, short as it may seem, photography has grown to be a distinct art—an art which has been made to subserve the strategy of war and the works of peace, which has been pressed into the service of science, till eclipses and comets are made to print themselves, and even the viewless winds compelled to leave the force and direction of their track recorded on paper. During the last five or six years there is scarcely a mode of life or learning into which photography has not been introduced, from the capture of a thief to the elucidation of some of the least known and most difficult of our scientific problems. If the Commissioners in 1851 had called for tenders to purchase the right of taking photographs in the building, what wonder would there not have been among the few amateurs who then had solved the mystery of taking pictures at all! Yet on the present occasion, when tenders were called for, there was an active competition among all the great photographic houses, which ended at last in the contract being given to the London Stereoscopic Company, for the sum of 1,500 guineas—a sum that has since been increased to nearly 2,000 for additional privileges. The first results of the efforts of this Company have now been given to the public in about a hundred large and small, plain and coloured, *carte de visite* views, and views adapted only to the stereoscope. The latter, as might be expected from the fame of this Company for such pictures, are among the best, and are really wonderfully good, when we consider the extreme difficulty of taking them. The light in the building is so extremely bad for photographic purposes, that at first it was believed that none could be taken there at all. This supposition was so near the truth, that even now, on bad days, it requires from 12 to 15 minutes' exposure of the plate to get a good negative; and when we remember that, in addition to this difficulty, the varied colours are so sadly metamorphosed in the process as often to destroy not only the beauty but the likeness of the picture, the care and cost required to get good views have been very great. Of these difficulties, however, there is no trace in the series which has just been issued. They are each as clear and sharp as instantaneous views, and the tinted views especially bring out every light and shade, and every tone of colour in the building. Here we see the nave as only photographers and policemen have the luck to see it—in the cool clear air of the early morning, when there is no dust, no cloud, when not a living being is visible over the whole expanse of the noble hall, when it looks like a fairyland of beauties undiscovered and unknown. In these pictures the statuary comes out with all the sharpness of high relief, and every column and rib of the nave may be counted. In some, such as the collection of glass in the English and Austrian Courts, the effect is more than stereoscopic—it is an optical delusion; less a picture of the places as we see them than the places themselves. The quaint, funny monstrosities of the Japanese Court are here reproduced to the life; here we get the long vista of ponderous wheels and thrusting pistons of the Machinery Annexe; here we find the Picture Galleries as visitors have never found them yet—quiet and empty; and here, above all, are the best specimens of the statuary. The tinted Venus of Gibson is so tinted as to avoid the discolouration of the marble, which, in the original, gives the goddess the appearance of having dirty legs; the veiled figures of Monti come out with beautiful distinctness; and the pale earnest features of the Reading Girl are copied with all the force of the statue itself. This latter is apparently the popular picture, as nearly 200 gross of its copies are sold per week. Some of the best gems of the Roman Court are among these pictures, though it is much to be regretted that, up to the present, no permission has been obtained to copy two of the finest works in it—Storey's beautiful statues of Cleopatra and the Sibyl. On the whole, this pictorial record of the finest Exhibition that has yet been held, is in every way worthy of the advance the chemical art has made since our last World's Fair in 1851. These views will be enduring records of what we did in 1862, and the only regret we feel in looking over this wonderful delineation is, that the art was not sufficiently advanced to have served the same purpose for our first great effort in 1851. Many more views have yet to be brought out before the series is complete. If they are only as good as those already issued, they will reflect high credit on the Stereoscopic Company.—*Times.*

# Correspondence.

## DISCOLOURATION OF SILVER BATH, ETC.

Dear Sir,—I have often wished, like many another photographer, that some means were devised to avoid the necessity of decolourizing the silver bath used for sensitizing albumenized paper. The published plans I have tried succeed only for a short time, or at the expense of the silver in the bath. I have now a printing-bath which has been in use for some weeks, sensitizing albumenized paper of various sorts; it is as clear and colourless as when first made, and has no sediment.

The obtaining such a treasure being, I may say, a happy accident, I am unable to give a formula for making it; but if I give the history of the bath, I am in hopes that you, or one of your readers more versed in chemistry than myself, may be able to suggest whence its good qualities are derived.

It was converted from an old negative bath by the process given in "Hardwich's Manual," viz., the iodide being thrown down by citric acid, which was afterwards neutralized, and the acidity just restored by nitric acid. After such an operation, what extraneous matter can there be in the bath? Possibly some alcohol and ether, though the quantity of these remaining must be small, seeing that the solution was concentrated by heat from 30 grains to 80 grains to the ounce.

The enlargement of photographs being at the present time an especially interesting subject, I am induced to enquire if you or either of your contemporaries have noticed in the Belgium Gallery, at the International Exhibition, an enlarged portrait of, I think, the Comte de Flandres. It is by Ghemar, of Brussels (Class XIV, No. 358). I thought it the finest enlargement I saw, as regards uniformity of definition. I find no notice of it by the Jurors, but that, you will agree with me, is no reason it should not receive honourable mention in other quarters, if deserving it.—
Yours truly, G. S. Penny.

*Cheltenham, August* 8, 1862.

[It is somewhat difficult to say what may be in an old negative bath. Mr. Samuel Fry has more than once described a method of making a silver bath with common water, which did not discolour, and we have seen in his atelier large baths which were perfectly clear after long use; but the plan does not always answer, "common water" being a rather indefinite term. We have more than once referred to the portrait of the Comte de Flandres, by Ghemar, as the finest enlargement in the Exhibition. You will find some particulars regarding it on pp. 39, and 289 of the preset volume.—Ed.]

## Talk in the Studio.

Photographs of Rome.—A fine and interesting series of photographs of the various treasures of architecture, sculpture, painting, &c., in Rome, produced by Mr. Macpherson, is now exhibiting in one of the rooms in which the Architectural Photographic Association held their exhibition, in Conduit-street. The number of pictures is between four and five hundred, of which one hundred and thirty are devoted to the Vatican sculptures. The interest of the subjects of these pictures does not require one word of comment, and the photographs are for the most part very good. We commend such of our readers as have the opportunity, not to lose the chance of inspecting them.

Photo-Zincographs for Reproduction.—More than once we have suggested the reproduction of rare old books—such as "Shakspeare's Sonnets"—by the new process of photo-zincography. By this process, which Sir Henry James has applied to a reproduction of "Domesday Book," every beauty, every flaw in the type, every peculiarity of punctuation or division in the arrangement of letters, is preserved. How important such trifles may become, has been recently shown by M. Philarète Chasles, in his letter on the publication of "Shakspeare's Sonnets." The idea has been taken up by Mr. Lovell Reeve, who is about to issue a fac-simile of the first edition of the "Sonnets," taken by this new process from the famous copy in the Bridgewater collection. This fac-simile we have now before us, and we cannot imagine a more perfect or interesting present to a book collector, or even to a reader of Shakspeare. The dedication of the sonnet will enable every one to judge of the value of M. Philarète Chasles's discovery. Lord Ellesmere deserves every credit for allowing this fac-simile to be made. Mr. Reeve, we are glad to say, proposes to issue other important books in the same style. "Much Ado about Nothing" is already in hand.—*Athenæum.*

Formic Acid.—A correspondent says, I have tried formic acid in the negative developer, as mentioned in No. 202 of the Photographic News, p. 339, and think it answers perfectly oven without the addition of nitric acid to the bath.

Photographs of Volunteers.—We were recently favoured by Mr. D. Combe, photographer, of Cheapside, with an inspection of a selection of portraits of Volunteers belonging to the City of London Rifle Brigade, of which he is a sergeant. The portraits were mounted in a handsome album, and had been prepared for presentation to His Royal Highness the Duke of Cambridge, Colonel of the regiment, at the annual inspection of the brigade. It contained excellent photographs of Lieut.-Col. Warde; the late Lieut.-Col. Montague Hicks; the Honorary Chaplain, the Rev. Thomas Dale, M.A., Canon of St. Paul's; Drs. Attkins, May, and Prophert; Captains and Adjutants Ewens and Smith; Sergeants-Major Southgate and Talbot; Musketry Instructor Grainge; the captain, lieutenant, ensign, and one sergeant, one corporal, and one private of each of the sixteen companies forming the brigade, and a group of the cadets. The album bore the following dedication: "To His Royal Highness the Duke of Cambridge, K.G., G.C.M., G.G.C., H.K.P., General Commanding-in-Chief, Colonel of the London Rifle Volunteer Brigade, these photographs of the officers, staff, non-commissioned officers, and some of the privates of the London Rifle Volunteer Brigade, are, by gracious permission, most respectfully dedicated by the artist, His Royal Highness's most obedient servant, D. Combe, Sergeant of N. company." His Royal Highness examined the photographs, expressed his admiration of their execution, and having graciously accepted the gift, thanked Sergeant Combe for his appropriate present.

Clean Fingers.—A correspondent says:—I would suggest for the benefit of your readers, who wish to keep their fingers clean whilst developing, that on removing the plate from the slide one corner should be wiped with a dry cloth just enough to take hold of; the liquid will not flow over the wiped part.

Holder for Cleaning Plates:—A correspondent says:—I send you a description of a plate-holder I use for cleaning glasses; it consists of a piece of board twelve inches square, two pieces of flannel the same size as the board are then laid on it, and then a piece of American cloth rather larger than the board (shiny side upwards) is stretched tightly over it, and secured at the edges with tacks. The glass to be cleaned may be laid on it, and will bear any amount of rubbing without becoming detached.

## To Correspondents.

F. P. J.—It is probable that your bath has a large accumulation of ether and alcohol, to which may be attributable your difficulty in getting the solution to run evenly over the plate. In this case exposing it for some hours in an open vessel, in a warm place, will evaporate some portion of the ether and alcohol. The effect may arise also from the use of a collodion giving a very repellant film. A change of collodion will test that. In any case the repeated moving of the plate in the bath, both laterally and up and down, will aid in causing the solution to flow evenly, by facilitating the evaporation of ether, &c.

D. Padgham.—See first article in the present number. The slight yellow tint of which you speak is very easily obtained, as it simply arises from sulphur, and is produced by the use of an acid fixing bath. It is, however, generally a sign of commencing decay, and such prints generally fade. Your toning bath, if not exhausted or decomposed, but merely inert, may generally be made active again by the addition of a little freshly made toning solution, of the same kind, or a little of a solution of chloride of gold.

G. M. E.—The purchaser of any lot of photographs at a public auction, has a perfect right to dispose of them as he thinks proper, and can be in no wise compromised by the use to which they are put by persons to whom he may sell them. If any copyright exist in the pictures, the person who violates that copyright only is responsible, and not the person selling them to him.

F. M. Y.—The extension of the body of the camera depends entirely on the size you wish to copy. If you wish to reproduce objects or pictures the same size as the original, the camera must be extended to just double the solar focus of your lens. The size of the box to be added to the camera must of course depend on the length to which the camera already extends. With your No. I triple, the equivalent focus of which will be a fraction under eight inches, the camera will require to be extended for objects the same size 16 inches. 2. No rule can be given for exposure, it must always be ascertained by experiment. Not only the kind of collodion, and the condition of bath, but the time of day, the time of year, kind of object, strength of light, and a variety of other conditions, will influence the matter. From one minute to three may be a rough approximation.

Robert Boyne, and some other correspondents.—The address of Mr. Bailey is, "Chemist, Wolverhampton."

J. Lewis.—M. Poitevin's treatise on "Photography without the Salts of Silver," is published in Paris at four francs and a half, and may be had of Lieber, 13, Rue de Seine.

T. A. S.—It is probable that you do not tone sufficiently deeply. We can tell you better on seeing a specimen. Remember that it is necessary to all the prints to become deeper in the toning bath than is required in the finished print.

Actinic.—A third piece of glass forwarded by this correspondent since Nos. 1 and 2, has been examined in the spectroscope. It is decidedly better than either of the others, and might safely be used in cases where a very brilliant light did not shine on the window. It is not, however, so adactinic as a good sample of silver coloured glass.

J. B. B.—The spot of light in the middle of the picture is a trouble which frequently occurs where portrait lenses, with small central stops, are used for landscapes. We have not met with it ourselves, and cannot state certainly either the cause or the remedy. It is attributed by some to diffraction, consequent upon the use of a very small central stop; and by others to reflection from some defect in the mounting. If it be the latter cause, the maker will doubtless remedy it. If the former, try the use of a little larger stop.

F. B. T.—Your ether has probably become ozonized Exposure to light and air has a tendency to spoil it for photographic purposes. The thin grey image you describe would arise from such a cause. If your bath, &c., work well with other collodion, only failing with the sample made from old ether, it seems easy to fix upon that as the cause. We can only recommend you to use this batch of collodion for cleaning plates.

L. M. C.—The ammonia should not be applied to dry plates in your usual dark room, as the vapours of ammonia are very detrimental there, and apt to cause fogging, &c. For the purpose of trying the experiment you must fit up an *impromptu* dark room. An old iodizing box, such as was used in the Daguerreotype process, will answer admirably for the experiment, we should think. We shall be glad to learn the results.

M.—Very foolish indeed, since a reference to our pages shows the statement to be simply untrue. Palpable falsehoods are not worth the trouble of denying, and we do not intend to notice the matter further. It is an old game, to obtain gratuitous advertizing. 2. Glass transparencies may be toned in a variety of ways. The old method of toning paper prints with a bath of hypo and gold, may be used; bichloride of mercury, followed by dilute hypo, or ammonia may be used, and some other methods. As a matter of taste, however, we prefer the warmer tones. Where the wet process is used, and camera printing, the free use of acetic acid, both in bath and developer, gives a fine warm tone. We have obtained various tones of purple and ruby, even with iron development by this method. Expose well and develop rapidly.

S. G.—For enlargement, a very perfect negative is necessary. The specimen sent is defective only in this particular: the enlargement is very good indeed, but the original negative has not been sufficiently perfect for the purpose. The slight, crapy lines running diagonally, which would probably scarcely show at all in the original, are here very palpable. It is not sufficient that a negative for enlargement be very perfectly defined up to the edges, and full of detail; but it must be as free as possible from structural workings in the film, and pin-holes or irregularities of any kind, as all these things contribute to produce coarseness when magnified in the enlargement. A negative for enlargement should not be varnished. The tone of your print is very good, but a little too inky for our taste.

Al Fresco.—It is purely a matter of personal choice; some operators prefer a tent in which they are entirely enclosed, and others merely a dark-box in which the hands and arms only are placed, the operations being watched through yellow glass. We know some first-class professional photographers who adopt each method. Of the two operators who have produced the best instantaneous marine pictures of the day, one works in a tent, the other in a dark-box. We cannot advise you which is best. Many photographers simply wash the developed plate, place it in a box and fix at home.

W. Tucker, R. Fowler, C. M. Smart, W. Mayland, and Thomas Ratcliffe; Received with thanks. Attention at an early date.

Several Correspondents in our next.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 207.—*August* 22, 1862.

## REGISTERING PHOTOGRAPHS.

It may, probably, be interesting to our readers, and save some of them delay and trouble, if we describe exactly and in detail the steps which have to be taken in securing, by registration, the copyright in any of the photographs which have been for the first time sold, or published, since the passing of the new law of fine-art copyright, on the 29th of last month. The first step is to procure from the registering officer of the Stationers' Company a printed form, with blanks, which require filling up. The Hall of the Company is in Stationers' Hall Court, which leads from the west-end of Paternoster Row to Ludgate Hill; the Register Office is at the right-hand corner, on passing through the gate. The following is a copy of the form of memorandum to be filled up:—

MEMORANDUM FOR REGISTRATION UNDER COPYRIGHT (WORKS OF ART) ACT.

I, of , do hereby certify, That I am entitled to the Copyright in the undermentioned Work; and I hereby require a Memorandum of such Copyright [*or*, the Assignment of such Copyright] to be entered in the Register of Proprietors of Copyright in Paintings, Drawings, and Photographs, kept at Stationers' Hall, according to the particulars underwritten.

| Description of Work. | Date of Agreement or Assignment. | Names of Parties to Agreement. | Name and Place of Abode of Proprietor of Copyright. | Name and Place of Abode of Author of Work. |
|---|---|---|---|---|
| | | | | |

Dated this day of , 186 .

(Signed)

*To the Registering Officer of the Stationers' Company.*

*N.B. Office Hours from Ten to Four.*

Under the head, "Description of Work," the photograph to be registered must be briefly described, using as few words as possible, but mentioning the distinctive characteristic or difference; thus, for example, "A photograph of Lord Brougham, standing, head in profile, arm extended." It is not necessary to specify the size, the registering officer suggesting, that since a copyright is obtained in the picture registered, and in all copies of it, whether smaller or larger, it is undesirable to say anything about size.

Some pictures are easy to describe, others difficult; but in all cases it will be wise to append either a print from the original negative, or a small copy of it, since the act permits a "sketch, outline, or photograph" of the work to be protected, to be entered in the registration. In ordinary cases, where the photographer is registering his own work, the next two columns will simply require the word, "none," filling in each; but in case any assignment, or sale, of a negative, in which it is desired to secure a copyright, an agreement in writing must be made, stating whether such copyright is acquired by the buyer, or retained by the seller, and the names of both, with their addresses filled in their proper place in the form. In all cases the name and address of the photographer must be filled in its place. The memorandum must be signed by the owner of the copyright or his authorized agent.

For each registration, a fee of one shilling is charged; and each picture, no matter how many in a series, is made the subject of separate registration. Copies of the form of memorandum, for filling up, are sold at one penny each; we should recommend photographers with copyrights to register, especially those residing in the country, to procure a small stock of the form of memorandum: these, with copies of the photographs, and the proper fees, can then be forwarded from time to time without any trouble, either by the hands of an agent or by post.

The process is a very simple one, but we have detailed the steps to be taken for the especial benefit of our provincial readers, as the authorities of Stationers' Hall cannot enter into explanatory correspondence in reference to registrations.

As a commentary upon our remarks on a former occasion, regretting the ambiguity of some of the phraseology of the act, we may mention that, on our presenting ourselves with some photographs to register immediately after the passing of the act, we were informed by the registering officer that no such registration could take place until a sale had been effected, in which case a memorandum, stating to which of the persons concerned in the agreement the copyright belonged, could be duly entered. These were the instructions he had received from the legal adviser of the Stationers' Company. After a long conversation on the subject, he resolved to consult again with the lawyer, and courteously promised to let us know the result. In a few days we received an intimation that the registration could be effected in the way we desired, without any sale, in the manner we have just described. If the reading of the Act, as interpreted in the first instance by the registering officer, had been correct, a factitious sale must, in all cases, have been effected before the registration could have been made, and the copyright secured.

## THE REVISION OF AWARDS IN THE EXHIBITION.

Our announcement relative to a revision in the Awards of Jurors in the International Exhibition, appears to have given rise to some misconception. We spoke of *revision*, and referred to a *corrected* list. It appears, however, that some of our readers have understood from this that a *reconsideration* of the awards was to take place, by which the decisions of the Jurors might be amended. This, however, was impossible, however desirable it might have been in some cases.

The Juries were dissolved on the completion of their work, and no alteration in their verdicts, could, under any circumstances, be made. The revision we announced, simply consisted in revising and correcting the official list of awards published by Her Majesty's Commissioners, into which, owing to the haste with which it was prepared for the press, many errors had crept. A revision of this kind is really more important to those whom it may concern, than a reconsideration of the decisions would have been. An award secured by a reconsideration of the case, would have implied in many instances, that the merit was at least doubtful; but the addition of a name omitted by inadvertence, is merely the late publication of a deliberate award. These errors consist, in some cases, of the entire omission of names in the hurry of transcribing, in others of the insertion of wrong names, from the mark indicating an award standing equally near to two numbers in the catalogue. In some cases the phraseology stating the reason for an award, is, through wrong transcription, incorrectly given. In all these cases the errors will be corrected, but it should be distinctly understood in all cases, that these corrections merely consist in a rigid adherence to, and exact statement of, the final decisions of the Juries, no power existing by which a single award could be altered in the verdicts of the Jurors after they were delivered. The complete list in its corrected form will be published shortly, with an explanation of the causes of error in the first edition.

## Scientific Gossip.

STEREOSCOPIC PHOTOGRAPHS OF THE ORGANS OF VOICE IN ACTION—SILVERING GLASS AND OTHER SURFACES.

THE photographer has carried his art into the most inaccessible regions of the earth; the glorious panoramas visible from the summits of Alpine peaks have been fixed and brought down for the admiration of the non-mountaineering section of the public; his instrument has been lowered to the bottom of the sea, and brought up again with an impression of the kind of ground on which mermaids and sea-serpents are supposed to exercise themselves; the heavenly bodies floating in space, have by his art been made to draw their own likenesses; the minute microcosms in a drop of water, and those elementary cells, hovering, as it were, between the confines of the animal and vegetable, have been self-imprinted in all their magnified beauty, disclosing new secrets to the earnest student; catacombs, grottoes, and caverns deep in the bowels of the earth have been illuminated by the electric light, and their hidden wonders fixed on the sensitive plate; but all these achievements fall short of one which has recently come under our notice —obtaining photographs of the interior of a living human body. For some years past it has been known that instruments had been devised by which those organs concerned in the production of the voice could be rendered visible. Mr. Garcia was, we believe, the first who brought the glottis and its movements during speech under the cognizance of our eyesight, and in 1855 he exhibited, at the Royal Society, his instrument, and at the same time described some of the results he had obtained with it in reference to the mechanism of the voice. Only a very limited portion of the whole extent of the glottis could, in this manner, be brought into view, and the instrument remained very incomplete until recently, when it may be almost said to have been brought to perfection in the laryngoscope of Professor Czermak. By means of this instrument the whole glottis and the adjacent parts are clearly seen; its condition during vocalization and the changes of the cords in the production of the different chest and falsetto notes, become patent to the eye; and the ingenious contriver has actually succeeded in producing photographs, nay, even stereoscopic views of the phenomena. It is needless to enlarge on the physiological value of this visual test, applied to the various speculations on the voice. We may notice it here, as a conspicuous example of an unseen process in the human body which has remained hidden through all by-gone time, being in our own day brought fairly into light and fixed by the wonderful art of the photographer for the benefit of all future students in this branch of science.

An invention, which may be of some importance to the photographer has just been made public, having for its object the precipitation of a film of perfectly bright, pure silver into a surface of glass. The inventor, Mr. Cimeg employs a mixture of ammonia, nitrate of silver, and a solution of Rochelle salt (tartrate of potash and soda); this mixture is applied to the surface of glass to be silvered, and after a short time the metal is deposited on the glass as a bright film. The silver is thrown down at the ordinary temperature of the air; thus it is not necessary to heat the surface as when other mixtures are employed. The film of silver may be strengthened by depositing over it a cheaper metal, such as copper. The process above-described is also applicable for silvering other surfaces; for example, it is very useful for giving a metallic and conducting surface to articles into which it is desired to deposit copper by electricity, where the article itself is not a conductor. The surface of paper, or of a woven fabric or other similar surface, may be silvered by first depositing the metal on to a polished surface, such as glass; the fabric may then be attached to it by suitable cement, when the whole may be stripped off together. This process is likely to be of considerable interest to experimenters. We have seen some very good results obtained by the ordinary Daguerreotype process, employing a plate of glass, silvered by Liebig's process: the effect produced being very similar to that of an ordinary collodion positive. We think good effects might be also obtained by preparing the silvered glass plate with iodine and bromine vapour, as in the Daguerreotype process, and then after exposure, developing with pyrogallic acid, as suggested by Mr. Kingsley. For the benefit of those who may wish to experiment with this process, we give the full particulars of the manner in which Mr. Cimeg prepares his solutions, &c. The sheet of glass, previously washed clean with water, is placed upon a table, and the whole surface rubbed with a pad of cotton or other soft fabric, wetted with distilled water, and afterwards with a weak solution of Rochelle salt in distilled water, about one part of salt in 200 parts of water. A solution of ammonio-nitrate of silver is then prepared, by adding nitrate of silver to ammonia of commerce, very gradually, until a brown precipitate commences to be produced; the solution is then filtered. For each square yard of glass to be silvered a quantity of this solution is taken containing 20 grammes (about 309 grains), of nitrate of silver, and to this is added as much of a solution of Rochelle salt in distilled water, as contains 14 grammes of salt: the strength of this latter solution being so adjusted to that of the silver solution, that the total weight of the mixture of the two in the quantities above mentioned may be 60 grammes. In a minute or two after the mixture is made it begins to become turbid, and it is then immediately to be poured on to the glass, which has previously been placed on a perfectly horizontal table; the plate, however, being temporarily blocked up at one end so as to give it an inclination of about one in forty. The liquid is poured on to the plate at the higher edge, so that it may run towards the lower; the pouring being done in such a manner as to distribute the liquid over the whole surface of the plate, without allowing any to escape at the edges. When this is effected the plate is placed in a horizontal position, at a temperature of about 68° Fah. The silver will begin to appear in about two minutes; before the expiration of ten minutes the plate will be covered, and in thirty minutes sufficient silver will be deposited for most purposes (about 2 grammes per square yard). The mixture is then poured off the plate, and the silver it contains afterwards recovered. The silvered surface of the glass is washed by pouring water over it four or five times, and the plate is set up to drain and dry. If it is required for photographic purposes, it may be used at once, only needing perhaps a polish with fine leather or cotton wool; but if it is intended to utilise the brilliant reflecting surface which the metallic mirror presents, it must be varnished. The inventor prepares the varnish of the following materials, viz.: gum dammar 20 parts, asphalte (bitumen of Judea), 5 parts, gutta-percha 5 parts, benzol 75 parts. This varnish dries, and sets hard on the surface, and the glass is then ready for use as may be required. Instead of varnish a layer of copper may be deposited over the silver by the electrotype process, and if this is made of a suitable thickness, the two metals may together be stripped off the glass, producing a sheet of highly polished plated copper. Plates and surfaces of other non-absorbant materials which will not act chemically on the silver solution may be coated with silver in the same manner as plates of glass. In order to silver paper, woven fabrics, and other materials, the metal is first deposited on to a plate of glass as already described; then a varnish is poured over the silvered surface, consisting of one part of gum lac dissolved in from six to ten parts of wood spirit. When this varnish is dry and hard, a solution of one part of gelatine in from six to ten parts of water is also poured over, and allowed to set into a jelly; the paper, leather, woven fabric, or other similar material to be silvered, is then laid on and pressed in contact with the jelly, when it is left to dry thoroughly; afterwards the material with the silver is stripped from the surface, and the process is complete. This process, which we ought to state is patented, is likely to prove of considerable use to electrotypists in coating their moulds of wax, gutta-percha, or similar material, with a conducting film; the article will only require to be placed in this prepared silver solution for it to become in the short space of twenty minutes or half-an-hour thoroughly coated with a metallic film of the reduced metal.

## Critical Notices.

### PHOTOGRAPHS OF VIEWS AND ARCHITECTURE IN CAMBRIDGE. By W. Mayland.

This series consists of a variety of landscapes in the neighbourhood of Cambridge, and of interior and exterior views of some of the architecture in that city. As a whole, these photographs are worthy of high commendation, the subjects are interesting, the treatment is artistic, and the photography nearly faultless, the delicacy of manipulation reminding us in many respects of the pictures of Mr. Vernon Heath.

"The Robinsou Crusoe, from Sheep's Green," is a 12 by 10 photograph of a noble old tree, the spreading limbs and graceful foliage of which are beautifully rendered. A great charm about this picture is found in the *entourage* of the tree, which is the principal object. A rustic cottage, embowered in foliage, small trees, and shrubs, with water in the foreground, reflecting the foliage, all combine to produce a picturesque effect. An opening in the foliage, showing the windings in the river, and giving distance, and a couple of youths fishing, helping the composition without disturbing the repose or destroying subordination, complete the picture.

"The Library, Trinity College," is one of the most perfect interiors we have met with. The noble and magnificently equipped and arranged library, presents a vista of apparently from a hundred and fifty to two hundred feet, the whole of which possesses satisfactory definition in every part, the perfection of which, and of the half tone and modelling throughout, gives a most marvellous effect of monocular relief, scarcely surpassed in the stereoscope. A memorandum on the corner informs us that the negative was taken in winter, with an exposure of fifteen minutes, iron development, and the full aperture of a Dallmeyer's triple lens for 12 by 10 plates. This print is 13¼ inches by 10½ inches, and possesses very satisfactory definition. The picture is both soft and vigorous; brilliant and full of relief, but without black shadows or patches of white without drawing.

"Kings College Chapel" is an excellent piece of photography, but scarcely an artistic picture, the building completely filling the plate; there is sufficient definition up to the edges of a picture 13½ inches by 10½ inches, and vigourous freedom from distortion, the architectural lines being perfectly straight at the extreme edges.

"St. John's, from Trinity," is a fine landscape, with the river in the foreground, the distant college being seen through an avenue of well defined foliage. "King's College from King's Meadows," and "Ditton," are two equally fine pictures.

"Thorwalsden's Statue of Byron in the Library of King's College," is a very perfect photograph, well rounded and soft, of a noble piece of sculpture. The interior of the library, indicated but not made out, forms an excellent background for the statue.

"The Avenue, Trinity College," is a charming piece of photography of a good subject. The sun glancing through the trees, athwart the avenue, and interlacing the walk with the long east shadows of the trees and their branches, giving it a most fantastic effect.

"King's College Chapel." This is a vignetted print of a very pleasing composition; the many pinacled building is in the middle distance, the foreground consisting of a mass of fine foliage. The time is winter, and the boughs of the leafless trees bend under heavy masses of snow, which is very finely rendered.

Two views of the interior of Trinity Chapel, one looking east, and the other looking west, are marvellously fine views of a very noble building. Every detail of the old and dark carving is made out, the shadows are rich aud transparent, and the prints are full of relief and vigour. The negatives were taken by a 6 by 5 triple, but these prints are 7½ inches by 6½ inches, thus giving a very wide angle, including a large portion of each side of the interior, whilst the definition is very fine throughout. The stereoscopic effect given by these single pictures is very striking. A view of the cloisters in Trinity College has the same characteristic. This is a very charming photograph, the lighting, the point of view, the amount of softness and detail, and great brilliancy, all displaying the taste, judgment, and manipulatory skill of the operator in a pre-eminent degree.

We recently referred to Mr. Mayland's card portraits as amongst the finest in the International Exhibition: the series before us affords evidence that his skill in landscape and architectural photography is not inferior to the ability displayed in his portraits. The artistic qualities of his pictures are good, whilst in care, delicacy, attention to minute details, freedom from slovenliness or manipulatory faults, uniform and good printing, they are unsurpassed.

### PHOTOGRAPHS FROM ENLARGED NEGATIVES. By W. H. Warner, of Ross. London: H. S. Warr, High Holborn.

Our readers will recognize the name of Mr. Warner as a frequent correspondent in our columns, and they will also be familiar with his announcement in our advertising pages, undertaking to produce enlarged negatives for amateurs and the profession. The photographs before us are specimens of the excellence to be obtained by the method of enlargement adopted, which is that described in the Photographic News Almanac for this year, and brought into recent notice by Mr. Heath's paper, at a late meeting of the Photographic Society. The method consists in producing an enlarged negative from a small one at two operations, a transparent positive being first obtained, and from that another negative. The whole of the specimens before us are on whole plates, and are enlarged from stereoscopic negatives; the amount of enlargement is not, of course, limited to this proportion, but Mr. Warner finds that an enlargement of this extent is pre-eminently satisfactory. These specimens are duplicates of some which appeared in the British Department of the International Exhibition, and were removed on account of injury from the damp walls.

To those interested in this mode of enlargement, we especially commend a view of the South Aisle in Hereford Cathedral, which is, in every sense, a very fine picture, and an excellent specimen of enlargement. As a picture, it is beautifully lighted, and a charming specimen of breadth. Architectural subjects, it will be readily seen, are trying tests for definition in this mode of enlargement, inasmuch, as unlike many subjects, portrait busts for instance, the necessity for fine definition, is not confined to a portion in the middle of the plate, but is carried to the extreme edges. This specimen and many similar ones, are therefore valuable as showing the amount of definition to be secured by the process.

The "Blind Harper, Raglan Castle," is another picturesque photograph and excellent enlargement. "Oscar," a fine portrait of a handsome dog, is also fine. A Norman doorway in Ludlow Castle, and another in Kilpick Church, as well as some others, also satisfactorily illustrate the excellence of the method, and are in themselves interesting pictures.

As our readers know, we have always recommended this mode of enlargement, feeling well convinced that by its judicious use a sufficient amount of definition could always be secured, whilst, in some instances, the sharpness is in no perceptible degree inferior to that of the original. The facility of securing many beautiful results with small apparatus, difficult or impossible with larger instruments, and the temptation to reduce the amount of *impedimenta* whilst on photographic rambles, are, we think, strong inducements to the amateur to be content with obtaining perfect small negatives, with a view to the subsequent production of large pictures from enlarged negative.

## PHOTOGRAPHS OF VARIOUS VIEWS. By Ernest Edwards. London: Published by McLean, Melhuish, and Haes, for the "Amateur Photographic Association."

The series of photographs before us is a striking illustration of the value of the Amateur Photographic Association, in affording a ready way for the amateur to publish his productions without entering the ranks and competing with professional photographers.

From the catalogue of the Association, we find that Mr. Edwards contributes not less than one hundred and nine negatives, prints from a dozen of which we have before us, and we may add that if the bulk be anything like the sample, which we do not doubt, Mr. Edwards may not only claim a very high position in the amateur ranks, but may ably try conclusions with some of our best professional artists.

The first print which arrests our attention is a view of King's College Chapel, Cambridge, from a similar point to one we have just noticed above. This is, however, a summer scene, in which the wooded foreground is thick with leaves instead of snow; and although both are excellent photographs, we prefer the effect of the summer picture, the leafy entanglement being highly picturesque; whilst the light, graceful form of the building, seen through and above the trees in the distance, has a very charming effect. There is a fine atmospheric tint in the sky, and the picture is tastefully vignetted. Altogether this picture is a photographic gem.

"Ryde Pier and Steamer."—This is an instantaneous picture, and is in no respect inferior to that we have just noticed: it is a fine composition, and is delicate, soft, and transparent.

"Whippingham Church" is a very excellent photograph of the church which Her Majesty has recently rebuilt at Osborne. There is a little under-exposure in the foliage, and this is scarcely, we think, the best view of the building, which is, however, one of which it is somewhat difficult to obtain a suitable position for getting the best effect.

"Netley Abbey, East Window," is one of the most charming photographs of the series, exquisitely brilliant, and perfect in chiaroscura, it is at the same time delicate and soft in the extreme; the climbing foliage, almost bridging the chasms in the broken arches, is very beautiful. Some other views of the ruins of this fine old abbey are equally good.

"Anchor Church, Derby," and "A Cleft in the Rock, Anchor Church," are two good photographs of natural curiosities, the chief charm in which, pictorially, consists in the beautiful rendering of the mass of luxuriant vegetation with which the rocks are overgrown, creeping plants, and grasses of all kinds, intertwining in fantastic wreaths. These would form fine subjects for the stereoscope, but they scarcely make pictures.

A statue of "Silence," in the Fitzwilliam Museum, is a charming photograph of a charming piece of sculpture. It is illuminated chiefly by a side light, and in the point of view selected, the camera is directed to the shadowed side of the figure; the attempt is a dangerous one, but the result is very beautiful when it is successful, as it is here. The vignetting is very judiciously managed.

The "Shield of Achilles" is a fine piece of photography, rendering with great delicacy every part of the magnificent design, and doing full justice to the *relievo*, a task not always easy with a bronze surface.

"The Library, Trinity College," is a beautifully executed small interior of this magnificent library.

The whole of Mr. Edwards' pictures are characterized by fine feeling and great delicacy of manipulation. It is only right to add that the printing is uniformly good, the prints are of fine tone, and the vignetting judiciously managed, the whole reflecting great credit on the firm who print for the Association.

## THE INUNDATIONS IN THE FENS FROM A PHOTOGRAPHIC POINT OF VIEW.*

As we passed the Magdalen Fen engine, I was much surprised at its unwonted state of activity. The large drain made to convey the waters thrown out by its wheel into the river Ouse, and which was usually nearly empty, was now full from bank to bank, and the surface of the water was covered with yeasty foam, caused by the laborious efforts of the engine to lessen its quantity. We learned, on enquiry, that the pig-headedness, if not something worse, of the occupiers and labourers on the inundated side had occasioned this unusual strain upon the Magdalen engine. It appears that immediately upon the breaking of the bank the Magdalen Fen men eagerly rushed to the culverts,† and stopped them up; but in the night some persons, actuated by the insane notion that if the waters were allowed to run through these outlets, it would lessen the quantity on the submerged land, opened the communications again; and in the morning there was a lake of about the area of 50 acres to greet the terrified gaze of the Magdalen Fen men. They proceeded at once to prevent the increase of the evil, by stopping up the outlet once more, and to prevent a repetition of the mischief, left it guarded night and day. We now turned into a narrower road, and in about eleven minutes we were at the foot of a bridge now useless, for all traces of the path beyond were obliterated by the cruel resistless waters now raging before us.

I shall not easily forget the impressions produced by the first sight of this extraordinary scene. I had, during our ride, endeavoured to picture it, but I saw at a glance that description failed entirely in conveying anything but the faintest outline. I knew the spot so well, and expected to see the monotonous flat of land made still more monotonous by being converted into an inland sea, but I was altogether

* Continued from p. 353.

† The culvert is an under-ground communication to connect the drains stopped by construction of the Middle Level drain, and is carried under its bed.

unprepared for the relentless eagerness of the destructive waters.

Immediately before me was the broken bank, with a gap in it about 100 feet across, through which the waters were rushing with a fierce triumphant fury, as though mad with joy at the mishaps that gave them their own again; but not without opposition though, for the wind, usually so fickle, seemed determined to be the farmer's friend, for it was blowing with most determined earnestness from the S.W., and further out the elements were having a most determined battle. The crests of the waves were white with fury at this bar to their victorious career, but in vain, for the wind was steady and determined, so lashed their sides with rage, and retreated to an unfortunate cottage a mile off, when finding the door open, they expended all their fury in banging it about most unmercifully. To the right the course of the railway could be traced for about a mile, when it was swallowed up by the waters, and the occasional gate house, or the posts of the telegraph, were the only indications of its course. Further out the waters were madly dashing against a bank, and occasionally leaping over it, whilst on the other side was comparative calm. In the extreme distance I could distinguish the towers of Walsaken and Emneth churches breaking the horizon line.

I turned from this melancholy scene to look at works in progress immediately near me. Several stacks of faggots were collected, and a number of sacks of clay filled in readiness, and at the foot of the bridge a temporary beer-house had been contrived. It was rudely constructed of poles and tarpaulin, but it appeared to content the navvies, who were congregated round it, busily employed in imbibing sundry pints of a muddy beverage called by the landlord beer. A tall countryman advanced from this group, and, having caught my eye, proceeded to narrate most circumstantially all the events connected with the catastrophe. I found him a veritable phenomenon in a smock frock, for in the space of a week he had acquired a new business, and one that proved more profitable than the old one. He appeared to be quite up to his duties, and proceeded to hold forth quite in the style of the professional guide. I learned from this old man, who informed me that he had been one of the anxious watchers for the breaking of the bank, that every precaution had been taken at all the weak points along the bank, but that it was evident to every one, long before the actual arrival of the catastrophe, that nothing short of a miracle could save the Fens from inundation after the breaking of the sluice. It appears that the water found its way through, some feet below the top of the bank, and spurted out on the other side, like the stream from the hose of a fire engine, but that in almost less time than it takes to tell, there was an aperture, twenty feet across, which continues to widen at an alarming rate, the earth crumbling away on each side and disappearing in the most extraordinary manner. Various attempts to stop it were made, but all in vain. Barges were knocked to pieces by the force of the waters, and the fragments were carried miles away.

I did not attempt to unpack, for the weather unmistakably said, no photography to-day. As, however much could be done in selecting spots for future operations, I left my companion in charge, and strolled on along the bank towards an unfortunate house, which the hanger-on informed me was an inn. A brisk walk of some ten minutes duration, brought me to it and truly it was a melancholy picture to look at. The house stood about 100 yards from the bank on which I stood, and was surrounded by several outbuildings, and the water was nearly up to the roof of some of them. A little nearer a gate peeped out just above the water, and evidently stood upon a higher piece of ground. The sign of the house had evidently been removed, for its announcement—"good entertainment for man and beast"—would have indeed been a bitter jest at the present moment. The waters were sullenly dashing against the closed door, as though angrily asserting that a public house should be open to all comers.

About a mile further on the bank I saw a large farm, with many outbuildings, and several cottages at a short distance from it, and therefore went still on. A strange feeling took possession of me as I wandered on alone. I looked out on the vast waste, and, far as the eye could reach, not a trace of human existence was visible—nothing but ruin and desolation. No sound came upon the ear but the howl of the wind, and the angry response of the waves. The clouds were wild and strong, and were coursing after each other rapidly, as though eager to get away from so dismal a spot. It seemed no great stretch of the imagination to fancy the deluge once more here, and I the last man left.

When I came up to the farm I found that it would be the best point for photographic operations. I therefore determined that on the following day, weather permitting, it should be my first point, for without carrying the camera far several very interesting pictures could be made.*

(*To be continued.*)

## THE TANNIN PROCESS.

BY PROF. EMERSON, OF TROY.†

Photography on dry plates possesses so many advantages over the wet for outdoor work, that great attention has been given by scientific photographers to experiments in this department, with a view either to devise some entirely new method which should not be subject to the defects attending the old methods, or so to improve some one of the known processes as to render it more easy and certain in the practical working. The vast amount of laborious research which has been made to this end, can only be appreciated by those who are familiar with the practice of photography in its different branches.

Among the dry processes, the collodio-albumen and the Fothergill have, until very recently, received the most attention, and in the hands of adepts have given excellent results. But as success in these methods depends greatly upon the mechanical state of the collodion, and the favourable condition of the sensitizing bath, it is evident that neither of them can be worked with certainty by the generality of operators.

Major C. Russell, of England, after a series of experiments extending through five or six years, has perfected a dry process, now known as the Tannin Process. Its advantages may be briefly summed up as follows:—1. It is simple. 2. It is not dependent upon the mechanical state of the collodion. 3. A sensitizing bath in ordinary working condition is sufficient. 4. The development of the latent image is under complete control. 5. It gives, if desired, great intensity. 6. It affords an excellent tone. 7. The prepared plates will keep well both before and after exposure. 8. The silver in the development is thrown down in a very finely divided state, and it is thus more favorable for obtaining extreme sharpness.

As might have been expected, this process has excited great interest in the photographic world. Many experiments have been made upon it, and thus far the testimony has been uniformly in its favour. Our own observations have extended through a year, and experience corroborates fully the favourable estimate which has been formed of it by others.

We give now the details of this process as worked by us:—The plate should be very carefully cleaned, and must be perfectly dry before coating with collodion; it is coated and sensitized in the same manner as for the wet process; it is then washed thoroughly in pure water with five or six changes of water; a good plan is to have a succession of baths of pure water into which the plate can be dipped successively without removing the plate from the dipper, as recommended by my friend, F. F. Thompson, Esq. (see

* A small portion of the preceding, through an error in the "making up," appeared in a former number.

† From *Silliman's Journal.*

*American Journal of Photography*, May, 1862).* After being thus washed with water, it is flowed with or dipped into a bath composed of fifteen grains of tannin dissolved in each ounce of pure water, the solution being carefully filtered. The plate should remain in this bath four or five minutes. It is then drained, and set up on one corner, on bibulous paper, to dry in a dark room or box. The ordinary exposure necessary is about four times as loug as a wet.

Two solutions are used in the development—

| | | |
|---|---|---|
| No. 1.—Pyrogallic acid | ... | 72 grains |
| Alcohol (95 per cent.) | ... | 1 ounce. |
| No. 2.—Nitrate of silver | ... | 20 grains |
| Citric acid | ... | 40 " |
| Water, pure | ... | 1 ounce. |

To develop—wet the plate rapidly with pure water, when the film is thoroughly moistened, flow the plate with water, to each drachm of which has been added two drops of No. 1, and one drop of No. 2; keep this developer in motion over the plate until the details are well out; then add to it drop by drop of No. 2, until the required intensity is obtained. Fix in hyposulphite of soda as usual.

Experience in the use of this process teaches—1. That dryiug by artificial heat is not necessary. 2. That the amount of acid in No. 2 may be judiciously varied with the length of exposure. It is better to have an excess of acid than too little. 3. Warming the plate in a bath of water heated 90° F., but using the developing solutions at the usual temperature, as recommended by Dr. Draper, of New York, and otheis, shortens the time of exposure necessary, so that this process may be worked almost as rapidly as the wet. 4. By the use of honey in combination with the tannin, fifteen graius of each to the ounce of water, as recommended by Mr. England, of London, great rapidity is gained. 5. A bromo-iodized collodion is to be preferred, and an old collodion works better in my hands than a new sample. 6. The silver bath should not be neutral, but ought to be decidedly acid; this may be done by addiug one drop of nitric acid for every twelve ounces of bath. 7. This process is peculiarly adapted to the production of glass transpareucies for the stereoscope, affording great beauty and richness of tone.

## A SHORT LESSON IN CHEMISTRY.—No. 1. †

The land, the water, and the atmosphere, together with animal and vegetable substance, constitute what is denominated the *earth*. All the matter of this earth, as varied as it is, as far as has been discovered, consists of sixty-three simple forms of matter, called elements, by which we mean such forms as are homogeneous throughout, and incapable of being reduced into any other simpler forms. Of these elements four, when isolated from all combination with other elements, are in the gaseous and aeriform state, their names are: hydrogen, oxygen, nitrogen, and chlorine. One element has never yet been isolated from its combinations, so that we do not know what may be its independent or elementary form; it is called fluorine. One of the elements, called bromine, exists in the liquid state when uncombined. The rest are solid. The sixty-three elements are divided into two groups, one of which is denominated the group of the metalloids and comprehends thirteen elements; the rest of the elements receive the appellation of metals. The study of the metalloids is the most important for the chemist; for it is, as it were, the key to a knowledge of all the rest. The following is a list of the metalloids: hydrogen, oxygen, nitrogen, chlorine, iodine, bromine, fluorine, carbon, boron, silicon, sulphur, selenium and phosphorus.

Now, although the earth contains no other sort of matter besides the metals and the metalloids, to the number already mentioned, yet there is an indefihite variety produced by their intermixture, or chemical combination. Mixture is totally different, however, from combiuation. Sugar dissolved in water, and lac in alcohol, are examples of mixture, because the sugar and the lac have not changed their nature by their solution, and can be regained in their original states by evaporatiug the water and the alchol. Commou salt and nitrate of silver are examples of chemical combination; for these salts show no signs visible to the eye of the metals or acids which form them; the acids have disappeared and so have the metals, and totally different substauces are formed from the combinatiou of acid and metal respectively, called chemical combinations.

Since mixture and chemical combination are so different it becomes an important question to ask by what cause this difference is produced, or, which is about the same thiug, to ascertain the cause or causes of chemical affinity whereby composition and decomposition are effected. Researches in this department of natural science demonstrate that there is something more than matter required to make up even an element of matter; that certain *forces* are always brought into play in every formation or transmutation of matter, and that one or more of these forces form a part in the composition of all matter. The forces alluded to are denominated *the imponderables*, and are recognized in heat, light, electricity, and gravitation. There is not a single atom of matter on the earth that is, or can be isolated from all these forces, if from any of them: and not a single combiuation or separation in chemistry is effectuated without the application or disturbance of these forces.

The precise method by which all this chemical work is performed, that is, the intellectual part of this work, is as yet in a great measure a mystery. We know the effects, we can reproduce the effects. by the application of these forces as immediate causes or agents; but we cannot always give a satisfactory *rationale* of the varied phenomena in chemical changes. For instance, in the film of iodide, bromide, or chloride of silver, nothing is now better known than the changes that occur whenever these films are exposed either to the light of the sun, or the diffused light of day. But we are very far from being iu a condition to explain philosophically, that is logically, as applied to cause and effect, the changes that we know must follow. We know that the chloride of silver, by being exposed to light, is changed into what is called a subchloride, which has a beautiful violet colour and is insoluble in solvents in which the chloride is quite soluble; but neither the microscope nor any other aid in science has detected any constitutional alteration to account for the change. Sufficient however, is known to determine that these imponderable forces are the very essence of chemical science. Certain generalizations, too, in their action have been well determined; so that we know that heat, light, and electricity, in many instances compose and decompose with almost equal facility; for instance, heat changes ice into water, water into vapour, vapour into its elements—oxygen and hydrogen; electricity with a slight modification of application will do the same. Again, visible heat (that is flame) will recompose oxygen and hydrogen iuto vapour, so will electricity. Withdiaw heat or apply its negative, that is, cold, or apply compression, which is simply a modification of gravitation, and vapour will be restored to water. Thus, then, by the co-operation of these forces, or by their antagonism, arise all the unspeakable and unintelligible phenomena of chemistry.

Harrison's New Lens.—The new lens, stated to include a very wide angle, has recently been patented in America. The specification runs:—"We claim the combination of two sets of cemented lenses, tho exterior surfaces of which shall form part of the same sphere, the axes of which shall be coincident, and the other curves of which shall be so proportioued to the focal distance of tho combination, and to the refractive and dispersivo powers of the glass used in their construction, that tho image found at the focus shall bo achromatic, and that said image shall bo upon, or almost exactly upon, a plano without distortion of form, and including a larger visual angle, substantially as before described aud represented."

* See letter from Mr. Thompson on p. 359 of the present Volume.
† From *Humphrey's Journal of Photography*.

## ON THE STUDY OF THE ELECTRIC SPARK BY THE AID OF PHOTOGRAPHY.*

BY PROF. OGDEN N. ROOD, OF TROY, N.Y.

Photographic images of the electric spark between the carbon electrodes of the voltaic pile were obtained on silver plates in November, 1840, by Prof. B. Silliman, jun., and Dr. W. H. Goode. These observers remarked the greater actinic activity of the negative spark as compared with the light from the positive electrode, which I believe is the earliest recorded observation on this point. These authors also noticed a double concentric structure in the impression from the electric spark similar to that described in this paper.

Photographs of the stratification and luminous discharges in Geisler's tubes, were obtained in the spring of 1860, by Professor W. B. Rogers, of Boston, operating with one of Ritchie's coils. These results were communicated to the British Association at their Oxford meeting in June, 1860.

Similar photographs were obtained by Gunther and Dove, and presented by the latter to the Prussian Academy, on the 27th of May, 1861. A photographic camera was employed, and an exposure of from 3½ to 6 minutes.† In the same number of Poggendorff's Journal, W. Feddersen, in a highly interesting article on the electric discharge from the Leyden jar, states that, by means of a concave mirror silvered according to Leibig's process, he obtained fine photographs of the electric spark, even when the mirror was in rapid rotation. Photographs of the spectra from the spark of Ruhmkorff's coil have also been obtained by Prof. W. A. Miller.

In all these cases the electric line was photographed from a position at right angles to its motion, a side view being obtained. My object in the present article is to describe a very simple and easy method of obtaining remarkably fine photographs of the electric spark from a point of view parallel to the direction of its motion, the pictures being as it were transverse sections of the spark and of the electric brush in all its variety. The very short duration of the electrical discharge renders its study by ordinary means difficult and uncertain; while photography, by revealing a mass of new details otherwise invisible, and furnishing a permanent record, which can be studied at leisure, offers advantages that cannot be too highly estimated.

*Method Employed*.—M. E. Becquerel showed, several years ago, that paper coated with the bromide of silver is sensitive to the light of the electric spark; the discharge of a battery of four Leyden jars in its immediate neighbourhood causing a slight darkening. When a single spark was allowed to strike the paper no effect was produced.‡

In experiments on instantaneous photography with the wet collodion process, I was often encountered by the well-known fact that, while those portions of the sensitive surface which had been acted on by a very bright light darkened strongly under the developing solution, adjacent parts, where the action of the light had been somewhat feebler, remained quite transparent and free from a deposit of silver. This rendered it probable to me that if the electric spark were made to strike directly on the sensitive surface, only those portions would be effected which were in immediate contact with the luminous atmosphere. Actual experiment confirmed this idea to a most surprising degree. When a single spark was allowed to fall on the sensitive surface, under the action of the developing solution, a fine intense, and sharply-defined image, full of delicate details, was produced. The sharpness and perfection of these images was such that they bore examination by the microscope under a power of 40 diameters, while there was not the least difficulty in enlarging them by means of photography as high as 20 diameters. The enlarged negatives then furnished good prints on paper. Sometimes the small original images were accompanied by an irregular partial halo caused by the diffused light of the spark, but this for the most part was so faint as in no way to interfere with the distinctness of their outline.

The question naturally arises whether these delicate and beautiful images are produced by the action of the *light* on the sensitive plate, or are owing to a decomposition of the silver salt by electrical agency: in other words, whether these pictures are photographs or electrographs. That they are due to the action of light the following experiments will render probable.

(1.) Sparks were allowed to fall on sensitive plates, and their form was observed by the aid of a lens of one inch focal length: on developing the latent images they corresponded in shape with those observed.

(2.) A glass plate was coated with plain collodion, free from iodide or bromide, and allowed to remain five minutes in the bath of nitrate of silver. It was then removed, and single sparks were allowed to fall on different portions of the wet collodion surface. Under the action of the developer the well-known spark images appeared.

A simple clean glass plate without any coating at all was placed in the nitrate bath for a few seconds. On its removal, and while still quite wet, sparks were discharged on different portions of its surface. When the sulphate of iron developing solution was poured over it as usual, clear sharp images of the spark were obtained!

As plain collodion, free from iodide and bromide, as well as simple glass plates moistened merely by the nitrate bath, have not been considered by photographers as sensitive to light, these unexpected results rendered it probable that the electrical discharge produced a decomposition of the nitrate of silver. I was, however, enabled to prove that these surfaces really are sensitive to *light*, in the following manner:—A plate coated with collodion, free from iodide or bromide, but saturated with a solution of nitrate of silver from the bath, was placed in a camera which was directed towards a window with a bright sky beyond. The lens used was the "portrait combination," its focal length being six inches, with an aperture of 1½ inches: the exposure lasted ten minutes, the full aperture being used. Under the sulphate of iron solution, a distinct image of the window, of no great intensity was obtained. Next, sunlight was concentrated by a "bull's-eye" condenser on a little stand, which, to avoid too great heat, was arranged so that its surface was about half-way between the lens and its focus, the bright spot on the stand covering an oval space ¾ of an inch in diameter and two inches long. A plate merely moistened by immersion in the nitrate bath was placed on the stand for ten seconds, and then developed by the sulphate of iron solution, which brought out an intense image of the oval spot.

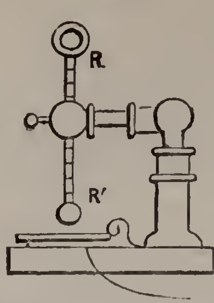
(3.) The image of the positive spark falling on a plate merely wet with nitrate of silver has a peculiar and definite form. If this form is really traced by *light* we should expect that the light would be able to act on another sensitive plate placed directly under and in contact with the first. This was found to be the case. A glass plate coated with sensitive collodion, on its removal from the nitrate bath, was covered with a piece of the very thin glass used for microscopic purposes, the latter having previously been moistened by a solution of the nitrate of silver: sparks were then discharged on the covering plate of thin glass. When the latter was removed and the collodion surface developed as usual, images of the spark were obtained. The definition was much impaired, and the intensity lessened. When the thin glass was blackened so as not to transmit light, and the experiment repeated, no images were produced, not even by allowing a large number of sparks to strike the same spot.

*Apparatus for the Production of the Photographs*.—For the generation of the electricity a small cylinder machine was used. The diameter of the cylinder was seven inches,

* From the *American Journal of Science and Art*.
† Pogg. Annalen, vol. cxiii., No. vii.
‡ Pogg. Annl., vol. liv., p. 54.

its length ten inches: the prime conductor exposed a surface of 200 square inches.

Fig. 1.



The apparatus for throwing the spark on the sensitive plate is seen in the diagram A brass rod R R′, terminated by a freshly polished brass ball six-tenths of an inch in diameter, is supported over the centre of the sensitive plate and insulated in the manner seen in the woodcut (*fig.* 1). The rod is graduated and held in position by a binding screw. The sensitive plate is supported on a silver disc, which is in metallic connexion with the rubber of the machine. A weak spring of platinum foil rests on the collodion film and connects it with the silver disc. R is connected with the prime conducter.

The manipulation was as follows:—A glass plate three inches square was carefully cleaned, coated with collodion, and sensitised in a bath of nitrate of silver of 40 grains to the ounce of water. The plate on being taken from the bath was held in an upright position, so that it could *drain* for one or two minutes: it was then placed on the stand, and the machine very slowly turned, until an apparently single discharge had been effected, when the plate was removed about three-tenths of an inch, and the operation repeated until twenty sparks had fallen upon it. The plate was then developed and fixed as usual. After each experiment the brass ball was wiped to remove dust, &c.

The pictures produced in this way are apt to be too intense, whereby the interior details are often unobscured. Some care must therefore be taken in the selection of a collodion; that which is suitable for "ambrotypes" is to be preferred. The following formula answered well in my hands:—

| | |
|---|---|
| Plain collodion ... ... ... | 8 ounces |
| Iodide of potassium ... ... | 40 grains |
| Bromide of ammonium ... ... | 20 do. |

This collodion should be used while still new, as it then is sensitive and not too intense in its action.

## THE STEREOGRAPH AND THE STEREOSCOPE.*

*Example* 2.—Suppose, however, the whole party could not be taken in, or condensed into the proper sized view at a less distance than thirty feet; in this case it would not be proper to make the allowance between the cameras of one foot, this being the tabular distance opposite thirty feet; such a distance would produce distortion by making visible at six feet a view that could not be comprehended by the eye at that distance; such relief as this, although exceedingly manifest, would produce pain to regard it. We will suppose in this case there is the same difficulty intervening between the party and the artist in the form of a pond or otherwise, and as before, the photographs have to be taken at the distance of sixty feet. Opposite thirty feet in the table you will find 1 foot 0·56 inches, and opposite fifty feet, 1 foot 8·95 inches; subtract the former from the latter, and the remainder will be 8·39 inches, that is, nearly 8 and two-fifth inches, which is the distance at which the cameras have to be placed asunder in order to produce the desired stereograph.

Whenever the preceding table is used in its application to views, it is absolutely necessary to regard the distances in reference to the *nearest* object in the view; for if the principal object should be several feet more remote, and the distance were measured to this principal object, all the nearer objects would be exhibited in distorted relief, which it would be painful for the eyes to behold.

By the observance of this rule, as exhibited in the table, photographers have been enabled to perform one of the brightest triumphs in the heliographic science, namely, by stereographing the moon, which shows that the moon is indisputably a globe, undulatiug with hill and dale, mountain and ravine. Simply to photograph the moon is a triumph: but to stereograph the moon is a much greater; for the mode by which stereography is effected presupposes that the photographer can see more than one surface of a body either at the same time or at different times, which phenomenon can be effected by regarding it from different positions, as from either eye separately and independently; or combinedly, from one and the same position; or separately, from two more distant positions; or finally, by causing the body to revolve so as to show more than one surface to the beholder. But the distance to the moon in round numbers is 237,000 miles from the artist; to look around her corners, therefore, at the parallactic angle of two degrees, he would have to plant his cameras at the distance 8,270 miles apart, a distance greater than the diameter of the earth, so that in imitation of the revered Archimedes of old, all that he could do would be to cry out: "Give me where to stand and I will *stereograph the moon.*" But, says the young astronomer, the moon not only revolves around the earth in her orbit, but also on her axis; perhaps you may take her photograph at two different times; that is, one photograph now, and one in half-an-hour or later, by which means two requisite pictures for the stereograph may be obtained. This suggestion is all useless, for just in the same time that she revolves around the earth she revolves upon her axis, and thereby presents the same surface to our view. The binocular photographs cannot thus be taken. But at a parallactic angle less than two degrees; as for example, at one degree and a half, which is less than double the moon's horizontal parallax, it would be possible for two astronomical photographers, if located at the extremities of the chord on the earth's surface subtended by this angle, to obtain stereographic effect from two photographs taken at the same moment of astronomical time. The difficulties, however, to be overcome by this method are very great; nor was it by this method that the triumph alluded to was gained. It is, moreover, true that, by the unequal velocity of the moon in its orbit, we do see a little more sometimes of the eastern edge, and sometimes of the western edge, so that by photographiug the full moon under these opposite conditions a partial stereograph can be obtained.

But it was not by this method that the moon was stereographed. The method by which a good stereograph of the moon has been obtained, depends upon the inclination of the axis of the moon to its orbit, by which we can look a degree and a half as it were over the top of the moon at one time, and at another as much angular space around the under surface. The task, therefore, of stereographing the moon is solved as follows: first, by ascertaining the time of full moon, when one of these phenomena would take place, and when the other, and at these times to take the respective photographs, which, when properly mounted, will produce a due degree of stereoscopic effect, in fact a degree that *may* amount to distortion.

If a small globe or marble be placed at the distance of six feet from the eyes, it is evident that each eye sees a distinct hemisphere for itself; it remains, therefore, to find the angular distance between the edges of the two hemispheres on either side. By a moderate knowledge of geometry we ascertain that this angular distance coincides with the paral-

* Continued from p. 394.

lactic angle for this distance; it is consequently two degrees. If, then, the inclination of the moon's axis to its orbit be one degree and a half, or thereabouts, we shall have a libration in latitude of about three degrees, which is more than enough to give an agreeable relief to the superimposed photographs. That the stereograph of the moon, to be had of all dealers in such materials, was taken as just described is evident, in the first place, from the fact that the south pole of the moon is to the right on the cardboard, and the north to the left, or *vice versâ*, by inverting the card on which the two photographs are mounted. In the second place, the difference in the distances between the corresponding points on either photograph is in the direction of north and south, and not in that of east and west; this is an infallible proof. This difference, too, between the maximum and minimum distance is of such a magnitude as to indicate the parallactic angle at which the photographs were taken.—*Humphrey's Journal.*

## PRINTING, TONING, FIXING, AND MOUNTING.

BY CHARLES WALDACK.*

The printing on albumen paper should be carried further than on the ammonia nitrate, as the prints lose more in the process of toning. The colour of the prints when taken out of the printing frame varies from a red to a violet black. This colour depends greatly on the kind of paper used; and somewhat on the strength of the silver solution. A paper giving dark prints is to be preferred. Red and vigorous prints can, however, be brought up in the toning. But when the prints are red and dim, the fault lies in the silver solution, which is not of the proper strength, and no toning will bring them to the proper shade.

When four card negatives are made on a whole plate, the box printing-frame is the only one that can be used, as it enables you to look at each one of the negatives. If one of the negatives prints quicker than the other, it should, when sufficiently printed, be covered with a piece of cardboard, and the printing allowed to go on.

Several causes induce the discolouring of the albumen paper, while printing: the principal ones are—

1. The heating of the negatives by the sun.
2. The use of moist paper.
3. The use of moist flannel, or cloth, on the back of the paper.
4. The use in hot weather of flannel, or cloth, which has been in contact with ammonia nitrate paper.
5. The silvering with ammonia nitrate of silver in warm weather.

The best prints are made in diffused light. To be printed in the sun, the negatives require to be more intense. Vignettes should, as much as possible, be printed in diffused light, as the paper requires to be kept very white.

The shading off, in vignette prints, is obtained by placing, at about three-fourths of an inch from the negative, a piece of cardboard with an aperture in it of the shape of the pictures, but cut a little smaller. When the printing is done in the sun, this aperture is covered with a piece of tissue paper; in diffused light a ground glass is substituted; or, when the light is weak, it is allowed to strike the negatives directly. Great care should be taken in printing vignettes, to have the printing-frame in such a position as to cause the rays to fall perpendicularly on the negative.

Silvered albumen paper being very sensitive, should be kept as much as possible out of the light. The prints can be kept several hours before being toned and fixed, by being placed in the dark.

Albumen prints should not be put in the same drawer or box with ammonia nitrate prints; to prevent them from getting brown when they come in contact with each other.

The operations which follow are—

1. The washing to remove the free nitrate of silver.
2. The toning.
3. The washing to remove the toning solution.
4. The fixing in hyposulphite of soda.
5. The final washing to remove the hyposulphite of soda.

The three first of these operations should be done in the darkest part of the room.

To remove the free nitrate of silver, the prints are put in a tray with clean water, and the water is changed five or six times, until all the nitrate of silver is removed.*

This being done, they are ready to be toned.

For the preparation of the toning bath the two following standard solutions are used:—

| | | |
|---|---|---|
| No. 1.—Bi-carbonate of soda | ... | 2 drachms |
| Water ... ... | ... | 16 ounces. |
| No. 2.—Chloride of gold (neutral) | | 30 grains |
| Distilled water ... | ... | 16 ounces. |

The toning bath is composed of sixteen ounces of water and one ounce of each of these standard solutions. In summer it is used at the ordinary temperature; in winter, to make it more active, it is made tepid, or bloodwarm. The prints are immersed one at a time, and as many as can be conveniently watched. They pass in a few minutes through all the intermediate tints to a bluish-black. The first prints which are immersed tone rapidly; but in proportion as the gold is taken up, the bath loses its activity: when this arrives, add one ounce more of each solution, No. 1, and No. 2. The toning is stopped by immersing the prints in a tray of clean water, kept at hand for the purpose. The real colour of the print is only seen after the fixing, and it requires considerable experience to discern to which tint the print has to be toned. A print which is undertoned assumes a red colour in the hyposulphite of soda. One overtoned gets inky blue. The toning bath should not be too active, as the toning would proceed irregularly. Too rapid toning has also a tendency to make more apparent the mealiness spoken of below. To prevent irregular toning, the print should all the time be kept in motion.

Acetate of soda, citrate of soda, phosphate of soda, &c., have been recommended by some writers as an addition to the toning bath. These seem, when fairly tested, to have no action whatever on the toning of the prints. We shall, therefore, not give the formula in which these salts enter, being satisfied that in photography, as in all pursuits, the shortest and least complicated method is the best. The toning bath given above, can compete for results with any used. The chloride of gold is what gives the tone, the bi-carbonate of soda is added to facilitate the separation of the gold from the chlorine. Perhaps acetate of soda or any of the other salts used possess also a reducing action, but in connection with bi-carbonate of soda, which is much more energetic as a reducing agent, their presence is useless.

Acetate of soda has been claimed by some writers to be a preventive of what is known as *mealiness*; experiments carefully conducted have convinced us of the fallacy of this claim. The mealiness in our opinion, results mainly from the use of a weak silver solution, or from not being floated long enough. With some kinds of thick and highly albumenized paper, it assumes the form of white spots: with thin paper it has the form of minute, mealy specks. These spots in thick or highly albumenized paper, can, on close inspection, be detected on removal of the paper from the printing-frame, and are brought out more distinct in toning. They result, we believe, from an imperfect formation of albuminate of silver.†

* From a work entitled "The Card Photograph."

* The first and second changes of water, containing most of the nitrate of silver, should be poured in a large jar, or keg; and a handful of salt thrown into it, which will precipitate the silver in the state of chloride. After settling, the liquid can be poured off, or drawn off with a faucet. When a sufficient quantity of chloride of silver is thus obtained, the mass can be thrown on a filter, and allowed to drain and dry; after which it can be sent to the refiner to be converted into metallic silver.

† What first made us suppose that imperfect silvering was the cause of these mealy spots, are the following facts. An inexperienced photographer undertook to silver albumenized paper, in a small quantity of solution, and not having the porcelain tray level, the upper part of the tray touched the bottom of the dish, while the lower part floated on liquid half an inch deep; when the prints were toned, the upper ones were spotted, and the lower ones perfect. The same thing being repeated, the spots could, on close examination, be detected on the removal of the paper from the printing board.

The mealy spots should not be confounded with the marbleized appearance, resulting from the imperfect transformation of the chloride of ammonium, or the chloride of sodium, into chloride of silver.

Before being fixed, the prints should be rinsed off, to remove the gold, which would otherwise communicate toning properties to the fixing bath.

The fixing bath is composed as follows :—

| | |
|---|---|
| Hyposulphite of soda ... ... | 8 ounces |
| Bi-carbonate of soda ... ... | 1 drachm |
| Water ... ... ... ... | 32 fluid ounces. |

On immersion in the hyposulphite, the real colour of the print shows itself immediately.

The fixing will not require more than ten minutes. It is done when the paper presents, by transmitted light, an uniform appearance, showing no opaque spots of undissolved chloride of silver.

The fixing solution will, by being used, acquire toning properties which are very objectionable, as they are due to the liberation of sulphur. The operator should thus not, for reasons of economy, use this solution too often, and in such way endanger the permanency of his prints.

The washing should be done with the greatest care for half an hour, the prints being laid on a frame, covered with strong muslin, and the water sprinkled over them, as described on p. 157. Where no such facilities for washing can be had, the prints should be washed in several changes of water, for two or three hours, the first changes being made at intervals of five or ten minutes. The prints having been dried are cut out on an even glass, with a sharp knife. To cut them of a proper shape and size, a mat or cleanly cut glass can be used.

Before mounting the prints, it is advisable to keep them for a short time folded up in a damp towel, to prevent their curling.

For pasting the pictures on the cards, use either starch or dextrine paste. Starch paste is made by mixing one ounce of starch with ten ounces of water, and warming gradually to the boiling point, stirring the mixture all the time. Dextrine paste is simply dextrine mixed with water, in the proportion of one ounce of dextrine to five ounces of water.

## Correspondence.

### MEALINESS IN TONING,

Sir,—As a slight return for the many useful hints I have received from your very excellent journal, I beg to place at your disposal a few remarks which may perhaps cast an additional ray of light on the perplexing subject of mealiness and uneven toning. The principles on which the process of toning are based, appear to be but imperfectly understood, hence it is the manifold remedies which have from time to time been proposed, have been based on empirical rather than on thoroughly understood grounds—abundantly successful in some cases, a total failure in others. My object, then, is to show that the remedies proposed, if judiciously applied in their proper places, are capable of performing all the promises which have been advanced in their behalf (omitting acetates and chlorides, as being altogether unnecessary, except as direct toning adjuncts).

The causes which produce mealiness and uneven toning, my experience induces me to believe, are mechanical, rather than chemical, when a print is placed in the toning bath, there are impediments existing on the surface of the paper which must be overcome ere the gold can settle where it is required, and unless those impediments act with unbroken evenness—mealiness or uneven toning will most assuredly be the result. An oft but unsuspected cause of uneven toning; is to be found in the irregular texture of the paper; if a print after undergoing the short washing usually recommended, is held up and viewed by transmitted light, it has an appearance similar to a partially fixed one, the transparency being very unequal under these conditions, even toning is altogether impossible, and the paper is declared worthless; but if the soaking is continued until this unevenness disappears, the results will be all that can be desired; and this fact will fully explain the reason why a thick paper is more prone to mealiness than the thinner samples, the latter requiring a much shorter soaking previous to toning, to open the pores, and thus rendering more even its texture than will suit the requirements of the former.

Another source of mealiness is a too strict adherence to a given formula, no allowance being made for strength of sensitizing bath, and amount of intensity of light, for be it remembered that when a strong bath is employed, and the printing is carried on in direct sunlight. the prints are more liable to become mealy than if the printing had been effected in diffused light. The reason of this is obvious, the greater deposit of reduced silver in the former case, forms a proportionally greater impediment to the action of the gold in the toning bath, and measures must be adopted to clean the surface of the paper as quickly as the gold can act. From close observation I have come to the conclusion, that this clearing process is the work which the carbonates and acetates have to perform, instead of being employed in merely rendering the bath alkaline. When the resistance offered to the gold is great, by the judicious increase of the clearing material the impediment is rapidly overcome, and the toning goes on satisfactoilry. With slowly-printed pictures a more alkaline reaction is sufficient, an excess of soda will retard rather than increase the rapidity of toning, giving, at the same time, disagreeable brown tones; whilst, on the other hand, if an excess of the reducing agent is not employed in toning pictures produced by direct sunlight, if the paper be at all inclined to mealiness, this much dreaded effect must follow, except, indeed, the toning is slowly performed, for in this case the impediments are removed fast enough to meet the requirements of the limited supply of gold.

I need go no farther to show the nature and constitution of the impediments spoken of, every intelligent reader of these lines will readily understand this as clearly as it would be possible for me to explain.

It will be sufficient for me to observe, in conclusion, that, by sticking to this theory of impediment removal, and tracing these obstacles to their several causes, I am able to obtain clear prints from every kind of paper, from the thickest to the thinnest, from every maker. I have tried, and I believe I have worked on samples from most *all known*. I have an idea that there is no paper sold which a clean picture cannot be printed on (the quality differing of course). When a bad paper is placed into my hands, I do not rest content until I have discovered the cause of failure, and the cause I have always found to be under control; and in removing that I have removed the evil, and exonerated the character of the maker. I could have entered more fully into details, but fearing to trespass on your valuable space, I have condensed my remarks as closely as possible. If a few hints on printing and its relation to toning would be acceptable, I will, at some future time, be most happy to place them in your hands.—I remain, yours respectfully,

A Photo's Assistant.

P.S. To explain a remark made on the clearing agents, I do not understand acetates to be alkaline, but they are no less agents or pioneers in advance, to clear the way for the gold.

[Our correspondent's hints are important, and go far to meet the case. We shall have pleasure in hearing further from him.—Ed.]

# Photographic Notes and Queries.

### Angle included by View Lenses.

Sir,—There appears to be a very erroneous impression prevailing with regard to the angle of view included by lenses of various constructions, and I must confess that I entertained similar notions until I instituted a series of comparisons between nearly all those at present in use for photographic purposes. The photographic, orthoscopic, portrait, and triplet are all advertised as embracing a *very large* angle of view, and I have frequently seen them recommended for taking views in confined situations. Now, if I understand the matter rightly, not one of these compound lenses embraces so large an angle of view as the single achromatic. Taking the angle of the latter at 36°, which will, I believe, be found about the average, the double and triple combinations vary from 24° to 30°. My latest trial was made with Dallmeyer's triplet, 18½ inches focus, measured from the back lens against a view lens of precisely the same focus. I had two cameras, the ground glass of that used for the triplet 14½, and the other 12½ inches long. The amount of view included was the same, within one-eighth of an inch, in both cases, consequently taking the angle embraced by the single lens at 36°, that of the triplet would be within a fraction of 30°.

I think this fact shows the unfairness of measuring the focus from the back lens of a combination; the equivalent focus ought, in all cases, to be stated. In the triplet in question the equivalent focus must be about 21½ inches, and it covers with sufficient definition, no larger surface than would a single lens of the same focus, viz.. 14½ by 12. I wish it to be clearly understood that I have not the slightest intention of disparaging this lens, I consider it of the very greatest value for architectural subjects, and for copying, added to which, its capabilities for instantaneous views when the whole aperature is used, are truly astonishing.

There is another misconception to which I would call attention. I have seen it stated in more than one work on photography that the intensity of light passing through diaphragms of different diameters is in proportion to the squares of their diameters; and, therefore, supposing a lens stopped down to one inch to require one minute for taking a picture, the same lens, with a stop of half-an-inch, would require two minutes. There can be no general rule laid down on this subject. With a bright light it would not require 1½ minutes, whereas, on a very dull day, 10 minutes might not be sufficient. I believe there is no better plan for judging of the intensity than that of carefully examining the brilliancy of image on the ground glass.—I am, sir, yours most truly, Baynham Jones.

*Cheltenham, 18th August*, 1862.

[We have repeatedly stated that, in the pictures produced by the triple lens, a very large angle is included with good definition. We are indisposed, at present, to discuss the question, but may remark that our correspondent's experiment does not appear at all conclusive. To test the lenses properly, it would be necessary to use a triple of an equivalent focus, the same length as that of the single lens, to try each lens with the same sized stop, and to use a plate larger than they were intended to cover, so that a careful measurement might be made of the amount covered and properly defined by each. By the usual calculation, if an exposure of one minute be required with an aperture of one inch, an exposure of four minutes would be required with an aperture of half-an-inch. The calculation upon which this is based is very simple; an aperture of half a square inch has an area of one-fourth of the size of an aperture of one square inch, and will, therefore, admit just one-fourth of the amount of light. A variety of circumstances, however, will modify the time of exposure, and our correspondent is right in his suggestion that the brilliancy of the image on the ground glass is the best guide.—Ed.]

### Toning Process.

Sir,—Seeing a few words about toning in the last number of the News, I forward, for the readers of your valuable pages, a method I have practised with great success for some months, and can produce a variety of tones. I tone as described in your pages some time ago, viz., by placing the print from the frame in a bath of acetate of soda, wash, and tone (or rather *half* tone) in the usual acetate of gold bath. I place them next in an old hypo fixing bath, one quart, with the addition of half-an-ounce of acetate of lead and half-an-ounce of nitrate of soda. I leave them in this bath till the prints are the desired colour (which will vary in time, owing to the depth toned in the gold bath), and fix in a fresh hypo bath if required. The lead and hypo will cause a precipitate, which I leave in the bottle, and as the hypo bath gets saturated with silver it redissolves the deposit. I generally throw away quarter of the hypo, making up the quantity with fresh, and adding a little more nitrate of soda and lead; it is as well to wash the prints in a little distilled water after fixing, previous to the thorough or final washing. Should any of your readers try this I think it will repay them for any extra trouble they may have.—I remain, sir, yours respectfully,

A. L. Henderson.

49, *King William Street, London, August 16th*, 1862.

### Rapid Fothergill Plates.

Sir,—As the subject of rapid dry processes appears to be now absorbing so much attention, we have sent you (accompanying this) two prints from Fothergill plates, which were exposed on the 29th ult., the first (the town from the Church Cliffs) was exposed at half past eleven in the morning, and received four seconds exposure; the second, (the Cliffs and Ledges) received but three seconds exposure, at half past one the same day, and we think you will agree with us that the latter is the best picture. Should you think the pictures sufficiently good, and the times of exposure sufficiently rapid to be worth notice, we shall be happy to furnish details as to their preparation and development.

We have now merely to add that the plates keep an indefinite period.—We are, sir, yours truly, H. & J. Walter.

*Broad Street, Lyme Regis, Dorset.*

[We shall have pleasure in publishing the details of the process by which the negatives were obtained with such rapid exposure. There is perhaps a trace of under-exposure; a second more in each case would have been quite sufficient.—Ed.]

### Nomenclature of Stops.

Dear Sir,—Would you excuse one at a distance suggesting your giving information which may be useful to many.

We constantly see references to trials of processes in your pages. Sometimes the nature of lens employed is quite omitted, occasionally it is imperfectly described, and sometimes, some not having a similar one by him can guess what is meant. We see a notice of a picture taken with A's lens and No. 3 stop. Now, if the information is to be useful, we must know more.

I would suggest that till makers adopt some mode of numbering stops, which will define their size, the diameter should be given, but perhaps Messrs. Ross and Dallmeyer would not find it hard to agree on a system of guages for all diameters and sizes of lenses. I have a Ross whole plate orthographic lens, till I reach the full aperture I find the diameter of the stops are two-tenths of an inch larger than the number of tenths denoted by that of the lens. I find this simple relation most useful; and in a 15 by 12 orthographic of theirs I find this changed for the worse, the numbering is wild.

By the bye I have often seen objections to the orthographic lenses, and those like it for landscape. I always use mine, and rarely stop down at all unless I have very near objects. It always works well, and gives me far better pictures on the glass with 0·85 inches of stops, 0·9 of aperture, than a view lens of another maker (but a good one) with only five-eighths of an inch. It is evenly illuminated, or very nearly so, and, of course, works fast. I have taken landscapes well lighted in five seconds, and clouds, on a heavy day, in the same time.

I have seen many complaints of films dissolving on varnishing. The following cause has not been I believe given viz., *overheating* to which one is especially liable when drying the plate artificially.—Yours faithfully, J. P. T.

*Rovitree, July 3rd*, 1862.

[We always give the best information with which we are furnished as to the lens and aperture used; but there is room for more precision in the matter. In stating our own experiments we always give these particulars definitely.—Ed.]

## Talk in the Studio.

Instantaneous Dry Plates.—Mr. Fowler, of the firm of Harvey, Reynolds, and Fowler, writes:—"I am somewhat surprised at the search of many of the contributors to the Photographic News for an instantaneous dry process. I have recently been with a gentleman who has been working dry plates as rapidly as Dallmeyer's quick acting lenses, and his instantaneous shutter will allow; and the results he has obtained are *quite as good* as any picture from a wet plate that I have seen of that class, and a great deal better than many. I will send you some in a few weeks, and you can judge for yourself. You will see street views, the bustle of a railway station, train starting, &c., faithfully given. As our firm will publish them, my object in sending the pictures to you will be partly for review, as well as to prove the existence of an 'Instantaneous Dry Process.'"

A New Application of Photography.—The *Philadelphia Press*, of June 21st, tells us that a new application of miniature photographic portraits has originated with Messrs. Whit and Yost, the extensive Bible manufacturers, of Market Street, Philadelphia. In the Bible—the text of which is conformable to the standard of the American Bible Society—they insert, as usual, blank leaves, suitably headed and divided for notices of births deaths, and marriages. Such records in a family Bible constitute good evidence in our courts of law. In addition to these they are introducing the novelty (patent applied for) of placing several cardboards, perforated for the reception of small photographic portraits, to follow the family register, thus accompanying the record with resemblances of the loved ones whose names are entered there. The idea is ingenious, and will, no doubt, meet with favour. The specimen alluded to is a superbly bound quarto illustrated Bible, in clear pica type, with index, concordance, metrical version of the Psalms, with places, after the register, for the reception of thirty-two *cartes de visite.*

## To Correspondents.

F. Z.—The purpose of albumen is simply to give the paper a better surface, and enable it to render delicate definition more perfectly; it is no aid whatever in securing permanency. Some authorities regard it as one of the sources of decay.

Cornish Chough.—The exposure and development appear to be right. The lighting is also good: with a trifle more reflected light on the shadowed side it would be perfect. The definition is, however, far from satisfactory, and you should not rest content with it. It may be the fault of the lens, in which case, the sooner you get rid of it the better. Before doing this, however, proceed to test it carefully. In the first place, examine your ground-glass, and ascertain if it have a surface sufficiently fine to enable you to see when you have obtained a sharp image. Some of the focussing-screens of cheap cameras are so coarsely ground, that it is almost im possible to perceive when the image is sharp. If you are unable to obtain a sharp image on a fine screen the lens is in fault. If, however, the image on the ground-glass be sharp, and that of the negative defective, the fault may arise from two causes, either the chemical and visual force of the lens are not coincident; in which case you must ascertain the amount of variation, and allow for it; or it is the fault of the camera, in which the sensitive plate does not occupy precisely the same position as the focussing-screen. This you may ascertain either by careful measurement, or by putting a piece of ground glass or a coated plate into the dark-slide, and having placed it in the camera, pull up the slide and open the back, so as to examine the image, which should be as sharp as it was on the focussing-screen. If it be not, the remedy is simple, and consists in a slight adjustment, either of the focussing-screen or dark-slide.

G. F.—A small amount of residue is not a serious objection, and may occur with a sample of pyroxyline in other respects good. If, as you state, the residue is two-thirds of the bulk of the solution, the pyroxyline is worthless. In our practice we frequently have no residue at all. We recently placed in a half-pint bottle the residues of two Winchesters of collodion (a gallon) which had yielded more residue than usual. After standing for a few weeks the residue is not more than half an inch in depth in the small bottle.

F. G. asks, "What is the cause of a bath giving excellent negatives with a plain iodized cadmium collodion and pyro developer, after being in use some time with a bromo-iodized collodion and iron developer, ceasing to give a picture with the former preparations, although working most satisfactorily with the latter? it does not proceed from acidity in the bath, as it has been strengthened, neutralized and acidified in the same proportions as it formerly was. The only thing I can account for the cause is the bromide of silver held in solution, if so, please state how that can be got rid of. This solution of bromide of silver, as I imagine, is most objectionable in the bath for iron development, causing lines and loss of brilliancy I get rid of this for a time by adding five grains of nitrate of soda to each ounce of bath, sunning and a few days' rest." Mr. Sutton holds the opinion that the use of a bromo-iodized collodion in a silver bath spoils it for giving good results with a simply iodized collodion. It has never occurred to us in our practice, however The case described by our correspondent is probably due to the accumulation of organic matter in the bath; and this view is confirmed by the fact that sunning improves matters. Neutralize it with oxide of silver or carbonate of soda, and sun thoroughly, then filter, slightly acidify, and all will probably work well. Bromide of silver is very sparingly soluble in the silver bath, and we see no reason to think that the trace which may be present would in any way injure your bath.

Subscriber to two Copies of the News.—We do not know of any house in London where you can obtain Disderi's portrait collodion. Harvey, Reynold's and Fowler, 10, Briggate, Leeds, are the English agents for it.

Hob-y-deri-dando.—The india-rubber lined baths answer perfectly, so far as we know.—We have one in use without any evil results. The thin sheet india-rubber can doubtless be purchased at any house dealing in such materials, such as Silvers & Co., or Burgess and Key. The price per foot we do not know. 2. Rouch's new tent has not been described in our columns in detail, but will be shortly. 3. The articles entitled "Amateur Mechanic" may possibly be republished, but it is uncertain when. 4. The covering of Smartt's Tent, so far as we remember, is a very stout "twill," which very effectually excludes the light; it is lined with a similar material in yellow. 5. We think it is probable that a camera maker would make you a dark-slide to your camera. Try Mr. Meagher.

T. H. Crampton.—The address of Mr. Bailey is "Chemist, Wolverhampton."

J. G. Lock.—The prevailing fault in your negatives is want of intensity, they are flat and feeble, wanting in contrast. The majority of them would have been good if they had been judiciously intensified. A collodion giving a little more vigour to begin with, would be also an advantage. The prints are all a little over-toned; but it would be impossible to get brilliant prints from such feeble negatives. Some of the negatives are a little over-exposed. An important defect in the portraits arises from injudicious lighting; you have too much diffused light all round the sitter; you require a more direct light from one side, you will then have the lights in the face clearer and brighter, and the shadows more perfectly marked. This would at once give the image relief, and prevent it appearing embedded in the background, and of a similar colour. The portrait negatives also require more intensity. There is a want of perfect definition, but it is uncertain whether it arise from the fault of the lens, or from imperfect focussing.

J. C. H.—So far as we can judge your tents will answer admirably; by the exercise of a little judgment the sitter may be very satisfactorily lighted. In some conditions of light it may be desirable, in addition to the shading proposed, to attach a cone with dark lining to the lens, so as to protect it still more carefully from diffused light.

Tyro.—You may take portraits with a single lens, but it will not give such good results as a portrait combination. 2. For portraiture we should recommend you to use bromo-iodized collodion, and an iron developer. 3. Portraits may be taken in the open air, but it is desirable to secure such a position as will enable you to secure some shadow, as diffused light all round gives a flat feeble image. If you expose rapidly a head-rest need not be used. 4. You must use some judgment; some negatives will need intensifying, others will be sufficiently vigorous without. 5. For card portraits a highly albumenized paper is generally used, its finer surface rendering the delicate definition better. Over print slightly, and over tone slightly, your prints will then, on coming from the hypo, be just right.

Lex Talionis.—Thank you for the offer of a list, the instances of such omissions are, we know, plentiful enough; we would rather not print it, however, the matter is of too limited interest. We do not wish, as you suggest, to "carry the war into the enemy's camp;" and a detail of his blunders or shortcomings would not interest our readers. The article in question did not originally appear in *Cosmos*, it is erroneously quoted from that journal by our contemporary. Appearing in two or three French journals without any acknowledgment of its original source, in the uncertainty thus created we simply accredited the author, not knowing to which journal it really belonged. Our contemporary, probably only seeing it in one credited that one, and made a blunder, as the article originally appeared, we have since ascertained, in *Les Comptes Rendus*. In a letter from the writer referred to, we learn that he had alluded to the matter for entirely another purpose, in no sense as a complaint, and that he regretted the misuse made of his incidental remark.

M. L.—See some remarks regarding the revision of awards on another page. Some of the prints on the screens have faded, but not many. It is on the damp walls the mischief has taken place. The same cause endangered the water-colour drawings in the picture galleries, but was fortunately seen, and precautions taken in time.

W. F.—Declined with thanks. See answer to Lex Talionis. Thank you for the card portrait, which is very good.

C. Scholefield.—The formula for developing given by Mr. H. Claudet, was correctly stated in our columns. An error had accidentally crept into the statement as first given in the *Photographic Journal*. In the present number of that journal it is corrected, as you will see.

A. B. C.—The fault is in your negative; the middle tint, which you say is perceptible, is insufficient for printing purposes. The appearance of the print indicates the use of a simply iodized collodion and under exposure. If you continue the use of the same materials, expose very much longer, and secure a much greater abundance of well marked half tone in your negative; you will then be able, by the same method of printing you now adopt, to secure the class of prints you require.

Youthful Aspirant.—Your error consists in not finding the correct focus of the lens. The negative to be enlarged, and the screen on which the enlarged image is to be projected, should each be a specific distance from the lens, varying with the amount of enlargement required. Thus if you wish to enlarge 3 diameters, with a lens of 6 inches equivalent focus, the negative must be placed 8 inches behind the enlarging lens, and the screen 24 inches from it at the other side. If you have a copy of the Photographic News Almanac, you will find a table of distances. Unless you have the correct distances you will not get an approximation to a clear image.

R. B.—You require, to get good results, to have a little more vigorous negatives, and to print a little deeper. If you then fail to get deep tones in the gold bath try another sample of paper. In order to secure good tones in the finished picture, it is absolutely necessary to tone deeper than is required, to allow for loss in the hypo.

Tit Tat To.—Chloride of silver is not unfitted, by standing in the light, for reduction in the usual way. The reduction is merely partially done when it discolours, as you describe.

W. F. W. W.—The black precipitate, and lustrous metallic film produced on adding acetic acid to your silver solution, indicate that the latter is impure. It is probably adulterated with sulphuric acid, which would produce similar results.

Several Correspondents in our next.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 208.—*August* 29, 1862.

## MR. PONTING ON INSTANTANEOUS PICTURES.*

In the period when success in photography was considered to be largely due to the possession of secret formulæ, it used to be a common remark with a celebrated Daguerreotypist, as a reason for avoiding conversation on his art, that "it was impossible to talk long upon a subject without saying *something*." In a work on the collodion process, by the manufacturer of a collodion of high reputation, but unknown constitution, it will naturally be expected that some part of the secret would ooze out. This secret has been the subject of much speculation and some investigation. One experimentalist evaporates the iodizing solution, and submitting the residue to microscopic examination, finds certain plumose crystals, which do not answer to the characteristics of any iodide he knows. Another, proceeding, chemically, applies the reagents for cadmium, and is satisfied from the result that the iodide of cadmium is used. Another examines and states that he finds cadmium and calcium. Still, amongst amateurs and manufacturers the matter remains undecided.

Mr. Ponting has shown that it was quite possible to write a useful book without divulging his secret, or saying much about the manufacture of his collodion. He has, however, said something, and we learn either from direct statement, or by implication, that it contains an iodide only, and no bromide; that the iodide is not, or at least not entirely, that of cadmium, and that it contains equal proportions of ether and alcohol. Beyond this, nothing is divulged as to the constitution of the iodized collodion, which has long held such a reputation for sensitiveness and stability.

On the working of this collodion, and other photographic operations, there is, however, much valuable information. The details of some experiments on the influence of acetate of silver in the nitrate bath, are very interesting, and well worthy of attention. We shall refer to this and some other parts of the book on a future occasion.

Our especial object at present is to call attention to Mr. Ponting's observations on instantaneous photography, a branch of the art which is of very absorbing interest to most photographers at the present time. It is very satisfactory to us to find that a gentleman who has so long and so successfully manufactured a simply iodized collodion, has, from more recent experience, arrived at a conviction which confirms the position we have always steadily maintained, namely, that a bromide properly used is essentially an accelerator, and that its use is imperative in instantaneous operations. Referring to recent discussions on the subject, he says: "This alleged fact of bromine being an accelerator was quite contrary to my own previous experience, for, in all experiments with this material, I found that it not only retarded the action, but produced a thin weak negative." A series of careful experiments were instituted, the issue of of which is a conviction thus expressed: "These experiments, which have since been fully confirmed in practice, clearly demonstrate that for instantaneous pictures, it is necessary not only to use bromide in the collodion, but a small proportion of nitric acid in the bath." A careful detail of the experiments referred to is given, which we subjoin:—

"Five samples of collodion were prepared as follows:—

| | | | | |
|---|---|---|---|---|
| No. 1, Iodized Collodion, containing 4 grs. of iodide to the oz. | | | | |
| No. 2, the same Iodized Collodion, with | | | ½ gr. of bromide added. | |
| No. 3, | ditto | ditto | „ 1 „ | ditto |
| No. 4, | ditto | ditto | „ 2 „ | ditto |
| No. 5, | ditto | ditto | „ 4 „ | ditto. |

"Three nitrate of silver baths were also prepared, of the strength of 30 grains to the ounce.

"No. 1. This bath was made according to the formula at page 22, with acetate of soda and acetic acid.

"No. 2. To this bath was added a quarter of a drop of nitric acid to each ounce.

"No. 3. This was left neutral, or nearly so, having a very minute proportion of acetic acid to prevent fogging.

"The developer was made with—

| | |
|---|---|
| Protosulphate of iron ... ... ... | 10 grains |
| Glacial acetic acid ... ... .. | 6 drops |
| Water ... ... ... ... ... | 1 ounce. |

"Two negatives were taken with each sample of collodion, one exposed two seconds, and the other four seconds, in the three baths in succession, being thirty negatives in all. A landscape lens with a small stop was used, in order to secure complete accuracy and uniformity in time of exposure, which it would have been difficult to obtain with so many negatives, had a shorter exposure been tried.

"Without wearying the reader with a detailed account of all the negatives, it will suffice briefly to state the results that came out.

"First, as to the baths. With the ordinary iodized collodion No. 1, the bath No. 1, with acetate of soda and acetic acid, was unmistakably the quickest of the three, the nitric acid bath, No. 2, being very slow; this, it will be remembered, is the precise results of the experiments detailed at page 19, except that a bath with nitric acid was not then tried. But with the collodions containing bromide, the No. 2 bath with nitric acid proved to be much quicker than the other two baths, their slowness as compared with the nitric bath increasing as the proportion of bromide in the collodion increased. No increase of sensitiveness was gained by the large doses of bromide; on the contrary, the collodion No. 5, with four grains of bromide per ounce, worked much slower than either of the other samples. The proportion of one grain of bromide to four grains of iodide, gave the best results, larger doses of bromide imparted a wavy appearance to the film that quite spoiled the picture, and no increase of sensitiveness was obtained.

"On comparing the negative taken with the No. 1, on iodized collodion, in the bath No. 1, with the negative taken with bromo-iodized collodion, in the nitric acid bath, the latter was markedly the better. The first was a very intense negative, with strong contrasts of light and shadow, and would have printed hard; the latter was a soft, though a sufficiently forcible negative, giving full details in the shadows, and hardly wanted further development; but, with *instantaneous* pictures, the development will have to be continued by using a weak solution of pyrogallic acid, with a little silver added, say

| | |
|---|---|
| Pyrogallic acid ... ... ... ... | 1 grain |
| Glacial acetic acid ... ... ... ... | 6 drops |
| Water ... ... ... ... ... ... | 1 ounce. |

Solution of nitrate of silver (strength, 50 grains to the ounce), five or six drops, or more if great intensity be required.

The iron developer must be previously washed off.

"These experiments, which have since been fully confirmed in practice, clearly demonstrate that for instantaneous pictures, it is necessary not only to use bromide in the collodion, but a small proportion of nitric acid in the bath; these, with an iron developer as strong as the operator can use, as described at page 30, strengthening by the use of the pyrogallic developer, is all that is requisite in the way of chemicals. But it must be borne in mind that everything must be of the highest degree of purity, and prepared with the utmost care."

* "Photographic Difficulties; How to Surmount them: Instantaneous Pictures; How to obtain them." By T. Cadby Ponting. London: Bland and Co.

On the use of this collodion in the operating room, he adds :—

"The same bromo-iodized collodion, with the nitric acid bath, was also tried for portraiture, and found to effect a considerable saving in the time of exposure; but the use of the two developers, and the long time occupied in the development, is somewhat against it. Where, however, a short sitting is desired, the extra trouble must be put up with; against this must be placed the ease and cleanliness of working with a collodion containing bromide."

As to the value of a bromide in securing immunity from spots, &c., we have testimony even in that part of the book which is devoted solely to the use of iodized collodion; and we are glad to find our own experience as to the marked effect of a very infinitesimal dose in this respect, in reference to which our friend Sutton has charged us with over refinement. Referring to transparent spots being common when using newly iodized collodion, Mr. Ponting recommends the addition to each ounce of from five to ten drops of a 20-grain solution of bromide of ammonium in spirits of wine. Twelve drops or minims of this solution would contain just half a grain of bromide, so that the addition recommended is from a quarter of a grain to half a grain of bromide per ounce. This, it must be borne in mind, is to be added to the collodion sold ready iodized, if used new and producing spots.

Mr. Ponting's book will be read with great interest by all photographers. He divides his work into six parts. These treat of the Chemicals, of the Manipulations, of Failures—their Causes and Remedies, of Positive Pictures on Glass, of Printing, &c., and of Instantaneous Pictures. Perhaps, if any exception be taken to the work at all, it will be to its title, "Photographic Difficulties." It is really rather a useful manual of formulæ and manipulations, than a treatise upon difficulties, which do not occupy a larger space than is customary in manuals. It is quite true, however, that if the photographer follow carefully the instructions given as to precision and care, he will not be likely to meet with many troubles, and in this sense the title may be regarded as no misnomer.

## TRANSPARENCIES ON GLASS.

We have recently received from one of our amateur readers, Mr. Thomas Ratcliffe, of Colne, half a dozen very beautiful stereoscopic transparencies. They are characterized by unusually perfect and delicate definition, fine tone, and atmospheric effect; some of them possessing natural clouds. The tones are chiefly of a purple black, and they are remarkably brilliant and clean. In a conversation with Mr. Ratcliffe we learnt that they were all from dry plate negatives, produced by the tannin process, or the resin process; and that the transparencies were on plates prepared in all respects as those on which were produced the negatives. They were all printed by superposition by gas light, and from the shortness of the exposure both in printing and in obtaining the negatives, it was evident that as dry plates they possess a considerable degree of sensitiveness.

In reference to the printing by gas light, Mr. Ratcliffe referred to a common fallacy in the instructions for conducting the exposure: it is usually recommended if a simple gas flame be used, without a reflector, that the frame holding the negative and sensitive plate should be moved about so as to secure equality of illumination all over the plate. This Mr. Ratcliffe strongly objects to, with very sufficient reason; it is next to impossible, as he asserts, to bring the two rigid surfaces of glass, that of the negative and sensitive plate, into absolutely perfect contact; and such being the case, if the rays of light strike the surface of the negative obliquely, refraction ensues, with a consequent loss of sharpness in the positive. But if the frame be held quite still, near to a moderately large gas flame, the rays reaching the surface of a single stereoscopic picture are so nearly parallel, and impinge so nearly at right angles, that no loss of sharpness is perceptible. Since Mr. Ratcliffe was in London, he has been so good as to respond to our request that he would prepare, for the benefit of our readers, a brief statement of the formulæ and method of manipulating, by which he obtained such excellent results, both in producing negatives and transparent positives. We shall now give his brief but practical description: it will be seen that the operations throughout are very simple, and that the method of using acetic acid in the first washing, dispenses with its use in the silver solution, and permits the use of a bath nearly neutral, and in good condition for wet plates, instead of preserving one for use with wet plates only. Mr. Ratcliffe writes:

"In accordance with the promise made you to forward particulars respecting the way in which I work out the tannin and also the resin process, I shall now endeavour to do so as briefly as possible.

"Tannin Process.

"*Preparing the Plates.*—Clean and dry the plates as usual, affix to plate-holder, breathe on the surface, and while moist pour over a dilute solution of albumen made as follows :—

| | |
|---|---|
| Albumen ... ... ... ... | 1 ounce |
| Water ... ... ... ... | 4 ounces. |

Froth well; then add 12 drops liquor ammonia. Put the solution aside in a cool place for twenty-four hours, then bottle for use. Filter through a small bit of sponge placed in the neck of the funnel, to take out the air-bubbles as you coat each plate; dry rapidly before the fire, and store away the plates for use.

"*Exciting the Plates.*—Coat with collodion (I use Mawson's negative), and allow the film to set pretty well, then immerse in the silver bath, the strength of which is 35 to 40 grains to the ounce, very slightly acid with nitric acid. Allow the plate to remain until arrangements are making for coating another, then remove without draining, into a small dish or tray containing—

| | |
|---|---|
| Water ... ... ... ... | 6 to 8 ounces |
| Glacial acetic acid ... ... | 20 minims. |

Proceed to coat and prepare plate No. 2; when the latter is properly sensitized remove plate No. 1 to another dish containing spring water, placing No. 2 in the acetic bath. Wash well, place on levelling stand, and coat with tannin solution, made 15 grains to the ounce of water, filtered prior to use; let this remain on the plate until you coat and prepare another plate, then stand on one corner to drain and dry spontaneously; when thoroughly dry store away for use.

"*Exposure.*—With a fair light one minute will be sufficient.

"*Lens.*—Portrait combination, 7-16th stop, 4¼ inch focal length.

"*The Developer* is made as follows :—

| | |
|---|---|
| Pyrogallic acid ... ... ... | 2 grains |
| Citric acid ... ... ... ... | 2 „ |
| Glacial acetic acid ... ... | 2 drops |
| Water ... ... ... ... | 1 ounce. |

Moisten the surface of the plate, or immerse in your tray of spring water for one minute, place on the levelling stand, and pour over about three drachms of developer, let this remain a few seconds, then add two drops of silver solution, strength 20 grains to the ounce of water. This is sufficient to bring out all the detail; if the developer becomes discoloured, wash the plate and use a fresh supply, adding four drops of silver, which in most cases is sufficient to bring up the required intensity. Fix with hypo as usual. If any deposit appears on the plate when dry, rub the surface with a little cotton wool prior to varnishing."

Mr. Ratcliffe is equally successful with resin plates, which he finds a trifle more sensitive than the tannin.

"Resin Process.

"Simply add to the collodion ½ grain of common resin to the ounce of collodion. Then proceed exactly as in the tannin process, omitting the tannin, viz.—

"Coat with albumen.

"Coat with collodion.

"Sensitize.

"Remove to acetic bath.

"Then wash well, and dry prior to storing away for use.

"Exposure about the same, if anything, perhaps rather quicker. Develop and fix as before.

"It may be asked, why use the acetic bath at all, why not add glacial acetic acid to the sensitive bath? In reply to this assumed question I have two reasons:—1st. Glacial acetic acid is liable to derange the bath, forming fine, needle-like crystals, which adhere, and spoil the surface of every plate you may immerse; and, 2nd. Using the same bath for wet plates, I prefer omitting glacial acetic acid, in the sensitive bath, and in lieu add pretty freely to developer.

"I am most firmly impressed with an opinion that when albumen is used as a base, the glacial acetic bath plays a most important part.

"Having now given you a description of the preparation and development of negatives, I proceed to the printing of transparencies, which I always accomplish by gas-light, with a good tulip burner, placing the picture within four inches of the jet. I find, according to the density of the negative, that 25 to 50 seconds is quite long enough. When printing, the negative ought to be placed on a stand, or kept very still, if the two plates, are not in perfectly close contact any movement, however slight, will cause, by double refraction, a great loss of definition and sharpness. This, I think, has been overlooked by amateurs generally.

"Develop and fix as in the tannin process.

"A variety of tones may be obtained by regulating the exposure and development of dry plates. Transparencies, should they be rather over-exposed, and have a reddish or brown tint, a very weak solution of hypo and 2 drops of chloride of gold, will bring a fine purple or black tone, which is very pleasing in transparencies.

"I have now given you my method. I claim nothing new, simply careful, clean, methodical manipulation. The specimens left with you are a proof of what might be done, if fully carried out by one having more time at his disposal than I can give to experimental photography."

The colour produced in the specimens of Ratcliffe were chiefly of the purple and black tones, very fine, but perhaps a thought too cold for the taste of some; by the processes described almost any tint, from red to black, could be secured by the modification of exposure and development.

There is another class of tone not so easily obtained, however, by the processes just described. The colour to which we refer is a rich sepia, or perhaps more nearly bistre; and is generally obtained in transparencies printed on albumen. The slides of Messrs. Ferrier and Soulier furnish examples of this colour. Some time ago we received some very fine transparencies from Mr. G. W. Hale, M.A,, of Eastbourne, which had the exact colour of those on albumen, and possessing a richness and depth we have rarely seen surpassed. We were informed, however, that they were produced on Dr. Hill Norris's plates. Mr. Hale has kindly furnished us with particulars as to his method of toning for the benefit of the readers of the News. We now subjoin his communication:—

"Much as transparencies on glass are to be admired, few photographers (amateur or professional) appear to me to know much about the printing of them. All the information I possess was bought by the tedious and expensive process of self teaching. I was not satisfied with the simple development and gold toning, the colour was not to my taste, so I worked away until at last I hit upon a method which produced the sepia colour, which all must admire. I send you a minute description of the way I proceed, and if you think it worth while to publish it, it may save many from trouble and expense.

"The negative must be a good one, to obtain good results, full of detail, not very dense, and with no great contrasts of light and shadow. The dry plate for the transparency may be prepared by any known process, except the oxymel (the colour of which will be black when developed my way); place the negative in a dark slide, and the dry plate on the top of the negative, the two films touching, place blotting paper on them till the pressure is equal all over, when the door of the slide is shut, expose at a shady window, avoid direct sunlight, no rule can be laid down for exposure, it is the essential point, and must be left to the operator's judgment. Having exposed, develop the plate as usual with

| | |
|---|---|
| Pyrogallic acid ... ... ... | $1\frac{1}{2}$ grain |
| Citric acid ... ... ... ... | 1 ,, |
| Water ... ... ... ... | 1 ounce |
| Silver, a few drops | |

Wash well, fix with cyanide or hypo, and wash thoroughly, the picture if properly exposed (it should be rather over-exposed) presents at this stage a feeble appearance, but all the detail showing.

"The plate being well washed from all trace of the fixing solution, take a little of the pyrogallic developer, a few drops of the silver solution, and a few drops of glacial acetic acid, pour it on and off the plate until the picture stands out nearly as much as you require it to do when finished. Wash well, and float the plate with a saturated solution of bichloride of mercury, until it is quite white, even in the deepest shade, the shadows of course whiten last. Wash again thoroughly, next take a 30-grain solution of ammonio-nitrate of silver, and pour it on the plate, it immediately changes to a greenish yellow tint, and gradually darkens; add a drop or two of ammonia, it will hasten the change of colour, and very soon the picture will stand out bright and clear, the brown sepia colour of the picture I send you. Some time after finding out this method of printing them, I read an article in your paper, by whom I forget, recommending bichloride to whiten, and ammonia in water, or cyanide of potassium to effect the change, either will do so I know, but I found the ammonio-nitrate made a much richer colour and gave a sepia tint, whereas plain ammonia and water gave nearly a black tint. Of course it is the ammonia that changes the colour, and I am not chemist enough to say why ammonia-nitrate should give a better colour than plain ammonia, but so I have found it, and I am sure any one else who tries will find I am correct. The transparency I send to you is printed on one of Dr. Hill Norris's plates. The colour can be made the same on albumen as on collodion."

## PHOTOGRAPHIC CHEMICALS:

### Their Manufacture, Adulteration, and Analysis.

*Potassium Salts* (continued).—*Benzoate of Potash.*—Benzoic acid is occasionally used in photography in conjunction with silver. Benzoate of ammonia is usually employed for the preparation of the silver salt, but we think the potash salt preferable, as it is more stable than the other. Benzoate of potash is prepared by adding the acid to a solution of potash until the liquid has a slightly acid reaction; the solution is then filtered and evaporated carefully over the water bath. Upon arriving at the proper degree of concentration it is allowed to cool, when the potash salt crystallizes out in delicate pointed crystals, which remain dry when exposed to the air. The salt is, however, very difficult to crystallize from water, so it may be preferable to evaporate the aqueous solution to a syrupy consistency, and after drying the salt, which separates on cooling, between blotting-paper, to dissolve it in strong alcohol; from the hot saturated alcoholic solution benzoate of potash separates in needles united in tufts, and sometimes in laminæ having a pearly lustre. The salt has a sharp, somewhat burning taste, and dissolves very easily in water.

*Soda Salts.*—After the detailed description which we have given of potash and its salts, it will be unnecessary to devote much space to the compounds of soda, some of these salts are, however, essentially different in character to those of potash. and a notice of these is, therefore, essential. The caustic alkali has, during the last year or two, been manufactured at our large soda works in considerable purity; this is the most concentrated and active preparation of the alkali, and is an entirely new branch of manufacture introduced of late years for exportation to America and other localities to which carriage is expensive. It is prepared in the Lanchashire soda works from the black ash liquors in which a considerable portion of the alkali is actually present in the caustic state. Upon concentrating the liquor in iron boilers, the whole of the salts present separate in a solid state, leaving the caustic soda with only a few impurities, which may, in great measure, be removed by throwing a little nitrate of soda into the pans. In concentrating the strong alkaline solution considerable annoyance used to be caused by the liquid continually frothing over. This is remedied in so ingenious a manner that a short notice of it cannot fail to be of interest to our readers. At the bottom of the pan in which the operation is conducted a conical pipe of sheet iron is placed, which is open at both ends, and reaches about an inch above the level of the fusing mass. The tube is supported by feet a little distance above the bottom of the pan, so that free passage of the liquid is allowed. Steam being formed at the bottom in contact with the heated iron, the liquid is forced out at the top of the tube, forming an artificial Geyser, similar to those of Iceland, altogether preventing any violent ebullition occurring in other parts of the pan, and effectually putting a stop to the boiling over. Several improvements have recently taken place in the production of this body on the large scale, but as we have referred to these in our recent articles on the photographically interesting chemicals in the International Exhibition, a second notice is not needed. All the impurities which we have already mentioned as being likely to be present in caustic potash, may occur in caustic soda, and may be separated in the manner recommended under the former heading. In the pure state, solid caustic soda forms a white opaque brittle substance of a fibrous texture, fusible below redness, very deliquescent, dissolving in water with considerable evolution of heat, and greedily absorbing carbonic acid. The aqueous solution is a colourless, caustic liquid, which, when concentrated, deposits colourless, four-sided tables of the hydrated alkali.

*Carbonate of Soda.*—The manufacture of this salt, carried on simultaneously with that of oil of vitriol, gives employment to an immense number of hands, many of the soda works in the north of England being amongst the largest chemical manufactories in the world. The carbonate is made from sea-salt, which is first converted into sulphate of soda by treatment with oil of vitriol, which liberates hydrochloric acid. By ignition with lime and coal the sulphate of soda is reduced to sulphide, and upon extracting the mass with water a somewhat complicated reaction takes place, and the liquid contains caustic and carbonate of soda. We need not enter into the details of the purification of this body, but will take the salt as it occurs in commerce, in large transparent crystals known as soda. In this form it consists in great measure of the compound with ten atoms of water. When gently heated it fuses in its water of crystallization, and if the heat be increased the whole of the water goes off. In dry air the salt effloresces, losing several atoms of water, the exact number varying with the temperature. From its mode of manufacture carbonate of soda is liable to contain many impurities; we do not here speak of some crystals which now and then come under our notice, and which, upon analysis, turn out to be little else but sulphate of soda; but the best commercial samples which can be obtained are almost invariably contaminated to such an extent as to be unfit for accurate work until purified. The impurities which may be present are:—*Sulphide of Sodium.*—This may be detected by adding a slight excess of hydrochloric or sulphuric acid, and applying the nose to the carbonic acid, which is evolved; if sulphide of sodium be present as an impurity, sulphuretted hydrogen will be at once evident by its characteristic odour. *Hyposulphite of Soda.*—If this salt be present the addition of hydrochloric acid will cause sulphurous acid to be evolved, which may also be easily recognized by its odour; in this case, also, sulphur will be gradually precipitated. *Sulphate of Soda.*—To detect this, after the excess of dilute hydrochloric acid has been added, add a drop of chloride of barium, if this impurity is present an insoluble precipitate of sulphate of baryta will appear. *Chloride of Sodium* may be detected by supersaturating with nitric acid and adding nitrate of silver, the well-known curdy precipitate will denote the presence of chlorine. *Ferro-cyanide of Sodium.*—To detect this impurity take a little solution of sulphate of iron, which has been allowed to become partially oxidized by exposure to the air, add a few drops of this to the suspected liquid, previously mixed with an excess of hydrochloric acid, the slightest trace of ferro-cyanide of sodium will be rendered evident by the production of the rich blue precipitate or colouration of Prussian blue. *Carbonate of Lime.*—This may be detected by adding a few drops of oxalic acid and then an excess of acetic acid; a white insoluble cloudy precipitate will show the presence of lime. *Carbonate of Magnesia* is, also, sometimes present; it may be detected by adding a considerable quantity of chloride of ammonium, nearly, but not quite, neutralizing with hydrochloric acid, and then adding a drop of phosphate of soda, the solution is then violently agitated, and afterwards allowed to remain at rest for twelve hours. *Potash salts* may also be present, but the detection of this base is attended with considerable difficulty; and, moreover, is of very little importance even if present.

Commercial carbonate of soda may be purified by pounding the ordinary crystals very finely, and washing them with cold water; they are then dissolved in as small a quantity as possible of hot distilled water, and the solution filtered if necessary. The liquid is now rapidly cooled by placing the vessel in cold water, stirring it all the time with a spatula, so that small crystals may be formed. Collect these on a funnel, and after the mother liquid has drained off, wash them with cold water till the drainings, mixed with excess of nitric acid, no longer give a precipitate with nitrate of silver.

# The International Exhibition.

## BRITISH PHOTOGRAPHIC DEPARTMENT.—APPARATUS.

We have before remarked that the display of apparatus at the Exhibition is not distinguished by any especial novelties; nevertheless, an examination of the respective contributions must prove interesting to photographers, inasmuch as they have an opportunity of inspecting, in close juxtaposition, the best work of the various manufacturers and dealers, and of ascertaining the speciality of each, to which it may be fairly assumed particular prominence will be given in the respective cases.

Messrs. Bourquin and Co. (3047), have long had a reputation for the excellent quality of their French goods. The bulk of their contributions to the present Exhibition consists, however, of articles of their own manufacture. Prominent amongst these are a great variety of photographic albums, of good quality and great elegance of design. An excellent idea is acted upon in many of these, in making the mount which surrounds the picture of a cream tint, by which the fullest value is given to the whites of the photograph, and any slight tendency to yellowness "carried off." Samples in great variety of styles in London—made passepartouts, mounts, and other forms of *entourage* for the photographic picture, are exhibited. Camera stands and cameras of excellent quality are also shown. We may mention amongst the latter a large universal camera, extending from four inches and a half to something like forty inches, and suitable for copying, enlarging, &c., as well as for ordinary work. A "Composition Printing Frame," by Mr. Hart, and some other articles complete the display.

Mr. Cox, of Skinner-street (3064), exhibits a large variety of useful apparatus. Amongst the objects which first attract attention, are seventeen medallion heads, glass positives. These are produced with as many different exposures on one plate, by means of a camera back or dark slide, described as the "Camera shield for producing four *cartes de visite* or seventeen medallion portraits on one plate, and with one lens." The dark slide is made to revolve by a repeating arrangement around the axis of the lens, and is arrested by a catch spring when it arrives at the position where the portrait is required. The improvement in this arrangement over the American Camera shield, is that the collodion plate does not revolve on its own axis, therefore the drainings of the plate will not flow over the picture, the dark slide being vertical at all points of its circuit. The medallion heads are very fine toned and brilliant collodion positives, produced, we understand, with Fisher's collodion, and a developer of protonitrate of iron, containing formic acid.

An ingenious instantaneous shutter is shown by Mr. Cox: it is attached to the central diaphragm, and works in the tube of the lens. It allows any amount of exposure that may be desirable. In its slower movement it works remarkably easy, therefore reducing the vibration to a greater extent than many others. The principle of its construction is this:—Two flaps or shutters of brass are affixed to the diaphragm, and worked by an axle, protruding through the brass tube in which the lenses are mounted, motion being obtained by giving this handle a twist or turn; therefore, if desirable, the flaps are opened and shut as quickly as the fingers can be snapped; but if half a turn only is given to the ivory knob, a slight spring catches the axle, and both shutters are arrested until the spring is released. A very neat, light, and compact binocular stereoscope camera is exhibited. It possesses the advantage of having all its parts attached, thus obviating a difficulty often experienced by the loss of loose parts in the field. This, with three double backs, is stated to weigh only 3¾ lbs., and measures when packed, 7¾ by 5¾ and 5 in. A neat field box, containing the chemicals for a day's use, and also forming a developing box; some portrait cameras; a Sutton's reflecting stereoscope; specimens of glass portraiture, &c., are also exhibited.

Mr. Dallmeyer (3069) has a very handsome display of apparatus generally, prominent amongst which, however, are his various lenses, with cameras especially adapted to the especial purpose for which the lenses are designed, specimens of which are exhibited in the case. A variety of triple lenses of different sizes, for pictures from 7¼ by 4½ to 25 by 21. Examples of the work done by these lenses consists of a number of Wilson's exquisite views, recently noticed in our pages; copies of maps; portraits &c. Amongst the latter we must notice here, as it is the only copy in the Exhibition, a very charming rural study, called "The May Gatherer." A pretty girl in rustic costume reclines upon a grassy bank, surrounded by the heaps of May blossom which she has just gathered. The easy repose of the figure, the good composition, the idylic sentiment, the perfect definition of every blossom and every blade of grass, the atmospheric sky, and tasteful vignetting, all combine to render this as charming a little bit as Mr. Robinson has produced.

Mr. Dallmeyer exhibits his compound stereoscopic lenses for instantaneous views, and several pictures taken with them, the instantaneity of which, and the perfect definition illustrate the excellence of the lens. There are also some new single combination view lenses for stereoscopic work. They are of 4½-inch focus, and of 6 inches focus respectively, and are made so as to give fine definition with very large aperture, and are thus suitable for instantaneous work where the double lenses are objected to. These lenses were, we believe, first constructed to meet the especial wants of Mr. Wilson, and one of his very fine instantaneous pictures is exhibited as illustrating their powers.

Examples of his quick acting portrait lenses, for pictures from card size upwards, are shown, and have their powers illustrated by photographs from the studios of Williams, Lacy, Robinson, Mayland, Hawke, Abbott, and others. We are almost disposed to think that as charming a display of photographs is to be found amongst these specimens, as there is on any part of the building. There is also a new enlarging lens of especial construction. It consists of two double combinations of very short focal length: it gives great intensity, and perfect definition both in the centre and margin of the picture, with freedom from distortion. Mr. T. R. Williams exhibits some fine enlargements produced by this lens.

As regards apparatus generally, the principal features of Mr. Dallmeyer's contributions are most excellent workmanship, simplicity of design, and great adaptation to a given purpose: these remarks especially apply to the new stereoscopic or Wilson camera, combining in one instrument, capabilities for taking stereographs, and also one picture on the full size plate used, which is 7¼ by 4½, when using the No. 1 triple achromatic lens. The central partition of this camera, which is removeable, is at once a simple and ingenious contrivance. Several forms of shutters for instantaneous pictures: the first, a simple flap shutter, which may be said to be sufficient for most purposes, where absolute instantaneity is not an object, such as sea views and the like; this shutter has the advantage of exposing the foreground more than the sky, and may be used to shade off the sky in long exposures. Next, is what is called a roller shutter, by means of which the opening and closing can be effected by one continuous movement, this also gives a greater exposure to the foreground, and is of especial use in the portrait room. The third shutter, invented by Mr. Mann, admits of the most instantaneous exposure, for it opens and closes at the centre, and therefore gives a maximum of exposure in a minimum of time. A description recently appeared in our pages. There are also other contrivances for opening and closing the lenses in the studio, which, however, in principle resemble those just referred to. The Bellows cameras exhibited are on the Kinnear plan, but remarkably steady when the bellows is expanded to the full length by means of the endless focussing screw. The *carte de visite* cameras, for two and more pictures, appear to be simple in construction, adapted to the purpose, durable, and extremely well finished. Among the square or trunk cameras of larger dimensions for the operating-room is a beautifully finished brass-bound camera for plates 12 by 12. This possesses all the appliances for moving the screen or collodion plate in both the horizontal and vertical planes, effected by suitable rack and pinions at the sides; the focussing being effected by screws. There are several well contrived boxes for apparatus, &c., one in tin for stowing away his New Stereoscopic Camera, in which every inch of space appears to be utilised. These and sundry other requisites for the Art, such as glass baths, pressure frames, &c., &c., all of good design and first rate workmanship, complete the contributions.

## THE INUNDATION IN THE FENS FROM A PHOTOGRAPHIC POINT OF VIEW.*

The next day turned out all that the most fastidious photographer could desire. A smart S.W. wind blew the clouds into compact masses, that arranged themselves into the most fantastic shapes. The sky indeed during our ride would have thrown Stanfield, had he been present, into a most ecstatic state of enthusiasm.

When we got to the works we found that twenty-four hours had been well spent by the busy workers. The

* Continued from p. 401.

panels* were all in position, and they were only waiting for still water to drop them home. This being a very momentous operation, there was an unusual assemblage of engineers and noteworthy personages on the works, and we were fortunate enough to secure two pictures, in which they were all introduced, one gentleman was caught in the very dignified act of blowing his nose. One of the pictures we took was extremely interesting, for one of the navvies is shown in the act of throwing a sack of clay into the boiling waters. The spray caused by the falling sack is just dashed up; and the navy's barrow is still turned upon its side.

Having completed our labours at the coffer dam, we packed up, and were soon on our way for the inundated farm houses. At a way-side inn, where we stopped for refreshment, we were very much amused by the conversation of some men, whose outward appearance led us to think them farm labourers, but whose very learned talk proved them to be Brunels or Telfords in embryo. Had the task of stopping the waters have been entrusted to them, they would have managed it on the first day of the outbreak. The plan of one of them struck us as worth some attention. He would have made one of the now broken bridges the base for his operations, for he would have placed the pile driving engines upon the bridge, and have driven a row of piles on each side, and then having taken off the top of the bridge, he would have filled up the space with sacks of clay. We left these sapient gentlemen to finish the dam with wind bags, and in a short time we reached the breach in the bank. We now lost all traces of human habitation, for we had to travel on a miserable soft road by the side of the bank, and so cut up by cart ruts, that several times we had to get out to lift the unfortunate conveyance out of the deep cuttings. Our progress was so slow that I could endure it no longer, but got out and walked on the top of the bank, leaving the conveyance to follow.

On reaching the farm house, I saw a female at one of the upper windows, who was calling for some one to briug the boat, for it was fastened to the bank, and she was in consequence a prisoner; as her calls were fruitless, for no one put in an appearance to her summons, I volunteered to personate the character of the jolly young waterman for her benefit; an offer which was very thankfully accepted. After some little trouble, for there were no oars in the boat, and nothing to manage it but a pole, I succeeded in making a start, but my next essay was anythiug but a success, for on placing the pole down to propel the craft, I found no bottom, and in consequence very nearly turned a somersault into the water. It turned out I was crossing a drain about 20 feet deep. I found my course, though a short one, very difficult to navigate, for I had no chart. I had to get through a hedge, and then found more dangers ahead in the shape of fruit trees in the garden. Shortly, however, I found myself under the window; and was repaid for all by the agreeable task of assisting a young lady out of the window. I tried to picture myself the hero of a *very small* romance, and a procession of gay cavaliers with rope ladders, gondalas, &c. &c., passed rapidly across the retina, but these were all cruelly put to flight by a gruff voice which proceeded from the governor, who put his head out of the window, and said "are you all right Mary," and on an answer in the affirmative being given, he proceeded to hand down various pails, jugs, &c., for I found that they were going about three quarters of a mile for water. This was indeed a bitter jest. Truly had the picture of Coleridge been realized: "Water, water everywhere, but not a drop to drink."

The wife of this gentleman had made herself quite famous, for when every one else had deserted their homes in terror, she heroically remained, and has continued to do so. The water determined to have the best rooms, but she disputed its claim inch by inch, and finally removed everything portable up stairs, and there she now holds undisputable possession. Every night, when the family are all in the house, the boat is moored to the drawing-room window, and they are secure from all intrusion, except from watery visitors.

Our conveyance had by this time struggled up to us, and I proceeded to prepare for work; but now came a difficulty I had not thought of before. I also wanted water, not to drink, but, at any rate, fit for photographic operations, and not a drop was to be had, but the dirty salt water all around me. After some consideration, during which I saw no way out of the difficulty—time was valuable, for it was near sunset and I could not afford to journey a mile and a half in search of water, if I could help it—I determined, therefore, to try the water near at hand; and tore off a strip from one of my cloths for cleaning glasses, and tied it on my tap so as to serve for a filter. I tried a plate, and found it answer very well. Of course it was impossible to intensify the pictures, I therefore well washed them, and coated them with glycerine, and put them aside for future operations. I noticed that the water produced a very curious effect on the plate when first applied. It appeared to rapidly darken the picture wherever it first touched, but after fixing there was nothing unusual in its appearance. When, however, during the washing of one of the pictures my supply of water failed me, and I could not, in consequence, cover the plate rapidly, I found that it was stained wherever the water first touched it, and that no after washing proved of any avail.

I tried four plates, and certainly they proved faithful representations of a most dismal and melancholy scene, but they were unfortunately not aided by the genial influence of the sun, for he turned sulky and retired to bed early behind a bank of clouds by no means attractive in appearance, and as there was no chance of his condescending to enlighten us any further, we packed up, and after a weary two miles journey, over ground made still more dangerous by the twilight that encircled us, we turned on to the gravel road with a lightened and thankful heart that we had not broken the wheels off, nor turned the conveyauce over, a contingency that seemed probable every moment, until we reached, what to us was *terra firma* viz., the turnpike road. In an hour and a half we were in Lynn once again, and quite tired of photography for that day. Y.B.

* The construction of the dam is very ingenious. Two rows of piles are driven at equal distance from each other, and extended across the stream. Each pile has two companions broader but not so thick, which are placed on each side of it. These are all bolted together, and so form immense groves, into which the panels, formed of thick planks of timber firmly joined, are fitted. These were dropped into the groves, and the space between the two rows filled up with sacks of gravel, clay, &c.

## A SHORT LESSON ON PHOTOGRAPHY.—No. 2.

BY J. TOWLER, M.D.*

The decomposition effected by means of chloride of sodium and nitrate of the oxide of silver, is a very interesting example of a group of similar decompositions, not only with nitrate of silver and any one of the soluble chlorides, but with pairs of other salts, as with sulphate of potassa and the salts of barium, lime, or strontia. Now, I mean by the soluble chlorides such salts, resulting from a chemical combination of chlorine and a metal, as dissolve in water. As a general rule for you, as a beginner, you may regard all true chlorides as soluble, with the exception of *chloride of silver*, *chloride of lead*, and *protochloride of mercury* (calomel). The soluble chlorides are those of potassium, sodium, lithium, ammonium, calcium, magnesium, &c., through all the metals. The chloride of silver produced by the decompositiou of any one of these chlorides is the same when washed as that from the chloride of sodium: it is always sensitive to light; it always changes colour in the same proportion, and is equally insoluble, when thus acted upon, in hyposulphite of soda. You will observe here what an extensive choice we have in the materials for producing the same effect, and will recognise hereafter from this observation a clue to the variety of formulas recommended and used by photographers. I must not omit to mention that hydro-

* From *Humphrey's Journal*.

chloric acid might be used instead in every case where chloride of silver is desired; it is not, however, always practicable in photography; because the materials employed for receiving the chloride of silver would be injured by this acid. But hydrochloric acid is also a chloride; it is the *chloride of hydrogen*. With this introduction to your lesson to-day, let us enter practically upon our duties:—I have here a sheet of paper of a very fine and homogeneous texture, which has been placed in the sunlight, but has undergone no change, as you would naturally suppose; but now observe attentively, and write down carefully, every experiment. Give me that egg. I will separate the white part from the yellow. This white of egg is pure *albumen*. The serum of blood (that thin transparent liquid which is separated from the clot after the coagulation of the blood), is also albumen. Besides this, we have other specimens of albumen, as the serum of milk, obtained by separating the caseine (curds), after the addition of an acid, or of rennet. Weigh out six drachms of the white of egg, and place it in a clean bottle; cork it up, and shake it effectually until the albumen becomes a complete froth, and set it aside to settle for a number of hours. By the by, here are exactly six drachms of albumen which I prepared yesterday. Decant off the thin portion from beneath the froth into a teacup; mix with this two drachms of rain water, or of distilled water, and fifteen grains of chloride of ammonium (sal ammoniac). Let these three ingredients be intimately incorporated, and then poured upon a clean dinner dish, so as to form a uniform layer on the bottom. Remove any bubbles from the surface by drawing over it the edges of a piece of writing paper several times. I will now cut up the sheet of fine paper, that has been lying in the sun, into small pieces; six by eight inches will be a convenient size. You observe I double each corner of each piece like the ears on the pages of a schoolboy's first reader, but with this precaution, that the ears all point in the same direction. Now, taking hold of two ears diagonally opposite, I bend the paper and lay the curved part on the prepared albumen, and then gradually lower each end until the piece of paper lies quite flat and swims on the salted albumen; or we may begin with the right edge of the paper, and lay this first in contact with the liquid and gradually drop the left hand until the same effect is produced. Now raise the nearest right corner, and see if there are any bubbles, which must be broken up by a piece of clean glass rod, after which the paper must be replaced. Take the glass rod in the left hand, raise the farthest left-hand corner with the right hand, and remove all the bubbles in like manner. The paper is now allowed to float or lie on the surface of the albumen for about three minutes; the upper surface of the paper is naturally kept dry all the time, not even a drop of albumen being allowed to come in contact with it, not that in this case it would be injurious, but because it is not necessary, and because you must habituate yourself to neatness in every operation. After the three minutes had elapsed, the anterior right-hand ear of the paper is raised by a pin held in the right hand, whilst the left hand seizes the raised ear; as soon as this is accomplished, the pin is pushed through the ear, and by means of the pin the paper is suspended on a wooden partition, with its lowest extremity just hanging over the edge of a dish beneath, which is placed there on purpose to receive the superfluous albumen. In this manner it is allowed to dry. The rest of the sheets are treated in the same manner.

Whilst they are drying, I will explain to you the philosophy of the chemical part of the operation. You will recollect the experiment in the first lesson, where the chloride was thoroughly washed, and afterwards placed in a teacup and exposed to the sun. This chloride was a white residue; if it had been perfectly dried in the dark, it would have been in the form of a fine impalpable white powder. When this was exposed to the sun's rays, it became coloured, forming a violet coloured layer on a white background. Now, see the analogy in the paper; the fine surfaced paper is equivalent to the white porcelain; it is a white background; the albumen holds in solution a soluble chloride; by draining, the chloride and the albumen, in intimate mixture, are spread uniformly over the surface of the paper, ready to be acted upon by nitrate of silver, so as to produce the double decomposition on and in the albumen, to a certain extent, chloride of silver in a state of very fine division. But before we place the sheets of paper on the nitrate bath, which I will shortly describe, it is certainly an advantage to coagulate the albumen on the dried surfaces, which prevents the solution of the albumen. This coagulation is best effected in the following manner:—The albumenized sheets are folded together into one roll, and then placed in a round tin box much longer than the roll of papers; the box is now dipped into a kettle of boiling water, deep enough for the water to stand higher on the outside than the top of the roll in the inside. In this way the paper is submitted for some time to the heat of boiling water, which renders the albumen in a measure insoluble in the media in which it has afterwards to be placed. The paper being thus prepared, I will now proceed with my experiments.

In this flat dish I have a solution of ammonia-nitrate of silver, which is prepared as follows:—Take an ounce of nitrate of silver and dissolve it in six ounces of rain water; after the silver is dissolved divide the solution into two portions, one containing two ounces and the other four ounces; to the former add liquor ammoniæ, drop by drop, until the brown precipitate which is first formed is redissolved; then mix the two portions together, and add thereto half an ounce of alcohol. This is the ammonio-nitrate bath for albumenized paper. I must tell you here that the ammonio-nitrate of silver forms a chloride which is far superior to the simple nitrate in sensitiveness to light; it is, therefore, on this account, preferable. Ammonia, however, would dissolve the albumen from the surface of the papers; I therefore add a counter-agent in the form of alcohol. This serves the purpose effectually. Now take your bath into a dark room, and place on its surface each albumenized sheet with the same precautions as already prescribed for albumenizing. Let each sheet remain about ten seconds in the bath; this time will be found abundantly sufficient for the purpose. On removing the sheets from the bath, pin up each by one of its corners in such a way as to allow the superfluous fluid to drain off into a dish beneath, and let them remain in this condition until they are perfectly dry. Drops of the ammonio-nitrate sometimes remain on the lowest corner; it becomes necessary in such cases to remove them by a glass rod, or a pad of cotton wool.

This lesson is somewhat longer than the last, I will, therefore, conclude it with a simple experiment, and resume the subject in my third lesson. I have here a leaf which I picked up in the woods; you observe all the chlorophyll has been destroyed, and that nothing remains but the beams and rafters, the reticular skeleton of the leaf. How beautifully minute is each fibre! and how artistic each mesh! Take one of our sensitized sheets of paper, place it on a piece of board a little larger than the sheet; upon this, in the centre, place the decayed leaf, and over this a plate of glass with weights on the corners to keep the paper and the leaf in juxtaposition. Now carry the board and expose the leaf to the sunlight. Observe how quickly the rays of the sun act upon the sensitized paper; in a minute I will remove it into the darkened room. Look, now, at the magic operation. Wherever the rays of light have been able to pass without obstruction, the paper is darkened; wherever the net-like fibres have intervened, the paper is white. This operation is a specimen of what is denominated *sun-printing*, which is divided into two parts: *positive printing* and *negative printing*. Keep the print in the dark room until the next lesson.

## THE STEREOGRAPH AND THE STEREOSCOPE.*

*Displacement of the Cameras (continued).*—Let A and B be the two lenses or the two eyes, and E and F two objects

* Continued from p. 405.

seen from A and B at the distances C E and C F from the plane A B, of which E F is twice C F; but the angle A E C is equal to G F C, therefore G C is double the side A C; hence we see that with a given angle the displacement of the cameras varies directly as the distance of the object. This point is quite manifest in the table. If, on the contrary, the angle varies and the distance remains the same, it will be apparent from the same figure, that the displacement will vary as the tangent of the angle of the parallax. But when both the parallatic angle and the distance change, the range for parallax is from 0° when the object is at an infinite distance, to 180° when the object is directly in a line joining the two lenses or the two eyes, as at C. In the latter case the picture is impossible or hypothetical, and then each lens forms its picture on the same space; there is, consequently, only one picture in every other case, as at D, E, F, and P, each lens forms a separate picture. When the parallatic angle is 0°, the object is at an infinite distance, and is seen by the lens A in the direction A P, and by the lens B in the direction B P.

*Law of the Anterior and Posterior Distances and their Differences.*—In the same figure let K O be a glass screen, and D an object seen by the lenses A and B respectively at the points I and N; it is required to ascertain what circular function the distance I N is, as also that of I K or N O its equal. Now on the two parallel lines A P and C F the angle A D C is equal to K A D; but the former is half the parallax. With the distance A C draw the arc C I K, draw the straight line I K perpendicular to A P, I K will then be the sine of half the parallax; hence the sum of I K and N O will be twice the sine of half the parallax, and will be the difference between the distances of two corresponding points of the photographs taken at the distance C D, and of two corresponding points on the photographs if taken at an infinite distance, or in practice at one mile's distance. As observed in the preceding paragraph, if the object theoretically were at C, the picture taken by the two lenses would be single or on the same space; if the object be gradually removed to D, to E, to F, and to infinity, the pictures of the object gradually separate, that is, the distance gradually increases and becomes a maximum at an infinite distance, and is then equal to the distance between the eyes or the lenses; but we see that I N increases as I K and N O decrease; that is, these qualities are complementary to each other; but the complement of a sine is the versed sine; hence the anterior distance between the corresponding points on the two photographs is equal to twice the versed sine of the parallatic angle.

[The careful reader will observe a discrepancy between the conclusions drawn here and the observations in the second and third paragraphs of this article, on a former page, as also in the note on the same page. The corrections to be made there are, in the first place, to substitute for what there appears: "the maximum distance shall not be greater than that between the centres of the two eyes, &c., nor the minimum greater or less than the difference of the distance between the centres of the two eyes and twice the sine of the parallatic angle," &c. The second correction consists in substituting *increase* for decrease, and *vice versâ*. The correction in the foot-note is simply also an inversion of terms, which will be quite evident to the reader.]

The nearer a lens can approach to the perfection of the eye, the more intimately will be the increment of distance from zero upwards be made manifest, and the better will be the stereoscopic effect of the combined photographs. But many of our photographic lenses are far from being perfectly* corrected either for spherical or chromatic aberration; hence the regular decrease of the distances between the corresponding points on the two photographs, beginning at the distant background is not always, in fact, is seldom maintained; and another reason why it is not observable in the photographs arises from the circumstance that many artists equalize the focus or divide it up, so that all the parts are apparently equally in focus, by focussing upon some points remote from the foreground, or by focussing not in the centre of the lens, but half-way between the centre and the periphery. This plan is probably right for an ordinary photograph; but such a photograph will be devoid of some of the conditions required to produce stereoscopic effect. The most beautiful results are produced by bringing near objects into focus; for they alone appear to the eyes as solid objects, whilst distant objects are projected flat on a distant background, and can be exhibited stereoscopically only by increasing the parallax, that is, by separating the lenses until this parallax be at least half a degree or more; in this case all the objects in front of those thus brought into accurate focus must be excluded from the scene. This last rule must always be observed; for, if the distance between two corresponding points in the mounted photographs be greater than that between two remote points, and this will be the the case where the lenses are not corrected, those points will be projected by the stereoscope on the unassisted eyes into the background; and the consequence will be distortion of relief.

From the preceding paragraph, it appears that the difference between the anterior and the posterior distance (the latter being indefinitely remote) between corresponding points at either station is equal to twice the sine of half the parallatic angle (neglecting the slight diminution by refraction); in accordance with this conclusion we derive the following tables:—

| Distance in Feet. | Equal Conjugate Focus Half an Inch. | Equal Conjugate Focus One Inch. | Equal Conjugate Focus Two Inches. | Equal Conjugate Focus Three Inches. | Equal Conjugate Focus Four Inches. | Equal Conjugate Focus Five Inches. | Equal Conjugate Focus Six Inches. |

The equal conjugate focus of a lens or of a combination, is half the distance between the object and the picture, when these two are exactly of the same size. This focus is by far the best for practical photographers by which to compare the powers of lenses; for it is not an easy mattter to find

* Do not imagine that I wish to disparage the productions either of this country or of Europe. We have lenses manufactured in both continents that do great credit to the practical opticians engaged in their manufacture, and vast improvements have been made within a few years in this department, but the same amount of refinement which is expended on microscopic combinations has not yet been brought to bear on photographic lenses, because it would be altogether too expensive an operation. Besides this, as far as our present knowledge extends, suppose that the utmost corrections be applied to the various lenses used, that is, supposing the lenses are corrected for spherical and chromatic aberration, as far as can be effected by a limited number of combinations, the sum and substance of the expression is, that with such lenses a picture can be taken of objects, situated in the *same plane*, in a similar conjugate plane, and free from the spectral colours. Such lenses as these will never produce pictures like those which the eyes give in the retinæ, and never can do so until the combinations have the same focal length for *near* and *distant* objects. The nearer these focal lengths coincide, the better the lenses for field work, other things remaining the same. That certain combinations are better than others, that the focal lengths for near and distant objects more nearly coincide in some lenses than they do in others will be admitted; but we must at the same time admit that we do not exactly know the physical and mathematical properties that produce this approximation at will. Before I have finished this monogram I shall have to return to this property of *focal depth* or approximation of extreme focal lengths, and shall endeavour at least to give a reason for my believing that it is impossible to devise any combination of lenses that will give a picture so accurately as that which is produced by the combined action of the eyes on the nervous expansions of the retinæ.

the principal focus of a combination, from the fact that it is not easy to find the optical centre of a combination, that is, for those who are not mathematical opticians; it is true we may approximate to the principal focus by finding its equivalent principal focus to that of a single lens; this is effectuated by finding a single lens, double convex, with a very small stop, that will produce a picture of the moon, for instance, of the exact same size as that produced by the combination, and then measuring the distance to the surface of the double convex lens from the picture; to the quantity thus obtained, add half the thickness of the lens if it is equally convex, and this will be the principal focal length of the lens and the equivalent focal length of the combination. If opticians and photographers, however, would use the *equal conjugate focus* for comparison, as I here propose, the difficulty of this comparison would be removed.

*Application of the preceding Table.*—Suppose a lens, whose equal conjugate focus is half an inch, produce a picture of an object that is five feet distant, then the difference between the distances of two corresponding points of this object on the two photographs, and two corresponding points in the distant background will be ·0208 of an inch, or about one-fiftieth part of an inch. Suppose now we wished to use a lens, whose equal conjugate focus is six inches, and were desirous to have the same difference ·0208 to exist, the object then would have to be removed to the distance of sixty feet, because the power of the latter lens is twelve times less than that of the former, or its focal length is twelve times greater; hence twelve times five produce sixty. This being the case, then we shall find the same difference opposite sixty feet with the latter lens, as opposite five feet with the former lens.—*Humphrey's Journal.*

## ON THE STUDY OF THE ELECTRIC SPARK BY THE AID OF PHOTOGRAPHY.*

BY PROF. OGDEN N. ROOD, OF TROY, N.Y.

*Form of the Positive Spark when Drawn from the Prime Conductor by a Short Thick Metallic Rod.*

The positive electrical spark under these circumstances consists of a combination of two figures, viz., a star and one or more rings. The relation which they hold to each other is modified by the distance the spark travels in the air; that is, by the tension of the electricity. The two figures are usually arranged with a considerable degree of symmetry. The very marked difference in these two components, and the fact that the annular form is, as I shall show, characteristic of the electrical brush, seems to indicate that each simple spark consists of two or more successive discharges of different intensity. The woodcuts showing the forms of the spark were executed from photographs enlarged nine diameters; in them them the bright portions of the spark are of course represented by dark shading, &c.

Distance of the brass ball from the sensitive plate $\frac{1}{10}$-inch. The most general form is that seen in diagram 2, at .1. The starlike figure is very distinct. One of the rings is included within its area, and faintly indicated by a deeper shade: the other ring is sometimes seen circumscribing it.

$\frac{2}{10}$. 2. The rays are larger and the external ring is plainly visible.

$\frac{3}{10}$ and $\frac{4}{10}$. .4. The rays increase in size, and the ring is well developed.

$\frac{5}{10}$. Like the above except that the rays begin to grow irregular.

$\frac{6}{10}$. Rays quite irregular; both rings distinctly visible.

$\frac{7}{10}$, $\frac{8}{10}$. $\frac{9}{10}$, $1\frac{1}{10}$, $1\frac{2}{10}$. The star loses its regularity, and the rings are no longer symmetrically disposed.

$1\frac{3}{10}$. No spark passes over: it is replaced by the electrical brush, or rather by discharges intermediate between the brush and the true spark, *fig.* 2, 1.

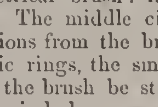
* Continued from p. 404.

These produce a strong impression on the plate, and yield intense sharp figures, consisting of three parts:—An external sharply defined circle, within a series of dots arranged in a circle; and finally, innermost of all, a broad ring

Fig. 2.

which may pass by delicate gradations into a star. This would indicate that the partial spark consists, under these circumstances, of at least three successive discharges of electricity of different tension. The circles on the plate seem to have exactly the same diameter they possess in the air. This is strongly suggested by the following experiment:—If the plate is held obliquely the partial sparks generally pass near its surfaces for some little distance before actually coming in contact with it, and their path is marked by comet-like tails (see *fig.* 3). The diameter of these tails

Fig. 3.



is the same with that of the circles. This is also true of the brush.

*Electrical Brush.*—When owing to distance or the use of a pointed wire these partial sparks become reduced in intensity we have the electrical brush: its form is slightly removed from the last. The middle circle of dots vanishes as well as the projections from the broad inner ring; and we have two concentric rings, the smaller one being most strongly marked. If the brush be still further reduced in intensity, the external circle becomes very faint, and finally disappears, and but a single circle is left.—*Fig.* 2. III, IV.

Electricians have long since arrived at the conclusion that the electrical spark passes by insensible gradations into the electrical brush, and I find that photography furnishes a beautiful confirmation of this view. Thus the figures I, II, III, IV, *Fig.* 2, are selected from photographs forming the first members of a series which would illustrate the gradual conversion of one of these forms into the other, and the other members could easily be added.

We have seen that while the electrical brush is characterised by the annular form, electricity of higher tension generates star-like figures, the rays being larger in proportion to the tension up to a certain point. Now the constant occurrence of a combination of these two forms, in the photographs of *bright sparks*, points out, I think, clearly, that these sparks consist also of more than one discharge; moreover, the ring, where it cuts the rays of the star, can often be traced under them, as though superposition had taken place. Again, when the bright spark travels some distance the ring is generally not symmetrically placed, as though the discharge producing it had followed a slightly different path. Indications are constantly observed which lead to the idea that even the star itself is produced by the overlapping of two stars, having rays of different size and different intensity.

The wet collodion film offers, of course, a certain amount of resistance to the passage of electricity over its surface, and thus furnishes uo with the different indications above described.

Finally, as the researches of Reiss, Kirchhoft, Helmholtz, and Feddersen, have shown that the electrical discharge is oscillatory and wave-like, I am the more inclined to regard these photographic figures as produced by a series of consecutive discharges of different intensity.

Before passing on to the next point of interest, I will allude to a curious modification which the positive partial spark undergoes if the machine be turned rapidly, so that a large number of them fall quickly on the same spot: see V, *fig.* 2. Many of the partial sparks are arranged rapidly around the point under the brass ball, the pointed portion being turned outward.—*American Journal of Science and Art.*

## Correspondence.

### FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

*Paris, 27th August*, 1862.

From the multitude of suggestions for new or revised formulæ in the various photographic processes, a sanguine person might conclude that we are fast approaching the goal of perfection and infallibility. If in a multitude of counsellors there is much wisdom, then photography is singularly fortunate, for surely no subject that ever engaged the mind of man can show a more formidable array of counsellors pregnant with experience and wisdom. It would seem to be very easy to take rank as an inventor or discoverer in photography, honey or treacle may serve your turn, but unhappily the glory thus acquired is very short-lived; and it behoves the ruling genius of the hour to make the most of his opportunity, for raspberry-vinegar may be looming in the future, and quickly terminate honey or treacle's existence.

I see by our Journals that the resin benzoin has been brought into action by an ingenious operator. He puts it into his collodion, and he puts it on to his positive printing paper, with what result I cannot yet inform you, as I have not had leisure to repeat his experiments; but as there may be something in it, I proceed to quote his formulæ.

First, as to the benzoinized collodion, take

| | |
|---|---|
| Ether ... ... ... ... | 100 parts |
| Alcohol ... ... ... ... | 50 ,, |
| Pyroxyline ... ... ... | 1 ,, |
| Iodide of cadmium ... ... | 0·5 ,, |
| Iodide of ammonium ... ... | 0·5 ,, |
| Bromide of ammonium ... ... | 0·1 ,, |
| Bromide of cadmium ... ... | 0·1 ,, |
| Chloride of cadmium ... ... | 0·3 ,, |
| Benzoin ... ... ... ... | 0·4 ,, |

His sensitizing bath is composed of

| | |
|---|---|
| Water ... ... ... ... | 100 parts |
| Nitrate of silver ... ... ... | 8 ,, |
| Acetic acid ... ... ... | 10 ,, |

The plate being sensitized, it must be well washed and dried. It will be nearly twelve hours before the plate becomes dry.

The exposure required is a little less than that required for the Taupenot process. Four minutes for a stereoscopic plate, 5 to 10 for a plate 10 by 12. Upon removal from the camera the plate is immersed in a dish full of water. The water employed for washing the plate will answer. When the film is thoroughly moistened, the picture is developed with pyrogallic acid, just as with wet collodion. The development must not occupy more than five minutes. The fixing is performed with hyposulphite of soda. Any wet collodion that gives good negatives may be employed in a dry state, by adding 0·27 of benzoin to 100 of collodion. This collodion succeeds very well when employed in the wet state; it yields very intense blacks.

The method of printing positives does not differ in principle from the ordinary process with chloride of silver, but only in detail. The paper is first prepared with the following solution, in which the paper may be wholly immersed, or floated.

| | |
|---|---|
| Alcohol at 36° ... ... ... | 100 parts |
| Benzoin ... ... ... ... | 10 ,, |
| Chloride of cadmium ... ... | 5 ,, |

It is more expeditious to immerse the paper than to float it. The sheets are hung to drain and dry in the usual manner, and they dry very rapidly; they may be dried by a fire if time presses.

The improvement effected by the benzoin is in closing the pores of the paper; air and moisture cannot penetrate the proof, which is thus protected from the chief, if not the only cause of its destruction. The benzoin also gives a gloss to the surface of the paper, but not so much as is given by albumen.

The paper thus prepared may be preserved for a long time: it is sensitized in the following bath, as with albumenized paper.

| | |
|---|---|
| Water ... ... ... ... | 100 parts |
| Nitrate of silver ... ... ... | 15 ,, |

In printing, this paper requires less exposure under the negative than albumenized paper.

Another operator recommends the following variations in the tannin process, as yielding the best results.

*Solution of Tannin*—

| | |
|---|---|
| Distilled water ... ... ... | 500 parts |
| Tannic acid ... ... ... | 4 ,, |
| Alcohol rect. ... ... ... | 25 ,, |

Dissolve and filter. The sensitizing bath consists of

| | |
|---|---|
| Water ... ... ... ... | 1000 parts |
| Nitrate of silver ... ... ... | 60 ,, |
| Acetic acid ... ... ... | 10 ,, |

The same collodion as employed in the wet process may be employed; if a little bromidized it will be preferable.

*Manipulation*—After the plate is sensitized, it is carefully washed in distilled water, allowed to drain for a moment, and then the tannin solution poured on. It is dried out of the reach of dust, and the edges of the plate covered with picture varnish.

The exposure in the camera is 10 to 15 times longer than when operating with wet collodion; but by warming the plate before the development, the exposure may be greatly diminished.

*Development* solution—

| | |
|---|---|
| Water ... ... ... ... | 500 parts |
| Pyrogallic acid ... ... ... | 5 ,, |
| Acetic acid ... ... ... | 50 ,, |

The plate being washed, a little pure solution of pyrogallic acid is poured over it, drained off, and again poured on, first adding a few drops of a solution of nitrate of silver of 3 per cent. The picture is fixed with hyposulphite of soda.

## PRINTING AND TONING DIFFICULTIES.

Sir,—Entertaining an utter aversion to all secret dodges, which only tend to retard the healthful growth and progress of our fascinating art, I willingly respond to your invitation by freely devoting a few of my limited moments of leisure to a further consideration of the subject on which I treated somewhat briefly in your last number; and as I purpose entering fully into the various windings of that apparently intricate and hitherto perplexing subject, I shall endeavour to simplify and arrange the various causes which produce the evils there spoken of. In order that I may accomplish this self-imposed task more effectually, it will be necessary for me to discuss the subject of printing and toning by pausing to make a few remarks as I enter upon each of the several stages pertaining to those interesting processes, avoiding unnecessary prolixity. I shall advance many arguments which have a tendency to support the new theory of surface impediments, I have launched into the photographic world, and if, by my humble efforts, one stone is added to the noble and fast growing structure of photographic art, my labours will be more than amply repaid.

Commencing with paper. Oh, what a mass of learned arguments has been advanced on this topic! but still photographers despairingly cry, "When and where shall we find a paper vendor honest enough to deliver us from this rapidly growing evil?" A great difference, I will admit, exists in the various papers now in the market, and known as albumenized papers, some samples of which are totally unfitted for photographic purposes; this may be attributed to an ignorance of the conditions required, rather than to any feelings of dishonesty on the part of the dealers; to remove this ignorance, I will now proceed to give the views I entertain on this subject.

The texture of paper employed in printing should be as fine and even as it is possible for art to make it, in order that the substances employed in the production of the picture may be retained without a flaw upon its surface; the more perfectly this can be accomplished, the more perfect will be the print produced, for a coarse absorptive texture is not only the most prone to mealiness, but I have known it to cause distortion in the image, when by long soaking the pores have distended, and, whilst drying, have twisted themselves into a different position. The importance of the above remarks will be more clearly shown in the following hints on albumenizing. When a thin solution of albumen is used on which to float paper of coarse and irregular texture, the quantity of that substance which remains on the surface of the paper, when dry, will be very uneven, the most absorbent parts contain the thickest layer of albumen, and consequently a larger share of the chloride used, and when sensitized it will evidently contain a double share of silver; this last, after reduction by light, when placed in the toning bath, will act as an impediment, which will mar the beauty of the print, because the adjacent portions of the paper, which contain less silver, will be thoroughly toned ere any visible effect has been produced on the parts which contain a double portion of silver and albumen, hence the cause of red spots, known as uneven toning; proof of this may be found in the fact, that, be a paper ever so good, if a wave of albumen should be allowed to accumulate near its edges, those portions of the paper will appear the colour of red lead; this red appearance is but the results of contrast, for if this portion be separated from the perfect parts of the picture, it will be readily perceived that it has undergone a partial change from the effects of toning. Another proof may be advanced, in the fact of an highly albumenized paper requiring a much longer time to tone than a more thinly coated sample; but I believe I have said sufficient to show the importance of my remarks on paper. I would just add in conclusion, the greatest care should be exercised by paper albumenizers, in order to secure a perfectly even surface on the papers used; and if a material of coarse texture is used, let it be made use of in a plainly salted condition. I shall next week (with your permission), have a few remarks to make on the silver bath.—I remain, yours respectfully,

A Photo's Assistant.

P.S.—An error, which doubtless was my own (as I have to write in haste), appeared in my last letter; speaking of 'toning after printing by diffused light,' it should read, 'a mere alkaline reaction is all that is required.'

## Photographic Notes and Queries.

### Free Nitrate in Toned Prints.

Sir,—In a recent number of the *British Journal*, in an article on Toning, George Dawson, Lecturer on Photography, at King's College, in speaking of the first washing, says:—

"The importance of thorough washing cannot be too strongly insisted on, not merely because it facilitates the toning, and prevents mealiness, but because, in the after fixing bath, free nitrate of silver is certain to generate sulphuric acid, to the permanent detriment of the pictures."

Now, though I perfectly agree with Mr. Dawson as to the importance of thorough washing, I think you will agree with me, Mr. Editor, that his chemistry is quite at fault, when he gives as a reason that "free nitrate of silver is certain to generate $SO_3$ in the after fixing bath," for I cannot perceive how any free nitrate of silver can pass through the toning bath of chloride of gold and acetate of soda without being decomposed; and if it be decomposed, how can it be present so as to generate sulphuric acid in the hyposulphite bath?—Your obedient servant,

W. W.

*Bristol, August 4th*, 1862.

[Free nitrate of silver would be decomposed in the toning, even without excess of alkali, and unless a very large excess of silver were present, it would not be likely to reach the hypo in the form of a nitrate. The sentence has probably been written thoughtlessly, for we believe Mr. Dawson is a good chemist.—Ed.]

### Angle included by View Lenses.

Sir,—In your note to my letter "On the Angle included by View Lenses" in the last number of your Journal, you say that "to test the lenses properly it would be necessary to use a triple of an equivalent focus, the same length as that of the single lens, to try each lens with the same sized stop, and to use a plate larger than they were intended to cover." You must allow me to say that I consider these conditions to be by no means necessary. In my experiments I did use the same sized stops, and I found that both lenses being of precisely the same focus as measured from the back lens of the triplet, the single lens included about one-seventh more subject on the *same* surface of glass than the triplet, consequently the angle was so much larger in the former.

My subsequent observation was to the effect that it was unfair to measure the focus from the back lens of a combination, but that the equivalent should, in all cases, be given. Such equivalent will include, I believe, precisely the same angle as that included by a single lens of the same focus and *no more.*—I am, sir, yours very respectfully, Baynham Jones.

*Cheltenham, 25th August*, 1862.

[On a little reflection you will see that your experiment is entirely fallacious. You used a single lens of shorter focus than the triple; and, therefore, from the same point and on the same sized plate necessarily included more subject with the short focus than with the long one. But no argument of any kind is thence desirable as to the respective capacities of the two lenses as to angle of view. It is unquestionably a very erroneous plan to state the focus of any compound lens as measured from the back glass. But, notwithstanding that you condemn the practice, you follow it in making your experiment. We repeat it that to make the results fairly comparable, lenses of similar *equivalent* focus should be used, and that it is desirable to work on glasses larger than the lenses are intended to cover, to facilitate examination of the exact extent of satisfactory definition in each.—Ed.]

## Talk in the Studio.

"Muggy Weather."—To most persons this particular kind of weather is most oppressive, not fit to do anything upon; but a photographer takes a very different view of it. He calls that weather "muggy" which is the best adapted for taking a person's "mug."—*Punch.*

Photographic Festival.—On Tuesday week Mr. Mayall entertained the whole of the persons employed in his establishments at a magnificent banquet at his residence at Pinner. Meetings of such a kind between the employer and the employed are always interesting, and indicate the existence of that good feeling which they are calculated farther to promote.

Balloon Observations.—Mr. Glaisher, whoso name is known to most of our readers as an accomplished photographer, as well as Superintendent of the Magnetic and Meteorological Departments of the Royal Observatory, at Greenwich, has recently, in company with an experienced aeronaut, made several balloon ascents, for the purpose of observing and recording meteorological observations, the result of which will, we believe, be reported at the forthcoming meeting of the British Association for the Advancement of Science, at Cambridge. The *Daily Telegraph* recording one of these ascents speaks in glowing terms of the exquisite cloud effects seen. It says:—"At about twenty minutes to eight the earth was entirely hidden; and at this time the cloud scenery was of a character to which Mr. Ruskin alone, in his very happiest moments, could have done justice. As the balloon went on its solitary journey, the clouds were breaking up, and in long swathes and folds of a ghostly white, their fragments passed dimly. By an optical illusion which will be easily understood, not the clouds, but the balloon itself, appeared to rise and fall; and suddenly, when it had passed through an aerial valley, a glimpse was caught of the upper plains of the sky. The contrast was marvellous. It was like passing from the obscurity of a churchyard into the glare of a conflagration. Close—so close as almost to seem palpable—clouds of the purest white, rose and fell like waves upon a sea of snow; and far away, over their level range, there was a glory of scarlet and gold, changing every instant, but only to become more varied and intense. In another minute this glorious sight was to be seen no longer." Would it be impossible to preserve some record of these effects by means of the camera, and has Mr. Glaisher opportunity for bringing photography to bear during these journeys? The results would be interesting.

Photography on Mont Blanc.—We find in the *Moniteur* an interesting description of an ascent of Mont Blanc, effected on the 11th inst., by M. Bisson, an eminent photographer, who had already performed the feat last year, but was desirous of completing his collection of views. His progress as far as the Grands-Mulets was not marked by any particular incident; he took various views from different points, and then proceeded to the Passage des Echelles, where he and his party crossed the ravines, some 300 feet deep, crawling on horizontal ladders, one by one, on their hands and feet. Their further progress to the Dôme de Goutté was, however, impeded by an unforseen incident. A bridge of ice and snow, which had hitherto served as a passage to the Grand Plateau, had broken down, and they found a yawning abyss, from 45 to 155 feet in width, before them. No other passage seemed possible, and M. Bisson was on the point of giving up the adventure, when he was hailed by three of his men, who, unperceived, had sought a convenient place, and with their hatchets hewed out a path, by which they had succeeded in gaining the icy crest of the Mont Maudit. They soon descended the rocks on the other side, and threw ropes to their comrades, by which the luggage was hauled up. M. Bisson and the rest of the party followed the new but dangerous path, which brought them two hours sooner to the Grand Plateau. There new difficulties awaited them; they had to hew 800 steps, and ascend the side of the corridor, which, in some places, had an inclination of 50 degrees. On reaching the end of the corridor, they were assailed by an icy-cold wind. On arriving at the summit, after some further labour, M. Bisson found to his regret that the silver of his plates was crystallized, the temperature having suddenly fallen 10 degrees centigrade, although it was exactly noon. At 2 p.m. he descended from the summit, but visited it again on the 14th, and returned to hamounix on the 15th without further accident.—*Times.*

M. Disderi's Work.—The recently issued volume by M. Disderi, entitled "L'Art de la Photographie," regarding which we have had several enquiries, may be had, we understand, of Messrs. Harvey, Reynolds, and Fowler, of Leeds, who are M. Disderi's English agents.

## To Correspondents.

*** Any of our readers having Nos. 41, 91, 101, and 104 of the Photographic News to dispose of will confer a favour on the Publisher by forwarding the same to this Office for exchange or purchase.

One in Difficulty.—The deposit of which you speak is unquestionably a form of fog. The addition of a trace more nitric acid to your bath, or of acetic acid to your developer may probably prevent it. The addition of a few drops of tincture of iodine to your collodion will sometimes prove a cure. If these fail, neutralize your bath with bi-carbonate of soda, or freshly made oxide of silver, and then sun it. Afterwards filter and faintly acidify, and it will probably work well.

W. H. H.—The presence of acetate of silver in the bath (formed by the addition of acetate of soda) will not, that we know of, be injurious to tannin and honey plates. The only probable effect will be increased density in the picture. 2. The bromo-iodized collodion of any respectable maker will answer. Thomas, Ponting, Rouch, Keene, Mawson, Perry, and others. It is probable, however, that all of them may, for tannin plates, require the addition of about a grain of bromide to each ounce of collodion, more than they already possess. 3. We cannot promise immunity from mealiness with any paper we know. It sometimes occurs with all. We recently used some very good from Bourquin. 4. You will find the last communication on photography in the natural colours, in an article entitled "Heliochromy," by M. Neipce de St. Victor, in the Photographic News, No. 182, Feb. 28th.

R. G.—We do not know any one who undertakes professionally to paint clouds on negatives for photographers. Those of Mr. Bedford, to which we recently referred, are done by himself.

Triplet.—In copying engravings, much depends on their character as to whether it is desirable to use iron or pyro for development. Since the time of exposure is not an object, it is as well generally, especially with good light and in warm weather, to use pyro, whereby you gain intensity at once, without intensifying. In a dull light or cold weather, or with a subject possessing much delicate gradation, it is better to use iron and then intensify. 2. The table of distances given in our Almanac is applicable either to the triplet or any other lens.

W. G.—The best material to apply to the edge of the tannin plate, when a tendency exists for the film to loosen, has, in our hands been Hughes' black varnish Agitating the collodion with a little bicarbonate of soda, and then letting it settle will make the film adhere better; but in that case the bath must possess sufficient acid to prevent fog. If your collodion were made according to the formula we give, you have probably failed to have the temperature sufficiently high, in making the pyroxyline, or the film would not readily leave the glass. Take care to leave the plate to soak a few minutes before commencing to develop and that will often help you.

W. W. S.—Your distilled water is most probably at fault. The turbidity you describe on adding the distilled water to the strong solution was right enough. It was merely a precipitation of iodide of silver which is less soluble in a weak solution of silver than in a strong one, and was in excess for the quantity of solution. The discolouration was altogether wrong, and, with the other effects you name, probably indicates impurity of the distilled water. Take all the solutions made with the water, and first neutralize them by the addition of a little bi-carbonate of soda—a few grains will be sufficient—then expose for a few hours to bright sun. The blackened matter will precipitate, and after filtration, and the addition of a trace of acid, the bath will be in working condition.

W. F. W. W.—In our answer to your queries last week there was an error. For "latter" read "former." It was to the acetic acid we referred in stating that it was probably adulterated with sulphuric acid. This would produce a sulphur compound with the silver, and cause the black precipitate, and might also cause the greasy metallic film on the surface of the solution.

W.—Distilled water is by no means always pure. Mr Barber's suggestion of getting rid of the impurities by neutralizing, or rendering alkaline the new bath, and then sunning, is always worth attention when there is any doubt of the purity. Some photographers do this with common water, never using it distilled at all. Of course there is a little loss of silver in such cases. Mr. Barber recommends neutralizing with freshly precipitated oxide of silver.

M. F.—There is no reason why you should not seal small glass positives to dark coloured glass, by means of Canada balsam. Such sealing was once the subject of a patent, but it is not now in force.

G. L.—Spirit varnishes generally require heat in their application. Too high a temperature, however, especially if the alcohol of which the varnish is made be very highly rectified, will cause the collodion film to be dissolved. Spirit varnishes are generally best adapted for negatives giving the hardest surface.

Positive.—Collodion positives receive less attention in our pages than negatives, because they are produced by fewer persons, and there is consequently less interest felt in them. We admire a good positive very much, the chief drawback is the fragile substance upon which they are produced. Those on enamelled iron plates, patent leather, &c., generally lack brilliancy, and are heavy looking. The proto-nitrate developer gives the most silvery white picture. Proto-sulphate of iron and acetic acid generally gives a more creamy tint. Backing with marone velvet gives a warmer tone to the shadows than black varnish. 2. Not at present.

R F. G.—Vignetting may be effected either by means of vignette glasses, or by an aperture in a piece of card, and fringed with cotton wool. The latter plan is in so many respects the best, as it permits less formal shapes, and more variety. Print in diffused light when using the latter, so as to avoid definite outlines to the graduated image. It is decidedly permissible in landscapes, and often valuable.

Ozone.—Thank you for the pamphlet. The subject is an important one, and shall have our early attention.

J. Losh.—The finish produced by your rolling press appears very excellent, from the samples enclosed.

Glasgow.—We do not know of any method of hardening bee's wax without adding some other substance to it. 2. If spermacetti be stirred briskly whilst melted, until it cools, the crystalline appearance will be largely removed.

Several Correspondents in our next.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 209.—*September* 5, 1862.

## PHOTOGRAPHIC PAPER.

Paper is unquestionably one of the most important substances used by the photographer: and printing is out of all proportion the most important operation. It is, indeed, as Mr. Hughes once aptly observed, if not the *be-all*, at least the *end-all* of photography. "All our other processes," he remarked, "are but preparatory steps to printing." For that we make our pyroxyline, prepare our collodion, purchase our apparatus, and rack our brains to produce perfect negatives. With this object before us we travel over land and water, climb glaciers, face water-falls, on mountain top, in sheltered valley, on open heath, in deep forest or dark glen—wherever or to whatever we point our lens, this is the consummation we have always in view—"the reward for all our labours." However important may be the mode of preparing paper, the proportion and age of the albumen, the quantity and base of the chloride, and the skill in albumenizing, it is quite certain that the material, texture, and sizing of the orginal paper exercise no inconsiderable influence on all operations upon it, and on the finished result.

Here is the photographer's great difficulty, he is performing a delicate chemical operation with a substance as to the nature and preparation of which he is ignorant. He may know the formulæ of his albumenizer: but he knows nothing of the processes of his paper maker. He does not know what enters into the composition of the orginal pulp; he does not know with any certainty the composition of the size on the surface. What is more and worse than this, from the out-cry which has arisen of late years, it would appear that whilst everything else in connection with photography has been progressing and improving, both in apparatus and chemicals, and in the knowledge of how to use them, paper has been growing worse. At one time an impression prevailed, that the use of the alkaline gold toning processes had introduced many of these evils as some drawback to their benefit in other respects. But we have recently received several letters from printers who have been trying the old bath of hypo and gold, and have experienced similar difficulties to those supposed to belong solely to the alkaline gold processes, thus pointing to the fact that much of the paper in the market is of unsuitable quality for giving good photographic results by any process.

We believe that paper is the only material used in photography, at the present time, that is not manufactured with an express view to the wants of photographers. We do not mean to intimate that paper is not manufactured with a view to photographic use; but that it has been simply paper of the ordinary manufacture, selected with a surface as perfect as possible. There has never been, that we are aware of, any searching enquiry, or any carefully instituted series of experiments in the manufacture of paper, with a view to ascertain what materials, and mode of using them, would yield the best photographic results. That such an enquiry is necessary there cannot be a doubt, and that the results would repay the effort seems very probable. Such enquiries have often been contemplated, and sometimes even promised, but there the matter has ended. We remember that about a year and a half ago, Mr. H. G. Bohn mentioned at a meeting of the Photographic Society the name of a manufacturer whose paper he thought would meet the wants of photographers; and shortly afterwards Mr. Hardwich, Mr. Sutton, and ourselves, waited upon the manufacturer in question, to ascertain if he would enter upon a series of experiments, with the assistance of photographers. He furnished us with samples of the paper he thought most suitable for the purpose, but did not undertake to try experiments. The samples he furnished proved on trial to be considerably less suited to the purpose than almost any in use. At a subsequent meeting, Mr. Bohn introduced another manufacturer, Mr. Busbridge, who expressed a deep interest in the subject, and promised to make any effort, aided by photographers, in producing a perfect paper. We were subsequently furnished with some samples of the paper he proposed for photographic use, and regret to say, that it turned out the very worst we ever printed upon. No further experiments, that we heard of, were undertaken, and so far as we know, there the matter ended.

M. Ernest Lacan, editor of *Le Moniteur de la Photographie*, from whom we had the favour of a recent call, during a hasty visit to London, furnishes us with some information, from which we hope that photographers may anticipate that an effort is really about to be made to supply them with a paper manufactured expressly with a view to their requirements, and in which the utmost care to secure the right conditions will be given at every stage of the operations. M. Canson, the manufacturer of a French photographic paper, which had at one time considerable reputation, but of which we have not heard much recently, has, we understand, entered into a treaty with certain gentlemen interested in photography, of whom we believe M. Lacan is one, to institute a careful investigation as to the conditions required in paper for successful printing by the processes at present in use. M. Pierre Petit, one of the ablest of Parisian portraitists, has undertaken to test the samples of paper produced, and pronounce upon their fitness for photographic purposes. We have a strong hope, from the high position of the gentlemen interested in the project, and their peculiar fitness to give it effect, that it will issue in the production of a higher class of paper, of a more definite and known composition and quality, than has before been offered to photographers. We hope shortly to be able to publish further information on the subject.

## CARD PORTRAITS.

We have before us a large accumulation of examples of card portraiture forwarded by different readers for our examination and opinion. Many of these are very excellent indeed, whilst there are others to which silence is the most favourable criticism we can award. In examining the various specimens, we are struck, however, as we have been before, with the increase of many good qualities which card portraiture has rendered imperative upon photographers. The photographic qualities are better, the manipulation is more careful, and there is at least some attempt, if not always successful, at artistic arrangement.

Amongst the most pleasing examples of card pictures we have seen at any time, is a series of vignetted specimens by Mr. T. B. Parkinson, an English artist residing at Dieppe. In the whole treatment there is a freshness and individualism, which at once arrest attention and command interest. It is one of the singular facts about photography, and one which gives great force to its claims to recognition as a fine art, that notwithstanding the apparently mechanical character of the operations, the artist *does* stamp his character upon his work, and just as much so in portraiture as in landscape, and other branches of photography. No one can have failed to notice that whilst all the sitters of one photographer may appear to be vulgar people, another artist, from the same sitters, would produce the portraits of ladies and gentlemen—using those terms in their best acceptation. Others again, without conferring vulgarity on their sitters, seem to produce an inevitably conventional and commonplace effect, in which characteristic their sitters all seem to possess a family likeness; whilst another artist, with the same sitters, would secure pictures in which every portrait was marked with more or less of individuality and distinctive character.

Amongst the latter class we must place Mr. Parkinson. All his pictures have excellent photographic characteristics, they are well-defined, round, delicate, clean, brilliant, well printed and of excellent black tone; but beyond all this, and arising from a combination of causes difficult to specify, is the freshness and individual interest of each portrait, which seizes the attention, and causes the exclamation, "That must be a good portrait, I fancy I must have seen the original somewhere." It is the living, thinking appearance every face possesses which thus arrests attention, and almost gives a look of recognitiou to the expression. Good photography is necessary to this result, but it is chiefly due to fine judgment in selecting the arrangement and pose best suited to each face, and especially to the management of lighting required to give a pleasing and natural effect to the features, and harmonise with the pose selected. A good deal depends also upon the manner, temper, and feeling of the operator re-acting upon the sitter.

In accordance with our custom, we always endeavour to obtain the particulars of manipulation for the benefit of our readers, when we meet with pictures which we consider to possess peculiarly good qualities. It often happens that there is nothing essentially new in the method, but it is always interesting to read a clear statement of the particular practice of any good photographer, and such statements often serve as encouragement to others, who may be at the time unsuccessfully using the same formulæ. We subjoin, therefore, some extracts from a long letter on his mode of working with which Mr. Parkinson has favoured us:—

"Regarding the mode in which I manipulate, there is nothing new in it; but I have used the same formula these last four years, and have never known it fail; whenever I experiment with other plans I never succeed so well, consequently I am always glad to get back to my old friend. The collodion I use is a mixture of Thomas's and Ramsden's, the former I add as I require density: when requiring to be very quick I use Hardwich's, which is prepared by Burfield and Rouch, and an even mixture of Thomas's negative, and Mawson's positive (this is the collodion that was always used by Lacy). It is curious that a mixture of so many collodions is so good; but, singular enough, I have never known it fail, although you could not work with any one singly, yet mixed they answer admirably, and I am sure no operator will ever regret having them on his shelf.

"As regards the silver bath, it is of the usual 30 grains strength, iodized with iodide of potassium. Prepare thus:—

| | |
|---|---|
| Nitrate of silver ... ... ... | 480 grains |
| Distilled water ... ... ... | 4 ounces. |

Dissolve.

| | |
|---|---|
| Iodide of potassium ... ... | 4 grains |
| Distilled water ... ... ... | 1 ounce. |

Dissolve.

Add these two together, well shake and filter; then add 100 grains of oxide of silver, well shake and then allow it to settle, carefully pour off the clear solution, leaving the residue of oxide in your stock bottle, filter. Add a few drops of a solution of—

| | |
|---|---|
| Nitric acid ... ... ... | 6 drops |
| Distilled water ... ... ... | 1 ounce |

until the bath works clear.

"A plan I always adopt is to keep enough solution in my stock bottle for two baths, thereby having one at work and one in the bottle, to which I again return it every Saturday evening, filtering and adding my acid on the Monday, the oxide of silver always remaining at the bottom of the stock bottle. The present bath I have, of course with additions, has lasted me two years. I develop with iron of this strength—

| | |
|---|---|
| Protosulphate of iron ... ... | 20 grains |
| Acetic acid ... ... ... | 20 drops |
| Distilled water ... ... ... | 1 ounce |
| Alcohol ... ... ... ... | 40 drops. |

"I vary the strength of this developer, but never exceed 25 grains, as it is so difficult to get the solution over withf out staining the plate. It is for that reason I use plenty o. spirits of wine. Bring the picture out fully with this Well wash and deepen with

| | |
|---|---|
| Pyrogallic acid ... ... ... | $1\frac{1}{2}$ grains |
| Citric acid ... ... ... | $\frac{1}{2}$ grain |
| Distilled water ... ... ... | 1 ounce |

to which is added a few drops of nitrate of siver solution, 20 grains to the ounce.

"Should the picture not be deep enough after fixing, pass over it a saturated solution of bichloride of mercury, and you will have the required density. With these two deepeners I can get almost any density I like, without fogging the shadows, or destroying the half tones.

"My prints are *papier Rive*, excited in an 80-grain silver solution, and toned with gold and carbonate of soda. I have tried nearly every description of toning, and find none preserve the whites so necessary in vignettes as the carbonate. My paper is always prepared the same day as it is used, and I forgot to add that there are a few drops of acetic acid always in the silver solution. I have thus given you my process just as I am in the habit of using it; but still, with the best of processes, if you have not a good arrangement of light and good apparatus, you cannot succeed.

"The new glass house I have built I will shortly describe, and have sent you some few pictures that I have taken in it, that you may judge of the light arrangements. It is 60 feet long, 15 feet wide, 8 feet high at sides. I have 14 feet of glass each side on the top, 18 feet at the sides, the first 3 feet nearly touching the ground, the rest about a foot from it. To this I have added curtains, so that with a screen to move about, I can secure nearly any light I like. You will see by the rough sketch, that I have about 8 feet covered in, which I use for my backgrounds, so by advancing or retiring you can get a good many shades with the same background. The lens I use is a French $\frac{1}{2}$-plate, with focus of 8 inches; but there is no name on it, and sometimes I use a pair of French stereo twin lenses, likewise without name, though exceedingly good.

"I use also a camera made for me by Francis, which is so good, and answers so many purposes, that I will describe it. It is large enough to take a plate $6\frac{1}{2}$ by $4\frac{3}{4}$, and by having the front to slide, to which is attached the lens, I am able to take two *cartes de visite* on the same plate; by removing the slide and putting in another, to which is attached my twin lens, it answers stereoscopic purposes, or two *cartes de visite;* again, by removing the inner division and putting in the larger lens, it will do for $\frac{1}{2}$-plate portraits or views. It is quite a *multum in parvo* camera. Another good plan it has is that the focussing glass has two hinges at the bottom, so that it lifts up and down, and does away with having to lift it in and out; and when travelling you can fit your dark slide on behind, which prevents your breaking the focussing glass; you can also pack your lens in the inside, and it will not make a parcel more than eight inches by ten or twelve inches.

I think I may lay some claim as being the introducer of the vignette *carte de visite.* I have sent them out of my *atelier* in large quantities these last two years; when there was none seen about in Paris or London; however, it is a dangerous thing nowadays to claim any priority of pictures or processes, so I only just mention it to you as perhaps you may know more about it than myself. I think Mr. J. R. Williams produced the first *vignettes* of the day when I was in England, but I do not know if he applied it to the *cartes de visite*."

The next series of card pictures which came under our attention, are by Mr. F. R. Window, with whose contributions in the columns of the Photographic News our readers are familiar. The specimens before us consist chiefly of portraits of theatrical celebrities, of which Mr. Window recently produced many thousands, for the dramatic fancy fair held at the Crystal Palace. The first point which strikes us is the prevalence of artistic feeling, as displayed in the great variety of pose, each one graceful, and the absence of a crowd of meretricious accessories. In this respect Mr. Window's pictures remind us of those of the late Mr. Lacy. Mr. Window aims at, and produces the utmost amount of force and brilliancy compatible with delicacy; and great crispness and perfection of definition, which he is very successful in obtaining. His pictures are all very striking, moreover, as portraits; lighting, general arrangement, and expression, all conducting to the desired end, a striking likeness, as well as a pleasing picture. Mr. Window uses a collodion containing a full proportion of bromide, iron development, and intensification after fixing, by means of bichloride of mercury and iodide of potassium. He works with Dallmeyer's No. 2 B lenses.

A series of card portraits by Mr. G. W. Hale, M.A., of Eastbourne, display many excellent artistic and photographic qualities. They are very round and forcible, well modelled and solid, exquisitely defined, well arranged, carefully lighted, and the printing and toning are very successful. Some of the prints are very tastefully vignetted. Altogether they are very far above the average of card pictures which we have seen.

A series of card portraits by Helsby and Co., of Liverpool and Valparaiso, claim attention for their great brilliancy, vigour, and roundness. There is, moreover, considerable, skill and taste manifested in the posing, albeit there is a little stiffness and formality occasionally in the accessories. The manipulation is careful, the definition fine, and the printing good. We have no particulars of their production, except that a Ross's ordinary portrait lens for 5 by 4 plates was used.

Mr. Bannister, of Carlisle, sends us some very good specimens, in which the portraiture seems happy, and the photography is very good, full of detail, and, at the same time, vigorous. The arrangement, generally, is good, but there is, to our taste, a little overcrowding with accessories, which distracts attention from the principal figure, and destroys subordination.

We have received from Messrs. Harvey, Reynolds, and Fowler, a portrait, they publish, of the Rev. J. B. Reade, with whose name photographers are familiar as associated with the early history of photography. The portrait is very excellent, but a little lacking in illumination at the lower part of the picture.

Some other specimens have not sufficient merit to warrant a specific notice.

## Scientific Gossip.

In these days of microscopic sharpness and collodion photography on glass, the subject of paper photography seems almost to have been lost sight of, except in its adaptability to translate the glass negative into a picture. This must be a subject of regret to all who remember the great things of which paper used to be capable, and the magnificent, and, even now, unequalled artistic landscapes and views which were familiar to the frequenters of photographic exhibitions of former years. It must be admitted by most that there is a peculiar breadth and charm about a picture from a good paper negative when of any size, which is wanting in one from glass, and every one must admit that the "belongings" of a peripatetic "paper" man are nothing in comparison with the bulky and heavy paraphernalia of a "glass" photographer, wet or dry. In spite of these positive advantages, the subject of paper negative photography seems almost dying out, and would e'er long vanish from recollection, like a badly-washed positive, were it not for the care and attention which it receives from a few experimentalists, who have not ceased in their endeavours to bring this branch of our art nearer to perfection, as regards sharpness and rapidity, without sacrificing the advantages of portability and artistic effect. It was only natural to suppose that paper photography should be more especially fostered by those whose avocations brought them in constant contact with this material, or whose business enabled them to experiment on its preparation on the large scale, and we are not surprised, therefore, to find that one of the most ardent and enthusiastic devotees of this branch of photography is M. A. Marion, the well-known manufacturer of photographic paper. This gentleman has recently made several useful and important discoveries in connection with negative photography on paper; they will shortly be published in the form of a pamphlet, and as we have received full details of several of these improvements from Mr. Marion himself, we think our readers will be pleased to have a brief outline of them. One of the chief mechanical improvements introduced, is that of albumenising and salting positive paper by machinery. It is well known how difficult this operation is, and what minute precautions are necessary to ensure success. It is almost impossible for even the most practised hand to avoid occasional failures, when so many obstacles constantly recurring are to be guarded against, such as dust, air-bubbles, fermentation, or filaments in the albumen, &c. In order to obviate these inconveniencies M. Marion has devised machinery which performs all the operations of albumenising and drying photographic paper without once requiring it to be touched by an assistant. The paper is 22½ inches wide, and may be obtained in continuous lengths, a hundred yards long if needed—so that practisers of panoramic photography need not concern themselves about one little difficulty in their way—that of obtaining proper paper on which to print their panoramas. To the ordinary photographer, the advantage of this kind of paper will be the perfect uniformity with which it is prepared; [and its freedom from dust, spots, and everything injurious.

The most important step which has been made in paper photography for some time, is undoubtedly the discovery of applying collodion to paper, and forming, in this way, a surface which may be iodized and sensitized beforehand, with scarcely any trouble, and then used with the facility of the waxed paper process. By M. Marion's process, somewhat of the rapidity and sharpness of collodion is communicated to paper, with the advantage of its being easier in manipulation, and more certain and uniform in its results. The collodion is prepared by dissolving in 1000 parts of good ether, 10 parts of collodion and 1000 parts of cerolein; 20 parts of iodide and 5 parts of bromide of potassium are then added, and 2 parts of iodide of cyanogen. When all are dissolved, add 20 parts of liquid ammonia. The iodides and bromides should be ground up in a mortar, in order to effect their solution, and the liquid should be filtered, and allowed to stand for twenty-four hours. When required for use, the collodion is poured into a porcelain dish, and the sheets of paper completely plunged in, and then drawn out again almost immediately. The liquid will be found to have thoroughly penetrated the paper; and it can then be hung up by one corner to dry. When dry, it may be passed through a cylindrical press to improve the surface. The paper in this state will keep good for any length of time, if away from damp; indeed, it is said to improve by keeping; pictures taken when it is a month old being very superior to those on new paper. The sensitizing process is very simple. A bath is prepared, containing 7 parts of nitrate of silver, 10 parts of acetic acid, and 100 of water. This is poured into a flat dish, and the collodio-iodized sheets floated on, and then immersed completely, and allowed to remain there for five minutes; they are then to be removed, and immersed in distilled water several times renewed. After this washing, they must be carefully dried between sheets of blotting paper, which must only be used once for this purpose, but which may, however, be set aside for ordinary blotting off and drying. The dessication of sensitive collodionized paper may be hastened by changing the place several times, and when it is nearly dry, it may be shut up in a preservative apparatus, which will absorb the still remaining moisture. The paper, when thus enclosed, will keep for several days, and even weeks, in a state of perfect sensitiveness. When washing the sheets, several may be put into the same dish; but not more than one sheet must be sensitized at a time. After exposure (which will not be so long as in the waxed paper process), the sheets may be returned to the preservative case to await development. The developing solution consists ot saturated gallic acid, to every ounce of which add two or three drops of sensitizing solution. In this bath immerse the exposed sheets, and watch the progress of development. From half an hour to one or two hours will be required for this operation to be completed. The development need not be pushed to so great an extent as in the ordinary paper process, as the fixing bath does not lower the tone of the picture. The development will have proceeded long enough when the sky is of a perfect opaque black, the lights and shades having assumed dark tints proportional to their intensity, and the shadows, represented by white portions, having preserved their vigour and original transparency. When properly exposed, the operation will proceed rapidly, and very little, if any, aceto-nitrate of silver need be added, beyond that put in originally. The hyposulphite bath for fixing should contain 40 per cent. of the salt; it can, indeed, be used saturated without fear, for, far from weakening the dark parts of the picture, as in the old process, the hyposulphite communicates to them a greater intensity, without injuring the white parts. When fixed, the negative must be washed in abundance of water, and then dried, and subsequently waxed. The wax and ammonia which are added to the collodion give the film a great aptitude for uniting with the paper, and preserve it better in the dry state after sensitizing. In our own hands, collodion on paper has proved all that could be desired in a negative paper process, and we confidently recommend those of our readers who are not wedded to glass to give it a trial.

A sample of glass has been forwarded for examination in the stereoscope, by Frederick D. Davis. We are unable to report favourably upon it. It is one of the light yellow glasses which so frequently come under our notice; allowing abundance of active blue rays to pass through, and being altogether unreliable for the collodion process, except in a very dull light.

## The International Exhibition.

### BRITISH PHOTOGRAPHIC DEPARTMENT.—APPARATUS.

Mr. Sebastian Davis (3071) exhibits a small but complete tourist's equipment, consisting of his stereo manipulating chamber, and the requisites for its use on the field. Mr. Davis, as most of our readers know; is an enthusiastic and able amateur photographer, and the exhibition of his clever tent or manipulating chamber is solely for the advantage of photographers, as he his not a manufacturer or dealer, to whom profit might accrue from publicity. Whether the equipment be manufactured at all for sale by any house we do not know; but as it is neat, light, portable, convenient and efficient, we append for the benefit of new readers a description which appeared in our fourth volume:—

"The special object of the stereo manipulating chamber, is to enable the tourist to produce stereograms by the wet collodion process without the incumbrance of heavy or inconvenient apparatus. This invention essentially consists of a portable and commodious folding chamber, and a light, cone-shaped camera, with rising front to carry the lenses.

"The chamber is capable of carrying the camera when packed in its interior, and has an aperture in front equal to the size of a stereoscopic plate, over which the cone slides when ready for use. Upon the internal side of this opening a frame is fixed, having silver rests for supporting the sensitive glass, and a shutter is hinged to the back to enclose it in darkness. Immediately beneath the frame is a longitudinal stop, glazed with yellow glass, and fitted with slides, in order to regulate the admission of light. Beneath this, and through the bottom of the box, a cloth bag is suspended to hold the nitrate of silver bath; over which a lid shuts for the purpose of excluding dust, light, or chance impurities. Upon the edges of the top and bottom of the box are hinged two flaps, each half the height of the box, the upper one supports the black covering free from the hand, and the latter constitutes the table for the developing tray, and the two, when closed, protect the contents.

"The developing dish is made of tin, and holds over its centre a piece of wood, which retains the damp glass without slipping when at a considerable inclination. By this arrangement the plate can be developed without fingering, until it be thought necessary to examine it by the transmitted light admitted through the opening immediately facing the operator. At the right-hand side the box has an arrangement for holding three glasses to contain the developing fluid, water, and the fixing solution. The stereo manipulating camera is fastened in the usual manner to the top of the ordinary stand, and its elevation can be regulated to the height and convenience of the photographer. A curtain, which is attached to the box, answers the purpose of the focussing cloth, the completion of a light-tight chamber when secured round the waist, and an outside wrapper to cover the whole when closed.

"The camera is accompanied by a novel plate box, which has been designed as a convenient arrangement for carrying wet plates without the risk of displacing the film. The box is made internally equal to the length of the plate, but about three-eighths of an inch wider. Upon the longer sides four pieces of wood are to be attached, a quarter of an inch distant from the ends; these pieces serve to retain a series of loose slips, having raised corners against the shorter sides of the box. By placing the wet plate face downwards, upon a pair of these slips, it will be kept steadily in its place, and will rest simply upon its four corners; additional slips and plates can then be arranged alternately in like manner, and a number of positives can thus be carried with complete security, and without the chance of the wet film being displaced by friction."

The advantages of the manipulating chamber as regards facility in operating must be very apparent. The plate, when removed from the bath is at once placed *in situ* for exposure, without the necessity of any dark slide, which is entirely dispensed with. Altogether, the arrangement is ingenious and convenient, and well worthy of the attention of the amateur.

Mr. G. Hare (3086) contributes an excellent display of cameras for the tourist, and for use in the glass room. Amongst these we may especially name a handsome panelled trunk camera for the studio, 12 inches square, with swing back and endless screw focussing arrangement; and a landscape camera, 8½ by 6½ on the same plan, but without swinging back. In these cameras the part of the body which carries the lens travels out at the front. Inside there is another body, which, like the outer body, remains fixed; the arrangement entirely prevents any light entering. A well and firmly made Kinnear bellows camera with various improvements; the focussing screen being so arranged as not to require removal from the camera. A light portable binocular camera in leather case, with three double and one single back, screw for focussing from the back, &c. The central partition for dividing the two stereo lenses is moveable, so a view may be taken $7\frac{1}{2}$ by $4\frac{1}{2}$ with a suitable lens. Amongst other stereo cameras is one which, with three double backs and a single one, is fitted in mahogany case, the outside measurement of which is $8\frac{3}{4}$ by $6\frac{1}{2}$ by 6, and the weight $5\frac{1}{2}$lbs. An instantaneous shutter, on Mr. Window's roller principle, and some other matters, complete the display. The whole of Mr. Hare's contributions seem characterised by excellent material and workmanship.

## THE INUNDATION IN THE FENS FROM A PHOTOGRAPHIC POINT OF VIEW.*

The day following was, unfortunately, one of the many we have had this summer—a glorious beginning, raising high the eager expectations, only to be dashed down, and swallowed up in the gloom that too surely follows it.

During the ride to the dam, the day had put on its best dress, and shone out radiant in blue and silver; but before we had exposed two plates, like a fickle maiden, and troubled with a bad temper withal, black looks had swept away all the sunny expression, aud the end was downright sulkiness. We had then uo alternative but—

"To learn to labour, and to wait;"

we, therefore, drove down to the break in the bank, and leaving the conveyance, started off ou an exploring expedition. We found the water a few inches lower, and were enabled, in consequence, to walk along the gravel bank, now just above its surface.

It was a strange sensation we experienced whilst walking on this very narrow path out into the centre of the water. Its narrowness was made still more apparent by the contrast against the immensity of water which hemmed us in all round, and though the road was as strong as gravel and long use could make it, it seemed to have all the insecurity of a plank bridge.

During our walk we picked up a prize as souvenir of the Fens. It was a fine specimen of the constructive genius of the aborigines of these parts—I mean the genuine thoroughbred Fenmen—and bore some very remote resemblance to the paddles frequently dug up in this district, but did not possess the merit of age. It had evidently been made by some clodhopper to meet his new requirements, and had probably been lost in his first essay to propel one of many cranky and rotten boats, uow so numerous, that one might think that they were some kind of marine fungus, for they have sprung apparently from nowhere with the rapidity of mushrooms. The sight of this quaint contrivance, which was but a piece of board roughly nailed on to the end of a splint of wood, would have immensely tickled the fancy of a genuine son of Neptune, and it would have been a sight worth seeing to have watched his face could he have seen the first efforts to use it.

We returned once more to our conveyance, tired and disappointed, for the day held out no sign of relenting; but as we had made up our mind to remain until after sunset we made a couch of the side of a hovel of straw, one half of which was in the water; and we were endeavouring to practice a little Mark Tapleyan philosophy, when our attempts at jollity under adverse circumstances were interrupted by a venerable man, evidently a clergyman, who, after commonplace remarks about photography, adverse weather, &c., informed us, with a most unchristianlike grin, that ill became his face—at least, so I thought—that some of his friends, who had occasion to unroof a hovel not far off, were astonished at the sight of an immense colony of snakes, and that on further inspection the hovel proved a secoud Noah's Ark, for it was peopled with rats and all kinds of creeping things. After malaciously watching the spasmodic start, and the alacrity with which we left our hitherto cozy couch, he wished us good luck and went on his way chuckling. Our stock of patience had evaporated in company with our Tapleyan philosophy, and we disconsolately drove off home, our journey being by no means enlivened by the consciousness that the day had been spent in vain.

We determined to try no more from the Lynn side of the water, and therefore took the train for Wisbeach. This journey, usually of 16 miles, was now stretched out to nearly 50, for we had to go round by Ely and March, iu consequence of the desire of Neptune to hold the line for his own purposes. Soon after our arrival we were joined by two or three photographic friends, and were soon ou our way for the Smeeth Road station. We here left our conveyance and took a boat for a sail in search of the picturesque. We started with hearts full of hope, and our boat full of apparatus, for one of our friends had a ponderous equipment, sufficient to load au elephant; but after we had got fairly started, I noticed with some uneasiness great masses of black clouds gathering on the horizon. I turned, therefore, to our boatman, for his opinion of the weather. He was an odd fish, of the salt water breed, who had knocked about the world all his life, and had evidently got well cured, for his face presented a strong resemblauce to a smoked haddock; his roving appetite was also satisfied, for he had anchored at Wisbeach, and had determiued "to go no more a cruising." When, however, the inundation first startled Wisbeach, his desire for a little excitement could not be quenched without gratification, so hoisting his boat on to a truck, he started on his adventures, once more, and took possession of the new sea. He has had no reason to regret the step, for the feverish desire for novelty tempted hundreds to have a sail over cornfields, and he has in consequence been doing a thriving trade. I had to wait some time for his opinion, for his little grey eyes looked out keenly from under his shaggy brows, as he slowly turned himself to all the points of the compass. At length the oracle spoke. "Mayhap we shall have a drop or two from the tail of the storm, but nothing to signify." Reassured we went on our way, but before we got two miles we clearly saw we were in for it, and therefore pulled with all our might for a barn about half a mile off, and which appeared to offer a welcome shelter. Our efforts were thrown away, for the gate was fastened, and in our attempt to get to the leeward we run upon a gravel road just under water, and all our labours to move the boat proving unavailing, we had no alternative left but to brave out the storm. V. B.

## DIRECT COLLODION POSITIVES ON GLASS.*

BY DR. SABATIER.

### *Direct Transparent Positives.*

After having shown that the light in the camera, and diffused light, give rise to two different colours and combinations; that the first yields a negative, and the second a positive, we are naturally led to enquire what takes place wheu we cause diffused light to intervene at the moment of the formatiou of the negative. Does the pyrogallic acid—the action of which is subordinated to the kind of light which has acted upon the film—continue to interrupt the work of reduction to form the combination determined by diffused light? Solicited simultaneously by two forces acting in opposite directions, which will it obey? If it yields to diffused light, the latter can then be employed as a substituting agent, and the superiority of this new agent over nitrate of silver, the alkalies and their subsalts, is unquestionable: as, henceforth, without washing or baths of any kind, we may transform a negative in course of formation into a positive; it suffices to inundate it with light, by opening the window or door of the operating room.

I must confess that it was not without emotion that I approached this touchstone, that I made my first proof, and I verily believe that my hand trembled when I opened the

* Concluded from p. 390.

door to admit light into the room. My eyes were fixed on the plate, and saw nothing beyond. Two, perhaps three, seconds, which appeared to me interminably long, elapsed before the collodion film exhibited the slightest change; but at the expiration of this time, I saw in twenty places at once, even the whitest spots become black. Like the liquid which has not yet attained its level, gradually ascends. invading the lower portions, following all the sinuosities, infiltrating itself into all the fissures of the negative: so all the white portions of the film became black, and the black portions appeared to become white. The diffused light had accomplished its work: in the interior of my imperfect negative, it had designed the most beautiful direct positive I had ever seen, such a one as it only could design.

Repeat this experiment. I know nothing more curious: it is extremely simple, as it consists merely in opening the window while the pyrogallic acid is making its negative. Do not fear a failure. Whatever be the duration of the exposure, or the nature of your collodion, you will certainly succeed: you will always succeed, provided,—

1. That at the moment when you admit the diffused light, your negative has not arrived at a perfect state, that is to say, is not completely finished.
2. That your sensitizing bath be perfectly neutral.
3. That you take for a developing agent pyrogallic acid, with the addition of acetic acid and no other.

The alkalies provoke the formation of the positive, energetic acids oppose it. And by energetic acids, I understand not only nitric, sulphuric, or hydrochloric acids; the presence of citric acid is sufficient for the production of the positive. The commercial sulphate of iron always contains a little free sulphuric acid, and that is the only reason which renders it unsuitable for the development of the positive.

A most surprising and astonishing thing, and worthy of fixing the attention, is that all the iodide of silver which, in the camera escapes the luminous impression, is not acted upon when the negative takes its bath of diffused light. The positive combination which develops itself takes place only at the expense of the iodide previously impressed, and which the acid has not yet reduced at the moment of opening the door or window. So that, in this case, the part played by the light is limited to changing the action of the acid upon the iodide, to substituting one combination for another.

If there was no objection to leaving, in the collodion film, the iodide remaining free. from the negative positive, we should have an image visible at the same time, both by reflection and as a transparency: but it is always best to remove this iodide, and spread upon the collodion film a white protecting varnish, translucent without being transparent.

By virtue of the intervention of the light admitted into the laboratory, to complete the work begun in the camera, the positive, not now obtained from a negative, but direct and really heliographic, will henceforth be one of the simplest and easiest things in the world to obtain; five minutes will suffice to produce a picture which four-and-twenty hours of assiduous care could not produce by other means. Art will certainly lose nothing, as, in skilful hands, the new method will give results equal, if not superior, to the finest that have been obtained up to the present time.

The only difficulty that presents itself is that of seizing the precise moment at which we must lift the shutter in some way, to give access to the diffused light; but a few experiments will soon point out the way of surmounting it. If the positive appears only in those places which ought to be the blackest, it shows that the light has been admitted too late; if it be so decided that the object you desire to represent is lost in the shadows, it shows that the light has been admitted too soon. Moreover the limit which separates the *too soon* from the *too late* is not so extremely precise, but that we may, with a little more or less, still obtain a satisfactory picture. According to the objects to be represented, and the effects to be obtained, we may arrive at the best results by making the formation of the negative predominate over the positive, and reciprocally. Experience is, of all masters, the one who most readily comprehends the lessons, and to whom they are most profitable.

For the production of a direct positive, either by reflection or transparency, any kind of collodion will answer. Still it is advantageous to add two iodides to the collodion, one of which is acted upon slowly by the light, and the other rapidly; such, for example, as the iodides of cadmium and potassium, because with this kind of collodion the negative appears to attain its perfection, while there yet remains in the collodion film sufficient impressed iodide to respond to the necessities of the positive, and there is then less risk of giving an ill-timed access of diffused light.

The negative not requiring to be so strong as when it is to be employed for printing from the time of exposure may be much reduced with advantage. If with the collodion employed twenty or thirty seconds of exposure are ordinarily required, then give only five or eight. This brevity of exposure, I am persuaded, will end in becoming instantaneous by the direct positive much easier than by any other way. If the exposure has been too long, the negative develops more rapidly, and stops quicker upon access of light. When the exposure has been too short, it develops slowly. The work must not be hurried.

It is scarcely necessary to add, that with a direct transparent positive we can produce a negative which will serve as a type for reproduction, nor that the collodion process is applicable to albumen. This every photographer will understand.—*Moniteur de la Photographie.*

## STUDY OF THE WET COLLODION PROCESS.

BY E REYNAUD.*

### 2. *The formation of Streaks, Specks, &c., in the Collodion Film.*

THE last of these accidents is caused solely by the imperfect collodioning of the plate; irregular motion, jerking, suffice to produce it; it is, therefore, useless to seek for any other cause than want of skill in the operator.

Specks, as well as streaks, are always caused by too great a proportion of water in the collodion. This water may be due to the ether or to the alcohol, or by rinsings left in the bottles. The bottles into which collodion, or the materials with which it is prepared, should always be rinsed with ether, or at least with alcohol.

The quantity of water contained in the ether is ascertained by the density of that liquid. This density should be at least 62° of Cartier's areometer, as I have before stated: the density of the alcohol must be 50°.

By using alcohol and ether in these conditions only, and taking all proper care in the preparation of the collodion, we may always avoid these streaks and specks, which destroy the value of the negatives whenever they appear.

### 3. *Spots in the Film produced during Sensitizing.*

These spots are most frequently produced under the following circumstances:

By too great a proportion of iodide in the collodion.

By too great an excess of iodine in the collodion.

By a too strong sensitizing bath.

Let us repeat in this place that the proportion existing between the iodides and the collodion containing them, must be 1 to 1½ per cent. If these proportions are exceeded, marbling specks make their appearance in the collodion film during sensitizing. An attentive examination of these specks proves that they are the result of an unequal action exercised by the silver bath upon dissolved iodides. These inequalities are produced by the veins which are inevitably formed at the moment the plate is immersed in the silver solution.

* Continued from p. 398.

Too great an excess of iodine also produces the same results by the same causes. We know that the presence of iodine in the collodion is betrayed by the tint which this metalloid communicates to the liquid; this tint should never be deeper than orange yellow. A silver bath in a too concentrated state will also cause the formation of spots in the collodion film, and by the same cause, that is to say, by a too vigorous action, by a too prompt decomposition of the iodides. To avoid this mischievous result, the silver bath must never contain more than 8 grains of crystallized nitrate of silver to 100 grains of distilled water.—*Moniteur de la Photographie.*

(*To be continued.*)

## A SHORT LESSON IN CHEMISTRY.—No. 2.*

The names of the elements of matter are in general arbitrary, being those which they had before chemistry was a science; and consequently there is nothing in them to indicate system or classification: such are sulphur, gold, lead, arsenic, &c. Those bodies that have been discovered lately, that is since chemistry has been developing into a science, have received appellations either in accordance with a rule, or indicative of their origin or constitution: such are platinum, iridium, &c., which take the termination *um* in imitation of the Latin termination for metals; as in *plumbum* (lead), *aurum* (gold), *stibium* (tin), &c.; whereas oxygen, chlorine, &c., are words compounded of Greek roots. But the moment we leave the elements and begin to deal with their compounds, the names of the combinations have been appropriated in strict subserviency to rules emanating from the science. In this way each compound receives a name which classifies it into a group, and carries with it certain specialities that individualize it in this group; that is, the very name tells almost all that a chemist wishes to know about the substance primarily. For instance, iodide of potassium, sulphide of silver, chlorate of soda, are very explicit terms and quite intelligible if the rules are thoroughly commited; that is, those rules in accordance with which they have been given. It is, therefore, necessary to teach you something about those rules by which all chemical combinations are named.

The simplest combinations are what are called *binaries* or combinations of pairs of elements. Such combinations take place either between the metals and the metalloids, or between pairs of different metalloids, but not between pairs of the metals. In such combinations one of the elements is regarded generally as the base of the compound, and is denominated as such; the other is an epithet or qualifying term, which takes the generic termination *ide*, accompanied sometimes by certain prefixes; for instance, the compounds of chlorine and lead, bromine and cadmium, sulphur and arsenic, sulphur and carbon, oxygen and iron, oxygen and nitrogen, are respectively called chloride of lead, bromide of cadmium, sulphide of arsenic, bisulphide of carbon, oxide of iron, protoxide of nitrogen, and peroxide of nitrogen. In each of these examples the metal is regarded as the base. Where the combinations exist entirely in pairs of metalloids, the rule is more frequently modified, because the bodies that result from such combinations are modified; in fact they are distinctly different from the preceding. The difference alluded to is *acidity;* for many of the binaries, arising from pairs of the metalloids, are *acid* or *sour* bodies; whereas those from pairs of metalloid or metal are seldom so. By a second rule in chemistry, it has been agreed upon to denominate all substances possessing an acid reaction, by the generic termination *ous* or *ic*, attached to one of the elements, together with certain prefixes, which indicate either the *degree* of acidity or simply the other element. Thus the compounds of oxygen and sulphur, oxygen and chlorine, oxygen and silicon, oxygen and carbon, hydrogen and fluorine, hydrogen and sulphur, hydrogen and selenium, &c., have an acid reaction, and are denominated, sulphurous acid, sulphuric acid, hyposulphurous, hyposulphuric, &c.; silicic acid, carbonic, hydrofluoric acid, hydrosulphuric acid, hydroseluic acid, &c.; again, oxygen with certain metals forms acid compounds; as for instance, with gold, iron, manganese, giving rise to auric acid, ferric acid, and permanganic acid. The termination *ous* indicates a less degree of acidity than *ic;* the prefix *hypo* or *sub* (under), diminishes both *ous* and *ic*, so that hyposulphurous acid contains a less quantity of acidifying material, or at least a less quantity of one of the elements than sulphurous acid; and hyposulphuric than sulphuric. The prefix *per*, or *hyper* (over), increases the intensity of acidity, or the quantity of one of the elements both of the *ous* and *ic* acids; for instance, perchloric acid contains more oxygen by weight in reference to the chlorine than chloric acid. The acids containing hydrogen as one of their elements, are very unique in their appellations, the prefix being *hydro* (for hydrogen), whilst the termination is *ic*, and the epithet between them indicates the base; that is the other element, whether simple or compound. The latter form is exemplified by hydrocyanic acid, &c.

The *ide* binaries are modified also by prefixes, these prefixes being *proto* (first), *bi*, *bin*, or *deut* (second), *sesqui* (one and a-half), *ter* or *trit* (third), *quadri* (fourth), *penta* (fifth), *per* (highest or last), snd *sub* (less or under); these prefixes indicate an increase or decrease in one of the elements; that is, of the metalloid, according to the expressions used; as, for instance, protochloride or mercury, sesquioxide of uranium, &c. Now in these two rules all binary compounds are comprehended, with the exception of a few substances that have long been known by common names, and which still retain their arbitrary appellations; as, for instance, *water* (protoxide of hydrogen), *ammonia* (nitride of hydrogen), *steel* (carbide of hydrogen). Now let us sum up the instruction of this lesson: Binaries are either *acid* or *non-acid* substances, of which the latter are distinguished by the termination *ide*, or have arbitrary names; the former by the termination *ous* or *ic*, accompanied with prefixes.———*Reservation.* . . . Not all acids are binaries, as I will show you hereafter.

*Examples:*

Bromine combines with cadmium, iodine with lithium—what are the names of the resulting compounds?

*Ans.*—Bromide of cadmium, iodide of lithium.

Carbon combines with hydrogen, phosphorus with hydrogen, arsenic with hydrogen, selenium with hydrogen—how are these compounds denominated?

*Ans.*—Carbide of hydrogen (carburetted hydrogen—old name), phosphide of hydrogen (phosphoretted hydrogen—old name), arsenide of hydrogen (arseneretted hydrogen—old name), selenide of hydrogen (seleniuretted hydrogen—old name).—*Humphrey's Journal.*

* Continued from p. 405.

## ON THE STUDY OF THE ELECTRIC SPARK BY THE AID OF PHOTOGRAPHY.*

BY PROF. OGDEN N. ROOD, OF TROY, N.Y.

*Form of the Negative Spark when Drawn from the Prime Conductor by a Short Thick Metallic Rod.*

The production of Lichtenberg's figures has been considered as indicative of a real difference between positive and negative electricity. Riess, who has examined this subject with great care, found that in addition to the marked difference in the two forms, the diameter of the positive figure is to that of the negative as 2·77 is to 1. The same physicist has lately made an elaborate examination of Priestly's rings, which are formed when a large number of sparks strike on polished plates of metal, and arrived at the conclusion that

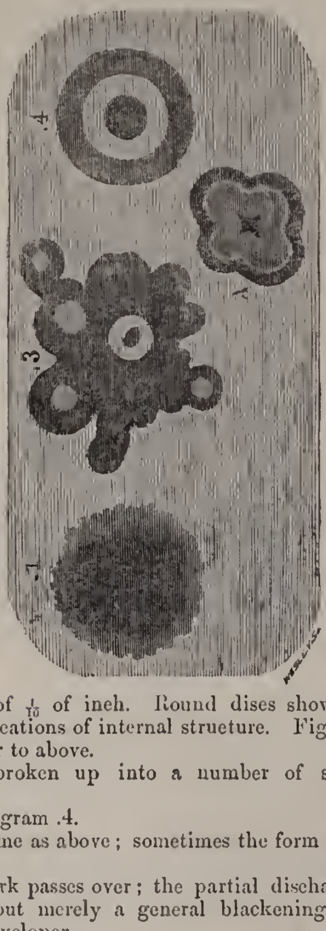
* Concluded from p. 418.

the set of rings generated by negative electricity is quite different from that produced by positive.* It consequently becomes very interesting to ascertain whether such difference also prevails between the photographs of the two sparks.

The apparatus was arranged as before, and sparks of negative electricity fell on the sensitive surface.

The form of the negative spark was found to be quite different from that of the positive: it was destitute of rays, circular in shape and often made up of a number of minute circles placed without symmetry. For short distances it was much larger than the positive spark, and never nearly so well defined.

Fig. 4.



Distance of $\frac{1}{10}$ of inch. Round discs showing by their shading indications of internal structure. Fig. 4, .1.

$\frac{2}{10}$. Similar to above.

$\frac{3}{10}$. Discs broken up into a number of small circles. See .3.

$\frac{4}{10}$. See diagram .4.

$\frac{5}{10}$. The same as above; sometimes the form at A is produced.

$\frac{6}{10}$. No spark passes over; the partial discharges produce no figures, but merely a general blackening of the plate under the developer.

If the sensitive plate be placed on the prime conductor charged with positive electricity, and sparks be drawn from the surface of the plate, the negative figure is produced; if the plate rest on a conductor charged with negative electricity and sparks be drawn from it the positive form is obtained; and finally, if the plate be coated on both sides with collodion, and insulated with a brass ball before and behind it, one of them being also insulated, while the other is in communication with the ground; if now a spark of either kind of electricity be allowed to pass from the insulated ball to the plate, and from the plate to the second ball, we obtain, as would be expected, on the opposite sides of the plate, the negative and positive images by development.

It is well known that when the knob of a jar, charged with positive electricity, is touched to a thin plate of pitch, a yellow star-like figure is produced by sprinkling the plate with a mixture of powdered sulphur and red lead; while if negative electricity is used a rounded red figure is formed. These figures bear the name of their discoverer, Lichtenberg. The method employed by Riess is much better calculated to give accurate results than the common one just mentioned: a small square plate of copper is coated thinly with black pitch on one side; the point of an insulated metallic rod touches the centre of the pitch surface, while the other side of the plate is in metallic connection with the ground. If now a spark from a jar charged with positive electricity be allowed to pass over to the pointed rod, and the latter still insulated be removed, then by sprinkling the pitch with a mixture of sulphur and red lead the star is generated in great purity: very perfect red negative figures are of course formed in a corresponding manner.

In repeating these experiments after the manner of Riess, I was struck with the resemblance existing between the red negative disc and the photographs of the negative spark. There is also much general resemblance between the positive yellow star and the photographs of the positive spark: this is greatly heightened if the yellow positive figures are produced in the following ways; the pitch plate is held at such a distance from the ball of the prime conductor, that no spark can pass over, the machine is turned, and the brush is allowed to strike it for an instant; on powdering the plate a multitude of small yellow stars, very much like the photographs, appear. They are often surrounded by small red circles, such portions having become negative by induction.

The results obtained with Leyden jars, and in a partial vacuum, as well as by the use of metallic plates, I propose to detail on a future occasion.

* Pogg. Annalen, vol. cxiv. No. 10, p. 193.

## AMERICAN PHOTOGRAPHS.*

The pencil of the artist was never more fancifully employed than when it delineated those battle scenes of the last century, which delighted the courts, and decorated the palace walls of France and Germany. But it must be admitted, nevertheless, that the object of giving an idea of what "a battle is like," which is a legitimate and universal bit of curiosity among men and women in all ages, was then more successfully accomplished than it is likely to be by means of photographic processes, so far as we know of them at present. When we gaze on the acres of canvas in Versailles, Munich, Berlin, or Petersburg, covered with the semblance of masses of men and serried squares and lines of infantry, clouds of cavalry and smoke, we know that the figures, with a few exceptions of prominent individuals, whose versimilitude is in proportion to the painter's skill, are purely imaginary, and that the wounded man in whom we take such an interest, or the dashing squadron leader heading his surge of horse against the rocky square, never existed at all in the world military, but, with the little drummer who is beating his *pas de charge* so manfully in the advance of his column, were picked up from the "models" of the day. The photographer who follows in the wake of modern armies must be content with conditions of repose, and with the still life which remains when the fighting is over, but whatever he represents from the field must be real, and the private soldier has just as good a likeness as the General. Barring faults of manipulation and artistic power, the likenesses must be like, and they must be real if the mechanism is of moderate goodness. When the artist essays to represent motion he bewilders the plate and makes chaos, and so far as we have yet gone, a photographic "charge" is an impossibility. Mr. Fenton was probably the first photographer who ever pitched his camera-stand under fire, but Mr. Simpson was out before him in the Crimea, and it is no disparagement to the former to say that the scenes in the trenches were much more interesting than the likenesses or groups, or other works of the photographer, though they were more ideal or less actual. It was considered something remarkable when Mr. Fenton succeeded in fixing on his plate the puff of smoke from a distant gun. After him, and perhaps with greater opportunity, certainly with greater success, came Mr. Beato, who has since been with the British armies in India and in China, reaping a golden harvest, whose reproductions of Oriental architecture were wonderfully good, but gave far less pleasure than the sketches of Mr. Lundgren, who was engaged

* From the *Times*.

for Her Majesty. The photographer, however, could multiply his copies as fast as he pleased, and every one could send home his image in jackboots, beard, dust, and topee for a few shillings. The artist could barely colour his drawings by working incessantly. The French had recognised photographers in attendance on their army in Italy, and for purposes of natural history, for architecture, and still-life, their work is not to be excelled. America swarms with the members of the mighty tribe of cameristas, and the civil war has developed their business in the same way that it has given an impetus to the manufacturers of metallic air-tight coffins and embalmers of the dead. The young Volunteer rushes off at once to the studio when he puts on his uniform, and the soldier of a year's campaign sends home his likeness that the absent ones may see what changes have been produced in him by war's alarms. In every glade, and by the roadsides of the camp, may be seen all kinds of covered carts and portable sheds for the worker in metal acid and sun-ray. Washington has burst out into signboards of ambrotypists and collodionists, and the "professors" of New York, Boston, and Philadelphia send their representatives to pick up whatever is left, and to follow the camps as well as they can.

We have before us a collection of photographs by one of the best known of American photographers, Mr. Brady, of New York, which includes, however, not merely the war scenes to which we have alluded, but a number of interesting portraits of the most eminent Americans, and of some strangers. First, there are two plates of the *Monitor*, one showing her deck, which seems raised a vast distance above the water, whereas it is only a few inches, and the cupola or revolving tower, with the shot-marks upon it from the *Merrimac's* guns. It is not too much to say that an Armstrong or a good solid shot gun would have destroyed such armour and such a fabric as the plate represents. There are but four marks on the armour, and those of the feeblest character. The other represents the crew on the deck in easy groups, which are creditable to the skill of the artist—a set of stout brawny fellows, in no particular uniform, and rather unkempt—of whom a few have the air of the genuine "old salt." For guns and the like the lens is well adapted in experienced hands, and here we have a striking "picture of the effect caused by the bursting of a 100lb. shell" on board the Confederate gunboat Teazer, which was captured by the Federals, deck stove in, iron stanchions gone, a great crater in the hold, machinery torn into ribands, but at best the craft, with its engines exposed on deck, and frail scantling, was a perilous thing to put a gun into. Mr. Brady's artist went down to Richmond, and has sent us some views which are of interest, but generally the sun of Virginia was too powerful, and the appearance of snow is produced on most of the photographs, and an excessive whiteness of colour diminishes the effect. Groups of wounded out in the open sun at Savage's Station, on the railroad to Richmond; "the house where Washington wooed his Martha," burnt by the Federals when they abandoned the line of the Pamunkey; Virginian farmers' wooden houses; the balloon and its *modus operandi*; the Confederate works at York town; the ruins of Hampton, destroyed by Magruder, with its venerable—for it was the oldest edifice of the sort in the States—church; batteries of artillery, horses and all, which would be a very curious subject of study to our Horse Guards, as they might get an idea of what the Federal cavalry are like, by examining the appearance, seat, equipments, and horses of the field artillery, which are unquestionably the best part of the Federal army. These, and the like, are all very worthy of attention. It can be seen from them that the work executed by the Confederates at Yorktown was very slovenly, but that nothing that was ever seen of the most slovenly European soldiery can equal the utter want of military smartnes in the Federal artillery. Men with unbuttoned coats, and open collars, and all sorts of head gear, are seated, with their overalls gathered half-way up the leg, in their saddle, with an attempt to dress in line, which renders their shortcomings more obvious. The most agreeable subject in the volume, perhaps, is one of a Confederate Lieutenant of the Washington family and name—for all the representatives of the *Pater Patriæ* are, and were, Secessionists—who was taken prisoner, sitting beside his college friend and relation, Captain Custis, of the United States' army, while a negro boy, barefooted, with hands clasped, is at the feet and between the knees of his master, with an expression of profound grief on his shining face. The Confederate, in his coarse grey uniform, sits up erect with a bull-dog fighting face and head; the Federal, a fair-haired, thoughtful looking man, looks much more like a prisoner; the *teterrima causa belli*, who appears to think only of his master, is suggestive enough. We can see here that the houses in which the better sort of people live in this part of the old dominion would not content the humblest of our tenant-farmers or yeomen; that the Federal soldiery do not improve in appearance during the war; and that their attention to uniform is of the smallest, and we form some idea of the difficulties of fighting in such a country, when we observe that every view is fringed by woods.

Turning to the volume of portraits, the eye is first arrested by Mr. Lincoln, sitting, in company with an ink-bottle, at a table, which does not conceal that foot, which he is so often said by the papers "to put down" on various questions—an odd, quaint face, sagacious notwithstanding the receding brow, and kindly despite the coarse heavy-lipped mouth, but with such capillary arrangements, that, in combination with the long-limbed, narrow body and great extremities, there is a gorilla expression produced by the *ensemble*. Next is Hannibal Hamlin, Vice President, who is chiefly interesting on account of what he might become. Turn over, and Mr. Stanton gives a sitting for his head alone, the lines of which do not stand comparison very well with the clear outline of Mr. Seward's features next to it. Why did not Mr. Brady give the full face of Mr. Seward, so that one could see his eye? In other respects the likeness, though it does not convey that air of "cunning and conceit," which Prince Napoleon's attaché attributed in his *feuilleton* to the Secretary of State, is characteristic and true. Pass over Mr. Bates, and we come to Mr Chase, who is standing with one hand outside his coat, over his breeches pocket, and the other on a plaster-of-Paris pedestal, looking as though he were waiting for some one to lend him a little money, and expecting it, too. He has one of the best heads among the Cabinet, though one cannot help remarking he has a defect in his eyes, and, oddly enough, so has General Butler, and so has Mr. Jefferson Davis. It is not too much to say that any stranger would be struck by the immense superiority of the heads and expression of Mr. Davis, of General Polk, of Beauregard, of Stonewall Jackson, and Lee, to most of the Federal chiefs, of whom few are at all striking in any way. M'Clellan looks small, and anxious, and unhappy; Blenker stands like a soldier and has the air of being one; and Burnside seems calm, and self possessed, and capable, ; Halleck's head is intellectual, but the face is dreamy and the lower jaw feeble; Pope, a stout, florid, sanguine-looking man, is like a German bass-singer in fine condition; and there is no other to speak of, excepting perhaps Meagher and M'Dowel, in the list of soldiers worth looking at a second time, after we have passed Banks, the unhappy recipient of Stonewall Jackson's favours. The few naval men in the book contrast advantageously with many of the soldiers, but some of the best of the latter are not here. "Stonewall" Jackson's likeness is something like that of Ney—a remarkable head, but without the beetle-brows, shaggy, and overhanging the full eye, attributed to him. From the Confederate soldiers there is but the thickness of a card-board to the Federal journalists, of whom the most remarkable thing is that they all seem to be above the age for liability to conscription. Literary men follow a group of the clergy, and the fine faces of Longfellow and Motley are among the best in the collection. Jefferson Davis, who comes after a batch of Federal politicians, is back to back with Jerrit Smith, and Mr. Stephens, the Vice-President of the Southern Confederacy, supports Mr. Charles Sumner. The portrait of Chief Justice Taney attracts one not merely on account of the air of the venerable old man, but because it is the likeness of the Judge who will, in all probability, prove the last that ever sat on the bench as head of the Supreme Court of the United States, and in whose person was signally demonstrated the complete worthlessness of that boasted palladium of the American Constitution, when the storm arose and the sword was unsheathed by violent and unscrupulous men. *Place aux dames!* In the photograph of Mrs. Lincoln, the loyalty and skill of Mr. Brady are as conspicuous as his gallantry, in adapting the focus to the subject; but he has treated the wife of the President, who is, of course, the "first lady in the United States," much better than he has Miss Lane, who did the honours of the White House for President Buchanan, and who won such praise for her discharge of them. The women's portraits, which are almost at the end of the volume, are not many.

Admitting many merits, and some very good specimens of the art in this collection, it does not appear from it that American photographers, among whom Mr. Brady occupies the highest place, have attained to that beauty of finish and fidelity which distinguish the better European artists, while they are immeasurably behind them in landscape. If one uses a magnifier to most of these subjects, it will be seen the paper is fluffy and the photograph spoilt by a sort of dustlike covering, such as we were familiar with here some years ago. But the portraits are of lasting attractiveness, although we are too apt when looking at them now, to forget that we are scanning the features of men who will be famous hereafter as actors in the greatest drama which the world has seen in these later ages.

## Correspondence.

### FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

*Paris, 3rd September*, 1862.

M. Adolphe Martin has made a communication to our Photographic Society on the employment of pyrogallic acid for the development of instantaneous pictures. On a previous occasion he communicated the result of his researches, which had for their aim the giving to sulphate of iron the qualities possessed by pyrogallic acid, as a reducing agent. He now proposed to solve the inverse question—to give to pyrogallic acid the same energy of reduction as possessed by sulphate of iron—which would permit our obtaining, by its employment, satisfactory proofs after a very short exposure.

He had proceeded very far in his task, when M. Collin, a skilful photographer, informed him that by substituting a pinch of alum for the dose of acetic, or citric acid, usually added to the pyrogallic acid, he obtained the result M. Martin aimed at. As to ascertaining the quantity of alum to be added, and the complete study of the process, M. Collin left the matter entirely in M. Martin's hands, and generously permitted him to publish the facts.

M. Martin applied himself to the task, and he soon discovered that there were two extremes to be avoided, *viz.*, the adding too large or too small a quantity of alum to the pyrogallic acid. If too little be added, a reaction takes place on the plate, on removal from the camera, between the nitrate of silver and the pyrogallic acid; a black mud covers the film, and the silver is reduced in the body of the liquid, to the detriment of the picture. If the dose of alum be too strong, a reaction takes place between the nitrate of silver and the alum; a white precipitate carrying down the silver is formed, and no image appears.

It was necessary, therefore, to keep within certain limits, wherein the reaction takes place between the three bodies, so that the equilibrium between the tendency to the first reaction (pyrogallic acid and nitrate of silver), and the tendency to the second (nitrate of silver and alum), be broken only by the action of light upon the impressed portions of the negative. We imagine from this, that the dose of alum employed will vary with the degree of concentration and acidity of the layer of nitrate of silver, which still moistens the plate at the moment of development, and that the nearer it may be to the state of equilibrium indicated, the less need be the time of exposure.

This process, as communicated to M. Martin by M. Collin, did not admit of the addition of nitrate of silver to strengthen the proof, and it is in the "Treatise on the Tannin Process," by Major Russell, that the solution of the difficulty was found.

After this lengthy preamble, M. Martin gives the operative process:—

A solution of 25 parts of alum in 500 parts of water is prepared in advance. Mix with 20 parts of this solution 380 parts of water free from salts of lime, and 10 parts of ordinary alcohol. Then shake the mixture and leave it to settle, until the air is completely expelled from the mixture of alcohol and water. Then add 1 part of pyrogallic acid. Develop by pouring the liquid on the surface of the film, without the addition of nitrate, and when the image is well out, pour on it a fresh quantity of the solution, to which a few drops of a solution of nitrate of silver of the strength of 3 per cent., to which, also, from 3 to 5 per cent. of citric acid is added.

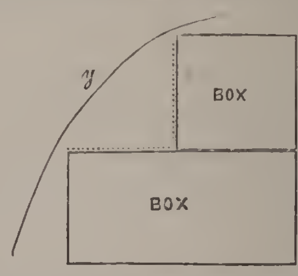
The solution of pyrogallic acid has the inconvenience of not keeping good more than four-and-twenty hours; but we can prepare before-hand large quantities of solution No. 2, in which the pyrogallic acid can be dissolved as required.

### RAPID DRY PROCESS.

Sir,—We have to apologise for not sending you the following sooner, but the pressure of business has prevented us, we trust, therefore, that you will excuse our tardiness.

In furnishing you with the details of our method of preparing "Fothergill" plates, we do not claim anything as new, but simply that we have adapted to this process many useful hints which have appeared in your pages (to which we are largely indebted). Some of the details may, perhaps, appear unnecessary to those who are already well skilled in manipulating dry plates; but where the results seem to depend on the fact, that all the minute particulars are carried out, it becomes difficult, if not impossible, to omit the smallest matter, without destroying the utility of the rest of the operation.

Before commencing operations, we light a good coal fire in our dark room, and place before it a rack for drying the plates, which we extemporise out of two empty boxes, one larger than the other, the larger one serving as a base, and forming a ledge for the plates to rest on whilst drying; on the bottom and sides of this ledge we place plates of glass, as recommended by Mr. Keene, to prevent the moist plates receiving any stain from the wood; these glass plates we cover with blotting-paper, on and against which the plates may rest, and over all we throw a sheet of yellow paper, to prevent any actinic effect from the blazes of the fire; the arrangement will be something like the following figure:—



The dotted lines being the glass plates covered with paper, the upright ones placed as vertical as possible, the line *y* being the yellow paper thrown over all. The plate being ready, is coated with Keene's wet process collodion, which we always iodize a few days or a week before using; it is sensitized in the usual 35-grain negative bath, which may be neutral or slightly acid with acetic acid; on removal from the bath it is rested on one end to drain on a piece of blotting-paper, and the back wiped with another piece. A pneumatic holder is attached, and 4 drachms of distilled water is poured on to it, scattering it as much as possible, similar to the manner of pouring on the developing solution; the water is worked round and round for about a couple of minutes, until it flows evenly and is thoroughly mixed with the moisture on the surface. It is then poured off, and is ready for the albumen solution, which is composed as follows:—

| | |
|---|---|
| Albumen ... ... ... ... | 1 part, |
| Distilled water ... ... ... | 2 parts, |

with about 6 grains of muriate of ammonia, and 4 or 5 drops of strong ammonia to each ounce of the dilute albumen; the solution is filtered through paper just before using, and is very much better when prepared some time—a month at least ought to be allowed before using it—what we are now using was prepared last September, and is now in excellent order.

As there are two of us, one performs all the preceding portion of the preparation, and after pouring off the water, let it drain an instant or two. The second operator takes hold of the pneumatic holder with a piece of paper, to avoid soiling the hand with the silver solution, keeping the plate inclined in the same direction, to prevent any solution flowing backward; about 1½ drachm of the albumen solution, for a stereo size, is poured on at the top edge, making it flow in one even wave till it reaches the bottom, it is then worked round and round for a minute or two, and poured off. The plate is then placed in a flat dish and washed, by shaking it in not less than three changes of water, too much cannot be used, as the plate will keep better if well washed, finishing with a fourth quantity poured over the plate from end to end; this may remain in the dish, and serves for the first water for the next plate. The water we use is the ordinary water supplied to the houses here, it is moderately soft, but contains a little lime and some chlorides, and we find it answers quite as well as rain water; we, however, take the precaution to filter it. After washing, the back is dried with a piece of blotting-paper to prevent too much water running down on to the drying rack, and also to assist in drying it quick. It is now placed on the rack (previously described), which is set as near the fire as safety will permit, and is frequently moved, so that it may not rest long in a pool of wet, and when it *looks* dry it is finally dried by taking it between the finger and thumb, and holding the back to the *clear* fire, as if for varnishing, until the back of the hand can no longer bear the touch of it. It is then placed in the preserving box, and may be kept almost any length of time; we have used them over seven months old, and found them work clean and well.

The exposure of the pictures we sent you, was given with a twin-pair of Lerebour's compound lenses, stopped in front to an inch opening, having a focus of 4½ inches, measured from the back lens to the ground glass. How long the plate will keep after exposure we are not able to say, as we usually develop within a day or two. To develop the plate we first wet it by plunging it in water, and then place it on the levelling stand, with a little water on it, four or five minutes, after which it is covered with a 2-grain pyrogallic solution, without acid or silver; the picture soon begins to show itself, and it is at this point that the greatest care is required, as if too much detail be allowed to come out at this stage the picture will be flat; on the other hand, if it be stopped too soon, you get a chalky picture, deficient of detail in the shadows; and, indeed, we believe, that by using a weak developer, and having patience enough, a good picture may be got with any short exposure. We have tried warm water to soak the plate, and warm developer, and find it very much quickens the operation; but we have found, hitherto, that it induces a tendency to fog.

When the picture is sufficiently out, 8 or 10 minims of a solution of citric acid is placed in the bottom of the developing cup, and the pyro solution is poured off the plate into it, and immediately returned on to the plate; this immediately stops the development. The solution of citric acid we use is—

| | |
|---|---|
| Water... ... ... ... . . | 1 ounce |
| Citric acid ... ... ... ... | 32 grains |

so that every 20 minims contains 1½ grains of acid; and we prefer citric to acetic as being more manageable, not being volatile, and giving blacker deposits. The remainder of the development is conducted as usual, by adding a few drops of a 10-grain nitrate of silver solution (which we keep for this purpose) to the developer, adding more and more, or using fresh pyro solution when it becomes discoloured, until the required density be acquired. We use no alcohol in the developer, the solutions flowing sufficiently well without it.

In conclusion, we attribute the sensitiveness we have succeeded in acquiring to the following causes:—First, a good and suitable collodion; second, the addition of muriate of ammonia to the albumened solution; third, the method of drying and *heating* the plates; fourth, a quick lens; and lastly to the method of development for which we are indebted to Mr. Wade, as communicated in your pages. We have prepared an experimental plate, with the addition of carbonate of soda, on Mr. Bartholomew's principle; should it prove successful, we shall be happy to communicate the result.

H. and J. Walter.

*Lyme Regis, Dorset, Aug. 28th*, 1862.

## PRINTING DIFFICULTIES.

Sir,—Whilst perusing that portion of The Photographic News dedicated to perplexed and despairing correspondents, the thought has often suggested itself, that if these anxious ones would only practise self-reliance, and seek out for themselves the causes of their troubles, what rapid strides would our art make towards the goal of perfection; for I believe these investigations, if persevered in by every practitioner of photography, would bring to light much useful knowledge pertaining to that art, which patient, untiring research alone is able to conquer? But whilst urging on the timid and irresolute to cultivate habits of self-help, I cannot overlook the fact, that many of the more fortunate ones are as ignorant of the causes of their success, as their less favoured brethren are of the causes of their numerous failures; hence it is a neglect of this study renders the numerous formulas so uncertain in their results, and seem to be launched into existence only to perplex and bewilder the admiring votaries of the black art. We will take, for instance, the case of A, who, having a sample of infallible paper, after numerous attempts to produce the vigorous and ivory-like prints promised in the advertisement, at length, in a fit of desperation, plunges a portion of it into a bath containing some twenty per cent. of silver; with a due sense of his presumption he hastily withdraws and dries it, then places it on the varnished surface of his faultless negative, closes the frame and exposes; the printing effected, then follow washing, toning, and fixing." Hurrah! victory!" Never was such a print seen. Adieu for evermore to printing difficulties, the secret is in the bath, and the bath is mine. Happy "Photo," enjoy your brief moment of bliss, for already are the clouds of adversity peering above the horizon; the sample of paper is expended, a fresh supply is ordered and received, bath the same strength, the same precautions duly observed; but, horror of horrors, the beauty of the finished print is found to be completely destroyed by the most virulent attack of mealiness that albumenized paper is heir to; the paper, its maker, and vendor are wished in a certain hot region, and an order is sent to another house for a fresh sample. Now, had he investigated the cause which gave him success, he would have had no difficulty in meeting the requirements of the undeservingly abused second sample of paper. The first sample contained a large proportion of a chloride, say of sodium, and, consequently, required a long floating on a weak bath, or a short floating on a strong one; failing to meet the requirements of the former, he hit upon the latter, and succeeded. The second sample of paper contained a comparatively small portion of the chloride, and required a weaker bath; by floating on a strong solution it speedily became saturated with the chloride of silver produced by double decomposition, a large portion of free nitrate in solution adhered to its surface, rapid drying made matters worse, the water was evaporated, but a stubborn impediment in the shape of nitrate of silver was left behind, which, after being exposed to the magnetic influence of the sun's rays, was the unsuspected cause of mealiness.

In my next letter I shall endeavour to provide a remedy for the evil our "Photo" friend was subjected to.

A Photo's Assistant.

## Talk in the Studio.

Decorations for Photographers.—The "Star of the Legion of Honour" is about to be accorded to meritorious French photographers; two artists are to be selected, we understand, for the decoration. M. Lacan informs us that he had endeavoured to give effect to the claims of M. Claudet, but he feared that the long absence of that gentleman from France had weakened the recognition of his claims. M. Bisson is mentioned as certain to receive one of the decorations, whilst, for the other, a variety of names are mentioned. In this country, Government is not in the habit of awarding honours of this kind; but it has recently been suggested, notwithstanding the dissatisfaction felt with the Exhibition medals, that an award by the Photographic Society might be made valuable in giving impetus to the art in some directions. A distinguished amateur informs us that he has intimated to Dr. Diamond his willingness to contribute £10 towards a medal for the greatest artistic excellence in photographs at the next winter's exhibition. He further suggests, that the establishment of a cup, or shield, which should become the property for one year of the most artistic photographer, and be competed for from year to year, might be found to act as an incentive to the production and exhibition of pictures of great excellence. We shall be glad to hear opinions on the subject.

Accident in the Photographic Department of the Exhibition.—A singular accident occurred in the British Photographic Department of the International Exhibition last Saturday morning, by which one of Mr. Breese's stands of stereoscopes, with eight of Cutts, Sutton, and Son's achromatic stereocopes, containing the exquisite instantaneous transparencies which have received so much admiration, were entirely destroyed. From carelessness or neglect of whom we will not undertake at present to state, the skylight by which the room is lighted had been left so insecure that, without any apparent cause, beyond, probably, a passing gust of wind, several of the sashes or frames near the entrance fell with a sudden crash; breaking off the table top, knocking the stereoscopes into fragments, and shivering the slides into a thousand pieces; the top of the case containing Mr. Sebastian Davis's manipulating chamber was also broken; but with this exception, the mischief was confined to Mr. Breese's stand. It is matter for profound thankfulness that the accident occurred at seven o'clock in the morning. otherwise the consequences might have been very fearful, for at no period during the hours when visitors are present, would less than a dozen persons have been crowding round the stand in question, and the falling sashes, which descended with sufficient force to smash a firmly made walnut table, would surely have maimed many, and probably killed some of those upon whom they fell. We believe arrangements are pending by which the Commissioners will replace the stand and stereoscopes, when Mr. Breese will replace the slides. One stand remains uninjured.

German Gymnastic Society.—We have received a copy of a group of the members of this Society, assembled in the grounds of the Crystal Palace, on the occasion of their recent festival. The photograph was taken by Messrs. Negretti and Zambra, on a 12 by 10 plate. Notwithstanding that the group consists of some hundreds of persons, the portraits of the majority are quite distinguishable, especially those of the most active and distinguished "Turners." It is an interesting memorial of an interesting occasion, as the first festival of the Turner Society will probably be the means of turning increased attention to gymnastic games in this country.

Photographic Exchange Club.—Members of the Exchange Club will please note, that the address of the Secretary will, in future, be as follows:—Mr. Frank Howard, 10, Lansdowne Road North, South Lambeth. We may here mention that several members of the old Stereo Exchange Club inform us that they have many exchanges due to them. We feel sure that the memory of defaulters only requires jogging to induce them to clear up all debts. We hope they will take this hint.

## To Correspondents.

*** We have to claim the indulgence of some of our advertizing friends, whose announcements are compelled, from the pressure on our space, to be omitted this week.

N.—To each ounce of collodion add 3½ or 4 grains of your iodide of potassium, or, better still, if you have it, add 2 grains of iodide of cadmium and 2 grains of iodide of potassium, and from half a grain to a grain of bromide of cadmium. The constitution of your plain collodion must determine in what proportion of alcohol these will need dissolving. It is impossible to give the exact proportions for an iodizing solution without knowing something of the plain collodion and its constitution.

Bewitched Bath.—We remember once meeting with such a difficulty as you describe: the lower end of the plate, that is, the end at the bottom of the bath, was covered for an inch or two into the plate with a dense, white, opaque deposit in every plate. The bath was a new one; and before we had time to examine carefully for the cause, the result disappeared of itself, or rather, apparently, as the consequence of using the bath a few times. We are still uncertain of the cause. In your case try making the bath a little weaker, and a little more acid. Take especial care that the inner frame and wire corners are well varnished, as minute traces of organic matter touching the corners of the plate will sometimes cause the evil of which you complain. Try another lot of water as well as fresh silver the next bath you make. 2. Your collodion will only contain, according to the formula you give, 2 grains of pyroxyline to the ounce, which is scarcely half enough. If you use all the alcohol of a sp. gr. of 805 the film will be probably very repellant. You may probably add one or two drops of distilled water to each ounce of collodion with advantage, and this, besides making the film less repellant, will make it still less contractile. Use your iron developer weaker, and try the result. Your second letter has arrived, but no plate.

R. H.—Shellac varnish will answer your purpose, or, perhaps, better still, the cement recently described in our pages by Mr. Window in his articles on apparatus. It consists of equal parts of beeswax, common resin, and powdered brick, and is used hot. This is not acted on by silver solutions.

Diamond Dust.—The slight black flocculent precipitate in your toning solution is probably a little gold thrown down; beyond slightly weakening the solution it will not do any harm. 2. Add a little tincture of iodine to your positive collodion. That will give it some of the good qualities of age, without materially interfering with its sensitiveness.

Old Photo.—No: certainly not. There is not the slightest necessity for publishing your name. It is enough for us, and the writer of each letter, to know that the intimation that the letters proceed from our own pen is an untruth; one or more from the same quarter. Suspicion is said to be the result of intense self-knowledge, and from the intimation here given we gain a glimpse of the probable habit of fabricating correspondence in our contemporary's pages. For the rest, he simply works out and proves your propositions, explaining "the reason why," which was not a matter of importance. Whatever might be the reason, the fact remains; and as the adage runs, "He who follows must ever keep behind." It is not worth while to contradict the assertion about the notices of apparatus, since a reference to our pages will show that they were promised by us weeks before the subject was named in our contemporary. You take the abuse more to heart than we do: the scurrility to which you refer is to us rather amusing, as a display of impotent anger; but is not worthy of notice.

Photos.—From the appearance of your pyroxyline, and its behaviour when dissolved, we should suspect that you had scarcely attained a sufficiently high temperature in making it. Are you quite certain that your thermometer registered correctly? They are not unfrequently slightly inaccurate. In any case a higher temperature with the acids you have, or a few drops of water at the same temperature, would give a cotton yielding a more limpid collodion. We have just dissolved 4½ grains of the sample sent in an ounce of equal parts of ether and alcohol. It dissolves perfectly and gives the right consistency, but the film is a little coarse, and possesses too much texture. We prefer for use with a bromide and iron development, a cotton which gives the right consistency with 5 or 6 grains to the ounce; but have produced very good results with 4 grains to the ounce. The formula we give may be modified by either a slight increase of temperature or a slight addition of water, or both, judiciously done, and will then, even with cadmium, give a very fluid collodion, without appreciable loss of sensitiveness.

Nil Desperandum.—The unsatisfactory colour of your prints arises from the imperfect character of your negatives. They do not possess sufficient vigour. To get better tones you must have more forcible negatives, which allow of much deeper printing. A good toned and brilliant print cannot be obtained unless the negative permit a slight approach to bronzing in the deep shadows of the proof without the rest being too much done.

B. 41—The lenses to which you refer are of French manufacture.

W.H.H.—The address of Bourquin and Co. is Newman Street, Oxford Street.

H. B. Y.—In attempting to albumenize your own paper, you will find the least difficulty with *Saxe* paper, which you can obtain of any respectable dealer. 2. You can use your portrait lenses for the magic lantern. You will find a good deal of information in our former volumes on the subject; we may especially refer you to Vol. V. p. 53 (No. 126), and p. 71 (No. 127). 3. We are generally at the office on a Thursday afternoon, but are uncertain at other times. If you will call we will advise you on the subject of your enquiries.

John Burns.—Your prints are very fine indeed, and it would be, as you think, undesirable to change your process. The only mode of avoiding the rapid discolouration of the paper, is to guard against having the bath too decidedly alkaline, and keep the paper in a very dry place. It does not always happen that a slight change in the paper injures the finished print, as the slight discolouration often disappears in the hypo.

A Constant Reader writes:—"Would any good Samaritan who has a copy of No. 76 of the Photographic News spare it? as the number seems hopelessly tardy in reprinting." If a single number only were out of print, it would soon be reprinted; but the demand has been so great recently, for completing sets, that very many numbers are out of print, and the question of reprinting a few scores of numbers is too serious to be undertaken hastily. The publisher is at the present time anxious to receive many back numbers at full price in order to complete sets. It has been suggested that readers unable to complete their sets might reproduce single numbers by photography, on a reduced scale, getting two pages in one.

Fred. Davis.—You will find a report upon your glass in the usual place. We have more than once stated where good samples of glass upon which we reported had been obtained; but there is no certainty of receiving exactly the same quality at another time.

Enlarging.—Mr. W. H. Warner asks us in reply to several enquires respecting his advertisement, to state that it is to enlarged *negatives* his terms apply, not to simply a print therefrom. The kind of negative required to enlarge from is one which is perfectly sharp all over, delicate, soft, and full of detail, and free from spots, defects, or texture in the film.

A. Gauss.—We will write.

H. R. Nichols, J. G. Lock, and several Correspondents in our next.

# THE PHOTOGRAPHIC NEWS.

VOL. VI. No. 210.—*September* 12, 1862.

## TONING EXPERIMENTS.

WE have recently been making some experiments for the production of mealy prints, and have succeeded in obtaining them at will. This, to some of our readers, with whom such prints are not uncommon, may probably seem an insignificant, if not an objectionable feat. As, however, in our own practice we had very rarely met with such results, it afforded us much gratification to be able to identify one of the causes by which they could be unerringly produced. The causes of irregular toning may be, and doubtless are, numerous; many of them have been pointed out from time to time in our pages, by a "Photographer's Assistant," and other intelligent contributors and correspondents. There is one cause, however, which we have long thought to be a much more common one than was suspected, and to which we have before referred; but have not, until recently, had opportunity of verifying it by satisfactory experiment. We refer to the use of a newly-mixed gold solution.

Recently devoting a day to printing, we tried two or three samples of albumenised paper, fully anticipating from the prevalence of recent complaints, that we should meet with mealiness in some of them. The silver bath was an old one, strength about 40 grains to the ounce, which was replenished with an equal quantity of an eighty-grain ammonia-nitrate bath, and when so mixed was just neutral, or slightly inclining to alkalinity. The paper was floated about two minutes on an average, in some cases longer, without any material difference in the result. Various iron portrait negatives were exposed, some requiring long printing and some very little, some in direct sunlight, others in diffused light. They were then, at the close of day, all washed for a few minutes in common water, that is, water from the New River, prior to toning. The gold solution consisted of—

| | |
|---|---|
| Chloride of gold ... ... ... | 2 grains |
| Acetate of soda ... ... ... | 60 grains |
| Water ... ... ... | 12 ounces. |

It had been mixed between two and three months, and had been used before. A very slight purple deposit existed at the bottom of the bottle, but beyond that there was no sign of decomposition. The prints placed in this solution toned very slowly indeed; but on adding about half a drachm of a two-grain solution of chloride of gold, which would contain about one-eight of a grain of the salt, the toning action was set up and proceeded most satisfactorily. To be certain that no trace of acid should enter the hypo bath, seeing that the toning solution had not been first tested as to its entire freedom from acidity,* each print was placed for a few minutes in a solution of carbonate of soda prior to fixing. They were then immersed for fifteen or twenty minutes in a fresh solution of hypo, one ounce in four of water. Every print turned out perfectly good and brilliant, with the various tints of purple brown and black, suited to each picture, which we had designed to produce; but in no case was there any mealiness.

We now proceeded to experiment with a few prints reserved for the purpose, which had been treated in all respects up to the toning, in a similar manner to those just described. A couple of prints were placed in the same toning solution and left until about half done. Observing first, that there was no sign of mealiness, we now added to the toning bath an equal bulk of a fresh solution of chloride of gold, one grain in four or five ounces of water, but without any acetate or other salt of soda.

* We found on subsequent trial that it was quite neutral to test paper.

The toning then proceeded very rapidly, but the prints in a few minutes became intolerably mottled and mealy, and remained so after they were fixed and finished. We next repeated the operation, cutting the print into two portions; one half, toned in the old bath, was all right; the other half, immersed in the bath with the fresh chloride of gold, was very mealy. We then made a fresh bath with the original proportions of gold and acetate of soda, and this on being used at once gave mealiness. Finally, all the solutions, old and new were mixed, and a print tried; mealiness was still the result, but in a modified degree. The solutions were then put away for subsequent use.

We believe there are other causes of mealiness; some there are undoubtedly, where the evil may be observed before toning at all. But we believe the cause we have indicated is a more common one than is suspected. We have before urged preparing the gold solution with either phosphate or acetate of soda, at least forty-eight hours before use, and with chloride of lime a still longer period; but from the experiments we have related, it appears that the former solution may be kept for weeks or months with advantage. Some portraitists we know who use the acetiate bath prepare it at least a fortnight before it is used. If it appear inert, a few drops of a fresh solution will commence the toning action, which appears to be continued by catalysis. The plan is a simple one. decreasing rather than increasing trouble. The method of testing the matter is also very easy, and we recommend those of our readers interested in the matter to repeat our experiments and prove to themselves that there is one method of producing mealiness at will, and this knowledge will be an important step towards avoiding it at will.

Since writing the above, we have read in the *American Journal* an interesting article by Professor Hime on toning, which will be found in another page. He notes the fact, which he has observed, that a bath which had stood until it had lost its toning properties, at once regained them and became active on the addition of a little hydrochloric acid. and then neutralizing it with carbonate of soda. The action set up, whatever it may be, appears to be similar to that produced by adding a trace of fresh chloride of gold. This fact is an important and interesting one: we recommend photographers to verify this for themselves, as we have recommended them to verify our experiments. Once assured of the fact by personal trial, it will prove of essential service in future toning operations.

## PHOTOGRAPHS IN NATURAL COLOURS.

THE Jurors in Class XIV of the International Exhibition had an opportunity, not afforded to the general public, of inspecting a series of photographs in natural colours, each tint in the original being reproduced in the photographs. They were produced by M. Niepce de St. Victor, by his method described in a memoir presented to the Academy of Sciences some months ago, and given on page. 100 of the present volume of the PHOTOGRAPHIC NEWS.

A dozen of these, on plates described as about the size of a playing card, were forwarded carefully sealed up from the light, and were opened in the presence of the Jurors. They consisted of reproductions of prints in which the figures were clothed in draperies of various colours. The colours produced were very bright but without gradation, various tints of red, blue, and yellow; green, purple, and orange were shown, all perfectly pure and vivid. Some of the colours, vanished almost as soon as they were brought into the light, whilst others continued for some hours; none, however, remained permanent. The pictures were valuable and interesting as illustrations of the possibility of reproducing some natural colours, and giving them a short tenure of duration. The problem of photography in natural colours remains still, however, for practical purposes, unsolved.

## PHOTOGRAPHIC CHEMICALS:

### Their Manufacture, Adulteration, and Analysis.

*Soda Salts* (continued).—The great similarity between potash and soda renders it needless for us to pass the various compounds of this latter alkali in such careful review as when we were discussing potash compounds. Some few soda salts, however, from their different physical or chemical properties, or from the fact of their being easier obtained in commerce, require a short notice. Among these latter we may take the salt *acetate of soda.* This is obtained by neutralizing acetic acid with carbonate of soda solution, evaporating the liquid until it is ready to crystallize, and then setting it on one side to cool. After the dish has remained undisturbed for several hours, the mother-liquor is poured off, and the crystals well drained. They are then dissolved in a small quantity of distilled water, and re-crystallized. The salt is then freed from the water of crystallization, by being heated in a dish with constant stirring. In this way it loses six equivalents of water, and becomes white and pulverulent; it easily fuses, and sustains, according to Thomson, a heat of 288° without decomposition, and does not begin to char till it is heated to 315°. A curious phenomenon occurs if the dry salt be fused, and left to cool in a large platinum spoon: while still fluid, it suddenly separates from the side of the spoon, becomes crystalline in the middle, and covers itself with a crust, through which a number of nacreous crystals shoot out from the interior, a quarter of an inch long and broad, and having a great number of sharply defined faces. These become dull and powdery on exposure to the air. This experiment does not always succeed, and when a portion of the salt has once exhibited the phenomenon, it does not show it again, or at least only imperfectly, if melted a second time, and the property is only restored by solution in dilute acetic acid, and evaporation. Acetate of soda crystallizes in transparent oblique prisms, which have a saline bitter taste, effloresce slightly in the air, and melt below the boiling point of water. The salt dissolves in three parts of cold water, and in 1·7 parts of water at 48°; it also dissolves in twice its weight of boiling spirits of wine, and is precipitated from the cold solution, by the addition of ether, in the form of a crystalline powder.

*Tartrate of Soda.*—This salt and the corresponding bitartrate differ considerably from the potash salt. It is obtained by neutralizing tartaric acid with carbonate of soda, and crystallizing. The crystals are permanent in the air, and melt in their water of crystallization when quickly heated. The *bitartrate* is formed by dividing a solution of tartaric acid into two equal portions, neutralizing one with carbonate of soda, and then adding the remaining tartaric acid. It crystallizes in transparent colourless prisms, which have a very sour taste, and dissolve in nine parts of cold water, and in 1·8 parts of boiling water. This great solubility offers a striking contrast to the corresponding potash salt. It will be remembered, that in our article on bitartrate of potash, we stated that it was of very slight solubility. This distinction is constantly made use of in chemical laboratories, to detect the presence of potash; a solution of tartaric acid being, according to Pettenkofer, a more delicate re-agent than bichloride of platinum, inasmuch as tartaric acid is capable of detecting a solution of potash in 700 to 800 parts of water.

*Carbazotate of Soda.*—This is another salt which differs greatly from the potash compound. It is formed by mixing carbazotic acid with soda, and evaporating down to the crystallizing point. It forms long silky needles, which are tolerably soluble in water, and are frequently used in chemical laboratories as a test for potash; the addition of a solution of this salt to one containing potash, immediately causing the precipitation of the slightly soluble carbazotate of potash.

*Lithia Salts.*—Of late years, lithia has become tolerably abundant, owing to the employment of it in medicine having created a demand for it; and we have, on several occasions, had under our notice collodion and iodizing compounds in which this element played a conspicuous part. As, however, the preparation and properties of lithia compounds are not generally known, we propose to notice them in detail. Lithia occurs in a few minerals only of the mica and felspar species in tolerable quantities, and until the recent spectrum discoveries, it was looked upon as a very sparingly distributed element. Now, however, it has been shown to occur in almost every source of the commoner alkalies, potash or soda, and must not, therefore, be regarded as rare. Its extraction from the minerals containing it is an operation requiring considerable chemical knowledge and skill in manipulation, and could not, therefore, be undertaken without the conveniencies of a well stocked chemical laboratory, even supposing the operator possesses the necessary experience. In preparing the salts of lithia, it will be advisable to start from the carbonate of lithia, which can be obtained at most operative chemists in a comparatively pure state. The carbonate of lithia is a white powder, which has a slight but distinctly alkaline taste, and turns reddened litmus paper blue. It crystallizes in small prisms or cubes, on slow evaporation, which effloresce slightly in the air. It fuses at a low red heat to a clear liquid, solidifying on cooling to a transparent crystalline mass. The fused salt is dissolved with great difficulty by water, but more easily when powdered, especially if the water is hot. Carbonate of lithia differs materially from the other alkaline carbonates by its sparing solubility in water, one part of the salt requiring about 100 parts of cold water for solution. It is insoluble in alcohol.

*Sulphate of Lithia* may be formed by neutralizing dilute sulphuric acid with carbonate of lithia, shaking the powdered carbonate into the acid until it is neutral, or nearly so, to test paper. The solution is then filtered, if necessary, and evaporated at a gentle heat over a water bath; when a crust commences to form upon the surface, the liquid must be removed, and allowed to cool; the salt, after complete deposition, must be well drained from the mother-liquor, redissolved in distilled water, and recrystallized. In these operations, it must not be forgotten that lithia is a somewhat expensive compound to be working with, and therefore the mother-liquors must be carefully saved and worked up afresh. Sulphate of lithia forms shining rhombic prisms; the crystals are slightly efflorescent, and are very soluble in water, although not more so in hot than in cold; they are also easily dissolved by alcohol, which is a rather remarkable property, and may be used to separate lithia from potash, soda, and many other accompanying bodies. When heated, the water of crystallization goes off, and the anhydrous sulphate of lithia is left behind as a white mass, fusible with difficulty, unless gypsum is present; in this case, however, it melts below a red heat. Its taste is purely saline, without bitterness.

## The International Exhibition.

### BRITISH PHOTOGRAPHIC DEPARTMENT.—APPARATUS.

The corrected list of awards is now published. The modifications in Class XIV. are not very extensive; a few names which were omitted before are now added, a few others which were included by mistake are now struck out, and in one or two instances the reason for the award or the phraseology in which it is expressed is corrected; but in no instance, we are assured, has the decisions of the Juries been modified either as to award or its reasons, the revision having consisted simply in the correction of errors arising from hasty copying in the former edition; the revised list being a strictly correct record of the final decisions of the various Juries. We regret to say that even now, on a cursory examination of the revised list, we find it not entirely free from error, misspelling of names in some instances occurs; in one case, where the name of Mr. J. Savage, of Jamaica, was omitted in connection with his award for a valuable series of photographs of the fish of the island, a blank occurring in the first edition of the awards—which blank was, by the way, filled up in a contemporary with the name of the preceding exhibitor, Captain Sellon—in the corrected edition the blank still remains. In another column we give a list of the corrections and additions made.

Whilst on the subject of awards we may refer to a circumstance to which our attention has been repeatedly called. Some exhibitors, it is stated, are making a somewhat unfair use of the awards of the jury, appending a notifications of honours to contributions who have not received them; in one instance, a card with the word "Medal" is attached to a case of apparatus to which no such award has been given. In another, we find a card with "Honourable Mention" appended to some very poor pictures by an exhibitor, none of whose contributions have received the slightest mention from the Jury. Whatever protest against the decisions of the Jurors exhibitors may have a right to make, they can scarcely be justified in thus misrepresenting them, and thus doing injustice to more scrupulous contributors. We now resume our notices of apparatus.

Mr. S. Highley (3095) exhibits a variety of photographic appliances, which display much ingenuity. Amongst these we find a photo-micrographic camera, with appliances for taking enlarged pictures of mounted or living microscopic objects. We cannot do better than append Mr. Highley's own description of this instrument:—

"It has a focal range of two feet, a frame to carry plates four and five inches square, a spherical arrangement to carry achromatized microscopic lenses of various foci, is fitted with a stage to carry the object; this stage has coarse and fine adjustments, and a micrometer head for determining the difference between the visual and chemical foci in the low powers; a tube carries the illuminating apparatus, which may be either a flame or a concave mirror, or an achromatic condenser. On an adjustible board attached to the end of the stand (which also forms the packing case for the camera) is fixed the light collector, which is similar to a solar microscope arrangement, only the long plane mirror is made of a polished slab of enamelled glass, this is used in connection with the achromatic condensors, the adjustments being made by aid of a racked wheel, and a pinion worked by a lever arm, of course the various light condensers are brought into play according to the requirements of the object under treatment. An arrangement is also made for taking living objects (such as expanded zoophytes) when in their most favourable aspect for a photograph, by viewing them through a yellow glass shutter hinged behind the lens mount, and another yellow glass in the back of the plate frame (the opacity of these glasses to actinic rays being tested by the spectroscope), the exposure being made at the right moment by raising the balanced shutter placed behind the lens."

We next find a novel looking instrument, described as a Photographer's Actinometer, the plan of which is ingenious, but we fear too complicated for general use. Its object is to determine the amount of exposure required by any object of any colour, or combination of colours, by any process, with any lens, at any hour. Mr. Highley intends to explain its use fully during the forthcoming session of the societies, so we will not at present do more than indicate the principle upon which it works. In the first place a test object is prepared, which shall consist of a variety of colours. That exhibited consists of a frame of moulded bars, between which are strips of various colours, such as blue, yellow, red, &c. This is the object to be photographed. What is termed a "mercurial shutter" is then attached to the camera in front of the plate to be exposed. This consists of a reservoir containing mercury, which decends into a glass cell in front of the plate at a given rate. It will be seen that as the mercury ascends in the cell, the light is shut off from the plate, which thus receives a graduated exposure, and enables the operator to ascertain the exact time of exposure received by each part of the plate, and determine the time required. We have, as we have before said, an impression that "trying a plate," and using a little judgment, is a better plan than the use of any actinometer we have seen. We shall be glad, however, to hear more of Mr. Highley's invention.

Mr. Highley also exhibits some examples of the application of photography to book illustration, one of which was issued in the *Quarterly Journal of Microscopic Science*, as early as April 1853, which was probably the first such application of photography in this country; our American brethren having, we believe, taken precedence of us in that matter. A series of transparencies of scientific and educational subjects for the magic lantern; a dropping bottle we have before described; a photographer's travelling lamp; an improved pneumatic plate holder, giving great control over the plate; a developing stand; and some other articles complete the contributions of Mr. Highley in this class.

Hockin and Wilson (3097) exhibit some excellent apparatus, prominent amongst which is Hockin's tent for working the wet process in the field. This, when packed up, measures 20 by 18 by 5 inches, and weighs, with its complete equipment of bottles, trays, chemicals, bath, tripod, &c., about twenty pounds. When expanded for working, the interior space is about 20 by 18 by 18 inches. A japanned tin tray fills a large portion of the table which forms the bottom of the tent; a recess in front of this, covered with a lid contains a series of bottles, holding the various chemicals; the bath rests in a bag dropping through the bottom of the tent, and is protected by a lid from light and splashes. A window with two thicknesses of silver flashed glass, one of which is hinged so as to open in a dull light, leaving one thickness only, is in front of the tent, and beside it, a small door to open and facilitate ventilation. The bottles hold sufficient chemicals for a dozen 12 by 10 plates, which size, or smaller, the tent is intended for working.

In an ingenious instantaneous shutter exhibited, the aperture, which is diamond shaped, opens from the centre, and gives an equal illumination during the exposure, to all parts of the plate. The rapidity of the motion is controlled by the amount of tension given to a vulcanized india rubber spring. An argentometer, for ascertaining the amount of silver in a solution by the quantity of a standard solution of chloride of sodium required to precipitate it. A chest containing a complete equipment of apparatus and chemicals, packed so as to occupy little space, together with some other articles, and the chemicals we have before noticed, complete the display.

## REVISED AWARDS.

The following is a list of the corrections in the revised edition of the awards, consisting of names before omitted, the suppression of names erroneously included, &c. A prefatory note, by Dr. Lyon Playfair, thus explains the former causes of error:

### NOTE TO THE SECOND EDITION.

The first edition of the Book of Awards was prepared under great pressure. The juries terminated their labours on the 26th of June, and the Award Books had to be copied for the printer and passed through the press, so as to be ready for the state ceremony on the 11th of July. By working all through the nights for a week, the Book of Awards was ready on the appointed day. It was necessary, however, to take the List of Awards as they had been prepared by the juries, without verifying them by the Minute Books. This verification has now been made, and various awards found in the Minute Book, but by mistake not copied into the List of Awards, have been added. Not a single instance, however, occurs of any new award having been made. L. P.

MEDAL.

United Kingdom.

| Name of Exhibitor. | Objects Rewarded and Reasons for the Award. |
|---|---|
| Caldesi, L. ... ... ... (Instead of Colnaghi & Co.) | For a valuable series of large photographs of antiquities, copies of cartoons, miniatures, &c. |
| Ross, T. ... ... ... ... | For the *excellence* of his photographic lenses (instead of for the *superiority* of his photographic lenses). |

New South Wales.

| | |
|---|---|
| Dalton, E. ... ... ... (omitted before) | For excellent photographic portraits of the aborigines. |
| Freeman, Bros. ... ... (omitted before) | For an excellent collection of photographs. |

France.

| | |
|---|---|
| Duriette and Romanet ... (Name before misspelled.) | Photographs. For excellent architectural views of Amiens cathedral. |

HONOURABLE MENTION.

United Kingdom.

| | |
|---|---|
| Joubert, F. ... ... ... (omitted before) | For photography on glass in vitrifiable colours. |
| Macdonald, Sir A. K., Bart.... (omitted before. The adjacent number, that of F. S. Beatty, receiving the award in error). | For excellence of landscape photographs. |

New South Wales.

| | |
|---|---|
| Gale, F. B. ... ... ... (omitted before). | For portraits of aborigines on glass. |
| Hetzer. ... ... ... ... (omitted before) | For excellent photography, especially his studies of trees. |
| Wingate, Major ... ... (omitted before) | For his panoramic view in the colony. |

South Australia.

| | |
|---|---|
| Camfield, Mrs. ... ... (In place of Rev. — Hall.) | Ethnological studies of the aborigines. |

France.

| | |
|---|---|
| Gaillard, P. ... ... ... (omitted before) | For excellent landscape photography. |
| Mathieu-Plessy ... ... (omitted before) | For excellence of photographic chemicals. |

Sweden.

| | |
|---|---|
| Carleman, C. V. G. ... ... (omitted before) | For general excellence of photographs. |

Sprosser, Wurtemburg, and an Exhibitor not identified, in the Zollverein, are now struck out.

## THE INUNDATION IN THE FENS FROM A PHOTOGRAPHIC POINT OF VIEW.*

To sit tamely in the boat, and endure all the fury of the relentless elements, was no part of our programme, therefore one of our crew jumped overboard, for the water was not up to the knee, and our united efforts proved successful, and the boat was soon over the road and into deeper water again. We had scarcely got fairly on our way again when a long and reiterated peal of thunder gave us fair warning to look out for squalls. Peal after peal followed, each one growing louder, and on glancing round, for I was at the oar and had my back turned to the wind, I saw at once that the storm would be of unusual fury. The view at this moment was one of the grandest it has ever been my lot to witness, and though it cost me a thorough drenching, I still consider it cheap at the price.

In the direction of the storm, which was now not half a mile off, nothing was to be seen; a black curtain of whirlwind, and hail, and rain, with an occasional fringe of lightning, shut out everything beyond; but in front of us, far away, was an opening in the gloom, through which could be seen but a glimpse of the glorious weather now so far away. This little aperture was now the only source of light, and was right out in the horizon, and the waves in consequence presented an appearance indescribable. Their crests were of silver whiteness, but the hollows were black as ink, and this extraordinary contrast gave to the water a solidity I had never seen before. Could the camera have snatched the scene at this moment with lightning rapidity, so as to retain the crispness of the waves, the picture would have strongly resembled a newly-ploughed field with the tops of the furrows tipped with snow. In a few moments the whole scene was changed. The last glimpse of fine weather was shut out from us, and gloom and murkiness hemmed us in all round. A cold shiver swept over the scene, as though all nature shuddered at the coming crash, and down came the storm in an avalanche of fury. Rain, hail, and lightning shooting out a hundred forked darts all around us, each one, possibly, on an errand of death and destruction, whilst the thunder not only deafened us, but gave forth a grating, crashing, rasping sound, as though the whole universe was split into fragments. In much less time than it has taken me to describe I was wet to the skin, not only so, but my boots were filled with water. At one moment I really thought our skulls—I mean our heads, not the oars—would be beaten in by the solid pieces of ice that came pelting down upon us. The boatmen and I pulled with all our might, but we were powerless, for the fury of the waves had driven us back again upon the road. Our companions had disappeared. They had collapsed in the most mysterious manner, and were safely stowed away under the seats in the stern, and buried under great coats. After shouting for some time, for we wanted help, and I was anxious that they should see something of the awful sublimity of the scene around us, a white face, with eyes dilated by terror, peeped out from under the covering, but an unusually large piece of ice maliciously hit him at the identical moment upon the nose, and he disappeared once more.

In ten minutes the whole scene was again changed. The storm was off on its mission of destruction to other parts, and we were left with hearts thankful that we had passed through it all, and were scatheless. Our companions once more resumed their proper proportions, and we were soon on our way rejoicing. There was no possibility of drying our clothes, so we kept to the oars, and as the sun shone out once more with more than usual brightness, we hoped, with its genial influence, aided by the fiery ardour that burns in the breast of all enthusiastic photographers—and we were enthusiasts—and assisted also by a S.W. wind, which was blowing quite bracingly, that by the time we had bagged our pictures and had packed up, our clothes would retain but little trace of the soaking they received, but would have resumed their normal condition.

We were by this time near the Mission House, a church establishment, having schools combined with a place of worship, all under one roof. The group of buildings would have furnished a picturesque subject, but there was not a spot of dry land really available for our operations. There was one of the many tunnel bridges, so plentiful in the fen district, just peeping above the water, but it was much too close. This quiet spot, usually so trim and pretty, with its neatly-kept little farm establishment, was now forlorn and melancholy. No piping voice chirping out the childish hymn came from the open door. Nothing but strife and contention was to be seen within. The sullen waters were angrily tossing the seats about, for they were all afloat and helpless.

Our boatman, pointing to the flag-staff—for in these parts, where the houses are so widely scattered, they do not employ a bell to call the rustic congregation together, but hoist a flag for a summons—said, with a contemptuous jerk of the head, "There's a pretty thing to call a flag-pole. Now, when they were going to put it up, the parson came to me, and ax'd me about it, for he know'd I knew summut about these things. I told him, if he left it to me, I would just put up the right thing, and make it all taut and square like, but arter he got all he wanted to know, he went and did it hisself, and a pretty job he's made of it. No, I reckon it a shame to call it a flag-pole. It's only just a tree stripped stark naked." After laughing heartily at his undraped simile, we started on our voyage again, and in half an hour reached the Middle Level bank, at our old point of operations.

* Concluded from p. 425.

All was now bustle with my amateur friends, for the task of building up their complicated photographic edifice was no light one. Three persons were not found sufficient, so the boatman was pressed into the service.

I hurried on my own preparations, for the fine weather I clearly saw would not last an hour, I succeeded, however, in getting one really good result, introducing a trace of the stormy sky, and a very fine effect of sunlight on the angry water. This picture was just snatched in time, for in five minutes afterwards all was black and gloomy again. My friends were unfortunate, for they attempted to intensify their negative, and as the water was salt, when they applied the pyro and silver to the plate, they produced a charming effect of curds and whey, but unfortunately for them this did not tend to improve the appearance of their picture.

We disconsolately packed up and started for home; having now a fair wind we hoisted sail, and were soon dashing over corn fields at the rate of six or eight miles an hour.

Our stock of patience was now fairly exhausted, for the weather obstinately refused to second our efforts, we therefore took the train, and leaving the Fens in their desolation behind, were soon a hundred miles away. V. B.

## M. BISSON'S SECOND ASCENT OF MONT BLANC.

M. Bisson's first ascent of Mont Blanc, accomplished about a year ago, was not entirely satisfactory to him; desiring to complete the collection of views he then made, each of which forms a stage in his ascent, he has resumed his rough and perilous enterprise. We follow with deep interest the details of this journey over mountains and precipices, which, thanks to the energy and coolness of M. Bisson, and the devotion of the men who accompanied him, was attended with the happiest results. The little party had not, this time, for its leader the usual guide of these ascents, Balmat, who has gained notoriety from being the first to plant his foot on the summit of Mont Blanc. His absence, however, did not deter M. Bisson. At 9 o'clock on the morning of the 11th of August he set out from the village of Chamounix, with the intention of operating the same day below the Grands Mulets, on the glacier of Bossons, near the junction of the two glaciers. He reached this spot at two o'clock, and planted his apparatus. His first essay was successful, he obtained a beautiful view of the Grands Mulets, which forms a very charming picture. This task accomplished, he wished also to obtain a view of the *Passage à l'échelle*, but it was not possible till the next morning, on account of the effect of the light. He then retired to his couch under a tent, having above his head blocks of ice from 200 to 250 feet in height, which at any moment might fall and crush him if the sun happened but to shine out. To make the tent warmer during the night, he had five young men sleeping near him, and sent the others to sleep at the Grands Mulets, because there was not room enough for them in his tent. They made the best of their accommodation. At 9 o'clock M. Bisson made tea for his companions, after which they went to sleep upon a beautiful bed of ice. At six o'clock on the morning of the 12th the men descended from the rock of the Grands Mulets, and rejoined M. Bisson and his party, rejoicing to meet each other again in safety.

M. Bisson then took his view of the *Passage des échelles*; the result was a complete success. His men figure in this landscape. He next sent them to pose under the blocks where they had passed the night, in order to make a picture which should commemorate that event. Our skilful photographer had the pleasure of succeeding in his task. He next crossed the *échelles*, in order to erect his tent on the cakes of ice, where he took two other types; namely, a new view of the *Passage à l'échelle*, but different from the first, inasmuch, as the ladder being too short, it was necessary for him to climb large blocks of ice to the only accessible place. At the first passage they were obliged to pass one by one on the ladder, which is horizontal, on their hands and knees. Thus, suspended at more than 100 yards above enormous crevasses, the passage was accomplished without accident, all his companions being at a certain distance from each other, and strictly observing his regulations, for fear of disturbing an avalanche of the blocks that surrounded them. M. Bisson next took a new view of the dome of the Goutté from a near point. He had now obtained his five typical views. At six o'clock in the evening they reached the Grands Mulets, proposing to ascend higher if the weather kept fair. The night was serene; they removed their gaiters and snow boots, and partook of soup and tea, and were comforted. The barometer was steady. At midnight M. Bisson decided to start again, and bravely and joyously, by moonlight, at two o'clock in the morning, they descended the rock of the Grands Mulets to ascend afterwards the dome of the Goutté and the little plateaux.

All attached to each other at seven feet apart, they travelled on for two hours, when an incident presented itself. A bridge of ice and snow, which crossed one of the large crevasses to the great plateau, was found broken. A crevasse, fathomless, and 17 yards wide, was before them; there were at least 60 yards above them. No other passage appeared possible. M. Bisson thereupon examined his position, to see what could be done, when three of the most desperate of his porters, to whom he had paid no attention, appeared more than 16 yards above him, having cut steps with an axe in the almost perpendicular wall that impeded their progress, up which they were able to ascend easily; they called out, saying that they had reached a bridge, which would doubtless permit their proceeding and crossing the crevasse. M. Bisson, unable to see them, hailed them. They came at all risks, and to get out of their position, made a leap of a dozen yards on to a plateau of snow, which the foot of man had never before trodden, and sought a new passage in order to reach their comrades, two of their number remaining on the spot. M. Bisson sought for them in vain. After the lapse of a quarter of an hour, they perceived Edward Ballin, whose elder brother was with M. Bisson, and very uneasy; they saw the figure of the young man appear upon the edge of the ice of Mont Maudit, alternately using his axe and straddling across the ridge, and standing out in relief against a sky almost black in the depth of its blue; making him a sign to wait, they descended the rocks, and threw cords to their two comrades to hoist them up by, and which served afterwards to haul up all their baggage.

M. Bisson could not help saluting and applauding him, and, preceded by his brother, who seemed to have but one wish, that of rejoining him, he descended in his turn, and like them, had the happiness to cross this dangerous passage, which enabled him to arrive two hours sooner at the grand plateau. Here new difficulties awaited them. They had to make eight hundred steps, and mount the side of the corridor, which had an angle of 50 degrees, in order to reach the summit, where a most violent icy wind surprised them. After occupying nearly an hour and a half overcoming these difficulties, they arrived. They had to mount the side. The German guide declared that his feet were frozen; unfortunately, this was true, for on the return to Chamounix he could not walk; the great toe of the left foot was black and swelled. Another four or five hundred steps had to be taken. The wind, which raised the snow in clouds, caused them some annoyance. However, M. Bisson, despairing of being able to operate on the summit, wished—but not alone, it is true—to attain it on this occasion.

All the young men, braver than might have been expected, reached the summit two hours afterwards, where they hoped that M. Bisson would have been the first to plant foot. It demanded all their energy to erect the tent, which was twice blown down. The artist, nevertheless, attempted two operations; to his great annoyance, he found the silver crystallized upon the plates, the temperature having suddenly fallen 10 degrees. After several hours' working, the men could endure the cold no longer; they struck the tent at two o'clock, the summit having been attained at noon

The echo of a canuon fired in honour of the intrepid photographer here reached his ears. At two o'clock they retraced their steps; they had to grope their way, as the wind had covered up their first footprints with snow. At length they reached the dangerous passage, and there pitched the tent upon a shelf two yards square, and where M. Bisson had the good fortune to obtain the sixth picture, the triumph of the expedition.—*Moniteur*.

## A SHORT LESSON IN PHOTOGRAPHY.—No. 3.

BY J. TOWLER, M.D.*

The prints that are produced by the action of the sun on materials imbued with the chloride of silver are either positive or negative. The mode of printing, and the ingredients used in printing either a positive or a negative on paper are exactly the same. The question, then, will naturally arise: what is a positive print?—what a negative print? You know what is meant by lights and shades; the sun shines on one-half the earth, it is light: on the other side it is dark, this hemisphere is in the shade. If you stand with the right side of your face next to an open window, the right cheek, the right eye, the right ear, aud, in fact, all the right side, will be suffused with light, while the left side will be comparatively dark—in the shade. Beneath the brim of your hat, the prominences of your eyebrows, behind the helix and lobule of your ear, or any irregular projection, you observe also a diminution of light, a shade, a shadow. The contrast, therefore, is produced by light and shade on all objects; pictures, to be natural, must have the same contrast as the objects: to be agreeable, there must be a proper gradation between the lights and shades; but the lights and shades must also be in their proper place. Now suppose you have a picture in which the lights and shades are found exactly in the same place as on the object from which the picture was taken, such a picture is called a *positive* picture; whereas, if shades exist in place of lights, and the gradations are exactly the reverse order, then the picture so formed is a *negative* picture. Besides this, in a photographic sense, the very outlines of a picture are all inverted laterally, that is, east becomes west, and west east; or a soldier parrying a blow with his right hand is represented in the negative as left-handed, and everything else laterally is equally interchanged. Now let us examine the print we made of the decayed leaf—is this a negative or a positive? To be natural, the paper, which is the background, ought to be white; the spaces between the fibres ought to exhibit the white background beneath; and the skeleton of the leaf ought to have a grayish appearance. Our print, you observe, does not exhibit these characteristics; these are, in fact, inverted; the lights are where the shadows ought to be. The print is therefore a negative. Hereafter I shall have occasion to refer to this subject much more extensively.

If I were to take the print and expose it again to the light, the whole paper would be darkened, and the picture would disappear. The print, indeed is utterly useless unless we can render it permanent. Now let us examine the condition of the paper as it exists at this moment. It is albumenized paper, containing originally chloride of ammonium, which, when the paper was floated on a bath of nitrate of silver, was converted into chloride of silver, and when the paper was removed from the bath, the surface was covered also with nitrate of silver. As soon as it was exposed to the light, the chloride of those parts upon which the light could play, was converted into the *insoluble* violet-coloured chloride; but the nitrate on the surface assists in blackening this chloride under the influence of the sun, and in connection with the organic substances of the paper and albumen, whilst the chloride on the shaded parts has undergone no change. We have, therefore, in this print the coloured chloride (subchloride), the white chloride and nitrate of silver present, of which the latter is soluble in water, and can be easily removed by washing the print in several waters; and the white chloride can be dissolved by a solution of hyposulphite of soda, in which operation we have again another example of double decomposition. Thus you will recognize on one side chloride of silver, on the other hyposulphite of soda; but chloride of silver cousists, as I have already taught you, of chlorine and silver; and hyposulphite of soda consists of the hypothetical acid called hyposulphurous, and the base soda; the latter body again, that is soda, is a compound of oxygen and sodium; whilst the former body contains sulphur and oxygen. You observe, then, we have in the solution, chlorine, silver, sulphur, and oxygen, and sodium and oxygen; as soon as these bodies meet in solution, they arrange themselves as follows:—the oxygen runs from the sodium to the silver, forming oxide of silver; sulphur and oxygen (as hyposulphurous acid) combine with the newly-formed oxide of silver, and form what is called hyposulphite of the oxide of silver. In the meanwhile chlorine hastens to sodium and forms a new alliance, denominated chloride of sodium (common salt). These new compounds are both soluble in water; they can, therefore, be removed from the paper by washing in several waters, in the same way as the nitric acid was removed. This operation of washing being performed, you observe that the picture has slightly changed in colour; but it is now *fixed*, by which term we mean that we can now take the picture into the light with impunity; for the lights and shades are no longer changed by light. Commit to your understanding thoroughly the decomposition just detailed, in order that you may become a chemist as well as a photographer; in order that you may have a reason for what you practise as an art; in order that your art may become a science.

* From *Humphrey's Journal*.

## ON AN ELECTRIC LIGHT REGULATOR.

BY M. SERRIN.

The electric light is quite a modern discovery. About the year 1730, when it was first observed in England, it was possible to obtain only a few phosphorescent gleams. In France, in Dufay's hands, these gleams became sparks darting from the body and face of an electrified person. These sparks then shone brighter in a Leyden jar, and, as the machines became more perfect, gradually developed into two great discoveries of the age—the voltaic pile and electro-magnetic action; so that by means of electricity we now obtain the most dazzling light and the intensest degree of heat. Hardly thirty years since, the luminous and calorific effects of powerful batteries were first studied, and contrivances are already devised for the purpose of rendering these effects contiuuous aud constant. M. Serrin's regulator, which we propose to describe, is one of the latest inventions, and is distinguished by new and ingenious solutions of the chief difficulty of the problem.

Before describing the mechanism which gives a distinctive character to M. Serrin's regulator, let us briefly indicate the general conditions which a regulator of the electric light ought to fulfil.

There must be a pile having at least 50 Bunsen's elements of ordinary size to produce a good light. One hundred elements united in tension give a more brilliant light; but this, again, is far surpassed by arranging them in two batteries, each of 50 elements, so as to produce quantity.

It is well kuown that the current produced by such batteries is, in some degree, like the lightning's stroke, and that there is real danger in closing the circuit by touching the positive pole with one hand and the negative pole with the other. Nevertheless, this energetic power, incessantly reproduced, manifests its presence by no external sign, whilst it is propagated through a circle formed of thick metallic wires. It shows itself with violence only on closing and breaking the circuit. If sharply closed, only a bright light is seen; if the circuit be suddenly broken, a bright light is also visible, generally of a different aspect; but if the two wires, or rather the two bodies which should complete the circuit, are made to approach each other, so that the circuit, precisely speaking, is neither wholly open nor wholly closed, then the double phenomenon becomes permanent, and the light extremely brilliant. No matter can resist this heat incessantly renewed, which is maintained as long as the action of the pile lasts, that is to say, for days together.

Thick rods of gold, iron, and platinum melt like sealing-wax, and their vapours give various colours to the luminous envelopes which seem to unite the two poles. Silica, alumina, and the greater number of the most refractory substances, taken separately, are alike fused and volatilised. There is, however, one substance—the only one, perhaps—which in some degree resists the action of this furnace, and which by conjunction of favourable circumstances, is a good conductor of electricity (a condition indespensable to the object in view), can be fashioned in any form, and his moreover, neither rare nor dear. This body is charcoal, such as concretes in gas retorts, or which can be prepared in pieces by particular processes. Round or square perfectly even rods are made of it, about thirty centimétres long, and varying in thickness from five to ten or twelve milimétres. Two of these rods are adapted at one of their extremities to suitable metallic pieces, one terminating the positive wire, the other the negative wire of the pile. These wires of good red copper, from three to four milimétres in diameter, covered with silk or cotton, may be several hundred métres or even several kilométres long, according to the distance between the pile and the extremites of the wire. The positive and negative charcoals are generally superposed vertically. Were their free extremities planed and placed in perfect contact, the current introduced by means of the commutator would not manifest itself; it would pass into the charcoal as into the copper wire, without giving any outward sign of its presence. The circle would be completely closed.

But if in the apparatus or regulator containing the charcoals there is an electro-magnet provided with a moveable armature conveniently disposed, the passage of the current would cause the armature to fall, and this movement communicating itself, for instsnce, to the supporter of the lower charcoal, would depress it from two or three milimétres, whilst the supporter of the upper charcoal remains fixed. It is clear that the free extremities of the charcoal being no longer in contact, the circuit of heat. In consequence of this destructive process, the space will be broken, light will burst forth, and that the phenomenon will persist, under the single condition that the circuit is neither completely closed nor broken—that is to say, beyond the limits which the current can traverse.

The better to appreciate other phenomena, let us now carefully examine the effects produced on the charcoals.

Charcoal resists fusion, but it is acted on by a kind of molecular disintegration, which rapidly wastes it, the result either of the simple action of the intense heat or the current itself, which tears off and transforms the last material particles. The wear is unequal, that at the positive being generally about twice as great as that at the negative. The combustion of charcoal by the oxygen of the air is of little account, for no marked difference is observable when the charcoals are kept in an atmosphere of nitrogen. It will be observed that the incandesceuce of the positive pole occupies more length than that of the negative, as if the latter underwent a less degree between the two charcoals becomes in a few minutes enlarged. At first only two or three millimétres, the distance soon increases to eight, ten, or even more, according to the nature of the charcoal and the force of the current.

To observe these phenomena to the greatest advantage, we must project on to a screen the image of the charcoals magnified eight or ten times, when the light becomes supportable, so that observers can study with facility the series of appearances which present themselves in this focus of light and heat, apparently so constant, yet so agitated. We cannot now enter into the details of the curious observations which have been made on the impurity of charcoals, on the colouration of the flames by the substances introduced into them, on the fusion of bodies placed, not in contact with the charcoals, but in the intervening space. We will confine ourselves to stating that the intensity of the light is notably diminished by a kind of waster, which forms from time to time on the point of the negative charcoal by the accumulation of particles from the positive charcoal, as if by the current. These wasters disappear and reappear at intervals, but they are very rarely observed with certain charcoals and at certain degrees of intensity of the pile; consequently, careful selection of the charcoal must be made in order to secure a more constant light.

The interval between the positive and negative extremities cannot be indefinitely increased in the regulator, and for two reasons:—1. The intensity of the current diminishes in proportion to the extent of this interval. 2. The intensity of the light diminishes with the force of the current. It is necessary, then to limit the increase of the space to prevent the diminution of light. This is one of the most important and one of the most delicate functions of the regulator; and for this purpose M. Serrin's mechanism is unrivalled in ingenuity. It is evident that the electro-magnet proviously mentioned is the regulator of the motive power to coadapt the charcoal; but this adaptation is a very complex process. 1. The centre of the focus of light must remain at the same level. 2. The charcoals must not come into contact, as the circuit would then be completely closed and the light extinguished, at least for a moment. 3. The movement must be made exactly at the right instant; that is to say, before the current has undergone a certain, hardly perceptible, diminution.

It is especially in accomplishing the last condition that M. Serrin's regulator acts with unequalled precision.

The armature of the electro-magnet can be likened to the scale of a balance with a fixed weight, of which the balancing space is limited to 3 or 4 millimètres by tangent screws, and which, instead of having counter weights on the other side, are supported by two springs, one fixed nearly in equilibrium, while the other receives a variable tension by a movement of the screw. Such a scale is easily made to descend by the superaddition of 10, 20, or 30 grammes, according to the degree of tension to be given to the second spring. Such is the principle on which M. Serrin has formed his ingenious apparatus. His armature is connected with all the supports of the negative charcoal, and oscillating vertically and freely within the narrow limits of three or four millemètres, the two springs keep it raised, and the superaddition making it descend is the attractive force of the electro-magnet. This force decreases with the force of the current; consequently it decreases when the charcoals, from being worn away, leave too great a space between them, and the light begins to fade.

The variable tension of the spring is, in fact, regulated by this datum. The instant this minimum is reached, the scale ascends; that is to say, the spring raises the armature, the surcharge due to the electro-magnetic force having become insufficient to restrain it.

These improvements seem to us all the more important, since M. Serrin, in constructing his regulator, has succeeded in uniting the freedom and accuracy of the automatic movements with a solidity which excludes all accidental causes of derangement.

We have proved that this apparatus is not less fitted to receive the induced current proceeding from powerful magneto-electric batteries set in motion by a steam-engine of three or four horse-power. In this case, the current is not continuous, but alternately positive and negative. There is no need of much complication in these batteries to rectify the current, leaving it in its original uncontinuous state; but in this case rectification is useless, the regulator adapting itself perfectly to the disconnectedness and to the alternation.—*Comptes Rendus.*

## ON THE PRESERVATION OF THE ALKALINE GOLD TONING BATH.

BY PROFESSOR CHARLES F. HIMES, OF TROY UNIVERSITY.*

The alkaline gold toning process, or some modification of it, appears to be generally adopted for positive prints on paper. In the many articles that I have noticed in the various photographic journals upon this subject, I do not recollect a practical suggestion with a view to the preservation of the toning properties of the bath after it has been once used. The old hyposulphite of soda and chloride of gold toner and fixer was used by operators, even after it had been demonstrated that prints treated in that way were, not only liable, but in most cases, certain to fade; and that, therefore, any change of method could scarcely be for the worse.

It must be admitted that the old process worked more uniformly, and independently of the quality of the paper, when albumenized, than the alkaline gold process; but the latter was objected to, previous to the ascertainment of that fact by actual trial, as apparently too wasteful; for

* From the *American Journal of Photography*.

in order to tone with rapidity the solution is required to be of a certain strength, and it is necessary to maintain this strength up to the last print, or gold will be economized at the expense of time, and after toning it deteriorates so rapidly that it soon becomes worthless. Many operators, even after they had adopted the new process, kept on hand an old hyposulphite gold bath, to be used when but few prints were to be toned. The conditions of deterioration of the toning solution are well known, but chemists are not agreed as to the precise nature of the reactions that take place, or as to the compounds formed. Without consulting opinions on these points, photographers know that the simple aqueous solution of ter-chloride of gold, in the stock bottle, will keep indefinitely, but that after it has been rendered slightly alkaline, an immediate change takes place; it begins to lose its properties, and the injurious reaction continues until the solution is rendered worthless for photographic purposes: the chloride of gold is precipitated after the lapse of a few days, at farthest, as a photographically unavailable compound. The organic matter, introduced by the prints in the operation of toning, assists in this work of deterioration, and complicates it. The reactions that take place in this case, as in chemical reactions generally, are rendered more energetic by boiling or heating the solution, as is frequently recommended, in order that the gold may be deposited more rapidly upon the print. The toning properties last through several hours unimpaired, frequently, except by loss of gold abstracted by the prints, and we keep the bath in its most active condition by adding chloride, with the certainty that there are causes at work which will ruin it for future use. If these causes could be counteracted, and the chemical reactions checked when the work of toning for the day is finished, the solution would retain all the properties it possessed at that time, and there would be no loss in adding chloride of gold at any time. The substances causing the injurious results in this case are the carbonate of soda and the organic matter, but chemical testimony agrees that the aqueous solution of ter-chloride of gold is unaffected by such substances when free hydrochloric acid is present. It is probable then, that hydrochloric acid would be effective in checking the reactions, and therefore be a convenient agent for preserving the toning bath unimpaired. The stock solution of chloride of gold is generally slightly acid to test paper, or, if it is not, it is well to make it so by the addition of a few drops of hydrochloric acid, so that the impurities, which are frequently present in the articles sold for photographic purposes, may not cause it to deteriorate. I have employed the following method in toning:—I add to every three ounces of water one grain of chloride of gold, from a stock solution of one grain to a drachm of water. I then throw in a piece of litmus paper, which will be reddened in a short time, then drop in a solution of carbonate of soda, until a slight alkaline reaction is apparent, in the partial restoration of the blue colour to the test paper. I prefer to render it alkaline in this way, rather than by adding a certain weight of carbonate of soda for each grain of gold solution, since two samples of chloride of gold are rarely of the same degree of acidity, and, in my experience, the bath works more rapidly when slightly, than when decidedly alkaline. When the prints are all toned, I pour the toning bath into a bottle, drop in hydrochloric acid until the test paper shows a decidedly acid reaction; the previous yellow colour, which had disappeared on addition of the carbonate of soda, will be restored, and the bath will keep for weeks in that condition. When it is to be used again, it is only necessary to neutralize, as before, with carbonate of soda, adding, of course, chloride of gold from time to time, as the gold is withdrawn by the prints.

The chief advantage in treating a toning bath in this way lies in being able to tone rapidly without waste, as the unused gold is preserved for future use. In connection with hydrochloric acid, as above, I experimented with aqueous solution of chlorine, and with aqua regia, but found the hydrochloric acid all that was required for the purpose. I also allowed a bath to stand until on trial it would not tone at all, and then treated it with hydrochloric acid, neutralized it, and found it to work well; the gold compound, whatever it was, yielding altogether, or in great part, to the acid, dilute as it was.

In course of toning operations sometimes a bath will not work, when there can be no doubt that there is chloride of gold enough in it; in such case, acidifying it with hydrochloric acid, and then neutralizing with carbonate of soda, will be found to remedy it. Simplicity and permanency are the two great desiderata in photographic solutions, as conducive to economy of time and money; and especially is this the case with amateurs who practice the art only at intervals. They need solutions easily prepared, that can be added to, and kept of uniform strength, without risk of deterioration. The use of hydrochloric acid, as proposed, gives to the alkaline gold toning bath somewhat of that character.

## THE STEREOGRAPH AND THE STEREOSCOPE.*

PROVIDED with two binocular photographs, endowed with the conditions of difference, as demonstrated to be requisite in the preceding paragraphs, the stereoscopic effect can be produced, by superposing the pictures of these photographs on one another in space, by means of two eyes *alone;* the effect thus produced, however, can be magnified by means of refracting lenses; or the rays of light proceeding from these photographs can be presented to the eyes under conditions for producing the stereoscopic effect with more facility or more proximity, by means of both refracting and reflecting accessories; but the *eyes alone* are endowed with the power of finishing the effect.

To be brief, a pair of lenses or reflectors can produce two conjugate pictures superimposed upon each other in space, forming thereby a solid picture, either a miniature or a magnified representation of the reality; but, inasmuch as we possess no medium by which a solid picture can be retained, the eyes alone can take cognizance of this reality, and can even do the work *without any accessories.* It becomes, therefore, my task to show, in the first place, how the superimposition of two pictures is effected: secondly, to demonstrate why the superimposition produces a solid picture; and thirdly, if possible, to give a physiological clue to the perception of solidity by the eyes.

*How Superimposition is Effected.*—There are three methods by which the superimposition of pictures can be effectuated; or, going directly to the origin of optical laws, it is well known that rays of light are made to cross by three different methods; and where they cross under homologous conditions, the intensity of the light by this interference is increased, and the picture is rendered more brilliant. The first method is exemplified by the crossing of the corresponding rays from two equal radiants, or two equally illuminated equal and similar objects; the second is manifested when rays from one and the same object, or from two equally illuminated equal and similar objects are made to impinge upon mirrors inclined to each other at a given angle, whereby the reflected rays of necessity converge, and therefore cross each other somewhere. We find, thirdly, a very forcible example of crossing or interference in the convergence of a pencil of rays produced by a single magnifying lens, where all the rays of the radiant that are caught by the lens are refracted and brought to a focus on the axis; and a more pertinent example, when two lenses are inclined to each other, and radiants are placed external to the obtuse angle and on the axes of the lenses; by this means the axes converge, and if the point of interference is at the same time the common conjugate focus of the two radiants, the superimposition of the pictures at this point will be very brilliant; or a similar phenomenon can be produced by placing a

* Continued from p. 417.

a single radiant either within or without the angle of inclination of the lenses, or in front of a pair of lenses not inclined, so as to produce a virtual image of the radiant, either nearer to the lenses or farther off. A single example will be sufficient to indicate what is meant by the foregoing remarks.

Let AB and CD be two equal and similar objects, situated in the same plane, and in the same line on that plane; let O and N be two lenses, two apertures, or the two eyes, whose centres are also in the same plane, and in a line parallel to the eyes. It is evident that each point on either object is an independent radiant from which rays emanate in all directions; but from the two corresponding points A and C, through the centres of N and O, only a single ray in either case can pass, that is, the ray AN in one case, and OC in the other, both of which are in the plane of the objects; these rays, therefore, cross at the point AC. In like manner the rays BN and DO cross at the point BD; joining AC and BD, we have the virtual image of AB and CD superimposed on the same line and in the same plane as AC, BD. This example is not a very familiar one of interference for the optician, but it is a correct one, and it subserves my purpose hereafter better than any other.

*Interference of Rays produced by the Eyes.*—The axes of all normal eyes converge more or less, those of short-sighted persons more than those of the presbyopic; because the nearer the point observed, the greater the parallax, and consequently the greater the convergence. By this convergence of the rays when directed to the corresponding points of the photographs, they are made to cross either in front of the photographs or behind them; and where they cross there will be found a new image. Now, the axes of some eyes cross more easily in front of the photographs, others more easily behind them; this peculiarity depends, I believe, on the difference in the distance between the centres of the two eyes, as well as probably between the distances of the corresponding points in the mounted photographs, and may be also on the difference of noses; for, where the distance between the eyes is less than the medium, and consequently less than that between the corresponding points on the photographs, the crossing takes place in front; and where the eyes are far apart, the interference or crossing is behind the plane of the photographs.

The new picture thus formed is equally stereoscopic by either process; but in the former it is always half, or about half, the size of the originals, in the latter it is magnified. In both cases the best effect is produced when the photographs are observed at the distance of distinct vision. As a general rule, those persons, the centres of whose eyes are less remote than two inches and a-half, see the stereoscopic effect easily by crossing the axes of the eyes half way between the photographs and the eyes; whereas those, the centres of whose eyes are farther apart than two inches and a-half, observe the relief by much less convergence, so that the axes of the different pencils of rays cross beyond the photographs.

Each phenomenon requires a peculiar method by which it can be observed. In the first place let the student learn to see double, that is, by holding up the thumb before the eyes to see two thumbs; when he is expert at this, let him next hold up in front of his eyes, at the regular reading distance, both his thumbs, and try if he can see four thumbs; as soon as this is effected, then, by bringing the thumbs closer together, so that their distance apart is about two inches and a-half, the two middle ones can be made to overlap each other, whereby three thumbs will appear. The difficulty is now overcome; for the eyes, when well practised in this strabonic exploit, are prepared for regarding a stereograph which is mounted in a special manner for the purpose, when, with a little patience, three photographs will appear, of which the middle one will be very distinct, finely defined, and in full and natural relief, exhibiting all the solidity of reality.

The two outside pictures are indistinct, and the eyes will soon learn to neglect them; or they may be entirely removed from the field of view by the use of a frustrum of a pyramid formed of cardboard, whose height is equal to half the distance of distinct vision, that is, half the reading distance; the side of its upper base one inch and a quarter, and that of the lower, three inches. By placing the lower base next the eyes and looking through it, the stereoscopic picture will appear alone and distinct. This accessory I propose to denominate the "strabonic stereoscope," and the stereographs prepared for such exhibitions, "strabonic stereographs;" because the photographs of which they consist are mounted an inverse order, the right photograph taking the place of the left, and *vice versa;* that is, they are mounted directly as printed from the uncut negative.

The second method is founded on a reverse principle, that is, by excluding the rays of light from the middle of a field of view comprehending a space of one inch and a quarter square. This is effected by placing a piece of cardboard of this width in the middle, half way between the eyes and the photographs, of which the latter are fixed at the regular reading distance; in the former case we have an aperture in the middle, or at the upper base of the strabonic stereoscope, instead of an opaque screen.

The same object can be effected still more simply as follows:—Take a slip of wood about two feet long, two inches wide, and one inch thick; take, secondly, a piece of cardboard of the size of a stereograph, and bisect the two parallel sides and the two parallel ends, and join the points of bisection. Where these lines meet we have the centre of the cardboard. From this point right and left on the longer line, mark off a space one inch and a quarter in length, and at either extremity thus marked off, draw a circle half an inch in diameter. Lay the slip of wood on its flat surface on a table, and tack the piece of cardboard to one end of the slip at right angles to the table, with an equal portion of cardboard projecting at either end. Previously, however, the wide surface of the slip must be divided longitudinally into two halves, by running a saw from end to end, so as to form a groove about a quarter of an inch deep; and at a distance from the cardboard, at the end equal to the reading distance, another groove is sawn at right angles to the former, and of the same depth: in the latter grove an ordinary or lenticular stereograph is placed, and along the longitudinal groove a piece of cardboard at right angles to it. Now let the observer look through the two apertures at the stereograph; it is evident that the right eye can see only the right photograph, whilst the left eye is restricted in like manner to the left. By concentrating the individual attention of each eye to its respective picture, by pressing the external parts of the balls of either eye with the fingers, or by compressing the eyes as in frowning, the two pictures may be caused to overlap each other, when a new picture will appear possessed of the full stereoscopic effect, apparently of a larger size than the originals.

Instead of the long slip of cardboard, a small slip, as already alluded to, one inch and a quarter in width, and of a length equal to the height of the stereograph, might have been inserted in a groove half way between the eye-piece and the stereograph and parallel with them. The operation is the same in both cases. As soon as superimposition can thus be easily accomplished, the apparatus may be laid aside, when, as in the former case three pictures will appear, of which the middle one will be in relief.

Of the two methods, which can seldom be practised without accessories by the same individual, I regard the former as preferable; because the results are much finer by being condensed to one-half the size, whereby the asperities of the paper and other slight imperfections are less observable. There is quite an indescribable charm in viewing the strabonic stereograph over that of the lenticular;* I can see

* The two methods, by which the stereoscopic effect is produced, are both *strabonic;* for the axes of the eyes in both cases cross each other. In fact, we have no method whatever of seeing this beautiful effect of stereoscopy except by *squinting*, if I must use the odious term; and more than this, we

both forms; the latter, however, requires an effort, whilst the former is, as it were, natural.

I now propose to give the rationale of these phenomena, together with that of the ordinary lenticular stereoscope. Superimposition of the photographs has frequently received an optical explanation; and the difference in the two stereographic photographs has also been observed; but the nature of this difference, and the mode by which this difference *produces relief*, have never yet, to my knowledge, been satisfactorily demonstrated.—*Humphrey's Journal.*

(*To be continued.*)

## WET OR DRY COLLODION.*

BY M. L'ABBE DESPRATS.

Various Reactions, &c.—While describing in our previous essay, some experiments tending to prove the action of electricity in photogenic phenomena, it seemed to us that, hitherto, we had not remarked that the electric current changes its direction according to the order in which two or more bodies were placed in contact to act reciprocally upon each other. But we were far from supposing that the exhibition of such a remarkable phenomenon would so promptly meet with a practical application. If we experience regret at the protracted interruption of our studies, it is chiefly because this delay has caused us to defer the expression of our entire sympathy with Dr. Sabatier, whose experiments, added to our own, have imparted to them a special value. The frank and disinterested expressions of the learned doctor, have struck all those who are seriously engaged in photography, and it is greatly to be desired that his example should have many imitators. For our own part, we believe it to be our duty to congratulate Dr. Sabatier publicly, and the reader will unite with us in recognizing the value of the results, entirely new, obtained by him, the attainment of which exhibits a rare perspicacity on the part of the enquirer.

To the theoretical considerations previously developed, we now proceed to add some others, more practical, and relating to the employment of the developing solution. Hitherto, photography on collodion has admitted only developers—protosulphate of iron and pyrogallic acid. Although it is not impossible to obtain good results with gallic acid, the slowness with which it produces its effect, has nevertheless caused it to be completely abandoned. The first two agents, beside giving greater delicacy of detail to the negative, admit also of a much shorter time of exposure. In this particular sulphate of iron is the more valuable, for, very often, it will be a third more accelerating than pyrogallic acid, which is also much more so than gallic acid. We say *very often*, but not *always*. In fact, with a collodion prepared simply with iodide of potassium, the acceleration is nearly the same, whether the development is effected by sulphate of iron or by pyrogallic acid. But if the collodion be prepared with iodide of cadmium, for example, the acceleration given by sulphate of iron is a third stronger than with pyrogallic acid. When, then, it is our special object to obtain instantaneous pictures, we must give the preference to sulphate of iron. We believe also that in the generality of cases this preference will be absolute. If upon this point we hesitate to speak positively, it is because the sulphate of iron in some measure only translates literally to the eye the latent action of light; while pyrogallic action, translating more freely, if I may use the expression, associates with it a part of its own peculiar action. The action of the sulphate is then completely in harmony with the action of the light, so that if the latter be complete the former will be so too. It is not exactly the same with pyrogallic acid. If the light has not had time to fully accomplish its work, the pyrogallic acid can, by its prolonged action, in part supply it by a species of continuation; but this continuation will always be more or less imperfect. The outline drawn by the light may be very well continued, with some advantage to the proof, but too frequently also, it will be enlarged at the general expense of its detail, and the delicacy of the half tones.

At the same time we must guard ourselves from saying that pyrogallic acid is to be rejected as an unfaithful interpreter; for every time that the duration of the exposure has been appropriate, that is to say, when the light has left nothing to the continuating action of the pyrogallic acid, the effects of good development given by this developer may be confounded with those given by sulphate of iron. It is our opinion that there is a marked difference between pyrogallic acid and sulphate of iron, that the first, by its prolonged action, by causing details to appear which at first were invisible, may strengthen to exaggeration the traits that first appear: while the sulphate of iron gives all it can give at once, and that the subsequent intensifying can act only upon the details spontaneously and freely obtained, and without causing them to appear anew. From this we conclude that a perfect picture may be obtained with sulphate of iron; for, we repeat it, all interpretation being to it impossible, it can act only as a literal translator of the luminous action.

A less prolonged exposure in the camera usually gives a more perfect negative, which is always more promptly obtained. These are, certainly, very appreciable services, and very capable of making us incline to give the preference to the sulphates: they are also employed by the most skilful photographers, and they would be even by the least experienced, if its employment were not accompanied by certain difficulties which it is not very easy to overcome. One of the gravest, if not the only one, consists in the inequality of the argentiferous deposit which forms the image. This inequality may sometimes be such that the plate, on removal from the developing bath, will appear marbled—almost opaque in some parts—while at others a greater or less transparency will permit of our appreciating an extreme fineness of detail.

Many methods have been pointed out for obviating this inconvenience, which is sometimes so serious as to render a good proof nearly impossible. It was thought that a too sudden action of the sulphate of iron was the cause of this almost constant failure, therefore a diminution in the strength of the solution has been recommended. It has also been thought that an acid added to the sulphate, by rendering its action less prompt, would secure to it at the same time more regularity. What happens in this case? As might be foreseen, the deposit becomes regular, but at the same time so light, that the negative constantly remains pale and without vigour. Hence the necessity of recurring to intensifying several times, and as, notwithstanding these successive processes, the negative always leaves something more or less to be desired, with regard to vigour of tone, it is thought advisable to attempt a final strengthening by means of pyrogallic acid. However valuable this may prove, it seems to us that we should begin with the acid. For, proceeding by the cumulative process, we complicate the operations without any appreciable benefit; without taking into account that the negative must inevitably display the nature to which it has been uselessly subjected from a complicated treatment. If the operator is not capable of mastering the action of the sulphate of iron, he ought to be contented with pyrogallic acid, which, less sudden in its action, acts, so to speak, of itself, and without requiring anything from the operator. But, suppose it be desired to develop by means of sulphate of iron? We may affirm that, most frequently, it is possible to obtain as satisfactory a result as possible.

Above all, it is necessary to comprehend the nature of the deposit forming the image, as well as the causes which contribute to its formation. An examination, even if superficial,

never regard a single word in reading or writing, or a minute point when drawing, without squinting—squinting is a natural process—but let us drop the vulgar word *cross-eyed*, and substitute the aristocratic term *strabonic*, (which signifies exactly the same thing), its origin, however, is from the majestic Greek; the term, therefore will be more respected.

* Continued from p. 296.

of what passes upon the exposed plate at the moment it is acted upon by the bath of sulphate of iron, suffices to indicate that the developed picture consists solely of metallic silver. This is evident upon mere inspection, but it is proved still further by the chemical action of bodies placed in contact, and from which only silver can be obtained. For what is upon the plate is impressed by light."—*Moniteur.*

## THE PHOTOGRAPHIC ART A BLESSING TO THE WORLD—CARTES DE VISITE.

Of all the arts, the one that seems most miraculous is photography, that the rays of the sun, darting through space with a velocity of a hundred and ninety-two thousand miles in a second, should, after bounding and rebounding from the walls of a room millions of times, till they cross each other in every conceivable direction, be directed on a bit of paper, and made to print a likeness accurate in all its microscopic details, would certainly have been deemed impossible before it was done, and yet there are large numbers of persons who by the daily performance of this miracle obtain bread and meat for themselves, and little shoes and bibs for their children.

The most valuable feature in this wonderful art is the cheapness and facility with which it is performed. Heretofore, a few individuals in the community have been able to have their portraits painted by artists who, after devoting years to study and training, have been able to produce a picture bearing some resemblance to the person for whom it was designed; but the pictures of the photographer, though possessing a fidelity unapproachable by any painter that ever lived, are produced with a rapidity and ease that places them literally within reach of all classes of the community. This art contributes a thousand fold more to the sum of human happiness than the art of painting.

The ease with which photographs are taken, and the cheapness at which they are sold, has reached its highest developement in the carte de visite. A man can now have his likeness taken for a dime, and for three cents more, he can send it across plains, mountains, and rivers, over thousands of miles to his distant friends.

One of the most interesting results of the ease and cheapness with which photographs are produced is the prompting which it will give many persons to have their likenesses taken frequently during their lives. What would a man value more highly late in life than this accurate record of the gradual change in his features from childhood to old age?

What a splendid illustration would such a series of photographs make in every household. First, the new-born babe in his mother's arms; then the infant creeping on the floor; next the child tottering by the mother's apron; then the various phrases of boyhood, till the sprouting beard tells of the time when the plans and hopes of life began to take form and purpose; another portrait with softer locks and eyes is now coupled with the series, and the stern warfare with the world begins; the features henceforward grow harder and more severe; lines slowly come into the forehead, and grey hairs mingle with the locks: the lines grow deeper and the head whiter, till the babe is changed into the wrinkled old man, so different but still the same! Even when life is closed the power of the photographer has not ceased. The fixed features, that return no answering glance to the last fond look of love surviving, are caught and indelibly preserved to its memory.—*Scientific American.*

### PRINTING DIFFICULTIES.

Sir,—In the numerous attempts made to trace the causes of mealiness, the silver bath is always passed over as too innocent to be an object of suspicion; but I entertain a very strong opinion that from this unsuspected source originate nine tenths of the evils connected with sun printing: a mere expression of opinion without proofs is very properly considered valueless, it is therefore necessary we enter into details. When the albumenized surface of a paper is brought into contact with the nitrate solution, in odedience to the laws of chemical affinity, a decomposition immediately commences, the silver uniting with the chlorine; thus forming the sensitive medium, whilst the liberated nitric acid enters into a new combination. Now it is very evident, that when the point of saturation is reached, this process of decomposition must of necessity cease, and no further chemical change can take place, consequently, whatever additional quantity of silver is removed with the paper from the sensitizing bath, it is to be found adhering to the paper's surface, in the form of a nitrate of silver in combination with water; drying evaporates the liquid, but the silver salt is deposited on the surface of the paper, the quantity being regulated by the strength of the bath and rapidity of drying. Now we have to examine the influence this free nitrate exercises in the after processes—it being a less sensitive salt to the action of light than the chloride of silver, if the printing is effected by diffused light, the greater portion is removed in the washings which precede toning, and therefore cannot effect much harm; but when the printing is performed in the full blaze of sunlight a large portion is reduced, and in spite of washings, will accompany the paper to the toning bath, there to retard the action of toning, for until this impediment is removed by the pioneers, carbonate or acetate, the gold cannot perform its work; it is therfore obvious that the quantity of these reducing agents must be regulated by the strength of impediment to be overcome—this may be pretty nearly ascertained by the roughness of the print's surface, in a slowly printed picture it is comparatively smooth, in a rapidly printed one the roughness of surface varies according to the intensity of light; in fact, when printing in a bright noonday sun I have known this free nitrate to become reduced so quickly that it has prevented the light from performing its duty on the chloride of silver, and when this red looking print has been immersed into the toning bath, the reduced nitrate of silver, yielding to the action of the soda, has disappeared, leaving a thin image similar to one derived from an insufficient supply of silver. It may be urged that this must have been the cause, but a portion of the same paper and the same negative, by removing the printing frame from the action of the direct sun's rays, the print has been altogether of a different character. But to return to my subject—In my first letter I endeavoured to show the necessity of employing a sufficient quantity of soda in the toning bath to enable the gold to work freely: you will now readily perceive my reasons for believing such a course necessary to secure satisfactory toning. There are attending this method of preventing mealiness, difficulties which will be treated on in their proper place. To prevent is easier than to cure: if the quantity of chloride each sample of paper contains was only known, to prevent would be an easy matter; but under existing circumstances we must learn by experiment the exact time required to saturate each sample of paper when floated on a sensitizing bath of a given strength, say 75 grains to the ounce (where time is no object 60 grains would be perhaps better). Now if this point could be ascertained by removing the paper from the bath just before it becomes saturated, a large portion of the free nitrate adhering to its surface would be converted into a chloride, and an excess of the pernicious salt would thus be prevented, and toning would proceed more regularly, for I am persuaded the nearer the toning bath can be to a neutral condition, the more brilliant will be the prints; and I once more repeat, the alkaline agent has, in my opinion, but little to do in giving tone to the print, its work is to clear the impediments which stand in the way, in the form of reduced nitrate of silver. From the general tenor of the above remarks, you will readily perceive they open a wide field for investigation: an investigation if opportunities permitted, I would fain undetake myself. Failing these, I leave the pursuit of these important enquiries to anyone who will kindly undertake them. Promising to renew this subject next week, I remain, yours respectfully,

A Photo's Assistant.

## Talk in the Studio.

Dramatic Expression in Photography.—We have just received from Mr. F. R. Window, unquestionably one of the most charming set of photographs wo have over met with. It consists of eight portraits of Mrs. Stirling, constituting a progressive series of illustrations. The lady is represented in the course of delivering her lecture on behalf of tho distressed operatives of Lancashire. In the first she has just entered, and saluted her audience, and is standing with the easy grace and winning expression of the assured favourite of the public. In the second, tho arms are slightly raised, and the countenance has assumed a look of earnest interest, as she states the case of tho sufferers whose cause sho is about to plead. In the third tho earuestness increases, one arm is raised towards the head which is thrown back; the other arm is also thrown energetically backward as sho becomes excited by the sad narrative sho is reciting. In tho fourth, the body is thrown a littlo forward, and tho arm, with finger indexed, advanced: the argumentative phase of tho lecturo has evidently been reached. In the fifth, with both arms advanced and body thrown back, she has reverted for a moment to narrative again, only to give point to the argument, which is renowed, and put with irresistible force, in the sixth, in which tho couutenance glows and tho whole pose is instinct with the certainty of a triumphant and uncontrovertible position. The case has been clearly stated; the argument brought home to every mind, and now the heart has to bo touched; and in the seventh wo have the appeal: the foot is advanced, and tho body thrown forward, the hands are raised towards tho hreast and clasped, the head is thrown a little to ono side, whilst the countenanco is full of touching appeal for practical sympathy with the thousands of suffering operatives. In tho eighth tho peroration is reached. Tho body is drawn up to its utmost height, both arms are raised, the eyes sparkle, and tho couutenance is illuminated as with tho inspiration of the sybil. In each of these, overy part of the figure is full of life and motion, and the expression so perfectly corresponding with tho action, leaves no doubt as to the inteution of each picture. The axiom that action is tho first part of eloquenco, never received moro forcible illustration than in theso felicitous renderings of dramatic power. The photography throughout is equal to the art. Delicato and soft, yet forcible and round, admirably defined aud exquisitely perfect in manipulation, being freo from speck or defect of any kind; and the printing and toning leave nothing to desire, the tone being a rich deep warm neutral tint, without the slightest mealiness, and possessing, in every print, perfect uniformity. The last thing which strikes our attention, proves its excellence by that fact, wo refer to the background, which is entirely devoid of curtain, column, pedestal, balustrade, or accessory of any kind: thero is nothing whatever to distract tho attention from the fino histrionic action and expression of tho charming lady aud talented artiste who is represented. Wo are rejoiced to seo Mr. Window, whom we knew as an ablo amateur, stepping at one stride into the very foremost rank of professional photographers.

Mr. Glaisher's Balloon Ascents.—In one of Mr. Glaisher's recent and most perilous ascents, in which he obtained a height of nearly six miles and became insensible, after passiug through tho clouds ho attempted to take a photograph of the scene, but was prevonted by the rapid motion of the balloon. He says:—"On emerging from tho cloud at 1hr. 17m. wo came into a flood of light with a beautiful blue sky without a cloud above us, and a magnificent sea of cloud below, its surfaco being varied with endless hills, hillocks, mountain chains, and many snow whito masses rising from it. I hero tried to take a view with the camera, but we were rising too rapidly aud revolving too rapidly for me to do so; the flood of light, howover, was so great, that all I should havo needed would have been a momentary oxposure, as Dr. Hill Norris had kindly furnished with extremely seusitivo dry plates for the purpose."

## To Correspondents.

B. B. L.—With a simply iodized collodion, or one containing a very small proportion of n bromide, a strong iron developer is apt to fog. The greater the proportion of bromide used, the stronger the iron solution may be with safety. In our own practice, with a collodion containing from half a grain to n grain per ounce of a bromide, we find a 15-grain or 20-grain iron developer most suitable. 2. In summer the silver bath need not exceed 30 grains to the ounce. In cold weather it may be stronger with advantage.

An Operator.—The most probable cause of the yellowness of the print enclosed is the use of an old or acid hypo bath. It may arise from other causes, but as you do not mention any of the particulars of production, we cannot say which cause has been in operation.

F. Amos.—In order to take large landscapes with the portrait lens you have purchased, first unscrew the hood and remove it, then unscrew the back lens and remove it, next unscrew the front lens and place it in the position before occupied by the back lens. The lens is now to be fixed to the camera for use with the front lens alone; the central stops in the tube will be a little in advance of the lens, as it should in using a view lens. Any camera which takes the plates the single lens will cover, and expands sufficiently for the focus of the lens, which will probably be about 22 or 24 inches, will do.

J. G. Lock.—There is still something to improve both in your negatives and printing. Your friend is wrong in pronouncing No. 1 a perfect negative. Chemically it is probably pretty good, but the lighting is very defective. The sun appears to be shining directly on the light buildings, which appear flat, and without the relief caused by shadow; whilst the green trees are in shadow and appear black and flat for want of light. You have thus a mass of white and a mass of black, without relief or gradation. No. 2 would be better for deeper printing and less toning. No. 3 scarcely possesses sufficient vigour. No. 4 is better, but the subject is not well lighted. No. 5 possesses the same fault as your former portraits, too much diffused light and no direct light. Negatives may be practically weak, that is, wanting in contrast, and yet require long printing. Vigour depends more on the relation between lights and shadows than upon the absolute amount of deposit. Read our series of articles on iron negatives and brilliant prints in last volume, or the articles on a similar subject in the Photographic News Almanac for this year. Never tone prints in the light, or the purity of the whites will be much degraded. Keep the dish with the toning solution in the dark, or in a room with yellow light, examining the progress of toning hastily by a weak daylight now and then. Stereoscopic negatives taken with a bi-lens camera always require the prints transposing on the mount. Negatives can be sent by post if packed in a case, but not otherwise.

Emil. Seelig.—We are at the office, generally, on Thursday afternoons, if you can call.

Richard Hilton.—The article to which you refer describes the method of getting similar stereoscopic effect, or relief, in distant objects, to that seen by the eye in near objects. To obtain simply the natural amount of relief produced by ordinary vision, the lenses should not be more than 3 inches apart. 2. The ammonio-nitrate bath for printing may be used with advantage. The time required for floating the sheets depends upon the amount of alkalinity, and the strength of the bath. With a very strong bath decidedly alkaline, ten seconds may be sufficient. If slightly alkaline, longer floating may be safely employed. To strengthen your bath, make it a practice to keep adding sufficient of a 100-grain solution to maintain always an equal quantity in the dish.

N. H. W.—We presume, that in speaking of a gallery facing south, Mr. McLachlan meant the sitter facing south. With the sitter facing north, the need for his arrangement would not exist. We do not know what coloured gauze, or net, he proposes in his background arrangement, but should presume a light grey. Your specimen of glass arrived in fragments, or rather coarse powder, so that we are unable to test it in the spectroscope.

John E. Browne, Canada.—We called and enquired personally about your remittances and order. We found both had been duly received. Tho reason given for the delay was, that a photograph ordered in your letter was not yet published. We understand that the order will be despatched as soon as the photograph can be procured. We hope the next time you write, you will be able to say you have received the goods safely.

Rapid Dry Process.—In the letter of H. & J. Walter, describing a rapid dry process in our last, in page 430, column 2, line 19, for Keene's "*Wet* Process Collodion," read Keene's "*Dry* Process Collodion;" and on the following page, line 71, for "Mr. Wade," read "Mr. Wardley."

James Date.—The prints enclosed are not mealy, but are examples of what has been styled *measles*. They bear every appearance of imperfect fixation, from the use of old or weak hypo. If either of them had these markings before toning and fixing, we cannot understand it. We never met with the dirty, yellow mottling exhibited, but from the cause just named. You need not apologize for troubling us: we have pleasure in assisting our readers.

Bewitched Bath.—Your negative has not arrived; but we have received an intimation from the Post Office authorities that a "packet containing broken glass, addressed to us, is detained, and will be delivered on payment of one shilling and four pence postage. We presume that this refers to your negative, which has been insecurely packed, aud insufficiently prepaid. We see no reason, from your further description, to believe that the collodion is at fault. It is most probably the bath, but we are unable at present to throw further light on the subject, beyond what we stated last week. To you, as to a correspondent above, we repeat that no apology is needed for placing difficulties before us. All we ask is the clearest possible description of the conditions. Let us know if the trouble continues. Your parcel has arrived since writing the above. We will examino the plate, and report next week.

R. G.—The sky is too dark, but only because the negative generally requires more development or intensifying. It lacks contrast generally.

W. Steele.—We remember seeing the advertisement you name. It was issued by some provincial firm; but we do not remember certainly whom, nor can we readily ascertain. The effect to be obtained was inartistic and bad, so we gave the matter very little attention. In reference to the recent advertisement to which you refer, we regret that we cannot control or be answerable for the *bona fides* of such announcements. We hope that it will prove merely a case of neglect, not dishonesty.

J. B. Boden.—In the case you refer to the writer has evidently omitted to mention that after dissolving, 12 ounces more water are to be added; 480 grains of nitrate of silver require 16 oz. of water in making a 30-gr. bath.

H. Cooper, Jun.—We shall be glad to receive your communication on the use of benzoin and other gums with paper in positive printing.

Un de vos Abonne's.—You will doubtless be able to order the *Moniteur de la Photographie* through any foreign bookseller, such as Dulau, or direct of of the publisher, Lieber; but we do not know of nny place in London where you will meet with it without ordering.

H. G. B.—Your note on glass-rooms, with comments, in our next.

G. G.—You will see from a photograph in another column that Mr. Glaisher has attempted to paragraph the exquisite cloud scenery seen from the balloon; but that at the time circumstances were unfavourable.

Several correspondents in our next.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 211.—*September* 19, 1862.

## PHOTOGRAPHY AND FORGERY.

The facilities afforded by photography, and more especially by photolithography, for effecting forgeries of bank notes and other documents, appear to have been considerably overlooked by those who are, or should be, most concerned. The sources of danger have been looked for in other directions, and it is from the imitative skill of the skilful engraver that counterfeit productions have been feared. In regard to Bank of England notes, a great safeguard has been believed to exist in the inimitable character of the paper, in quality, design of water mark, &c. But since the robbery of bank note paper, from the Laverstock Mills, this reliance has vanished into thin air, as the genuine paper manufactured for the bank authorities is now actually in circulation as the basis of the forgery. The bank authorities themselves rely upon the simplicity of the design and characters upon their notes, and upon the mode of printing adopted as their surest protection against imitation. Others maintain that complexity of design, produced by artists of the first ability, is the truest source of safety, arguing that, notwithstanding the skill and enterprise which have, unfortunately, been engaged in the nefarious profession of the forger, it must always happen that genuine art will be in advance of the spurious or counterfeit art. It is further argued that the number of persons who would be able, with any chance of success, to imitate the designs of genius, must necessarily be very few, and "these," as it is argued by an old writer on the subject, "by the legitimate use of their talents, can acquire competence; they, therefore, are not likely to employ their time, or risk their lives, in felonious imitations. Nay, if, in the perversity of the human mind, a first-rate artist were inclined to turn forger, he could not then do it successfully, because, even in the very first rank of historical engravers, one cannot imitate the engraving of another in a work of importance without the difference of manner being visible."

Adopting these and similar arguments, the bank authorities have held, we believe, that their position was impregnable, and that the precautions against forgeries of their notes were as complete as it was in the nature of things, or at least in the present state of science, possible to make them. Moreover, they may, and we believe do, argue, no forgery has ever yet been executed which they could not, themselves, detect; and as they could only become losers by counterfeits produced with such skill as to deceive their own tellers, and induce them, without question, to convert them into specie, they were not called upon to entertain further anxiety upon the subject. They believe that their own safety from deception is absolute, and that, for the public safety, they have done sufficient, or, at least, all that was possible; and there the matter must rest.

But the imitation produced by photography is absolute in all its parts. The most complex design of the most skilful artist is as easily produced as the most simple commonplace production of the greatest bungler. The secret marks however unobtrusive; the signature, no matter how marked its individuality or character, are all unerringly produced by the lens and camera, in the negative image. The ordinary silver print from such a negative, it is true, whilst it might deceive some persons if well executed, would speedily be detected on careful examination. It is for this reason, we doubt not, that the subject has received comparatively little attention, and excited no apprehension hitherto. But this is not the real danger. It is from the processes of photolithography, photoglyphography, and similar processes, by which photographic impressions can be produced in printer's ink, in the very material, and of the exact tint of the original, that the danger is to be apprehended; and that danger threatens the bank authorities themselves as well as the public, for it is possible to produce, by these means, imitations, which not the most skilful teller, or the most practised expert, could detect, or make oath as to the forgery.

Let us take the case of photozincography, photolithography, or the processes which have at present attained the highest state of perfection. The first of these methods, the invention of Colonel James, is practised at Southampton, for the production of the maps produced in the Ordnance Survey. The second, the invention of Mr. J. W. Osborne, and practised under his superintendence, at Melbourne, for the production of the maps and plans issued by the colonial Government of Victoria. Specimens of the work of both these gentlemen are exhibited in the International Exhibition. *Fac similes* of maps, engravings, manuscripts, pages of printed books are exhibited, all of which would defy detection. These are gentlemen, it may readily be said, from whom there is no danger of forgery. But their processes are made public; and not only may be, but actually are, practised by others. We refer those interested in the matter again to the International Exhibition; Mr. Ramage, of Edinburgh, exhibits a series of photographs in the British Photographic Department, perhaps the finest we have seen. By which process they are produced is not stated, but it is probable that the method is similar to that of Mr. Osborne. They are very perfect copies of engravings, and we have no hesitation whatever in saying, that by the same method and the same manipulator, *fac similes* of Bank of England notes might be produced which would entirely defy detection. It so happens, that these notes offer very especial advantages for imitating by such means. The design is clean, bold, and well marked: they are produced, not from engraved plates, in intaglio, printed at the copper-plate press, the printed impression of which always present a slight amount of relief which may be felt by the finger; but by block printing at an ordinary typographic press. Such an impression can, therefore, be imitated by the photlithographer without difficulty, and in such a manner that the Bank authorities themselves may be deceived.

Mr. Osborne, who is now in London, on a visit to the Exhibition, recently informed us, that wishing to call the attention of bankers in Melbourne to this danger, he produced by photolithography copies of various of their signatures, of which they admitted they would be unable to repudiate the genuineness. Any colour of ink, resembling either printing or writing ink, or any number of colours, may, of course, be easily produced, so that an actually written signature, instead of the printed signature now used, would not be an absolute safeguard.

We do not enter at present into any extended examination of the means by which such forgeries might be prevented, our object being rather to call the attention of those concerned to the existence and imminence of the danger. The means of prevention require careful consideration, and are not so easy and simple as might at first sight appear. Some years ago the subject came under consideration in the United States and in Canada. Coloured inks were employed for some parts of the note, and black for the other; but it was found that the coloured inks, not possessing, like black, a carbon basis, were easily discharged by chemical means, and photographic copies of the remainder easily produced, the coloured portion being supplied by a subsequent operation.

This difficulty was subsequently met by the use of a green formed of the oxide of chromium, which resisted the action of chemical re-agents. A geometrical pattern in this colour was printed first all over the paper, and the value, denomination, &c., of the note subsequently printed upon that in the usual way with black ink. This was an effectual check to ordinary photographic imitation, but it would be little or no check to the photolithographer, whose art would furnish him with means of evading this difficulty. A variety of means might be suggested of making the imitation difficult, but they would require more consideration than we can now give to the subject.

We may remark, before concluding, for the information of those of our readers who may be tempted to amuse themselves with experiments in this direction, that the pastime is a dangerous one; as the attempt to copy one of these notes by any process whatever, and for any purpose, is a felony, the consequences of which might be awkward.

## Scientific Gossip.

### TO PURIFY WATER.

Pure water is as essential for the well-being of the photograph as for the health of the operator, and a systematic perseverance in the employment of an impure source of this liquid will be attended in either case with the most serious consequences. The mortality of a town is, in the majority of cases, in proportion to the amount of impurity contained in the water with which it is supplied; and those who are engaged in photographic printing on a large scale can speak from experience as to the parallel holding good, in a remarkable degree, in the case of photographs. Of all the multifarious impurities which are liable to contaminate water, those which come under the class "organic" are by far the worst. These act not so much by what they themselves are capable of doing, as by the evil example they may be said to set other bodies with which they are brought in contact, acting, in this respect, after the manner of a ferment, and inducing a decomposition amongst a set of otherwise peaceably disposed atoms, of which no one can tell the end. Hence extremely minute quantities of such matter are capable of producing very extensive mischief. We have so often insisted in these pages on the paramount importance of pure water in all the operations of photography, that it is with no little pleasure we now draw attention to a plan, by which this necessary freedom from contamination can be secured by anyone, at a mere nominal expense either of money or trouble. The method is due to Mr. H. B. Condy, and consists in the addition of a solution of an alkaline permanganate to the impure liquid, when the organic matter will be rapidly destroyed. The process is as elegant as it is effectual. By the peculiar chemical properties of the permanganic acid it is capable, when employed in appropriate combination, of not only burning up every trace of organic matter in a water as perfectly as if it had passed through a furnace, but it also removes many of the mineral constituents which are sometimes almost as objectionable. An experiment of Mr. Condy's shows this in a striking manner. He made a saturated solution of oxide of lead, by shaking common white lead in distilled water, and filtering; this, on being tested with hydrosulphuric acid, gave the well known reaction of lead—a black precipitate. Four ounces of this liquid were then taken, and to it were added a few drops of a very weak solution of permanganate of lime. Upon standing for half an hour, the pink colour had disappeared; and when filtered off from the precipitated peroxide of lead and binoxide of manganese, there was only a brown tint communicated to it on testing with hydrosulphuric acid. A little more permanganate of lime was added, and the liquid allowed to stand for some hours, when, upon filtering again, not a trace of lead was found in solution. This is a very remarkable experiment, inasmuch as lead is a most difficult impurity to remove from water, whilst it is the most poisonous of ordinary metallic contaminations. Water containing iron in solution can also be purified in the same manner, so as to render it fit for use in dyeing and other industrial purposes; but the chief use of the permanganates as purifying agents is when organic impurities are to be removed. Hitherto no methods of purifying water can be considered of much efficacy. Filters remove suspended impurities only; ebullition merely destroys the vitality of animal and vegetable impurities, and precipitates carbonate of lime; alum introduces, in most cases, more than it removes; alkaline carbonates, lime, &c., merely touch some of the organic impurities; whilst even distillation itself, as ordinarily conducted, leaves much of the original organic impurity still in the water, whilst it deprives it of the dissolved gases which render it fresh and sparkling as a beverage. Of all purifying agents, filtration through animal charcoal has hitherto been looked upon as the best; but this is only partially effectual, and is tedious and somewhat expensive. Nothing that we are acquainted with at all comes up to an alkaline permanganate (either of lime or potash) in value and perfection of result, and we consider that Mr. Condy, in drawing attention to this simple and ingenious method, deserves the thanks of all practical photographers. The rationale of the process is easy to understand. Permanganic acid consists of the metal manganese united with a large excess of oxygen. This has been joined to it by powerful chemical methods, and the affinities between the metal and metalloid are sufficiently feeble to cause the oxygen to fly off on the slightest opportunity being offered. Pure water being incapable, under ordinary circumstances, of taking up more oxygen, will dissolve a permanganate unchanged; but if organic matter be present, the case is different. This, no matter how complicated its composition, invariably consists of the elements hydrogen and carbon, in conjunction, sometimes, with nitrogen, sulphur, &c. Now all these are substances greedy of oxygen, and exercising, in consequence, a powerful reducing action upon the highly oxygenized manganese compound, the carbon becoming acid, the hydrogen water, the other elements are burnt into perfectly harmless compounds, whilst the manganese is reduced to the state of binoxide, which falls down as a brown insoluble powder.

When absolutely pure water is required for some special scientific object, it can be readily procured by mixing it with an excess of permanganate of potash, and distilling it once. This we have verified ourselves, and can vouch for the extreme purity of the product. For all ordinary purposes distillation would not be required, and in this case the cost of applying the permanganate process on a large scale is very trifling. The quantity of permanganate necessary to purify 10,000 gallons of water would be contained in one gallon of Condy's fluid, the price of which is only 10s.; at this rate 200 gallons, or one ton of water, could be purified at an outlay of 2½d. On a practical scale, Mr. Condy recommends a wine-glassful of solution of permanganate of potash to be poured into a hogshead of offensive drinking water, and mixed up with a stick. Generally this quantity will render it as sweet as fresh water; but should it be very impure, half a wine-glassful more may be added. So long as organic matter remains, which is known by the pink colour of the liquid gradually vanishing, add the fluid. If too much has been used, it need occasion no uneasiness, for it is merely necessary to continue stirring for a short time with a stick, or, on a small scale, to filter it through blotting paper, for the excess of permanganate to be decomposed. The precipitated peroxide of manganese must be left to subside, and the clear liquid may then be poured off.

One great advantage in employing permanganate of potash as a purifying agent is, that any excess of metal which may be present, either by addition of too much of the pink liquid, or by not separating the precipitated peroxide of manganese, will not prove injurious, even if the water be used for drinking purposes; for physiologists have shown that the metal manganese is a frequent constituent of the human frame, and is invariably present in races who depend much upon oats for their food.

When used as a *test* for impurity in a water, a few drops of the pink liquid may be mixed with a tumbler of water, and the effect noticed. The relative impurity of two or more waters may be found by adding a certain quantity of permanganate to equal amounts of the water, and noticing which retains the deepest colour of the permanganate; this one will be the freest from organic impurities. Waters which rapidly decompose the permanganate are not fitted for drinking purposes.

## The International Exhibition.

### REVISION OF AWARDS.

The revised list of the Awards of Jurors is not, we regret to state, a correct list. To what extent the errors exist we do not know; nor to whom such errors are due; but it appears probable that some one still remains responsible for an amount of blundering truly startling. We have not taken the trouble to search for errors, but a sufficient number come unsought to indicate the large crop which might be reaped by one seeking them. In the case of Mr. Savage, to whom we referred before, the award is given, but the name is omitted. Mr. Tucker, of Trinidad, whose letter we give below, receives his award, but for an incorrectly described contribution. Mr. Cruger, of the same Island, sends a fine collection of drugs, and receives an award for "141 good specimens of timber." Mr. Devinish sends timber, and is rewarded for "drugs" These errors all stand in the "revised list." These gentlemen all reside far away; the only advantage is the honour; but what honour would be for Mr. Mudd to receive a medal for an improvement in boot-jacks, when he had contributed photographic landscapes? Or for Mr. Williams to be rewarded for an automatic toasting-fork, when he had contributed portraits? Some of the revisions made are scarcely more satisfactory. Here is a flagrant case: Mr. Crookes, whose name is well known to photographers as a chemist and physicist of very great ability, recently discovered, by the aid of the spectroscope, a new element—thallium. His claim to the discovery was never doubted. He sends a specimen of the element, of some of its compounds, a drawing of its spectrum, full description, &c. These were in the Exhibition at the proper time, and duly shown and catalogued. This contribution was entirely ignored, unnoticed, unmentioned, whilst a French contributor, who sent a specimen two months after the building was opened, and did not even claim the discovery. received a medal "for the discovery of new and abundant sources of thallium." The discoverer of the element's very existence was unnoticed; whilst he who discovered that more of it was to be found was medalled! How the remedy was applied, when the authorities were compelled to recognise the blunder, we prefer to let the *Daily Telegraph* state, which has some excellent remarks on the subject:—

"Dr. Lyon Playfair, in a preface to the second edition of his book of jurors' awards, is very careful to inform the public, that although several additions have been made to the original list of *décorés*, no single instance occurs of any new award having been made. The explanation is, that in copying from the papers sent in by the juries, there was no time to refer to the minute-books for the verification of details. We question the validity of the grounds on which the Special Commissioner for Juries gives utterance to this singular boast, on behalf of those bodies, that they have determined not to award medals to exhibitors whom they have confessedly overlooked in haste. At any rate, some of the newly published awards, in the second edition, come very suspiciously after strong representations of injustice. One example may be cited. Mr. William Crookes, the discoverer of the new element, thallium, and the exhibitor of several of its compounds, was passed over by the jurors of Class 2; while M. Lamy, a Frenchman, who brought a specimen of thallium into the building about two months after it had opened, received the honour of a medal. Mr. Crookes had sent in his case, containing not only the compounds we have glanced at, but the element itself, a drawing of its spectrum, some minerals containing it, and full written descriptions of its chemical properties, before the opening of the Exhibition. However, as we have said, he was ignored in favour of his foreign rival—who, by the bye, never pretended to have been the discoverer of thallium. On the contrary, in a paper read by M. Lamy before the Académie des Sciences, the honour is freely given to Mr. Crookes. Under these circumstances, our countryman appealed to the Commissioners of the International Exhibition, laying his case very strongly before them. He gets his medal for the 'discovery,' as appears by the second edition of the Book of Awards; and at the same M. Lamy retains *his* medal for the 'discovery' also. We confess our inability to understand this. One or other 'discoverer' must have been first, and both cannot well be entitled to a medal. But what more especially strikes us in the aspect of this case, is the difficulty of conceiving that the omission of the Englishman's name should have been the result of mere accident. Does the 'minute-book' of Class 2, section A, really and truly show that the jury gave two medals for the 'discovery' of one object? Plainly speaking, we don't believe it. There is too glaring an evidence of the fact that, having been forced into an act of justice to Mr. Crookes, the jury shrank from the disagreeable task of officially withdrawing their countenance from M. Lamy, and so took the egregious course of complimenting each gentleman on being the original discoverer of a new field in science."

The following is the letter from Mr. Tucker to which we have referred;—

"Sir,—In No. 202 of the News, and among the list of Jury Awards, honourable mention is made of my name, for views of British Guiana. Allow me to correct one of the numerous errors made by the Jurors or Commissioners. My views are views of the *Island of Trinidad*. Again, Mr. Devinish, of this Island, to whose energy we owe the fine collection of woods, obtained honourable mention for *drugs*, and Mr. Cruger, the botanist, who made the valuable assortment of drugs, fibres, &c., has had awarded to him a medal for the *woods*.—I remain, dear sir, yours faithfully, William Tucker.

"*Trinidad, British West India, August 22nd*, 1862."

Our notices of apparatus are compelled to stand over from pressure on our space.

### HARMONY AND SUBORDINATION IN PORTRAITURE.

Sir,—Being an artist of long experience in portraiture, and having lately taken to photography, I cannot help thinking that some of the impressions made upon my mind in the juncture of my experience in these two things may be useful, and, if read with care and thought, may, as a nucleus of suggestion, become profitable to the numberless students in the latter art.

I have been led to this thought by your excellent remarks upon backgrounds, which, from time to time, appear in your journal; and feeling that you take the high and artistic view of photography, I would, while I supported your admirable opinions, show that you are driven to the conclusion you most rightly arrive at, by the use and abuse amongst photographers, of material which could and ought to be of better quality, as well as better applied.

Now, I would first endeavour to make it known, that both in photography and the works of the pre-Raphaelite in painting, such is the power of nature when very perfectly represented, as it is in the productions of both when well executed, that in the degree in which Nature is so truly and fully imitated, there is less necessity for that very legal and binding arrangement of parts, which, in weaker productions, would be a positive necessity; nevertheless, wherever you meet with a work, by either of the above-mentioned powerful presentations of nature, in which, to the strength of individuality, is united a very exquisite distribution and balance of parts, adjusted and composed in accordance with all the rules of art, that work you will very soon see carried all over the world, and to be found in every show case, and every album and collection, especially if its subject have any universality of interest; thus showing that the laws of art belong to truth, and meet with sympathy if put into practice in pictorial art, as much as they do in music, or in poetry.

Law always belongs to a polity, or rather to anything composed of numbers that has to be brought into a whole—a unity. Pictorial and representative art, therefore, must have its own series of laws. Every work must be a whole composed of parts; those parts must graduate from largest to least, and (for it is all a principle of a polity) from strongest to weakest, and from high to low.

Upon this gradation depends all the harmony. Gradation is the truest illustration of harmony. In art equality never can be harmonious, nor can it in any whole pretending to a unity; while upon contrast and variety it hangs for interest and for vigour, these must always be in true subordination. But I do not wish to be too æsthetic. I will come at once to the matter on hand.

There is in art always a principal object which should immediately arrest the attention of the spectator; it should rivet him at first, absorb him at once, however varied and multiplied the parts may be, or howsoever brilliant. There are many ways of producing this, but it must be done—infallibly done—and maintained. This is signally omitted in many of the clusterings of natural objects together, which we see produced, for stereoscopic purposes, often, nay, nearly always, interesting, but sadly lacking in this excellence.

In a portrait, it is needless to say this climax must be the head; in a group, the leading figure. In a portrait the head, not the chair. In the artist's whole length, which is the photographer's *carte de visite*, it ought not to be the pedestal or the column, these accessories should be introduced so as to lead up to the climax of the composition, and carry, even if they be large objects, the spectator's eye forward to the principal thing.

The *carte de visite*, even in some of the best show cases in London, is a pedestal with a man near it; it might be catalogued as the portrait of a pedestal, and a column, and a lord. It surely requires more judgment to use these appliances well in photography than it does in painting, for a painter can play and sketch about his canvass with lines and forms; a painter, too, has more facility of throwing imaginary shadows to bring his quantities into true gradation, for the gradation of quantities is a very delightful and very subtle idea; he may, perhaps, throw a large shadow over part of a balustrade, and thus has quite as much of it, but what he has is under subjection.*

The backgrounds of the great masters in art, such as Sir Joshua Reynolds, had their columns, their pedestals, their buildings in great abundance, often, but they subserved.

The splendid whole-length painters, Titian and Velasquez, not forgetting Rubens and Vandyke, all used these additions, but they bound them down under limits of larger and less, many and few, under variety of colours and of tone, tending always to foil something on the one hand, to enhance something on the other, and never to weaken the principal figure; and—let all colourists awaken to this fact—that they put their brilliant colours upon that principal figure, and broke those colours down again, not only by gradations both of similar colours and tones, but into tints of them, down even to an elegant degree of the infinitessimal, which yielded that look of excessive finish—which word, *finish*, is only another word for the most tender gradation; for what the artist calls *finish*, and the nicest possible perception of gradation, are really synonymous.

A painter begins with his principal figure, or head, and ends with it—it is his first and his last; if surrounding parts have derogated and detracted by their persistence and strength, he coruscates either with hair or velvet cap, or anything else he can. Rembrandt did so with both light and dark, hot and cold colour. While the strength of accompaniments being kept at a distance from the head, keeps up this key-stone idea, and the work delights, nay ravishes, the eye of the beholder, and there is a certain satisfaction that if this principle be moderately well carried out, it never can torture or tire the eye. And to further illustrate, this torture is excessive on looking at some of the modern whole-lengths, called *carte de visite*, and is not only brought about by the existence of many strong parts, but also by the fact that those parts are lineal and narrow, the cornices are petite, and the balustrades sometimes dwarf-like in character, as if they ought not to be used until they had grown bigger; if painted, liney in execution, and in most cases not copied from good architectural examples. It should be known and remembered, that the Greek architects exquisitely felt, and deeply studied, the exact relative size of all the parts—their projection and their breadth. I appeal to any one, whether there is anything more common looking, more vulgar than bad architecture; the architecture from the pencil of a carpenter or a small builder?

These portions of background are mostly done by men of little higher artistic calibre: roses are put in the centres of the pannels of pedestals, where the Greeks would have put a beautiful basso relievo. Fluted columns, too, put with no feeling for breadth, though they are so beautiful, if well adapted. All narrow, all consequently weak draperies—their poor folds insipid and limpid, while yet they are tortuous, corrugated, harassing and hard. The columns, &c., it may be confessed, are of artificial manufacture, or painted; they should at least be done from fact, and let an artist do them if possible, and not a mere line and rule man. There is a way of giving them a full, soft edge—a look of thickness; and this in spite of the necessity that they should be very true, and very square, and straight, even to an extent of correctness and care most elaborate.

There may be plenty of forms in them, for it is not a multiplicity of forms that is wrong, they might have many more; multiplicity of parts always gives fulness, and, if in the right place, yields a look of plentifulness; but, of course, there must be a corresponding quantity of broad and flat portions, and divisions.

I would further suggest to the photographer, if he lives in London and determines to improve his taste in these respects, to study the building of St. Paul's, as being so wonderful, not only in its beautiful outline, but in the perfection of its parts and details; this, as well as all the buildings by Sir Christopher Wren. He can see any engraving he may desire at the print-room of the British Museum, and if he goes there and asks the amiable keeper for the works of Piranesi, he will get such an admirable illustration of round edges, that it will quite dispel his notions of cutting edges—so cutting that against them you could almost cut your hand.

I propose to leave these remarks with you for the present, willing to do more if needful, and to be more elaborate if required, or to take up other portions of artistic decorations, as they come into the hands of the photographer; and if, sir, you care as much for the theory of art, as you manifestly do in your excellent paper for the formulas of science, I am, sir, yours very respectfully, F. T.

* The amount of licence assumed, and in some instances justified, by painters in the distribution of shadows, whether they exist in nature, or solely for the purposes of balance and pictorial effect, will probably astonish most photographers when first brought under their attention. Mr. Frank Howard, in his preface to his "Sketcher's Manual," says, "He must insist, in the present state of opinions on art, and practice of professors, that the picture must be made, honestly if you can, but make a picture. And so long as those pictures by Sir Joshua Reynolds, and others, continue to receive admiration, in which the figures are supposed to be lighted in front, by moons introduced into the background, amateurs are fairly entitled, and will, probably, be contented to avail themselves of the license." He further says, in the body of the work: "The production of common pictorial effect will be shown to be very easy, if the amateur will condescend to make use of the expedients employed by the most celebrated artists, namely, to introduce shadows of all kinds and degrees that may suit his purpose, whether possible to be found in nature under such circumstances or not!" We wonder what would be said to the artistic painter, or composition photographer, who should attempt to gain pictorial effect by similar licence.—Ed.

## PRINTING WITH THE SALTS OF URANIUM.

Printing and toning with the salts of uranium are in their infancy. Notwithstanding this, it is certainly an attested fact, that vigorous prints can be obtained by these salts; and that the ordinary toning with chloride of gold is modified, perhaps improved, by the introduction of the same salts; and yet photographers do not like any innovations, and frequently, on this account, allow very powerful reagents, and their successful applications, to pass by unnoticed. The following methods of printing with nitrate of uranium have already appeared at different times in the photographic journals; it will do no harm, however, to present them altogether. We translate them from the "Photographischer Almanach" for 1862, a very interesting practical little work, a valuable *vade mecum* for the amateur and photographer, published by the Institute at Elberfeld; unfortunately its value is limited to those who either speak or understand the language of the Teutons. We intend to cull from its contents, and from the contents of all available sources in any language, the sweets of photographic lore, for the benefit of our readers; nor do we deem it illegitimate to take the step, since we are willing and desirous that we should be served in the same way; nay more, we will labour hard to discover and collect together whatever may be useful in the art of photography, or instructive in its science, in order that our fraternal journalists may not task us with meanness, but may meet with an adequate indemnification for our stealth from their columns. Our readers can assist us materially, by their experience, to make the collection just referred to; and we hope to find several of our friends awakening up from their lethargic inactivity, and, if they do not feel inclined, have not the time, or the chemical knowledge to enter into a course of independent photographic experiments, let them, at least, try to test the experiments of others and report results.

### Printing Process with Nitrate of Uranium.

*By H. de la Blanchere.*

*First Method.*

Take 10 drachms of distilled water;
,, 2 drachms of the nitrate of the oxide of uranium.

Filter the solution and preserve it in the dark. The paper must be floated for five minutes in this bath. When dry, it is exposed under a negative in the printing frame, for a time varying from one to ten minutes in the direct rays of the sun, and from fifteen to sixty minutes in the shade.

The picture is developed by immersion in the following solution:

10 grains of nitrate of silver, crystallized and slightly acid.
10 drachms of distilled water.

The picture appears in about thirty seconds, and becomes more vigorous; as soon as it is sufficiently developed, it must be washed in several waters, and then fixed. It may afterwards be toned with gold in the usual way.

*Second Method.*

The sensitizing bath is the same as the preceding. As soon as the paper has been exposed to the light, it is immersed in the following bath.

10 drachms of distilled water;
1 drachms of alcohol, specific gravity, ·849;
5 grains of nitrate of silver;
1⅔ ,, of nitrate of cadmium;
1⅔ ,, of nitrate of uranium;
¼ a drop* of nitric acid.

The bath must be very slightly acid.

*Third Method.*

The sensitizing bath as before.

*Developer.*

1000 grains of distilled water,
1 grain of chloride of gold;
¼ of a drop* of hydrochloric acid.

The picture must lie in the bath as long again as in that containing nitrate of silver; the tones become blue or blue-black, and the middle tones are easily attacked by the bath.

*Fourth Method.*

Developing with a salt of mercury;
2000 grains of distilled water;
1 grain bichloride of mercury (corrosive sublimate).

The image will be perfectly developed in two or three minutes in this bath. The tone by this developer is the most beautiful and vigorous. As soon as the prints are thoroughly developed, they are washed in water for fifteen or twenty minutes, and then dried.

### Printing Process of Houdoy.

The paper is floated in a lukewarm solution of five parts of gelatine in one hundred parts of water, and after this for ten minutes in a bath of nitrate of uranium—20 per cent. strong. It is then dried in the dark. It is afterwards exposed beneath the negative for one to ten minutes to the direct rays of the sun. The print is developed by immersion in the silver bath, and, as soon as the image has appeared with sufficient vigour, it is placed in the following solution:—

1000 grains of water;
80 ,, sulphate of the protoxide of iron;
20 ,, acetic acid.

The picture quickly assumes great vigour of a sepia tone; it is then instantly well washed in water and toned in a bath of chloride of gold one grain, and water 100 grains. By this means the picture is retained quite on the surface of the paper.—*Humphrey's Journal.*

* One fourth of a drop of nitric acid is obtained as follows:—Drop into a test-tub three drops of water and one drop of nitric acid. One drop of this solution will be equivalent to one fourth of a drop of nitric acid.

## A SHORT LESSON IN CHEMISTRY.—No. 3.*

Before I proceed any further in reference to chemical nomenclature, I deem it necessary here to describe what is ment by acids, alkalies, and bases. As the word implies, an acid is sour; to taste chemicals, however, is a very inconvenient method of testing them, and one that is seldom to be recommended; hence we have recourse to other distinguishing characteristics. In short, the distinct properties of an acid are as follows; in the first place it has a sour taste; secondly, it turns blue litmus† paper red; thirdly, it combines with bases so as to form new compounds in which neither acid nor base can be recognized, unless they are again separated. An alkali is a substance whose taste resembles that of *urine* (of course you will certainly verify this test); secondly, it restores red litmus paper back to its original blue; thirdly, it turns yellow turmeric‡ paper brown, or red-cabbage§ paper green; and finally, it combines with acids so as to neutralize them or remove their acidity. All alkalies are bases; but not all bases are alkalies.

Bases are substances, either simple or compound, that neutralize acids and form with them a class of bodies totally different both from the acids and bases; the bodies thus resulting from the chemical combination of acids and bases

* From *Humphrey's Journal.*

† Litmus is a dye-stuff, prepared from a lichen called *Roccella tinctoria.* It is sold in the form of cakes or squares of a violet colour. To prepare the ble paper, take one part litmus and four of water, mix or dissolve, and brush the solution over unsized white paper. Dry the solutions and keep them in close vessels in the dark. Red litmus is prepared from the blue by immersing the sheets in dilute sulphuric acid or vinegar, and then drying, &c., as with the blue.

‡ Turmeric is a root (*Curcuma longa*) which yields a dye-stuff to alcohol as tincture, or by decoction to water. For these purposes take one part of the pulverized or rasped turmeric to five parts of ordinary alcohol in one case, and one of turmeric to ten of water in the second. The unsized sheets of white paper are immersed in either of these fluids and afterwards dried.

§ Cabbage paper is prepared by steeping white unsized paper in the infusion of red cabbage, and afterwards drying.

are denominated salts—a most important class of chemical substances.

*Acids.*—It was supposed, at an early period in the development of chemical science, that oxygen was the acidifying principle; but we know now that we might as justly say that oxygen, too, communicates the alkaline property: for the metals potassium, sodium, lithium, calcium, etc., are not all alkaline: but, when combined with oxygen, they are the veritable alkalies or alkaline earths. Still, most of the acids contain oxygen as one of their elements, and we have frequently several acids of the same element, modified especially by a change in the quantity of the oxygen. Let us take, for instance, sulphur and oxygen; of these two elements we have have at least seven compounds as follows; hyposulphurous acid, sulphurous acid, sulphuric acid, hyposulphuric, monosul-hyposulphuric, bisul-hyposulphuric, and trisul-hyposulphuric acid. In the same way we have three oxygen acids with phosphorus, two with nitrogen, at least four with chlorine, aud two with arsenic, etc. On the other hand, as I observed in the preceding lesson, we have a well defined class of acids called the hydracids, in which oxygen is one of the elements, whilst one of the metalloids is the other, as for instance: hydrosulphuric, hydriodic acid, etc. But both this class and the preceding are seldom, if ever, found uncombined with water, which becomes, as it were, a constituent part of each acid and inseparable from it until decomposition takes place.

*Bases.*—This term when applied to inorganic chemistry simply signifies either an oxide of any of the metals, or the metal itself, just as we combine either with an oxygen acid, or a hydracid. It is, in fact, the substitute of the oxide of hydrogen, or of hydrogen in acids; for instance, hydrated nitric acid (nitrate of the oxide of hydrogen) consists of one equivalent of nitrogen, five of oxygen, and one of water (oxide of hydrogen). Now the oxide of hydrogen is the base of nitric acid, and can be set aside, and any other oxide can be substituted instead, whereby a new chemical body is formed, called a salt. In like manner hydrochloric (chloride of hydrogen) may have the hydrogen removed by a metal alone, whereby hydrogen is set at liberty from its combination and escapes as a gas, whilst a new combiuation of chlorine and a metal gives also rise to a salt. An oxide of a metal might have been used instead of the metal, in which case a double decomposition would have ensued; the hydrogen in this case allies itself with oxygen to form water; whilst the chlorine combines with the metal to form the chloride. Now the mode of naming these salts is simple and rational; we do not lose sight of the elements in the name; the base is always retained entire, and the metalloid in connection with the oxide of hydrogen, or simply with hydrogen, is also retained. For example, carbonic acid (carbonate of the oxide of hydrogen) and oxide of iron give rise to a salt called carbonate of the oxide of iron; and and hydriodic acid (iodide of hydrogen) and magnesium combine to form a salt denominated iodide of magnesium; sulphuric acid (sulphate of the oxide of hydrogen) and lime produce chlorite of lime. Thus, then, we see that salts arising from acids ending in *ic* produce salts in which the *ic* is changed into *ate;* whilst the *ous* in acids is changed into *ite*, the prefixes being used with salts in a manner analogous with either acids or bases.

## HUMIDUS DRIED UP.

BY COLEMAN SELLERS.

In my last communication I told about the great duel fought on the Harlem River, and in as impartial a manner as possible stated how Humidus (that's me) got worsted, and intimated too that a goodly row of tannin plates were in my box awaiting exposure, as soon as a certain changing box, at that time being made by Mr. Pearce, should be ready for use. Those plates were exposed, and lots more made and exposed since then, and now letters of congratulation come in from all quarters, speaking kind words and hailing my conversion with joy, until I have really begun to imagine that I have been a great sinner, through all previous time. Now I want it clearly understood that it was not the picture of this or that of our dry amateurs that influenced me in my change from wet to dry; it was Thompson's changing box; I saw it, and liked it so very well, that as soon as I reached home, I had one made. It holds twelve plates, and cost, all told, five dollars and fifty cents; I note this for the benefit of those interested. It is no easy matter to describe a mechanical device without an engraver, hence my description of it may not prove satisfactory to those who wish to furnish themselves with similar outfits. In the first place there are prepared thirteen very light wooden frames, of a size suited to the plates to be used; mine show a section of wood one-quarter inch square, and being made for ordinary stereoscope plates, measure outside three and eleven-sixteenth inches by seven three-sixteenth inches, and one-quarter inch thick; twelve of these plate frames will make a pile three inches high. The rabbets in these frames for the reception of the plates are five thirty-seconds of an inch deep. The plates are held in by a light steel spring three aud three-eighths iuches long, stuck into a notch on one side of the frame, and swung into a groove on the opposite side, crossing the centre of the plate. One of the frames has a focussing ground glass permanently fastened into it. A holder is made with two sliding shutters, one, as usual, for exposure, and the other to admit one of these frames and to slide so close to it when in as to allow no room for shaking; in this holder the entire ground-glass frame is always carried, and the focussing is accomplished by drawing open both shutters front and back; after focussing, the glass and frame are taken out and put in the pocket. The plate box consists of a holder with the same double shutter sliding on opposite sides, but with space between the shutter for twelve frames, *i. e.*, three inches. This box or holder is provided with two knife edged springs passing through the sides, or rather ends, in such a manner that when the box is held horizontally, one shutter on top and the other forming a bottom, the edges will separate the bottom one of the frames from the remainimg eleven frames, which will all rest on the springs or knife edges. It is evident now that if the bottom slide be pulled out, the bottom frame will fall out; and if the box was sitting in the exposing holder and the openings coinciding, it would fall into the holder, and could be secured by shutting the slides. If now, the slides being all shut, the spring latches are drawn back, the pile of frames will fall into the space made for them by the removal of the one frame, and space will be left on top of the pile for the exposed plate to be dropped from the exposure holder into the plate box by drawing back two slides. The frames are thus made to descend in succession, and are exposed in the same order; the whole affair is cheap, and very convenient, and, as I have said before, was the means of my *conversion.* It may not be so good as the box made by Mr. Stock, for the same purpose, but it has never missed fire in my hands, aud is very light and portable. The frames so nearly fill the box that the air makes a cushion, and they fall into place without the slightest sound.

Having thus described the box, which Mr. Thompson tells me he bought from some Englishman, I would add that as yet I have only used tannin plates in it; these plates I have prepared by using a very old collodion and an acid bath; I albumenize the edges of the plates with a margin of one-eighth of an inch. From the silver bath I pass them through two water baths, then into a tray, through which the water from the hydrant is constantly running. I next immerse them in the tannin bath, and stand them to drain on a small graduate measure, before draining on blotting paper. Finally I stand the drained plate in a box, which is lined with clean white muslin, and covered with blotting paper on the bottom. This routine gives six different operations to be gone through with, and regulates the time of washing.

If a drained plate be put into the drying bath, the rough drained one put down to drain in its place, a plate be removed from the tannin and placed on the graduate to rough drain, a plate then taken from the washing tray, held a moment to drain before plunging into the tannin, then each of the other plates changed from their respective baths in their course towards the tannin, the plate in the silver bath will be ready for removal, and another can be flowed and silvered. This system, in my hands, gives me eighteen good plates in one hour. I do not dry by artificial heat at all, and I develop the plates by the formula given by Mr. C. W. Hull, in the Circular published by Mr. Stock, and which appeared last year in this journal. The tannin process has exceeded my expectations, and I have had every reason to be satisfied with it. I have, however, confined myself to long exposures in preference to any of the short times, and subsequent accelerating formulæ; but still, for what I have seen of the other dry processes, I am inclined to think that Mr. H. T. Anthony's solid milk plates are better; these are prepared as follows—No, I won't go into the milk business now, it is too hot, and my letter has reached too great a length; I hope it will interest some of your readers.—*American Journal of Photography.*

## THE COST OF SILVERING PAPER AND TONING PRINTS.

BY CHARLES WAGER HULL.*

Among the many valuable suggestions thrown out each month in the various journals devoted to photography, I do not remember ever having met with one practically setting forth the cost of silvering paper of various sizes; nor in conversation with many amateur as well as professional photographers, have I ever met with one who had taken the trouble to find out, but most would like to know. It must, however, be understood that my experiments alhough conducted in a laboratory (not a laboratory for photography, but for the chemical department of my business), were not by any means reduced to that nice system of exactness involving the weighing and determination of the one hundredth part of a grain.

The experiments several times repeated prove that for all purposes the method is near enough. Knowing the strength of the silver bath by the hydrometer, and also the superficial measure of the paper floated, it was no difficult task to determine the amount of silver each piece required.

The paper in each experiment was salted sixteen grains to the ounce, and floated about one minute and a half on a seventy-five grain bath. The silver was calculated at fifteen dollars (£4. 2s. 6d.) per pound.

Each Card, less than three-tenths of one cent. (A cent is one halfpenny.)

Each Stereoscopic, less than three-fifths of one cent.

Each 6½ by 8½, less than one and a half cents.

Each 8 by 10, two cents.

Each 11 by 14 a trifle over four cents.

Now, if we choose to extend the calculation into the toning, and take gold as worth five cents per grain, and allow one grain to each sheet of albumen paper, the cost of prints to the amateur can soon be reached.

In the experiments alluded to, no account is made of the drippings from each sheet or piece when hung up to dry, all of which is carefully secured, and which, so far as this calculation is concerned, is all clear gain. One little trick in silvering paper which but few know, or, if they do, do not practise, is at least worth an incidental mention; and that is, when you lift the paper off the silver, do so very evenly and very slowly, and you will find that the surface silver will nearly all follow down, and but few, and very few drops will be afterward left to drain from the corner. Let such as have never taken this care, try it, and be satisfied that the saving is worth at least all the knowledge cost.

In your last number, I find our friend Sellers has a few words to say in his usual charming style; but am indeed sorry to learn that the only inducement he had to go into the "dry" was Thompson's nice box. Most of his friends have thought him converted at last, yet it appears not, but he will be ere long; time works wonders—more wonderful than his conversion to the "dry" will be. Let him keep on working that box and he will be all right yet. In his communication he states that he works the formula given by me on Stock's Circular; in the pyrogallic solution he uses one ounce of the alcoholic pyro to the ounce of water; if I so wrote for the Circular, it was wrong, it should be one-half ounce to the one ounce of water.

## ON THE CONVERGENCY OF THE OPTIC AXES IN BINOCULAR VISION.

BY PROFESSOR CHARLES F. HIMES, OF TROY UNIVERSITY.*

In his monograph on the stereoscope, Sir David Brewster, while treating of the union of binocular pictures by the unaided eyes, when placed as they usually are—the right-eye picture on the right side, and the left-eye picture on the left side—states: "The distance in this case must be greatly less than the distance of the eyes, in order that the optic axes, in passing through similar points of the two plane pictures may meet at a moderate distance beyond them." p. 83. "We cannot thus unite figures the distance of whose centre is equal or exceeds two and a half inches." p. 97. "It is impossible to obtain, by the ocular stereoscope pictures in relief from the beautiful binocular slides which are made in every part of the world for the lenticular stereoscope." p. 123. Professor Wm. B. Rogers, in his able and exhaustive papers on Binocular Vision,† substantially endorses these statements, while disproving Sir David's theory of binocular vision founded on the successive convergency of the optic axes to the different points of an object. This assumption of a positive point of convergence of the axes, either before or behind the slide, in every case of the union of supplementary pictures, is counter to my own experience, and observations in cases of others. The limit of separation of similar points, and consequently of the size of the pictures from right to left, depends upon the constitution of the eye, which prescribes a limit to the movement of the axes, or, in other words, to the number of degrees through which the eye can be rolled. It is plain, however, that within these natural limits, unvarying habit established others within which movement is easy, and in most cases involuntary, beyond which requiring effort, and even painful. There does not, however, appear to be an instinctive tendency to converge the optic axis in looking at objects. Many persons must have noticed, that new-born infants appear cross-eyed, but that there is not a decided in-squint or out-squint, but a peculiar working of the eyes, an apparent want of concert in their movements, which appearance vanishes after a short time, to the great delight of all interested. From this early period there is an unvarying practice of convergency of the optic axes, and the limits within which it is done are, practically, parallelism on the one hand, and the angle formed by the axes when we look at objects placed at the distance of distinct vision, on the other hand. It might be presumed that within these limits there would be others, peculiar to the occupation of the individual, but the habit, within the above range, is so thoroughly formed early in life, and the power so frequently exercised at all periods, that probably no decided effect would be noticed.

The opinion expressed in the remarks quoted, must be founded either upon the hypothesis, that it is impossible to render the optic axes parallel or divergent, or that when the axes are in either of these positions, and the supplementary pictures are presented, so that the axes pass through similar points, no union, attended with the usual

* From the *American Journal of Photography.*

† *American Journal of Science,* Vols. XX. and XXI., New Series.

effect, can take place. The first supposition only proposes a difficulty similar in kind to that of closing one eye whilst the other remains open; an operation contrary to our uniform habit of working the eyes in concert. The second supposition is met by facts to the contrary. Pictures more than three inches apart can be united, and the difficulty in so doing does not lie entirely in the unusual position of the axes. Every one who has made the trial of uniting pictures by converging the axes to a nearer, or more remote point, will recollect the unusual exercise of the visual organs it required; and in either of those cases there is plainly nothing unusual in the position of the axes, the difficulty being, as Prof. Rogers has shown, in the necessity of violating the habit of converging the axes and accommodating the eyes to the same point. Sir David notices, that it is easier to get stereoscopic effect by transposing the pictures, and uniting them by converging to a near point; and the only explanatory statements made by him lead us to infer, that he considered the difficulty to be in the convergency. "This tendency," he remarks in one place, "to a distant convergency is so rare that I have met with it only in one person," and as the ordinary binocular slides could not be used on account of their size by the method of distant convergency, there was no advantage gained by its use, over the other ocular method. The difference between the two arises no doubt, from the fact, that the points of accommodation and convergence more nearly agree in one case than in the other, for when the similar points are nearly the distance between the eyes apart, the axes will be nearly parallel in passing through them to a more distant point; but when the pictures are transposed, the point of convergence will be between them and the eyes, the accommodation of the eyes will be about the same in both cases. When the pictures are separated by a distance equal to, or greater than that between the eyes, it will require effort, as in the preceeding cases to prevent the axes from converging, and for similar reasons. Those, who have overcome this difficulty by continued exertion, will perhaps remember that, even after they had succeeded in producing three pictures, or rather in reducing the four, by causing the two interior ones to coalesce, there was an indistinctness, a hazy, atmospheric appearance, although the relief was evident; that sometimes there was an instantaneous clearing up, and at other times this took place gradually, just as the habit was overcome suddenly or gradually, and the eyes were permitted to accommodate themselves to the pictures, whilst the axes remained in the same position. If, for the photographic pictures of the previous experiments, you substitute two circles of about half an inch in diameter, they will be more readily caused to overlap, by converging the axes either to a nearer or more distant point, probably because there is so little about them to invite that involuntary scrutiny by the eyes, which causes the axes to converge to the point observed. In uniting pictures by convergence to a point beyond them, it is of assistance frequently to look at a distant object, and introduce gradually the slide before the eyes; but when the distance between the points to be united equals, or exceeds, that between the eyes, we cannot be assisted in that way. In some such cases, when persons have succeeded in obtaining the relief, it has been by staring at the pictures, as if gazing into vacancy, as is done sometimes in resting mind and body, or when the mind is abstracted in thought, and persons and things are stared at, but not noticed, the visual organs being inactive, whence it also seems that the normal state of the axes is that of parallelism. In this case, as in the preceding, the complete effect generally follows a hazy appearance.

Having obtained the control over the eyes necessary in the previous experiments, it will be easy to acquire the power of uniting pictures farther apart, or of rendering the axes divergent, or rather convergent to a negative point. The best method is to take an ordinary stereograph, and cut apart the right and left pictures, put them in their proper position, and unite, and separate them by a gradual motion, the axis will remain fixed upon the similar points, and follow them, although you will be unconscious of any change, and the point of accommodation of the eyes will remain the same. If difficulty is experienced in uniting them in their proper positions, they may be allowed to overlap a little at first. When a separation of three inches is passed, in the above experiment, a change will be felt, and probably during the first trial all will become confused at three and a half inches, but up to that point the stereoscopic effect will be complete. By practice I have acquired the power of uniting the ordinary binocular slides as readily without as with an instrument, and by the method just given have experimented on the limit of separation of the pictures for my eyes, and afterwards by means of larger photographic pictures produced for the purpose. I found at first, that it required effort to overcome three inches, but by prolonged practice atdifferent times, I increased the distance to four inches. Exercise of this kind is, however, uselessly severe; further experiments in that direction were therefore abandoned, and the limit now appears to be three and a half inches. After an hour's exertion, as above, great difficulty was experienced in reading; it required conscious effort to prevent the letters from becoming double; the habit of converging the optic axes to the point of accommodation had been so broken that it became necessary to retain them in position by a decided effort. In reading old books, the old-fashioned s'es were peculiarly annoying, as they invaribly doubled, and when anything unusual or difficult was met with, as, for example, the rendering of a word in translating, the eyes immediately attempted to assist in overcoming it, by turning the axes, in all directions, causing the letters and words to march and countermarch from right and left.

No such effect results from a moderate amount of exercise in using the ordinary stereographs. The weariness of the eyes in all the preceding cases is not wholly due to the unusual character of the muscular exertion, but in part to the fact that the eyes notice many details when the supplementary pictures are combined, that otherwise would be neglected, perhaps even in looking at the scene itself. To take an extreme case: a line may appear to be a blemish, in a single picture it *may appear to have* no perspective position; by binocular examination of the slide, it turns out perhaps to be a twig, which extends far into the foreground, all other parts of the tree having been cut out; there are dots, which turn out to be leaves, and so forth; the eyes instinctively, as it were, run over, and study these, exceedingly multitudinous and minute than Pre-Raphaelite, details of the photographic representations, they work rapidly and severely, and soon become fatigued.

Since convergence of the optic axes to a positive point does not appear to be essential to the perception of relief by means of pictorial representations, it is not simply accessory to the perception of the relief of the objects themselves? Is not the effect in all cases due to the simultaneous presentation of two supplementary pictures to the retina, without regard to the angle formed by the optic axes? The successive convergency theory must at least be modified so as to consider perception of distance dependent merely upon the movement of the optic axes, not necessarily from one positive point of convergence to another. Whether this movement is simply a criterion by means of which we unconsciously form an estimate of distance by long experience, or whether there is an absolute and necessary connection between this motion and our ideas of distance, so that we *see* and do not *estimate* distance, is a matter of dispute, but there is something so plausible and analogical in Dr. Berkley's theory, which meets all cases of convergence, whether to a positive or negative point, that we insert the conclusion of his argument: "It remains that we enquire what ideas or sensations there be that attend vision, unto which we may suppose the ideas of distance are connected, and by which they are introduced into the mind. And first, it is certain, by experience, that when we look at a near object with both eyes, according as it approaches, or recedes from us, we alter the disposition of our eyes, by lessening or widening the interval between the pupils. This disposition or turn of the eyes is attended with a sensation, which seems to me, to be that which in this case brings the idea of greater, or lesser distance into the mind. Not that there is any natural or necessary connection between the sensation we perceive by the turn of the eyes, and greater or lesser distance. But because the mind has by constant experience, found the different sensations corresponding to the different dispositions of the eyes to be attended each by a different degree of distance in the object."*

These views of Dr. Berkley's, Sir David Brewster, however, considers totally erroneous, and contends that our perception of distance is not the result of experience.

## Correspondence.

### FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

*Paris, 17th September*, 1862.

M. Roussin has published some interesting observations upon the various salts of silver applicable to photography. He has lately given much attention to albumenized plates, and the best conditions for success in this branch of photography. In seeking to modify the proportion of iodide usually introduced into the albumen, he remarked, that within certain limits the time of exposure varied in the inverse ratio to the quantity of iodide added. The greater the quantity of iodide, the less time is required for the light to impress a plate sensitized, washed, and dried. He also remarked that, by considerably diminishing the proportion of iodide, and proportionally increasing the time of exposure, he obtained images as vigorous, and blacks as intense as with stronger doses of iodide. This observation naturally led him to enquire if the presence of iodide of silver was really indispensable to the formation of the photographic image, as hitherto supposed. It was very easy to solve this question. He took the whites of new-laid eggs, and beat them into a froth without adding any foreign substance, and next day covered several well cleaned plates with it. These plates, dried, immersed in a fresh bath of nitrate of silver, strength 8 per cent., and washed during four hours in several waters, then dried, were exposed in the camera and developed in the ordinary manner, with gallic acid and nitrate of silver. The time of exposure was double or triple that of an iodized albumen plate. The picture obtained was extremely vigorous, the blacks were unusually intense, and a perfect harmony in the landscape was preserved. The positive proofs obtained from these negatives were remarkably delicate, and entirely free from the pin-hole spots which so often invade the best albumen negatives.

This singular fact, of a perfect picture obtained under the ordinary conditions of photography without the aid of iodide of silver, naturally led M. Roussin to enquire if certain salts of silver, did not, like the albuminate, possess the property of being reduced by the action of gallic acid after exposure to light. Chemists must have long known that iodide of silver prepared in the dark and mixed with gallic or pyrogallic acid and nitrate of silver keeps for a very long time without undergoing any alteration, while this same iodide, exposed during a few seconds in the test-glass which contains it, to the action of solar light, is energetically reduced by these same substances.†

This ready method of testing the photogenic property of the insoluble salts of silver is general, and permits our readily premising those which may advantageously be mixed with albumen before sensitizing to replace the alcaline iodide. Every experiment consists—1st. In placing in complete obscurity, and putting into a perfectly clean glass, a neutral solution of nitrate of silver, then adding some drops of any organic or inorganic salt capable of determining a precipitate in the nitrate of silver: it is important for the nitrate of silver to be in slight excess to be assured that none of the precipitating salt remains in the supernatant liquid; 2nd. To expose this mixture to the sun for a few minutes, and shake it; 3. To take it back into the dark room, and then to pour into the glass either gallic or pyrogallic acid. It is well to solarize only one half of the mixture, but to add simultaneously to the two portions the same proportion of pyrogallic acid, to judge with certainty of the true alteration caused by light. M. Roussin made some experiments in this direction; the oxalate, tartrate, succinate, benzoate, carbonate, phosphate, and arsenite of silver, &c., are energetically reduced by a solarization of a few seconds, and may be employed like the iodide of silver itself, with less rapidity, doubtless, for obtaining photographic pictures. This new path may lead to advantageous results. Perhaps, among the considerable number of insoluble precipitates of silver, substances will be found more specially impressionable by some rays of the spectrum, and capable thereby of being modified under the influence of certain hostile hues, green and yellow, for example. Perhaps we may find among the very unstable combinations of silver a substance more sensitive than iodide of silver itself.

Whatever it be, it is well ascertained that the employment of the iodides is not indispensable for obtaining images, and that the albuminate of silver well washed and dried, is decomposed like the iodide of the same base under the influence of light, and yields remarkable negatives.

In a note presented to the Academy of Sciences, from M. H. Claudet, on the substitution of formic acid for acetic acid in the developing solution, the following advantages are claimed for the former:—

1st. The image appears as quickly as with the protosulphate of iron and with greater intensity.

2nd. If the exposure has been well timed, there is no necessity for intensifying the negative, as is generally done when protosulphate of iron is employed.

3rd. The exposure is one-sixth of the time required for the ordinary process with neutral bath, and the developer of pyrogallic acid and acetic acid.

We may readily conceive, that if a picture can be obtained instantaneously under the glass roof of the operating-room, and at a distance of twenty-five feet, a process of such great rapidity must be very useful for fixing the images of moving objects.

### THE GLASS ROOM—MODES OF LIGHTING.

Sir,—I have been for some time past contemplating the erection of a glass room, and although, as an amateur, I shall require it chiefly for taking copies of various works of art, I should like it to possess the form and arrangement by which I may also secure well-lighted and pleasing portraits of my friends.

On examining the various authorities for advice as to the best plan, I am a little bewildered by the general vagueness of the instructions given. In Mr. Lake Price's book I find some useful hints, but he is not very precise as to the amount and position of the glass required. In your own pages, of which I have been a constant reader, I find a very valuable article on the details of construction, from which I intend to profit; but the article does not enter into the question of lighting in its artistic bearings. I have, however, gathered, from time to time, many useful hints on this part of the subject, scattered through different numbers of the News. Some time ago I read a very clear article on the subject, by Mr. Sutton, which appeared to me, at the time, most in accordance with good sense of any which I had read; but from a subsequent remark in your pages, in answer to a correspondent, I gleaned that you did not quite agree with the plan

* An Essay towards a New Theory of Vision, by George Berkley, M.A., Dublin, 1792.

† It is essential that the iodide of silver be perfectly washed, or, at least, that it contains no trace of alkaline iodide before solarization. It is also preferable to leave in the supernatant liquid a slight excess of nitrate of silver.

proposed. Whilst recently discussing the matter with a friend, he placed in my hand a copy of your "Liverpool Contemporary," containing "A Chat about Glass Houses," by Mr. A. H. Wall, in which he gives a diagram, similar to that you gave some months ago, of the glass house of Mr. Fitch, without side light at all, of which he speaks very highly. He also strongly recommends the use of a front light upon the sitter, and quotes examples in confirmation of his opinion.

Now, sir, notwithstanding the vagueness of which I have complained amongst other writers, I have found them all agreed in two things, namely, the importance of avoiding a front light, and in the value of a proper amount of side light. Mr. Wall says he is the first to recommend a front light; but I am sorry he does not give his reasons for the recommendation. He says it serves "to secure roundness;" but that is just what all other writers have stated it does *not* do; flatness being regarded as its general result. Will you be so good, then, as oblige me with answers to the following questions:—

1. Is a northern aspect absolutely best, and why?

2. Is there sufficient advantage in the use of white glass over green to justify the extra cost?

3. Is a side light absolutely necessary, and why? Is top light absolutely necessary, and why?

4. Do you think, from the authorities Mr. Wall quotes, or his own opinion, that a front light is desirable?

5. Do you approve of Mr. Sutton's plan of a glass house, given in his *Notes*, September 15, 1861?

As I wish to get the best house I can with the least trouble and expense, I shall be glad to receive an early answer in your columns.—Your obliged reader, H. G. B.

*Kensington, September 2nd*, 1862.

[The vagueness, of which you complain, doubtless arises from the impossibility of laying down absolute rules for application in varying circumstances. It generally happens that glass houses have to be built to suit the exigencies of the position, not as the photographer would *choose*, but as he *can*, and individual judgment must generally be used to meet each case. We have not space here to enter into the subject at large, but will answer your questions categorically.

1. A northern aspect is, undoubtedly, best, and for many reasons. It is generally a pure, steady light, casting no direct, abrupt shadows, and, unlike the south or other quarter from which the sun directly shines on to the sitter, it is not subject to troublesome fluctuations from passing clouds, rendering perpetual variation in the time of exposure necessary.

2. A great deal of actinic light is, unquestionably, stopped out by green glass; but it unfortunately happens, that white glass is apt to turn yellow by exposure; it is doubtful, therefore, whether the advantage gained by its use is commensurate with its cost; especially, as in building a house, you can have more glass to compensate for the loss by colour.

3. A side light is most important to good results: a portrait taken with direct vertical light is generally far from pleasing. Wherever it is possible, the room should have glass in the sides; but where it is impossible, then the room should be large enough to make the light from the top virtually a side light. In the room of Mr. J. R. Williams, referred to, he is enabled from its large size, and by closing completely some of the many blinds at the top, over the head of the sitter, to allow the light to fall on the sitter much in the same way as if it were from a lofty side light. A top light is not absolutely necessary; but if it be absent, the side light should be very lofty to compensate. You require, in truth, facilities for allowing the light to fall upon the sitter at about an angle of 45°, more or less, as the character of the model may require, and it is immaterial whether the light enters at the roof or sides, if the proper angles be secured. For card portraits a greater proportion of direct side-light is required than for large heads.

4. All the light which falls on the sitter should be, in a certain sense, front light: that is, it should fall from various parts in front of the sitter. If, by front light, you mean a window in front of the sitter, we decidedly disapprove of it. All the top light, and much of the side light, may be front, and if there be a window in front, but 8 or 10 feet from the ground, that is permissible. But all light striking the sitter at an angle with the floor of, say, less than 25° or 30°, we should regard as injurious, giving a flat effect to the face, and most disastrous to the expression of the eyes. It is always desirable that the sitter look into darkness, if possible, not simply because it is easier and aids in producing a better expression, but because the pupil will be more dilated, and will, in the photograph, look darker and brighter. With light directly in front of the eye, on the other hand, the pupil contracts, and the eyes look small, light, and poor. The front light in the glass-houses of Mr. Window and Mr. Fry, is there from the necessity of the position, not as a matter of choice. In Mr. Window's it is of dark blue glass; and in both of them, it is not only a considerable distance from the model, but the model is always placed in such a position with regard to it, that it becomes, practically, a side light.

5. We consider Mr. Sutton's plan the best, in principle, that we have seen proposed. The objection we made to it was, simply, that in the proportions given the light admitted would be insufficient for use in large towns. The late Mr. Lacy, who had the most clear and precise views on lighting the model, of any photographer with whom we have met, stated to us, that if he had another glass-house to erect he would build it upon this principle, slightly modified. We regret that, by his untimely end, our readers lost some papers on the principles and practice of lighting, of which he had just commenced the preparation.—ED.]

## PRINTING DIFFICULTIES.

SIR,—Having in my last letter endeavoured to prove that the presence of free nitrate of silver on the surface of the paper causes mealiness, I shall now briefly consider the conditions which qualify it to act.

Strictly speaking, this salt is insensible to the photogenic action of sunlight; yet, strange to say, from experiments made, I find its presence is absolutely necessary to produce a satisfactory image on the surface of the paper; this fact, at first sight, would appear an unfathomable paradox, but a little consideration enables us to see through the matter more clearly. The fact of our being able to remove by washing all traces of free nitrate from the paper before its exposure proves that up to that time it exists in an independent and inert condition; but when brought into contact with actinic light, immediately a portion of the salt enters into a combination which no amount of washing can remove.

Several months since, whilst studying the singular properties of light, I imbibed the idea that what we are accustomed to term actinism is nothing more than an electrical action; that idea recent research bids fair to prove correct. Now, sir, I believe the combination spoken of to be effected by electric influences, the two salts (chloride and nitrate of silver) being necessary to produce the action and reaction which ultimately change their character, and they are united into one, thus forming the coloured substance which gives stability to the picture.

The beautiful laws which govern atomic combinations teach us that these chemical changes are not under the precarious government of chance. Atoms unite with atoms in regular undeviating proportions, which go to prove, in the case now under notice, that when the chloride of silver a paper contains has combined with its chemical allowance of free nitrate, be the sensitizing bath strong or weak, not one atom more will it exercise an influence on; what remains must exist as a free salt, or it must seek a connection elsewhere. But another difficulty here presents itself, which, if left unanswered, must upset all my former arguments. Free nitrate of silver, I repeat, is not affected by light; true, but the most humble artist who fathoms his difficulties by adding a little more "hacid to that 'ere bath," has always at his finger ends sufficient evidence to prove that this salt, when brought into contact with an organic substance, immediately becomes a sensitive medium; and cannot we find an organic companion for the free nitrate that chlorine has turned her back upon? Most assuredly we can, we have the paper itself, and, in addition to this, the albumen; this last, in my opinion, is its chosen companion, their ties of friendship being regulated by the intensity of light which cements them, and from this intimate connection springs an oft repeated source of mealiness: the thicker the layer of albumen, if a chloride is not added in a proportional quantity, the more virulent the disease. Taking these remarks into consideration, the term free nitrate I have hitherto employed, may, perhaps, be more appropriately termed an excess of albuminate of silver; a portion of this last salt is necessary in giving colour, but the boundaries are too wide to allow the albumen to take its fill without interfering with the surface of the finished print; for this excessive supply must be removed ere the gold is permitted to act evenly, and this fact, I am happy find, you have proved in your very interesting experiments, although you have anticipated the remarks I intended to introduce with the toning bath. I shake hands with you, sir, and tender my thanks for your influential endorsement to the correctness of my remarks, "a short floating, followed by a weak toning bath gave clear pictures." Why? because the surface impediment was removed fast enough for the gold to work evenly. Again, a portion of this last substance was added to the bath uncombined with the reducing agent, and mealiness ensued; for what reason? because the subordinate had become the master, the gold acted quicker than the pioneer could keep up with it, and, consequently, was deposited on an uneven surface; the addition of a little acetate of soda would have restored the balance, and all would have gone well. Hoping you will excuse the liberty of these remarks, I shall be glad to hear that you are continuing your researches in this interesting field. I hope to continue the subject next week, if not trespassing on your space.—Yours respectfully, A Photo's Assistant.

## Photographic Notes and Queries.

### Crowded Accessories in Card Pictures.

Sir,—I am quite satisfied with what I believe to be your honest and candid opinion of my photographs, in your News of September 5, to which I refer, although by difference of opinion expressed, we may arrive at right conclusions. You say that there is a little overcrowding of accessories in my photographs, and your opinion being generally in favour of plain back grounds, which I believe to be a popular error, is my apology for writing to you as an artist and photographer of twenty years daily study and practice, I beg to submit that the accessories in one of the cards sent to you, of the gentleman standing, was not subdued enough to represent well what was intended; for the others I have no apology to offer, as I believe them to be correct.

I think that a plain background may do for busts and vignettes, &c., but to desire a full length portrait in an unfurnished room, or worse still to my feelings, standing against an unmeaning plane, a thing only to be found in the glass house of a mechanical photographer, I think ridiculous, for the following reasons: first, I can never find such in the works of the great masters; and that the inhabitants of this world should be represented as they really are in connection with the things thereof, even the birds of the air have the sky and the hedge for a background, for without which, either exterior or interior, I think the figure intrusive, and can have no relative position, except between the extremes of something and nothing, which if you will allow your fancy to go with me, as in my imagination it looks like a man out of the world, and the inhabitants of other worlds looking at him, as an over conspicuous individual, who has nothing about him to connect him with any world, and everything in subordination to the same individual.

The true artists, whether in photography or otherwise, ought, in my humble opinion, before they have pretensions to art, be capable of connecting their sitters with places and things suitable for their position in life, their manners, habits, &c., whether in the well furnished apartments, the crowded street, or from the lake to the mountain top, all is required, and by a careful manipulation, proper lighting of the subjects, and the relative positions of sitters, the whole can, will, and ought to be, made use of by the artist photographer.—Yours respectfully,

*Carlisle, September* 12, 1862. F. W. Bannister.

[Without entering here into the discussion as to the respective merits of plain and pictorial backgrounds, we must remind our correspondent that his arguments only support the *use* of accessories; whilst our remarks referred to their *abuse* or "overcrowding." We never object to the judicious use of accessories for securing harmony and balance in a picture; but we contend that they should be always kept in proper subordination. The eye should not have to wander over a variety of objects, and then discover incidentally that there is a man or woman amongst them. Our correspondent's specimens were good and well composed, but some of the accessories were, to our taste, too prominent. A communication from another artist in the present number, has some remarks to the purpose on this subject.—Ed.]

### Instantaneous Dry Plates.

Sir,—In the search after a rapid dry process, I do not think sufficient attention has been given to the fact that this has been completely and satisfactorily discovered by Dr. Hill Norris. I am, myself, an advocate for the wet process; and, living by the seaside, have been forced to take instantaneous pictures, as the only means of catching the rapidly changing beauties of water, mountain, and sky. But I am compelled to admit that there are things attainable by his plates that I could not otherwise have accomplished. Of course I also believe a wet plate would beat his, where I could bring it into competition *under equal circumstances*. But how often have I gone into the dark room, with exactly the proper lights and shades in nature, and came out with my wet plate, to find all the effects reversed by a change of clouds! With the other, I could wait patiently till the propitious moment arrived.

I also enclose you a print, taken in a gale of wind, with stones placed on the camera to keep it down, the instrument deluged with spray, and, altogether, under difficulties that would have hopelessly made wet photography too wet for success. It was taken last October, without direct sunshine, as you will observe, from internal evidence.

Can no plan be suggested by which this most valuable process can be secured to the public? I, for one, feel humiliated at having to purchase instead of making my plates.—Your obedient servant, Hercules Macdonnel.

*Sorrento, Dalkey, County Dublin, Sept.* 12, 1862.

[The specimen enclosed contains a rocky foreground, with boiling surf dashing against it, and angry sea beyond; in the extreme distance are well defined hills and stormy clouds. The foreground is a little black, but all the rest is well exposed. The exposure has been quite instantaneous, and the effect is very grand. We are compelled to admit, however, that we hear of occasional cases without such success. Something more should be known as to the conditions of success, even if the secret of preparing the plates remain undivulged, as we fear is at present only too probable. Dr. Hill Norris has promised us a communication shortly, which will doubtless throw some light on the subject.—Ed.]

### Formic Acid in the Developer.

Sir,—In my last note to you I said that I had tried the use of formic acid in the negative developer, as given by M. Claudet, but without the addition of nitric acid to the bath; but the pictures I obtained were always slightly fogged, therefore I added nitric acid, rather less than the given proportions, which made it necessary to lengthen the exposure considerably, and rendered it almost impossible to obtain sufficient density, without the addition of silver to the developer, which the formic acid deposits in metallic particles on the plate, and therefore renders it useless; I have tried both bromo-iodized and plain iodized collodion, separately and mixed, but not Thomas's, as was recommended, as I wished, if possible, to avoid the expense, having some of Fisher's by me at the time.

I find that the picture appears immediately the developer is applied, but is completely fogged long before sufficient density is obtained, which I at first attributed to over-exposure, but on trying a little shorter period the picture did not come out at all; can you, or any of your readers, oblige by telling me where I am at fault. B. G. P.

[We can only suggest that the bath is out of order, probably containing organic matter. This, with the heat of the weather, would induce a tendency to fog. If the tendency exists from other causes, formic acid would probably increase it, having itself a reducing tendency.—ED.]

## Talk in the Studio.

THE PHOTOGRAPHIC "OUTCAST."—The editor of the *Photographic Notes* says: "The meanness of the recent attack on the NEWS by the *British* is quite characteristic of that journal. There are four English journals of photography, three of which are in harmony, and the fourth an outcast. The meanness, buffoonery, and vulgarity of the latter have rendered it an outcast, and its hand is against its rivals. One day it contains a timid side blow at the *Notes* in an answer to a correspondent; another day 'our esteemed and excellent friend Dr. Diamond' has a leader of his pulled to pieces in an ill-natured way; another day the NEWS is charged with unfairly copying without proper acknowledgment; and so on. This sort of thing, and the acute business talent of the proprietor, which sometimes shocks people, and renders legal interference necessary (as in the case of the usurpation of the title of the *Photographic Society's Journal*), have rendered the *British Journal* an outcast, and I verily believe that, when to its agreeable features of meanness, vulgarity, and buffoonery, you add ponderous editorial twaddle and conceit, you have in the *British Journal of Photography* a newspaper without parallel in the English language. Query, could Mr. Greenwood's last effusion have found a place in any other journal in England?"

TAXATION FOR PHOTOGRAPHERS.—The *American Journal* says, in the number for September 1;—To day begins the *regime* of taxation. Photographers, like the rest of business men, must fork over for the benefit of the Govenment; we hope they will do it with good grace, and make it up with the public if necessary. Also, photographers like other able-bodied men, must stand the chance of being obliged to go soldiering. But we hope to hear no complaint; it is the only sacrifice of the sort for the country in our lifetime; the end in view is peace and prosperity for ever.

EARLY PHOTOGRAPHIC OPERATIONS.—A "Constant Reader" sends us the following:—"Perhaps the following, which appeared in *Notes and Queries* last week (3rd S. 11, 127), may be appropriately transferred to the pages of the PHOTOGRAPHIC NEWS. 'In 'Rational Recreations,' vol. iv. London: 1774. Recreation 43. Writing on Glass by the Rays of the Sun. Dissolve chalk in aquafortis to the consistence of milk, add to that a strong dissolution of silver. Keep this liquor in a glass decanter well stopped. Then cut out from a paper the letters you would have appear, and paste the paper on the decanter, which you are to place in the sun, in such a manner that its rays may pass through the spaces cut out of the paper, and fall on the surface of the liquor. The part of the glass through which the rays pass will turn black, and that under the paper will remain white. You must observe not to move the bottle during the time of the operation.'"

A LEARNED DISQUISITION ON PHOTOGRAPHY.—The following was delivered by Mr. J. Toole at the Royal Dramatic College Fancy Fair at the Crystal Palace, during the operations conducted by him and Mr. Paul Bedford in their photographic hut:—"Amber, or oxide of cadmium, is a vegetable substance obtained from mustard and cress, grown in a warm situation, on a blacking bottle, constantly kept damp with paregoric elixir. In three days it forms into small berries; these are then subject to the gas evolved in the decomposition of the fero-sesquiquequadrate of the cyanuret of potassium; and if carried further, becomes a dry crystallized bicarbonate in the shape of a small white powder, which forms the Epsom salts of commerce: and when calcined with equal portions of gunpowder and cold cream, is known in the Arts as Photos! To produce our rapid pictures you must get a spoonful of germinifluous mixed with a few tried postage stamps, together with a little klatuka. Hold the glass to the fire for five seconds, then gaze earnestly on it for a minute; the picture is then perfect. You can "*see it at a glance;*" and then, to use the words of Lord Byron, "*There you are.*"—*Builder.*

## To Correspondents.

R. N. S.—The best mode of removing a mounted print from its card-board, in order to place it in an album, is to place a piece of blotting-paper of the same size, soaked in water, upon the print, and leave it for a quarter of an hour. It will generally be found easy, then, to lift the print away from the card. If the adhesive material do not yield to cold water, hot water may be used.

TANNIN.—Various articles on celestial photography have, from time to time, appeared in the NEWS. An interesting paper on the subject, by Warren De la Rue, will be found on p. 438 of our fifth volume.

J. H. W. H.—Salted paper is best floated for a short time on a strong silver solution: say two minutes on a 60-grain bath. The best plain-paper prints we know are those of Hennah, of Brighton, of which examples may now be seen in the International Exhibition. They are excited on the ammonio-nitrate silver bath. 2. The enlargement of negatives is too extensive a subject to be described in this column. An article on the subject will be found in the PHOTOGRAPHIC NEWS ALMANACK for this year. A paper on it, read by Mr. Vernon Heath, at the Photographic Society, appeared in our columns a few months ago. We shall, probably, have another article on the subject shortly.

YOUNG PHOTO.—We have repeatedly described the method of recovering the silver from the washing water of prints. First, precipitate the silver in the form of a chloride, by adding common salt. After standing a few hours, decant the clear water and dry the white powder, at the bottom, which is chloride of silver. Place this in a crucible with double its weight of a flux, such as borax, or a mixture of carbonate of potash and carbonate of soda. Subject the crucible to a very great heat, which will reduce the silver to the metallic state. It will be found in the form of a button, at the bottom of the crucible.

H. B.—Without knowing something of the process or manipulations used, we cannot even suggest a cause for the imperfect toning of your prints. From appearance we fancy the paper is in fault.

JOHN H. UNDERWOOD.—Your charming stereographs received. We will notice them shortly.

J. C.—You are right in your conjecture as to the best lens for the purpose. We do not believe it can be equalled at a less cost. For your purpose, however, especially if the price be an object, the No. 1 of the same maker might answer. We know many who use it with perfect success for card pictures. The stereoscopic lens requires too small a stop for such a purpose, to be sufficiently rapid. 2. The use of a small central stop in portrait lenses is apt to produce the disc of light in the centre, of which you complain, especially when pointed to the light. When it is necessary to use it under these trying conditions, paint an annulus of black round the posterior surface of the front lens, or fix an annulus of blackened card in contact. This will probably prove a remedy.

JUSTITIA.—If you forward us one or two prints we can better judge of the defects of which you complain, and help you with our advice as to the means of remedying them.

CASSANDRA.—The best mode of removing the earth from your powdered metallic silver (the settlings of developing solutions), will be simply to wash it, when the earth being soluble will be removed, and the metal remain. 2. The use of alcohol in the ammonia nitrate bath is said to prevent discolouration to a large extent. The use of citric acid would probably be the best mode of discolourizing, by causing a precipitate of citrate of silver, which will take down with it the colouring matter. Then add a portion of a stronger solution, made as at first.

THICKHEAD.—The formula by which you state the prints are produced, ought to give good results. We cannot suggest the cause of their unwillingness to tone, unless the paper be faulty. So far as we can judge, however, you do not print sufficiently deep to get good tones. 2. There are a variety of holders for the plate whilst developing. Mr. Solomon makes one, which is, we believe, efficient.

P. L. F.—Scotch glue is used for mounting by most professional mounters. A sponge is more convenient for applying it smoothly to photographs than a brush. The advantage of glue is, that it admits of the print being rolled at once, and affords facilities for greater despatch.

BI-CARBONATE OF SODA.—A correspondent, whose letter is at this moment mislaid, asks if carbonate of soda and bi-carbonate of soda are not the same thing, and if so, why the matter is complicated by the use of the prefix *bi*. Our correspondent should remember, that as a general rule, all variations in scientific terminology imply a distinction of some kind, and it would be useful to the humblest of our readers, to possess for reference, if they have not time for study, some elementary work on chemistry. We can recommend that published in Chambers's *Educational Course* as simple, comprehensive, and cheap. The prefix *bi* always implies that two atoms of the substance to the name of which it is attached, are united to one of the base. Thus in bi-chloride of mercury there are two atoms of chlorine united to one of mercury. In bi-carbonate of soda there are two atoms of carbonic acid united to one of the base. The bi-carbonate is a feebler alkali than the carbonate.

FRED. DAVIS.—See article on the subject of a red deposit on the shadows in the NEWS for August 1.

J. H.—The difficulty in taking life-size photographs direct is an optical one. It would be difficult to make a lens to do the work anything like well, with any approach to a reasonable exposure. The cost of such a lens would be enormous.

BEWITCHED BATH.—Negatives intensified with bichloride of mercury, and blackened with hydrosulphate of ammonia, or hyposulphate of soda, are sometimes acted on, both by light and by the atmosphere, but more by the latter than the former. When well varnished we have not found them alter, although we have heard of cases in which they did so. We are glad you found our advice help you out of the difficulty. We have not had time to examine the plate carefully yet.

W. H. H.—To strengthen your toning bath add more unused solution, made by the same formula. Always keep sufficient mixed, ready for use a few days beforehand.

FRED. DAVIS.—Silver flashed glass will do whenever it may be obtained. The last good sample we saw was got of Mr. Rouch.

Several correspondents in our next.

A communication from Mr. Harmer on "Double Printing," and one from Mr. Cooper on "Printing on Resinized Paper," with several articles in print, are compelled to stand over till next week.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 212.—*September* 26, 1862.

## IMPROVED METHOD OF PRINTING.

We call the attention of our readers to a communication on another page. which. if we rightly appreciate it, is likely to effect a revolution in the method of preparing paper for positive printing, in which we hope that albumenized paper will, if not entirely superseded, retire into its proper position, as useful for exceptional purposes, but by no means the proper material on which to produce artistic photographic pictures.

We have often stated our conviction that the capability of admiring, or even tolerating, pictures on albumenized paper was an acquired taste. We believe that most persons of taste are agreed that the glazed surface for pictures in monochrome is essentially vulgar in effect. Very few photographers like it for its own sake. They tolerate it, because they have become accustomed to it; and they have suffered themselves to become accustomed to it, because, in spite of the objectionable glaze, certain desirable qualities were secured in the prints, which were not easily, otherwise, attainable. It aided in rendering more accurately than plain paper the delicate detail of the collodion negative; and, by keeping the image on the surface, it aided in producing more brilliant and vigorous prints. These were desirable qualities, and, in virtue of them. albumenized paper has gradually taken position as the recognized material for photographic prints.

The introduction of the alkaline gold toning process aided in giving it a more permanent tenure. It became possible to produce pure whites in place of the cheesy tint, which at one time prevailed, and which, when combined with the vulgar glazed surface, rendered albumenized prints intolerable. Since the *furore* for card pictures has prevailed, the necessity for the albumenized surface to register the delicate gradations in these small images, has become more than ever recognised.

Nevertheless, we should like to see albumenized paper fall into comparative disuse. For large portraiture, especially for large heads, it is most inartistic and unsatisfactory, as well as unnecessary. For photographic landscapes it is not less so. For reproductions of paintings and engravings, it materially destroys their value and artistic character. For solar camera pictures it has, fortunately, never to any extent been used, nor should be for any style of photograph larger than a stereograph, or album portrait. The pure, rich, deep velvety black of a mezzotint engraving, with its delicate gradations into a dead white, are, surely, to everybody's perception, superior to the gaudy brilliancy and offensive glaze of the best albumenized print. As Mr. Sutton said in a paper on the subject some seven or eight years ago, "A print on plain paper may be dead, foggy, inky, sunk in the paper, &c. &c.. but, in its most unhappy state, it does not look *vulgar*; there is always a certain *sentiment* about it, even in its very worst phase of failure."

Mr. Henry Cooper, jun.. describes on another page a new method of preparing plain paper, by which, we believe, dead, inky, sunken-in prints may be altogether avoided. and rich prints with the texture and colour of a mezzotint engraving secured. The specimens he has forwarded with the article, although the results of early experiments. and produced, in some instances, as he states, from imperfect negatives, possess qualities which justify us in believing that all the characteristics desirable in photographic prints may be obtained. The surface is fine, hard, and close in texture, with just such an approach to gloss as is obtained by rolling, or burnishing at the back, plain paper. The image is perfectly defined, registers the sharpest lines and most delicate gradations in the negative, and is of a rich deep black, free alike from inkiness or redness. In some the lights are quite white, whilst in others the resin has communicated the faintest approach to a cream tint in the lights, quite distinct from the yellowness produced by sulphur toning, and more nearly approaching the colour of India paper—a tint very desirable in the light of a portrait. We apprehend that, although the specimens we have received are black in tone, any gradation of warmer colour may be secured by those who may prefer such tints. We conceive that for artistic effect, the texture of surface, the colour, and the vigour of the prints will leave nothing to desire.

Regarding the permanency of such prints, we should conceive, *a priori*, that they furnish ground for a much stronger assurance of their stability than prints by other processes. Albumenized paper has not certainly conduced to the permanency of photographic prints, if it has not contributed, as some suspect, to the facility with which they occasionally fade. Paper, saturated with resin, as a basis of operations, affords, in its own nature, a strong guarantee of its power of resisting many of the causes of decay, one of the most active and insidious of which is damp. It will. probably, moreover, be much more readily cleared from all trace of the hypo fixing bath, which clings with such tenacity to the fibres of a material readily permeable by aqueous solutions.

As regards the photogenic character of the combination formed by the contact of nitrate of silver and gum benzoin, little is known at present; Mr. Cooper states that the paper is more sensitive than albumenized paper, and the tone and quality of the image decidedly indicate the presence of some other silver compound beside the chloride. Benzoin contains benzoic acid, and some portion of benzoate of silver will doubtless be formed, a substance of which little is known, but which certainly belongs to a series readily blackened by light. But if the preparation only served to close the pores of the paper and keep the image on the surface, it would aid materially in obtaining brilliant prints.

Not a trifling element in the advantages which seem to be presented, is the increased facility it affords in various of the manipulations. The paper is prepared by immersion, instead of floating, in the alcoholic solution of benzoin and chloride of cadmium, and if any streaks or irregularites appear in drying, they can be removed by a subsequent immersion. The paper being entirely saturated with the resin, is, unlike albumenized paper, free from the tendency to curl up at any stage of the operations; Mr. Cooper, it will be seen, is willing, in order to facilitate experiment, to furnish samples of the paper at a price which can barely reimburse him for expenditure.

It is a somewhat singular circumstance, that the letter of our Paris correspondent a month ago, informs us of the experiments of a French operator in a similar direction. About the same time we received a communication from Mr. Cooper, informing us that he was experimenting with benzoin and other resins, in preparing paper for positive prints, and we know that he has been for some time past engaged in dry plate experiments with the same materials. This is another curious illustration of contemporaneous experiment in parallel directions in different countries. We shall be glad if our French *confrères* aid in giving precision and value to the process on the Continent, by their practical and experimental skill. If general practice and experience endorse the results already obtained, we repeat our conviction that a revolution will be speedily effected in the preparation of paper for positive printing.

Whilst referring to artistic printing, we cannot omit to call the attention of our readers to a short communication in the present number of the News, from Mr. Harmer, on double printing and vignetting, in which he describes the method employed in producing the specimens in the International Exhibition, of which we expressed a very high opinion a few weeks ago. We strongly commend the subject to all our readers interested in artistic positive printing.

## PHOTOGRAPHIC CHEMICALS:

### Their Manufacture, Adulteration, and Analysis.

*Lithia Salts* (continued).—*Chloride of Lithium* is not a difficult salt to prepare. The starting point being the carbonate, this is dissolved in dilute pure hydrochloric acid, until the effervescence nearly ceases, and the acid reaction to test paper is only slight. The liquid is then filtered, if necessary, and transferred to a dish placed over a water bath, which is kept heated until the excess of water and acid has been driven off, and the dry salt is left behind. As the contents of the dish become thick and pasty, they must be kept constantly stirred with a glass rod, and when apparently dry, the heat must be continued for some little time longer, until all the hydrochloric acid is driven off; this may be ascertained by holding a glass rod, dipped in ammonia, over the dish; if a trace of free hydrochloric is present in the latter, it will render its presence evident by the formation of white opaque fumes. When all the free acid has been removed in this way, add sufficient distilled water to effect complete solution of the mass, and evaporate again, but not quite to dryness. The chloride will be deposited in the form of cubical crystals, resembling common salt. These are deliquescent in the air, and melt at a dull red heat, volatilizing at a white heat, losing, at the same time, a portion of their chlorine, and becoming converted, by absorption of oxygen and carbonic acid from the air, into carbonate of lithia. When this salt deliquesces in the air, it gradually forms large rectangular prisms with four sided summits, containing four atoms of water of crystallization. When the aqueous solution of the chloride is rapidly boiled down the same salt separates in the form of needles, united together in feathery tufts, like those of sal-ammoniac. Upon being heated, these melt in their water of crystallization, and then dry up, becoming converted into the salt first described. If these feathery crystals are very gently dried, and then thrown upon paper roughly dried, or moved about with the finger, they instantly become opaque, the opacity commencing from the point of contact and gradually extending throughout the whole mass; in this state they fall to pieces on the slightest blow, and form a crystalline powder. Both the latter mentioned hydrated and the anhydrous chloride of lithium deliquesce rapidly in the air, and are very soluble in water and alcohol. When the alcoholic solution is set on fire, it burns with an intense crimson flame. This crimson colour, which salts of lithia communicate to the flame of spirit or gas, is a very delicate test for the presence of the metal, and, in a somewhat modified form, is constantly used at the present time as a test for lithia. Instead of looking at the coloured flame direct with the eye, it is narrowed by placing a slit in front of it, and the flame is then viewed through a prism. The effect of this is to refract all the other colours (such as those given by soda, strontia, &c.) to other parts of the field, and leave the pure red of the lithia unmingled with anything else. This is the branch of analysis to which the name "spectral" has been given. We shall probably recur to this subject before long, for the present this sketch will suffice to show the manner in which it is applied to the detection of lithia salts.

*Iodide of Lithium.*—This salt is coming into some little importance as an adjunct to the usual iodizing agents for collodion. The method of preparation not being detailed in books, we will give it somewhat fully. The best plan is to adopt what is known as Liebig's process, for the preparation of alkaline iodides. One part of phosphorus is placed in a basin, and covered with forty parts of hot water, so as to melt it. When it is liquid, twenty parts of iodine are gradually added with constant stirring, taking care to allow one portion to be dissolved before a fresh quantity is added; violent action takes place, and a great portion of the phosphorus is converted into the amorphous variety, which, however, in no way interferes with the process, as the amorphous phosphorus unites with the iodine just as well, although not quite so fast. The colourless liquid, which consists of a solution of phosphoric and hydriodic acids,

$$P + 5\,I + 5\,HO = PO_5 + 5\,HI,$$

is then poured off from any excess of phosphorus, and baryta water is added, until the mixture becomes alkaline: the whole is now to be thrown on a filter, and the insoluble phosphate of baryta filtered off, and well washed. The solution, which consists of iodide of barium, with a trace of free baryta, is then to be evaporated to dryness over a water bath, with constant stirring, and the dry residue heated to the fusing point. It is now to be redissolved in water, and filtered, when it will consist of almost chemically pure iodide of barium. To this, sulphate of lithia (prepared, as shown in our last chapter,) is to be added in quantity just insufficient to precipitate all the baryta, and the mixture, containing the precipitate suspended in it, is boiled down to about one-half its original bulk. When sufficiently concentrated, it is allowed to cool, and is then filtered through a double thickness of paper. To the filtrate a small quantity of pure carbonate of lithia is added, which removes the last portions of baryta, and the solution being evaporated down, yields pure iodide of lithium. This process is very simple in practice, although somewhat complicated to read, and has the great advantage of yielding a perfectly pure product. Iodide of lithium forms very deliquescent, acicular crystals, which contain six atoms of water of crystallization. They are very soluble in alcohol, and are, therefore, well adapted for employment as an iodizing agent in collodion.

The other salts of lithia are very little known, and are of no special interest to the photographer.

*Baryta Salts.*—The earth, baryta, is of importance, both on account of the special value of some of its compounds, as well as its employment as a test, and re-agent in the preparation of other salts. In the above description of the method of manufacturing iodide of lithium, baryta water is used, and in very many similar operations it is also employed. *Caustic* baryta is best prepared from the nitrate. This salt is thrown in small quantities at a time into a red-hot crucible, the cover being put on, and the heat being well kept up between each addition, until the mass has become quite solid. Too much nitrate of baryta must not be added at once, as the salt is apt to boil over. When the crucible is half-full of baryta, the heat is raised to a bright red heat, and kept there for a quarter of an hour. The crucible is then allowed to cool, and is broken up in order to remove the baryta from it. Baryta in this state forms a greyish-white, porous friable mass. When moistened with water it falls to pieces, and becomes very hot, the heat being often sufficient to raise the hydrate produced to redness, and then fuse it. It forms a white powder, fusing at a low red heat, forming an oily liquid. It dissolves in twenty parts of cold, and in two parts of boiling water, forming a colourless solution, which deposits the crystalline earth on cooling: the cold solution, when exposed to the air, becomes covered with successive films of carbonate of baryta, until, at last, nothing remains but pure water. The best way to prepare the hydrate of baryta in the pure state is to boil some of the caustic baryta produced by the ignition of the nitrate, in water, and to filter the solution whilst hot; the filtrate is then allowed to cool, and the crystals of hydrate are deposited. Some persons recommend mixing the nitrate of baryta with its own weight of heavy spar, previous to heating it to redness. This prevents the frothing up, but is attended with no other advantages. If the operator has not any caustic baryta, he can prepare the crystals by adding potash to a cold aqueous solution of chloride of barium, or nitrate of baryta: the crystals are washed with ice-cold water, or with alcohol, till all the potash salt is separated; they are then dissolved in hot water, and the solution is left to crystallize. Hydrated baryta in this state forms transparent, colourless, four-sided prisms, which contain nine atoms of water of crystallization. When heated to the temperature of boiling water they melt, lose water, and leave a white, friable, residue, containing 20 per cent., or two atoms of water. This, when heated to redness in a crucible, froths up violently, fuses, and leaves hydrate of baryta in a state of tranquil fusion. These crystals, as well as the aqueous solution, are difficult to preserve in the air in the pure caustic state, as they greedily absorb carbonic acid, and become converted into the white insoluble carbonate. On this account baryta water is frequently used as a test for carbonic acid. For instance, if a little of the solution be placed in a test tube, and the breath be blown through two or three times by means of a glass tube, it will become quite thick and white from separation of the carbonate of baryta.

## DOUBLE PRINTING, VIGNETTING, &c.

BY R. HARMER.

Having had several enquiries as to the method adopted in printing the small volume of photographs exhibited by me in the International Exhibition, Class XIV, I will endeavour as clearly as I can to explain my way of working. My object, in adopting this style of printing, has been, to secure the best possible effect from the negative, by printing in a style most suited to its characteristics. The method of proceeding is determined by taking the proof first in the usual way, having done this, and examined the result, should there be any defect in the back-ground, I then print as a vignette, in the following manner:—Place in the pressure frame, outside the plate glass, a piece of brown paper, examining it by the light to see that there are no defects; having placed the negative in the frame, I tear out, in an irregular form, sufficient of the brown paper to give the size vignette required, filling in between the glass and brown paper with cotton wool; a much more effective vignette can be produced in this way than with the vignette glass, which merely gives a shaded oval, not a vignette as understood by engravers. Photographers who prefer the vignette style will do well to study the vignette engravings of Finden.

The proof having been printed the required depth, is now taken from the frame, the brown paper removed, and inside the frame a mask of black paper placed, in which an oval or other shape has been cut, suited to the subject printed, the print is now laid in the frame, care being taken that it is in the right position with regard to the shape of the mask; having screwed down the frame, the glass of which should be perfectly clean, a small piece of cotton wool, slightly damped to make it adhere to the glass, should be placed on the high lights; the proof may now be again exposed to a subdued light, until a tint is produced a trifle darker than the half tones.

When toned and fixed, if these hints have been followed, the result will be a vignette on an India tint ground, with white margin.

Another style of printing is effected by having two ovals or other shapes, cut in black paper, the one to be $1\frac{1}{2}$ inches or 2 inches larger than the other. When the negative is placed in the frame, lay the mask with small oval over it on the varnished side, and the sensitized paper on it, print to the required depth, remove all from the frame, and place next to the plate glass the mask with large oval. Then, the print being carefully laid upon it, is exactly centered, and then exposed to the light, the high lights having been covered up with wool as before directed, until the tint around the proof is of sufficient depth for toning to the shade of India paper.

When a negative gives hard, black and white prints, the high lights may, instead of being protected, be exposed for half the time required to produce the tint, a much more artistic proof will result, in large portraits very much resembling a fine chalk drawing on tinted paper.

If the usual paper be used, mounting will of course be necessary, but for book illustration as in the volume exhibited, paper albumenized on both sides, will do away with the necessity of mounting, and bind up much better.

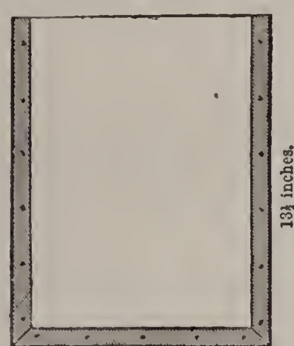
Being but an amateur, working at photography for the love of it, I may conclude by observing, that if the exhibition of the volume in question, and these hints as to the method of working, should lead a few to a more artistic way of printing, I shall feel amply repaid for the time spent in producing both.

## WATERPROOF VARNISHES AND CEMENTS.

### The Nitrate Dipping Bath, and how to Construct it.

BY H. R. NICHOLLS.

Suppose the size of the plate to be ten by eight; select some good wood—*yellow pine*—which should be sound and free from knots. It should be three-eights of an inch in thickness, and cut to the following size:—Ten inches and a half long, and thirteen and a-half inches wide; let it be planed smooth on the insides, that is, the side of the wood which will be the inside of the bath when finished. It is then to be rubbed smooth with glass-paper, known technically by the term of "Middle 2," across the grain of the wood, using a flat piece of cork, about five inches long and three inches wide, as a rubber, over which the glass-paper is held by the hand. It should be rubbed until the wood is quite level and free from ridges left by the plane. It is then to be baked in an oven, not too hot, as the wood must not be scorched. Treat also in the same way three other pieces of pine, three-quarters of an inch square, cut according to the diagram which forms the sides and bottom of bath.



While hot the inside of each piece is to be coated with the pure gutta-percha compound, about the twentieth of an inch in thickness, spread out with a flat piece of wood. Now place one of the thirteen and a half by ten and a half pieces on a flat board, coated side up, and arrange the three strips which form the sides and bottom of bath, upon which place the other piece thirteen and a half by ten and a half, coated side down. Upon these place heavy weights, and allow them to remain eight or ten hours to harden the compound. The next step it must be screwed with five-eight No. 5 iron screws from both sides. It may then be smoothed off on the outside, and varnished with brown hard varnish.

Such a bath I have in constant use, in which the nitrate of silver solution has remained continuously since last November, and keeps in good working condition, seldom requiring to be filtered.

## NEW METHOD OF PRINTING:

### On the Use of Gums Insoluble in Water for Preparing Positive Paper.

BY H. COOPER, JUN.

Some long time back the idea struck me that if we could dispense with albumen, gelatine, and arrowroot in our photographic paper, and employ in their place a gum or resin *insoluble* in water, and giving a moderate degree of gloss to the surface, our prints would be much more permanent than heretofore. After numerous experiments, I have found that benzoin seems to be the best suited for that purpose, either alone or mixed with a small quantity of some other gum.

I will presently give the formula for both methods; but will first call attention to the advantages of the benzoinized paper compared with that in general use.

1st. The simplicity and facility of preparation and cleanliness of the result; spots and streaks of any kind, with ordinary care, rarely occurring.

2nd. The moderate expense, as it can be prepared with the best materials at about half the cost of albumenized paper.

3rd. The extreme sensitiveness, and consequent quickness of printing, which is a great advantage where time is an object. With the proportion of chloride I recommend it also bronzes rapidly, so that brilliant prints may be obtained in full sunlight from their negatives. Time is again saved, as a thin negative is much sooner printed from than an intense one, if they are both printed in the same light.

The paper is of a slightly creamy tint, which I do not think any drawback, as it gives a warm colour to the picture which would be often desirable even were the paper *perfectly* white; which is a condition very difficult to obtain.

Another recommendation is, that it can be prepared by persons who have not had much practice, so that everyone preparing it for himself, will be able to vary the quantity of chloride at pleasure. This is one of its great advantages over albumenized paper. Many persons would be glad to prepare it themselves if it were not for the skill and practice required, that they might know the proportion of salt it contained. One disadvantage is, that the quality of the prints depends more upon the paper itself than it does in albumenized or plain paper. It should be rather stout, possessing a very hard and even surface. *Saxe* paper appears to me the best, though that requires picking through to remove any sheets that are thin and porous.

I will now state as shortly as possible (as I know your space is valuable) my method of preparing the benzoinized paper. You must first procure some of the finest Siam gum. That containing the most perfect "tears" is the best. Pick the tears clean from the transparent yellow part of the gum, though there would be no harm in using all, except that it would render the paper more yellow. Place the picked gum in a glazed wedgwood capsule, which is to be supported some distance above a spirit lamp, or other convenient source of heat, so that it may be heated gradually. Stir the gum with a piece of wood until it is fluid, then remove the capsule to a farther distance from the flame, and allow the benzoin to remain in a state of fusion for fifteen minutes, keeping it covered with a sheet of card or wood to present the too ready access of the air, for if it be left open it will become more yellow by oxidation. When the quarter of an hour is expired hold it for a minute or so over the lamp, to render it as liquid as possible, then pour it on the bottom of a plate or marble slab, and allow it to become quite cold when it may be taken from the plate or slab.

*Solution No. 1.*

| | |
|---|---|
| Chloride of cadmium ... ... | $\frac{1}{2}$ ounce |
| Spirits of wine (methylated is preferable to the pure) ... ... | 10 ounces. |

When solution is effected add ten drachms of the benzoin as above. Shake occasionally till dissolved. and then set aside, to settle, in a cool place; this will take two or three days. When it is settled pour off the clear portion into a clean bottle for use.

*Solution No. 2.*

| | |
|---|---|
| Benzoin ... ... ... ... | 1 ounce |
| Sandarac ... ... ... ... | 1 drachm |
| Copal ... ... ... ... | 10 grains |
| Chloride of cadmium ... ... | $\frac{1}{2}$ ounce |
| Methylated spirit ... ... ... | 10 ounces |
| Oil of cloves ... ... ... | 10 drops |

Dissolve as before.

Pour into a perfectly flat dish enough of either of these solutions. (There should not be less than a quarter of an inch in depth.) Take the paper by the two opposite corners. and totally immerse it. The solution will immediately render it nearly transparent. Remove air-bubbles. &c., and allow it to remain half a minute. Raise one corner with a pin, and *draw* the paper from the solution, so that the liquid may flow off in one sheet. If streaks appear, immerse and withdraw again. Drain as closely as possible, by which a great saving in solution may be effected. Loss of time may be obviated by two persons being employed. one to immerse the paper, the other to remove, drain, and hang it up to dry. The room should be rather warm to prevent chilling. The paper is soon dry. As both sides of the paper are alike acted upon, either may be sensitized, although, of course, the hardest and smoothest is the best.

To sensitize the paper, float from five to ten minutes on the usual silver bath, provided it be at least 50 grains to the ounce. A good means of preventing discolouration of the bath from organic matter, is one that was proposed some time back, though I do not think it has been very generally adopted: I mean that of adding a small quantity of common salt to it. The bath is never filtered, but only returned to the bottle every night, and shaken up. I also add 5 per cent. of alcohol.

The paper, prepared with benzoin, does not curl in drying, which makes it much easier to print upon. Print rather deeply, as the print will lose considerably in the after process. Wash the prints well; then let them soak for one hour in water at 70°, and tone in a bath made as follows:—

| | |
|---|---|
| Distilled aqua ... ... ... | 20 oz. |
| Chloride aur ... ... ... | 4 grains. |
| Acetate of soda ... ... ... | 2 drachms. |

Mix twenty-four hours before using.

I may here mention that I have adopted the soaking in tepid water before toning, with a sample of paper that gave dreadfully mealy prints under any other treatment, and have found it to succeed capitally. Thanks to "A Photo's Assistant" for the hint.

Tone to the required tint, as the prints do not change much in the hypo bath, which is 6 ounces to the pint. Wash with great care.

This process is most applicable for large pictures, and I think it would be very suitable for solar camera pictures, or for any prints where development printing is adopted, iodide and bromide being used, instead of a chloride, in the first preparation.

I had hoped to have sent you some specimens worthy of the process, but have been so occupied with other matters, that I have not been able to prepare any. I have enclosed two or three of the first prints I did upon the benzoinized paper, as they are the only ones I have by me. They are not from good negatives, as at first I was fearful that the paper might stick to the negative, but I have found that there is no danger, if a hard spirit varnish be employed. I am of opinion that a great deal may be done in the direction I have pointed out with gums, or resins, insoluble in water, and I do not doubt that a better, even than benzoin, may be found. I would recommend that the benzoin *alone* be tried first, as it is much more simple than No. 2. As some might like to try the paper before preparing any, I will enclose a sheet upon the receipt of address, and seven penny postage stamps.

*5, Aberdeen Park, Highbury.*

## A SHORT LESSON IN PHOTOGRAPHY.*—No. 4.

In my last lesson I remarked that the picture of the decayed leaf was a *negative* print. It lies on the surface of the albumen; and if the albumen could be separated from the paper, it would be quite transparent in the lights, so much so, indeed, that light would easily pass through those parts; whilst through the more opaque parts it would meet with considerable obstruction. This sheet of printed albumen, therefore, might be now used instead of the decayed leaf, from which a new picture might be obtained, having the lights and shades inverted, and presenting a true pictorial representation of the leaf on a white background. Such a print is in reality a *positive*; and the transparent albumenized, in the true photographic sense, is a *negative*. But the albumen cannot be stripped off from the surface of the paper; nor can the paper so albumenized be made perfectly transparent, nor allowing that it can be made practically transparent, is this the general and most commodious way by which negatives are prepared.

Before I proceed to show you the manner of making a negative, such as the photographer understands by the expression, I must here inform you that we have two methods of printing: the one by the direct rays of the sun, the other partly by the same means and partly by chemical action afterwards. The former process is called solar printing; the latter is denominated printing by development. The inorganic salts of silver, which easily change colour by the action of light, are the bromide and the chloride; others are acted upon, although less sensitively and less sensibly as regards the change of colour, yet much more distinctly in some unknown physical way. For instance, the yellow iodide of silver becomes gradually grey when exposed to the sun, or to diffused light; but it does not change colour to the same extent as the chloride or the bromide, not even when it is treated with nitrate of silver. Nevertheless, light acts upon it in a most miraculous way; and now to work to show you this.

I have here a substance denominated *pyroxyline* or soluble gun-cotton (for there is a gun-cotton which is insoluble in the menstruum which dissolves pyroxyline). You cannot distinguish this cotton from ordinary unprepared cotton, either by the taste, smell, or sight, if it has been thoroughly washed. One of these bottles contains pure and very strong alcohol, nearly absolute alcohol, consisting of at least 95 parts of absolute alcohol, and 5 parts water; its specific gravity never being greater than ·809, that is, alcohol stronger than this may be used, but not weaker. The other bottle contains concentrated ether, whose specific gravity may range from ·720 to ·715. Weigh out 18 grains of the pyroxyline and place the same in this clean four-ounce vial; to this now add 7 drachms of the alcohol; cork the bottle and shake it well, until the cotton is thoroughly imbued with the alcohol and disintegrated. To the mixture add 8 drachms of alcohol and 10 drachms of ether; again cork and shake well together. You observe with what rapidity the cotton is dissolved. This solution is *collodion*, ordinary, normal or plain collodion, to distinguish it from the collodion after it has been sensitized for photographic purposes.

This normal collodion may now be filtered, or set aside until all insoluble particles have settled, when it may be decanted from the sediment. If, on the other hand, the collodion is to be filtered, we require a special filtering apparatus, well known to the pharmaceutist, which allows the filtration to proceed in an air-tight vessel, and thus prevents evaporation. Collodion does not filter easily through paper, but it may be filtered through a layer of clean common cotton-wool, placed somewhat loosely in the tube of the funnel. Whilst it is filtering let us proceed to the sensitizing solution. For this purpose I take

2 drachms of alcohol
8 grains of iodide of potassium dissolved in the smallest quantity of water, and holding in solution
1 grain of iodide † of silver
3 grains of iodide of cadmium, and
4 grains of bromide of cadmium.

As soon as these salts are dissolved the solution is filtered through filtering paper. To every 10 parts of the normal collodion add 1 part of the sensitizing solution, and allow the mixture to stand in a cool, dark place for a day or two. It is an advantage to prepare this collodion, and to use it in the dark room, that is, never to bring it to the light until it is exposed to receive a picture.

For albumen prints, paper is the background or receptacle; for collodion prints, glass is the background. The glass for photographic purposes must be thin, homogeneous, endowed with parallel plano surfaces, and free from all kinds of flaws. When cut into the proper shape and size, each plate is prepared to receive the collodion film as follows:—The sharp edges all around, and on both sides are first taken off with a file, the plate is then fixed in the vice or on the pneumatic holder, cleaned and polished. To effect this we require alcohol, rotten stone, small pieces of canton flannel, of about three inches square, and two thin clean dry silk cloths. The rotten stone is kept in a bottle with a large neck, which is closed by a piece of gauze, with open meshes, tied round the orifice. Pour a little alcohol upon the middle of the plate, then dust some of the rotten stone upon the alcohol; now rub quickly the mixture over the whole surface, by means of a piece of canton flannel, until the glass is dry. Proceed with the other side in like manner. Take one of the silk cloths in the left hand, and then, holding the glass within thick folds of silk, clean both edges and surfaces thoroughly with the other silk cloth. Now breathe upon either surface; any imperfection in the cleaning becomes visible on the film of vapour by a want of uniformity, either of the film itself or of its evaporation. Clean and polish once more if imperfections are thus discovered. When these are thoroughly removed, be careful finally to remove all particles or fibres, either of silk or cotton, which adhere tenaciously to the glass by reason of the electricity developed by friction whilst cleaning. Such fibres can be easily brushed off with a light broad sable pencil. The glass is now ready to receive the collodion. If the plate is of small size, hold it by the left-hand corner, between the first finger and thumb of the left-hand, and pour the collodion upon the plate, beginning at the farther right-hand corner; and incline the plate with the left hand whilst pouring the collodion with the right hand. When the surface of the plate is nearly three-fourths covered, cease pouring any more collodion, but incline the plate now in two directions, so that the surplus collodion may flow off by the nearer right-hand corner into the collodion vial. As soon as the film has set, or is nearly dry (a condition which takes place in a few seconds), the plate is immersed in a bath of nitrate of silver, and is allowed to remain in this bath until the surface becomes uniformly of a cream colour. If the bath is in good order the film assumes this colour in a couple of minutes; the plate is then taken out from this bath, and the superfluous nitrate of silver is allowed to flow back again into the bath for about a minute or so, and is then introduced into the plate-holder and exposed to the view in the camera for a second or so, as the case may be. The great tendency of young photographers is to expose too long; a fraction of a second in a well-lighted view, and a second or two, when the sky is cloudy, is sufficient time with most lenses. Of this department I will teach you more hereafter.

I will now return with the plate-holder into the dark-room, and see what we have got. The film seems to have undergone no change whatever; but the moment I apply what is called a *developer*, the picture becomes manifest, as if by magic. There is now so much to be said, and seen, and done, that it is better to postpone further development until the next lesson.

* From *Humphrey's Journal*.

† Iodide of silver is prepared by dissolving a grain of nitrate of silver in the smallest quantity of water in one test tube, and two or three grains of iodide of potassium in the same manner in another. Then drop gradually of the latter solution into the former as long as a yellow precipitate is formed. As soon as the precipitate subsides, decant the supernatant liquid, and wash the residue several times with water. This yellow substance is iodide of silver, which may be kept a long time in the dark room without change.

Marine Glue.—Dissolve 4 parts of india-rubber in 34 parts of coal tar naphtha—aiding the solution with heat and agitation. The solution is then thick as cream, and it should be added to 64 parts of powdered shellac which must be heated in the mixture till all is dissolved. While the mixture is hot it is poured on plates of metal in sheets like leather. It can be kept in that state, and when it is required to be used, it is put into a pot and heated till is soft, and then applied with a brush to the surfaces to be joined. Two pieces of wood joined with this cement can scarcely be sundered—it is about as easy to break the wood as the joint.

## ENGLISH APPARATUS.—EXAMINATION OF DALLMEYER'S BINOCULAR CAMERA AND LENSES.

BY DR. VAN MONCKHOVEN.*

[Dr. Van Monckhoven is preparing for the press a new edition of *Traité dé Général de Photographie*, of which the substance of this description will form a chapter. When the article first appeared in the *Moniteur* some months ago, the worthy doctor requested us to reproduce it in our pages, which the pressure on our space has hitherto prevented us from doing. As the author has recently reminded us of our promise, we hasten to fulfil it, feeling much pleasure in recording the tribute of a continental author to the superiority of English lenses and apparatus. We may remark that the description has already been reproduced in an English journal, but without any reference to the journal in which it originally appeared. We mention this simply to remove the chance of further false charges, from what a continental *littérateur* recently styled our "aggressive" contemporary.—Ed. P. N.]

"I send you a description of the stereoscopic apparatus of Mr. Dallmeyer, which has obtained, as you know, well merited success in England and in Germany. It is with this instrument that the instantaneous views of the Boulevards of Paris have been secured by Messrs. Ferrier and Soulier. During my last visit to Paris I was able to ascertain that this apparatus was still nearly unknown there. This determined me to send you a detailed description, with the diagrams which

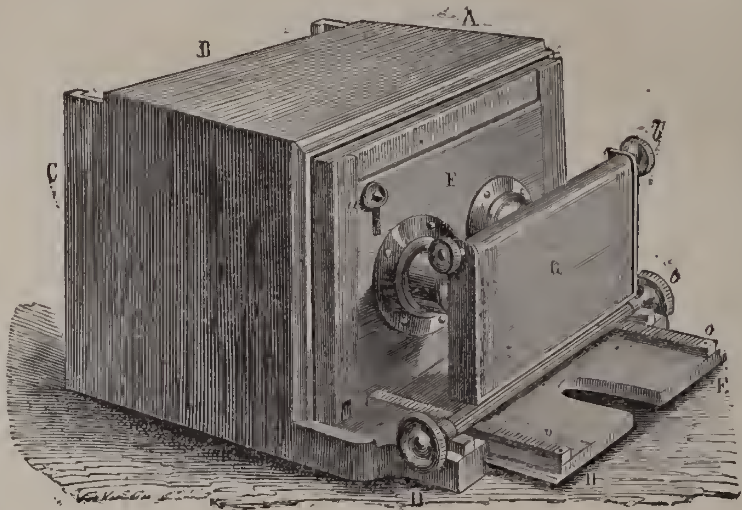


Fig. 1.

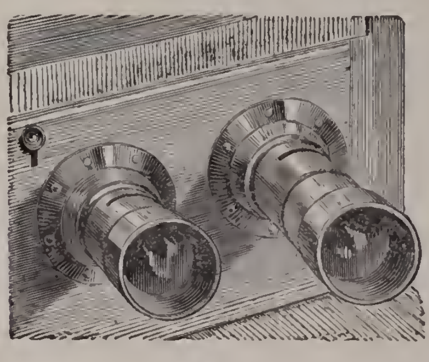

Fig. 2.

I have had executed for the fourth edition of my *Traité de Photographie*.

"All the world agrees at the present time to regard Messrs. Dallmeyer, Merz, Secretan, and Voigtlander, as the first opticians of Europe. I understand by the term optician, not a simple manufacturer, but a man perfectly familiar with mathematics, as well as practical optics, who does not confine himself to empirical efforts after perfection, but having enough of genius to create at once theoretically, an instrument, which his practical skill shall bring subsequently to absolute perfection.

It is necessary that an author should keep himself familiar with the works of such manufacturers. The English journals had repeatedly recorded the great progress realized by Mr. Dallmeyer, in his binocular stereoscopic apparatus, and I eagerly availed myself of the first opportunity of ordering a set. The result of my experience on trial was so satisfactory, that I made some diagrams of the instrument, persuaded that a minute description will be found useful to those readers who have not had an opportunity to examine the apparatus itself.

Figures 1 to 10 represent the different parts of the apparatus; figure 1 showing it complete. Before speaking of the value of the lenses, we shall first examine the camera.

Figure 1 is a drawing of the whole apparatus. A B C D represents the body of the camera, which is made of polished mahogany. The corners are brass-bound, in order to afford the best possible protection from the effect of change of temperature. The camera is fixed upon the tripod stand, by means of a nut and screw. The back part of the instrument carries, at B, the ground glass, which is not seen in the diagram. In the method adopted by Mr. Dallmeyer, this part, instead of moving, as is customary, is stationary, as he prefers that the ground glass should remain absolutely fixed and steady, as affording better facilities for focussing. The front part, F, carrying the two lenses, are put in motion by a pinion, *c*, travelling upon two racks *o o*, fixed to the part E, which is the base of the moveable body of the camera; whilst

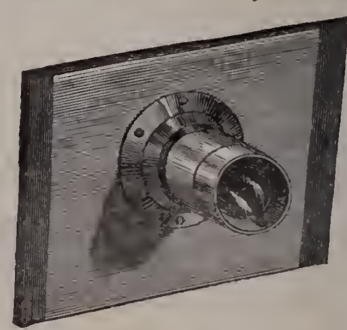

Fig. 3.

the pinion *c* is attached to the lower part D extending in front of the camera A C.

The focussing is thus rendered very easy. Whilst examining the image on the ground-glass, the pinion *c* is easily turned by the hand. The front piece F, which carries the lenses, can be raised or depressed at will, and fixed in its place by the nut *a*. When it is necessary to remove the front the lenses should be drawn out, as is shown in figure 2. This front can be withdrawn and replaced by another carrying the triple lens, fig. 3.

The interior of the camera (fig. 4.) is arranged very inge-

* From *Le Moniteur de la Photographie*.

niously. When operating with two lenses it is necessary that a partition should separate the two images; but when, on the contrary, it is used for single pictures, the partition requires to be withdrawn. To obtain this object the manu-

Fig. 4.

facturer makes use of a pliable piece, fig. 6, which can be placed in the groove *a*, fig. 4, belonging to the moveable part B of the camera; and on fixing it by closing the bolts *b* and *d*, it is easily seen that in lengthening or shortening the camera the pliable partition yields to these movements, and divides the interior completely into two distinct parts.

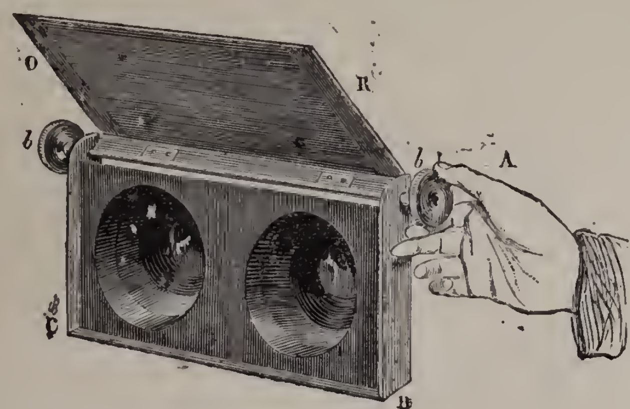

Fig. 10.

The chassis, or dark-slide, fig. 7, carries a small inner frame, fig. 8, for stereoscopic plates, with corners of silver wire. The dark slide itself will take plates seven inches and a quarter by four inches and a half. We recommend the reader to make use of plates of these dimensions, even for stereoscopic negatives. They are, of course, too large, but they aid in avoiding those stains on the print, which, as all photographers know, are apt to occur on the edge of the negative. These plates are intended for groups and

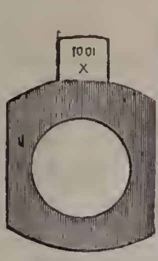

Fig. 5.

Fig. 6.

views on the entire plate, to be taken with the triple lens after removing the partition.

The dark-slide, fig. 7, merits especial attention for the ingenious arrangement devised by the manufacturer to receive the excess of silver solution. Fig. 9 shows this arrangement. The silver wire serves to keep the glass steady, whilst it rests on *c* at the extremities only. The nitrate solution which had accumulated flows into the groove *b*, which is coated with wax. Even when using the stereoscopic inner frame, fig. 8, the solution can only flow into the groove. The arrangement is very ingenious and we recommend it cordially to French cabinet makers. In conclusion, so far as the camera is concerned, we may remark that it is of mahogany, polished and varnished, this wood being generally preferred for such pur-

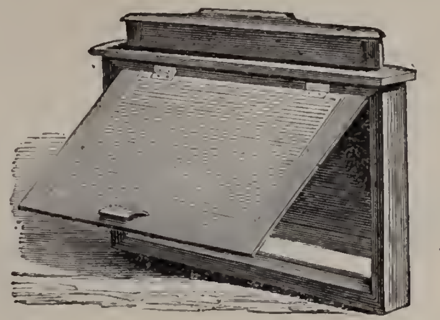

Fig. 7.

poses in England and Germany. The body of the camera can be extended from three inches and a half to seven inches.

The lenses carry upon the hood the instantaneous shutter. This consists of a simple piece of polished mahogany, which is shown closed in fig. 1, and opened in fig. 10. The part C B in the latter is fixed upon the lenses. A rod of brass, furnished with two milled heads, *b b*, carries the lid or shutter O R. One great advantage secured by this shutter consists in the fact that the sky receives less exposure than the foreground, and thus affords facilities for securing the delineation of clouds in instantaneous views.

In using this shutter, a certain amount of skill is necessary in the manipulation. We think that, in the act of opening and closing, a movement may be communicated to the plate, unless the operator possess considerable skill and coolness. It has not our entire approbation, and we are convinced that some better arrangement may be found.*

We come, finally, to the lenses. They are double combinations, of an inch and a quarter, and an inch and a half aperture, and three inches and a half back focus. Fig. 2 shows the open-

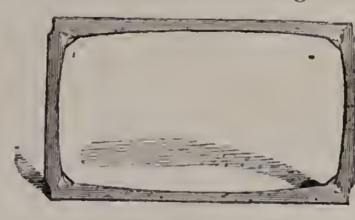

Fig. 8.

ing in which the diaphragms are placed, one of which is shown at fig. 5. These diaphragms are numerous. In counting from the largest, the time of exposure is just doubled, except in the case of those marked with a cross, X, which only require one-half more exposure than with the one preceding. These lenses may be used with their full aperture, and we confess to have been enraptured the first time we examined

* A new shutter has since been brought out by Mr. Dallmeyer which is not open to these objections.

them. We focussed a tree nearly ten yards distant, and the background of the landscape, situated about a mile and a quarter beyond, was perfectly well defined. In a second experiment, we focussed the same tree at the same distance, and persons passing between the tree and the lens were all defined with a perfection truly satisfactory. The quality

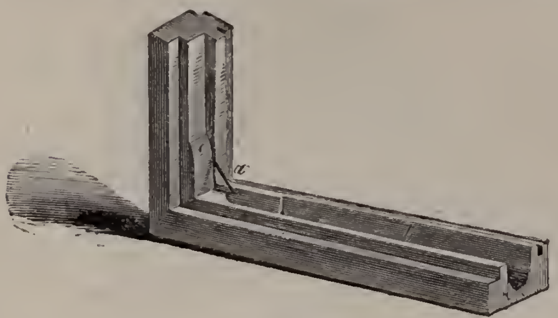

Fig. 9.

which the English call "depth of focus," it will be seen, is here very admirably obtained. As double lenses for views, that is to say, possessing fine definition, with great intensity and brilliancy united, we have never seen lenses which were comparable to these.

The use of diaphragms permits the employment of the same objectives for reproductions and for enlargements, which demand great precision and delicacy. For these purposes sufficient definition is here obtained with a diaphragm of medium size; and with the great advantage over single lenses (which are being abandoned more and more), of giving more correct lines, and a more luminous image.

By removing the partition, fig. 6, and replacing the front, carrying two lenses with that, fig. 3 furnished with the triple lens, the apparatus is transformed in a second into one for larger single views. But of the triple lens we shall speak on another occasion.

## WET OR DRY COLLODION.

BY M. L'ABBE DESPRATZ.*

Beside the iodide of silver photogenically modified, there is also that which has not been affected, besides free nitrate of silver. At the moment when the plate is put in contact with the sulphate of iron, all this free nitrate of silver is decomposed, the iodides remaining intact. But what becomes of the nitric acid? we need not examine this question here: as to the silver, that is to say, the base with which the nitric acid is combined, one portion becomes free and diffused in the water of the bath, while the remainder combines with, and adheres to, the iodide which has been modified by light. Thus, for the sulphate of iron developer to be active, is it necessary for some nitrate of silver to remain upon the plate; do we require a proof of it? then carefully wash the plate upon its removal from the camera, and it will be impossible to obtain anything in the sulphate of iron bath; whereas, if, after the washing, the plate is sensitized anew, the developer, by the restored nitrate, will become active again, and nearly as uniformly and as strongly as if the plate had not been washed.

The free nitrate of silver on the plate must be reduced to the metallic state, in order for an image to be formed; it is necessary to ensure the deposit as regularly as possible. To obtain this result with certainty, I proceed to give the various methods in which I have experimented.

It is first necessary to be sure that the silver solution is spread uniformly over the plate. It must not be in excess. We must therefore take the precaution of letting it drain properly before exposure in the camera. If, at the moment of submitting it to the sulphate bath, we remark, especially on the edges, any liquid veins, they must be absorbed by blotting paper. For when they come in contact with the bath, the reduction of the silver is made in too large a mass of liquid, and there will be a formation of a metallic deposit which will extend irregularly, so as to be too thick in some places, and not thick enough in others. Supposing, then, that the nitrate of silver is spread uniformly upon the plate, it then becomes necessary to maintain it so, or at least to do nothing to expel it from the place it occupies. For it does not exist in a state of combination, but simply in that of simple superficial juxtaposition.

If the plate is placed on a levelling-stand, it will be possible to obtain, most frequently, a good development, especially if the dimensions of the plate be not too large. To this end, it is sufficient to raise it slightly on one side, and to pour on this upper side a sufficient quantity of developing solution to flow in an even uninterrupted stream to the opposite side. Practice in this method will give sufficient skill to secure a good negative generally. It is not always successful, and we now proceed to describe two other methods which are, of a certainty, much more preferable.

Take a flat dish about one-third longer than the glass negative. Then pour into it a sufficient quantity of the developing solution to cover the plate amply—the dish being inclined so as to bring the liquid to one of the narrowest sides—then place the plate on the clear space of the dish, collodion side uppermost. Then, inclining the dish, cause the liquid to flow over the collodion film as evenly as possible. *Almost always*, if not always, the deposit of silver is formed instantly, and with perfect regularity. Nevertheless, if the developing solution arrives suddenly upon the plate in too large a quantity, it may derange the coating of nitrate of silver, and cause an irregular deposit of that metal. This method, therefore, requires a certain manual dexterity; another and simpler method, and which we still prefer, is as follows:—the dish containing the sulphate is placed level; a layer of liquid, eight-tenths of an inch deep, at the most, is sufficient; we then rest the plate on its longest side, the impressed film opposite the liquid. Then, by means of a silver hook, lower the plate slowly and regularly into the liquid. By proceeding in this manner we do not disturb the layer of nitrate of silver, and the deposit is always made with the desired harmony.

In the fear of extending this article to too great a length, we must defer what we have to say on the *concentrated* sulphate of iron developing bath, and upon that mode practised for intensifying, which seems to us the most preferable.—*Moniteur de la Photographie.*

* Continued from p. 443.

## Proceedings of Societies.

### North London Photographic Association.

The first meeting of this Association, after the summer recess, was held at Myddelton Hall, on the evening of the 17th inst. Mr. G. Shadbolt in the chair.

The minutes of a previous meeting having been read and confirmed, Mr. H. Greenwood and Mr. James Cooper were elected members of the Society.

Mr. Wharton Simpson exhibited a large series of prints, 7 by 4½, instantaneous and otherwise, photographed by Mr. Wilson, of Aberdeen, and published by Messrs. Marion and Co. The prints were examined with great interest, and received much admiration. In answer to questions, it was stated that they were produced by the wet process, with Dallmeyer's No. 1 triple lens. The magnificent cloud effects of many of the instantaneous pictures were specially admired.

The Secretary read a paper by Dr. Maddox on photomicrography, or the production of enlarged images of microscopic objects. The paper was accompanied by a number of fine specimens of transverse sections of plant stems, parasitic insects, &c. At the conclusion of the paper, these were carefully examined and pronounced of unusual excellence; but no discussion ensued.

Professor Emerson, of Troy University, United States, in answer to a question by the Chairman, stated that he had not done anything with photography in connection with the microscope, except prepare some dry plates for the experiments of Professor Rood, and the dry plates were found to answer as well as wet collodion.

A collection of stereographs was then exhibited by Professor Emerson, who explained that they had not been brought with any especial view to being shown in this country, they were merely the prints he had received as a member of the Amateur Exchange Club, in the United States. He had thought, however, it might be interesting to the meeting to see the work of American amateurs in the art. The stereoscope was shown one of a cheap form, got up by Mr. Anthony, with his (Mr. Emerson's) improvement.

The Chairman explained that the instrument possessed a facility of separating or closing the lenses. The object of the arrangement had been explained by Professor Emerson, in an article in *Siliman's Journal*, which had been reprinted in most of the English journals, and members might remember it.*

The majority of the stereographs shown were very good; and included specimens by several photographers, whose names are well known to English readers, such as Anthony, Borda, Hull, Shriver, Thompson, Sellers, and others. There were excellent specimens by the tannin process, by the milk process, and by wet collodion. Each slide had a label at the back, with the name of the photographer, and particulars of lens, process, exposure, &c., after the manner described on p. 612, Vol. VI. of the Photographic News.

Mr. Simpson called attention to one picture described as taken with Harrison's new lens, and asked if it were by the new lens intended to include a very wide angle, and, if so, what was the real focus of the lens.

Professor Emerson stated that it was. The lens had a focus of two inches and a half, and covered a picture of five inches square. The lenses consisted of two sections of the same sphere, and were arranged in the combination in their proper position as parts of a sphere. He was not aware whether the focus named was intended to express the equivalent focus or the measurement from the back glass.

The Chairman conceived that it must refer to the measurement from the back glass, as otherwise the plate would be almost in contact with the back of the lens if it were of any dimensions at all. Moreover, the print did not appear to include a very wide angle of subject.

Mr. Simpson asked Professor Emerson if he had had any experience in the ammonia acceleration of dry plates, and if there were any tendency to fogging induced by its action.

Professor Emerson stated that the accelerating action of ammonia was unquestionably a fact, and he had used it successfully. He had, on first trying it, found some tendency to fog, but by care in developing, and the regulation of the proper proportion of citric acid, the difficulty was removed.

The Chairman asked at what time the plates were submitted to the ammonia, and if any difficulty were experienced, as was sometimes in the Daguerreotype process with iodine, in securing even and regular action all over the plate.

Professor Emerson said it was applied shortly before exposure, and no difficulty was experienced in getting regular action. He just placed a saucer in the bottom of a box, and in it a piece of cotton wool saturated with ammonia.

Mr. Simpson suggested that the ordinary iodizing box, used in the Daguerreotype process, would answer the purpose.

Professor Emerson: Very well indeed.

Mr. Hislop asked Professor Emerson if he had had any experience in the hot water acceleration of dry plates.

Professor Emerson pointed out some excellent specimens, taken on tannin plates in 30 seconds, in which the aid of hot water, in developing had been used.

Mr. Hislop said he believed that experiment in that direction would be well repayed. He had recently been trying it with plates simply washed and dried, as he had before described. With a stereo lens and small stop he had obtained a good negative in ten seconds. The plate, before development, was immersed in water at about 200°, and then developed with the ordinary pyro solution. The result was as good as if the plate had had, under ordinary circumstances, three minutes' exposure

* See p. 8 of the present volume of the Photographic News.

The chief difficulty he experienced was the tendency of the plate to dry when thus heated.

Mr. Simpson then exhibited some prints on resinized paper, by Mr. H. Cooper, jun. He had only just, before coming to the meeting, received the communication and the specimens, and could not, therefore, enter into details of the manipulation (see page 494); but he was so much impressed with the importance of the process, and the promise of the results, that he lost no time in calling attention to the prints.

The specimens were examined with much interest, and high opinion of their promise expressed by many members; both as regarded quality and probability of permanency.

Votes of thanks having been passed to the several gentlemen who had contributed to the interest of the meeting, the proceedings terminated.

## Correspondence.

### PRINTING DIFFICULTIES.

Sir,—Before dismissing the silver bath, and the troubles it but too frequently gives birth to, I feel bound to add a word or two on the subject of printing from weak and dense negatives.

If the quantity of silver a paper contains is governed by the amount of chlorine mixed with the albumen, then must the formulas given to meet the requirements of the above mentioned class of negatives, be based on uncertain grounds, for I am at a loss to understand in printing from a hard negative, how a weak bath is to meet the difficulty if a strongly chloridized paper is used; and on the other hand, I am equally at a loss to discover what improvement can be derived from the use of a strong bath in connection with a weakly salted paper for printing from a negative of a feeble character.

If my former remarks, which treat on the chemical decomposition that follows the floating a salted paper on the surface of the sensitizing bath, are correct, it necessarily follows that formulas given for the purpose of getting the best results faulty negatives are capable of producing, are empirical, and, as such, uncertain in their practical working. As the results will depend entirely on the quantity of chlorine the paper contains, it is evident the larger the proportion of silver in the form of a chloride, its surface is chemically prepared to absorb, the more vigorous must be the prints, let the bath be weak or strong; that is to say, if the floating is sufficiently long to produce saturation, if not, there cannot exist the necessary proportion of free nitrate to give the print the equally necessary stability to secure brilliancy in its finished state; but I need go no further into details, the conditions required to obtain a weak or strong body of reduced silver in the paper are obvious, viz.: a weakly salted paper slightly albumenized for a dense negative, and a strongly salted one, with a proportionate increase of albumen for a feeble one,—the strength of bath in both cases may be the same, although a little difference should be observed in the time of floating.

With these remarks I bid adieu to the silver bath, but before examining the negatives previous to printing, I shall briefly detail the results of a series of experiments entered into during the past week, with an acetate toning bath. Selecting a sample of paper, which, under ordinary treatment, invariably produces mealiness; and another, that under the same circumstances gives good results. I floated each for two minutes on a 75-grain bath, hung it up, and allowed it to dry spontaneously. After the exposure in full sunshine, and the usual washings, I immersed the first two prints in the acetate bath, made by the formula given with your remarks on toning. The changes proceeded rapidly; but, "angels and ministers of grace defend us!" Such a crop of mealiness never before greeted mine eyes. Anticipating this result, I had provided an equal quantity of acetate of soda in solution to that the bath contained, this was added, which brought it up to the strength recommended by Maxwell Lyte. After a few minutes I immersed two more prints, this time the action was slower, but still mealiness—though greatly modified—made its appearance in paper No. 1; paper No. 2 was all right. I now added, drop by drop, from a bottle containing a saturated solution of the acetate, until the progress of mealiness was stayed. I then submitted several prints to the action of the bath. Paper No. 1 gave good results, but paper No. 2 found the dose too strong, and became washy and pale, thus proving the impossibility of producing a formula that is capable of meeting the requirements of every kind of paper. The first sample mentioned, is, in appearance, the most perfect I ever saw, but from the slight diminution of strength sustained by the silver bath, I attribute its faults to injudicious salting, the quantity of chlorine being altogether disproportionate to the large amount of albumen which covers its highly glazed and perfectly even surface; and for this reason it requires a large excess of the clearing agent to remove the unusual quantity of what I shall now term a bastard albuminate of silver. Although for experiment I used a new bath on this occasion, for ordinary purposes I would strongly recommend an acetate of soda bath, to be made two or three days prior to its being used; for, as I have before observed, as a general rule, the more evenly the gold and reducing agent can be balanced, the more brilliant will be the finished prints, and this balance can be best produced spontaneously.

Whilst treating on the toning bath, I shall have a word or two more on this subject. At present I shall conclude by urging photographers to refrain from running to all points of the compass for supplies of paper. Get two or three samples of different strengths, and adhere to their use. I myself am almost bewildered with the varieties I have to print from, and all in one batch, to be toned in one bath; and no argument will persuade my employer that he is doing wrong. Like a remark I once heard made, by one whose knowledge of mechanical philosophy (in spite of a former red tape successful examination), was but scant: "if water can be safely boiled in a tin vessel, there is no visible reason why oil should not." So he believes that a toning bath that will tone one paper satisfactorily, should give the same results with every sample submitted to its action.—Yours respectfully, A Photo's Assistant.

## FRONT LIGHT IN GLASS ROOMS.

Sir,—Your correspondent, "H. G. B.," did not honour my "Chat about Glass Houses" with a very attentive perusal, or he would not assert that I gave no reasons for my belief in the value of a front light. If the writer will again refer to the article in question, he will find I recommend the front light for the following reasons:—

1. Light from the front falls upon advancing surfaces, and so gives emphasis to their prominence.
2. The shades fall upon the retreating surfaces, and so keep them back in their places.
3. The side of the face in shadow receives a subordinate light from the front, which, stealing softly into even the very deepest shadows, gives them detail and transparency.
4. By the same means it also secures greater delicacy and softness for the less strongly marked shades, and marks the retiring surfaces more palpably.
5. Able men, building glass-houses, and having a front light (whether they get it originally by accident or design matters not), *use it*. In Mr. Window's room (which is rather a small one), the light is subdued with coloured glass; in Mr. Fry's (which is a large one), the distance itself subdues it; but both these gentleman, although perfectly able to exclude the front light, nevertheless use it.—Yours truly,

A. H. Wall.

## MORE JOURNALISTIC COURTESIES.

Dear Sir,—An article by Mr. Dawson, in the last number of your "Liverpool" contemporary, entitled, "A Lesson for the Learned," has brought very forcibly to my remembrance an old adage which tells us, that "We cannot touch pitch without becoming *defiled*," for it shows that even the mere attachment to the *staff* of a "publisher and proprietor," who renders his periodical a disgrace to journalism by its abusive scurrility, tends to deprive a man of the power of writing in courteous and gentlemanly terms.

Do *gentlemen* usually convey covert insinuations in their "few words of explanation?" for I do not understand the meaning of words, unless "*in the guise of a letter from a correspondent*," be so intended.

I was going to quote another old adage, which tells us, that "The old woman would not have known where to look for her daughter, unless she had been in the oven *herself*;" but a new light has broken in upon my mental vision; *perhaps* I am guilty of an injustice, in supposing it possible, that a person holding the situation of "Lecturer on Photography, at King's College," could be guilty of writing in ungentlemanly terms; and, perhaps, it *may* be the case, that what I took for covert insinuation, was, in reality, intended for a *home* thrust, to afford a gentle hint to us of the outer world, that in the journal with which Mr. Dawson is connected, letters have *sometimes* been concocted for the *sole* purpose of aiming sarcasms and inuendos against the *News* and *Notes*, in the "Answers to Correspondents;" and, *perhaps*, also, "the Editor" is coupled with the words, "were he one of my pupils," merely as to hinting the *author* of these concoctions, and *not*, as I imagined, in continuation of a covert insinuation.

As Mr. Dawson recently deplored the existence of "*much ignorance* in quarters where it ought not to be expected," allow me to mention, yet another old adage, which tells us, that "Charity begins at *home*," and also to recommend him as "a photographic teacher," to prevent the dissemination of untruth through the pages of the "*Liverpool*" *Journal*, by correcting the errors that are sometimes to be found in the answers to *bonâ fide* "correspondence."

As abuse, scurrility, sarcasm, inuendo, and covert insinuation are foreign to the notion of a "British" gentleman, the term "British" is a *misnomer*, when applied to any journal which habitually uses such weapons of attack. I have, therefore, designated it the "Liverpool."—I remain, dear sir, yours truly, George Price.

[We, some weeks ago, intimated our intention of passing unnoticed all further scurrilities in the Liverpool Journal, and have suppressed several letters sent for publication on the subject. In deference, however, to a frequent and valued correspondent, who, in a private note, urges that as he speaks not under an *alias*, but in his own name, and is known to many readers of both papers, he has a claim to be heard on a subject concerning all our readers—we waive our resolve. Until we received this letter, we had not read Mr. Dawson's communication. On doing so, we find him fighting a phantom, and as the amusement is harmless we leave him to it.]

## DECOMPOSITION OF NITRATE OF SILVER BY ACETATE OF SODA.

Sir,—In a late number of the *British Journal of Photography*, Mr. Dawson gives what he termes, a "*Lesson for the Learned.*" Now, it is because I believe Mr. Dawson to be a good chemist, that I am the more puzzled, when he states, that you may add a solution of acetate of soda to a solution of nitrate of silver, without decomposition; that is to say, without the formation of acetate of silver, giving as a reason that it is so, because it is so very insoluble.

If that white flocculent precipitate, which, from the fact that it is so insoluble, is immediately thrown down, in a curdy mass, on the mixture of these two chemicals, is not acetate of silver, I should much like to know what it is.

As Mr. Dawson's letter was meant in reply to a correpondent of yours, who, curiously enough, dates from this same city, and has the same initial, I must add, that I am not the same man. Bristol air, I suppose, makes us dull of comprehension.—I am, yours obediently,

M. Willett, M.R.C.S.

*Bristol, September 24th, 1862.*

## IODIDES AND BROMIDES IN COLLODION.*

DEAR SIR,—As the question of iodides and bromides is under discussion just now, I would wish the opportunity of saying a few works on the same.

As rightly implied in your editorial, Mr. Sutton's experiments were in a direction away from that which should have given the elucidation desired. He, however, proved that the exclusive use of bromides is accompanied by loss of intensity and of sensitiveness, and this corroborates Mr. Hardwich's statement in a general way, that bromide of silver is less sensitive to the invisible image than iodide of silver. But Mr. Blanchard's experiments appear to have approached closely to a solution of the question of the superiority of a bromo-iodized collodion over a simply iodized one, in point of sensitiveness. Similarly, the experiments of Mr. England apparently point out that a *bromo-iodized* collodion is the most sensitive *under iron development.* On the other hand, I think, it will be held established, as per Mr. Sutton's experiments, that a simply *iodized* collodion is equally sensitive *under pyro development.*

It will have occurred to all experimenters that a bromo-iodized collodion under pyro gives a hard negative, on account of the apparent inactivity of pyro on the bromide salt. It will also have occurred to them that the advantages of an iron development are manifest to perfection *when* there is a bromide in the collodion. And, therefore, under these circumstances, there would, at first sight, appear no little difficulty in establishing the superiority of one system over the other, opposed as they are to each other in radical principles.

In all experiments in such cases, it is of importance that the character of the collodion, the salts and bath employed, and the developers used should be carefully noted. To say that an iodized collodion was employed and compared in results with a bromo-iodized collodion, and found superior to it, will, in fact, prove nothing; what is required is a scrupulously correct detail of every thing—1st. Collodions, whether of one or several samples, and with or without organic reactions; 2nd. Iodides and bromides, whether cadmium, ammonium, potassium, or others, and the proportions used; 3rd. Age of iodized collodion on use; 4th. Developer, whether pyro or iron, and of what strength and age.

It is necessary to show that the collodion is with or without organic reactions, or, at least, of what age, when we consider that density is reciprocally as age and organic reactions, and sensitiveness, now reciprocally and again inversely, as them, and that they materially affect the resulting negative; and that collodion with a slight organic reaction is necessary under iron development, at least sufficient to yield the requisite tangibility of image under iron development, and with the use of a bromide, a salt known to reduce intensity. It should also be shown whether one or more descriptions of collodion are used—a very important information—as it would be a fallacy to array the results of a sensitive collodion bromo-iodized and developed with iron, against those of an inferior one simply iodized and developed with pyro, or *vice versâ.*

The description and proportion of the iodides and bromides used should be carefully noted. A great deal more, as regards sensitiveness, depends upon the combination of iodides and bromides than is suspected, and I shall be better understood on this subject were I have concluded, yet no importance has been attached to this matter. Beyond the generally received fact that cadmium is the most sensitive, no attempt has been made to establish others. It has also been the practice to diminish intensity by a bromide; but this is correct only in principle, and not always successful in practice.

The constitution of the nitrate bath is no unimportant matter in experiments, one abounding with acetate of silver and alcohol, &c., is the least desirable. The only one admissible is a pure unadulterated bath, having had a little careful working. As the question of fused and recrystallized silver is still in an unsatisfactory condition, the best salt from reputable dealers will answer, and, as regards organic matter in water, let the liquid be cleared by light and oxide, and we shall have a good, stable working bath, rectified with nitric acid and oxide.

With developers we have merely to proceed on the received axiom, that the more energetic the developer the shorter the exposure, and, under the circumstances, we hold iron superior to pyro. But iron development is seen to perfection in the presence of bromide, and when of some age and of a good strength. Moreover, Gaudin has shown what is proved in daily practice among the Parisian portraitists, that the proto-acetate is superior to the sulphate. The larger the proportion of bromide, the greater the strength necessary in the developer; but when pyro is used we must eliminate the bromide principle.

Admitting the general correctness of the above principles, I propose to use a collodion of well known quality, durable, sensitive, and yielding sufficient density with a bromide under iron development; a bath made up of pure recrystallized silver and water, from which the organic matter has been precipitated by oxide of silver, and which has been sufficiently saturated with iodide by the immersion of a dozen plates in it, and very slightly acid. As the principle of sensitiveness is under investigation, I will use iodide of cadmium as the chief component of my iodizer, for I want a stable and progressively sensitive collodion. My developer, acetate of iron.

To solve the question of *increase of sensitiveness by the presence of a bromide in collodion,* I propose to iodize a portion of the above-mentioned collodion with iodide of cadmium only. Another portion, with 3 grains of iodide of cadmium to $1\frac{1}{2}$ grains of iodide of ammonium, and a third portion with 3 grains of iodide of cadmium, to $1\frac{1}{2}$ grains of bromide of ammonium.

When a month old (say two months in England), coat, sensitize, and expose plates to the same subjects, at one and the same hour of the day. It will be found that the iodide of cadmium is not the most sensitive, because it has not sufficiently ripened, and because it has not attained its maximum sensitiveness. The *first* in the list of sensitiveness will be the iodide of cadmium plus *iodide of ammonium* collodion; and the *second* the iodide of cadmium plus *bromide of ammonium.* I have also added to a portion of the cadmium iodized collodion, as much ammonium iodized collodion as would give the proportion of 3 grains of iodide of cadmium to $1\frac{1}{2}$ grains of iodide of ammonium, as before, and to a separate portion of bromide of ammonium collodion as would give in the resulting collodion 3 grains iodide of cadmium to $1\frac{1}{2}$ grain bromide of ammonium. In both cases I have secured within a week increased sensitiveness over the simply iodized cadmium collodion, but the iodide of cadmium plus iodide of ammonium collodion, was superior in sensitiveness to the iodide of cadmium plus bromide of ammonium collodion. I have kept these collodions for long periods. The simple cadmium collodion continued permanent until it attained its maximum sensitiveness, *i. e.* it kept the longest, and excelled the other two in sensitiveness; but the iodide of cadmium plus bromide of ammonium collodion was inferior in durability and sensitiveness to the iodide of cadmium plus iodide of ammonium collodion.

I next tried these collodions with a pyro developer of the usual strength, of 1 grain to the ounce, and found as usual, that the bromized collodion was inferior in sensitiveness to the iodized ones; but I also found that the iodized ones under pyro development were inferior in results than when developed by acetate of iron.

* This communication from Mr. Augustus Webb, of Meerut, India, has been in type for some weeks, but on account of its extreme length has stood over. We are now compelled to divide it, but shall endeavour to complete it next week, when we shall probably have a word or two to say on the subject. —ED.

## Talk in the Studio.

Novel Photographic Forgeries.—The novel mania for collecting rare postage stamps, and the scarcity of some of the specimens, has given rise to a novel application of photography, as a means of counterfeiting the coveted labels. Many foreign stamps, it is well known, are printed in some dark, neutral tint —brown, or black, or purple. These are easily imitated by photography, together with the cancel marks upon them, rendering detection to an untechnical eye very difficult.

Photographic Sale.—We notice with regret that early in November, the whole of the photographic effects of Mr. Roger Fenton for sale, consisting of lenses, apparatus, &c., and several hundreds of published and unpublished negatives, will be offered for sale.

The Colour of Infinite Atoms.—Any substance in infinite division must of necessity be black, from its not having breadth enough to reflect a ray of light, which requires certain definite dimensions that philosophers have measured. Metals of all colours exhibit the same phenomenon; white silver, yellow gold and red copper may all be reduced from solutions in powder so fine that they are black.

Mr. Thompson's Changing Box.—Most of our readers will have become aware that Mr Thompson of New York, whose interesting letters on photographic matters in America appear in our pages, has a very excellent changing box for dry plates, which is the envy of many of his photographic brethren in the States. The only information that he could give on the subject was that he bought the box of an Englishman whose name he he did not remember. This box converted Mr. Coleman Sellers from wet photography to dry photography, and he immediately got a box made as nearly as possible on the same model, and has recently described it in detail. We are glad to be able to inform our American as well as our English readers that Mr. Jabez Hughes is the manufacturer of the changing box in question. We have just had a letter from Mr. Werge, who is manager of Mr. Hughes' Oxford street business, in which he says: —"I am the veritable 'Englishman' who sold the camera and changing box to Mr. Thompson, who is one of the firm of Thompson Brothers, Bankers, Wall Street, New York. Mr. Hughes has one of these changing boxes in use now at Ryde, and I dare say you saw the camera and change box too when you were down there last April, if not, if you will have the kindness to call at 379 Oxford Street, I can show you one. We have made the changing box in various sizes from stereoscopic to 9×7. It is but fair to state that Mr. Rayne, one of our workmen, is the inventor of the changing box."

Photography at King's College.—Mr. Dawson, lecturer on photography at King's College in a recent note mentions that his classes are just about to reopen, and asks us to remind our readers of the fact. Amateurs contemplating further instruction will find in Mr. Dawson a first-rate photographer and able eacher.

Large Panoramic Pictures.—Mr. Ross is progressing with the manufacture of complete sets of apparatus for large-sized panoramic pictures. We have before us a print of 16 inches by 7 inches, produced by a lens of 5 inches diameter, and 9 inches focus. The photograph is a view of a square in Bath, taken by Mr. Dawson, and, as exhibiting the capabilities of the lens, is a most satisfactory picture, although we cannot help regretting that the same amount of good photography was not expended on a more interesting and pictorial subject. We have also seen a complete set of apparatus with a lens of 6 inches diameter, and 11 inches focus, intended for pictures 18 inches long. Mr. Ross calculates that the panoramic lens, with an aperture of one-seventeenth of its focus, will cover two inches of picture for every inch of focus. This, with the last-mentioned lens, would give 22-inch pictures, but in case of the large lenses it is deemed prudent not to push them too far. For the size most commonly used, the lens of 3-inch focus, producing 10-inch pictures, porcelain baths of the proper curve, have now been made.

South London Photographic Society.—The members of this society propose to conclude their open air season by a meeting at Dulwich, on Saturday, October 4th, where they will dine together at the "Greyhound Inn." Members desiring tickets, which are five shillings each, are requested to make application before October 1st, to the Secretary, Mr. Alfred Harman, 3, Albert Cottages, Hill Street, Peckham.

Photographs at South Kensington.—The recently issued report on the Museum at South Kensington states, that the number of photographs issued during the year is 8884, and the amount received for them £705.

## To Correspondents.

W. C.—Unless you have some skill in landscape painting do not attempt to paint skies in your negatives. The attempt is perilous, and failure is more common than success. The method adopted by Mr. Mudd is, however, the nearest approximation which may be attempted by unpractised hands with any chance of success. In his case, the bulk of the sky is blacked out with any opaque colour, lamphlack answering very well. A few delicate, irregular streaks near the horizon, resembling stratus or cirrostratus clouds, are formed by clearing away a portion of the opaque colour, and allowing the sky, which is not too dense, to print through. In all cases the painting should be done at the back of the negative, which prevents any attempt at clouds from printing sharp or too well defined. In some cases clouds are painted on very thin, semi-transparent paper, which is placed at the back of the negative. No plan can be laid down which would be applicable to general cases; judgment and artistic skill must always be exercised, and, in all cases, beware of attempting more than you can certainly effect well.

T. P. G.—The "Photogen" is a patented apparatus; but the patent refers to the manufacture of the lamp, not to the use of it. Anybody possessing one is quite at liberty to use it, provided it has been manufactured by the patentee. The cost is about £5 or £6, and probably about £1 fitting up. The material used costs a few pence for each picture. The apparatus consists of a lamp, with flue or chimney, in which to burn a pyrotechnic preparation, which emits, during combustion, a very vivid, white light. The chimney is to carry off the fumes, and must be connected with the open air. The patent refers to the lamp used. We have seen very respectable photographs produced by its aid.

R. G.—With a bromo-iodized collodion a much stronger pyrogallic developer may be used than with an iodide only. But we always prefer iron and subsequent intensifying. We shall be glad to see you when you are in town. We are always at the office on Thursday afternoon. For any other time we must make a special appointment.

Z. C.—India-rubber cement, made by dissolving india-rubber in chloroform or bisulphide of carbon, is the best material for joining the edges of vulcanized tubing. 2. Condy's fluid, or a solution of an alkaline permanganate, may be used for purifying the water of which a silver bath is to be made; but should be added to a silver solution. 3. Hyposulphite of soda or sulphate of iron falling into a nitrate bath will spoil it. If only a small portion fell in, it might be possible to remedy it, but as a general rule, it would be best to throw the whole down and make a fresh bath, as it is unwise to work with a silver bath of doubtful quality. 4. The addition of too much acetate of soda to a bath is injurious: excess of acetate of silver will, of course, be formed, and this will have many injurious effects, one of which will be that you name, a tendency to form in small crystals on the plate, and we do not know of any means of preventing it. The addition of nitric acid will decompose the acetate of silver, and leave free acetic acid in the bath.

J. C. L.—We think it probable that if you add a printing-bath made with distilled water, and given to discolouration, to one made of common water which does not discolour, that bath will be likely to discolour in future, but we have never tried the experiment.

R. C. H., Aurungabad.—So far as we know, both the collodions you have used for your tannin plates are simply iodized, and in our experiments a freely bromized collodion is necessary for good results by that process. So far as we understand the steps you have taken, that is the only defect. But we cannot understand your getting a faint image without any intensity. Try the addition of a bromide to your collodion, and development at the ordinary temperature.

R. H.—We cannot state here at length the steps necessary to recover the silver from various waste solutions: instructions have often appeared in our pages. In old developing solutions it will be gradually precipitated in a metallic form, if left to stand. From fixing solutions it should be precipitated by means of liver of sulphur. Full instructions are given in No. 126 of The Photographic News, p. 50, Vol. v. 2. We know of no method of removing the gloss from your background painted in oil, except giving it another coat of oil flatting. That is, paint mixed chiefly with turpentine. 3. The changing box described by Mr. Sellers, is made on the pattern of one which is made and sold at Mr Hughes' establishment, in Oxford-street. 4. The negative of your card picture is a little lacking in intensity. If it were a little more intense it would admit of deeper printing and toning, and more brilliancy would be the result. With this improvement, and a little more perfect background, the picture would be good. The position of the figure is somewhat stiff.

J. D. D.—Several articles on the production of photographic transparencies have recently appeared in our pages. There is one in the number for August 29th, and another, by Mr. England, in the number for April 11th. Instructions for painting such slides appeared in the News for April 4th. We do not know of any one having second-hand slides for sale. Several photographic houses publish such slides. We may mention Bland and Co. Negretti and Zambra, Horne and Thornthwaite, and others.

Varnish.—It sometimes happens that the intensity of a negative is much reduced by varnishing, when the collodion is of a very powdery character. In such a case, a coating of albumen, or gum water, while the plate is wet, would prevent the varnish penetrating. The use of an amber or crystal varnish would also aid you.

Several correspondents in our next.

*** Our Correspondents will aid us in our endeavours to solve their difficulties if they will in all cases state details of their operations when failures occur; and when referring to former articles in the News giving the exact reference. Letters intended for the Editor should be addressed expressly to him.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 213.—*October* 3, 1862.

## SILVER IN THE WHITES OF FINISHED PRINTS.

We call the attention of our readers to an article on another page, by Mr. Spiller, in which a somewhat startling announcement is made. Mr. Spiller has been conducting a series of very delicate experiments, for which his well-known chemical skill, and the appliances of the laboratory at the Royal Arsenal, have given him unusual facilities, for the purpose of determining the average quantity of silver and gold in the toned, fixed, and washed photograph. The results obtained are, in themselves, sufficiently interesting and curious, and will be suggestive of the amount both of gold and silver still to be saved by properly directed care and appliances. But apart from the interest of the facts educed in this direction, there is the incidental discovery of another fact, which will, we apprehend, take all photographers by surprise, and suggest new and very serious considerations as regards the permanency of all albumenized prints, no matter how minute the attention to every known condition of stability.

The whites of all carefully treated photographs are believed by photographers to consist, as they ought to do, of white paper only, albumenized or otherwise, without any trace of any chemical whatever. The salts of silver formed in sensitizing, which have been protected by the dense parts of the negative, such as white skies, shirt fronts, &c., and thus not reduced by light, are supposed to be dissolved in the fixing bath of hyposulphite of soda, and removed from the print there and in the subsequent washings. Mr. Spiller has discovered that this is not the fact. A silver compound of some kind remains with the albumen, undissolved by the hyposulphite of soda. What this compound may be, we cannot, at present, say. The chloride of silver is undoubtedly removed. The compound termed by photographers, albuminate of silver, is sensitive to light, whereas, the silver left in the whites of the albumenized print is clearly insensitive to light, as the prints do not darken when exposed; it is there, nevertheless. When Mr. Spiller first discovered its presence, he at once suspected that it was the result of careless manipulation in the individual prints under examination. He at once made enquiry of the various civilians and artillerymen "told off" to photographic duties in the Arsenal, and found that the usual proper amount of care was exercised in fixing and washing the prints, and that the presence of silver was not due to any manipulatory neglect. A number of other albumenized prints were examined, and the whites of every one, when touched with sulphide of ammonium, yielded the characteristic stain of silver. The whites of plain prints, on the other hand, gave no stain whatever. Not quite satisfied still, Mr. Spiller procured several samples of paper, plain and albumenized, and exciting all on the usual silver bath, they were dried, and then washed, and fixed in the usual manner, but without exposure to light. The result was, that notwithstanding the utmost care used, the albumenized paper, which should have possessed no trace of silver, gave unmistakeable evidence of its presence; whilst the plain paper, treated in the same manner, was perfectly free.

Now, as the albumen itself contains sulphur as one of the elements of its composition, it is tolerably plain that the elements which cause fading and yellowness existing side by side, constitute a predisposing cause of destruction, and that they only require an exciting cause to put them into injurious operation.

We have just taken a dozen albumenized prints at random, the produce of both amateur and professional photographers, the whites of every one, when treated with hydrosulphate of ammonia, manifested the presence of silver, the stain being deepest in those in which the paper was most highly albumenized. Plain paper prints, and resinized paper prints, on the other hand, remain unaffected under the same treatment. This circumstance affords additional inducement for prosecuting the resinized paper printing experiments.

We recommend our readers to repeat this experiment for themselves. Let them test the whites of any of their albumenized prints, by just touching them with hydrosulphate of ammonia, a brown stain, indicating the presence of silver, will be the result. To make the experiment more satisfactory to those unpractised in chemistry, let them try its effects on albumenized paper which has not been in contact with silver, and also upon the whites of a plain paper print; in both these cases the sulphide will have no effect, and produce no stain whatever.

The presence of a serious evil is discovered: the remedy remains to be found. Mr Spiller is still experimenting for that purpose. Our own remedy would be to discard, as soon as possible, the use of albumenized paper.

## PHOTOGRAPHY IN AMERICA.

We have recently had the pleasure of spending several evenings in the company of Professor Edwin Emerson, of Troy University, U.S., who is on a few years' visit to Europe, and have had some chat with him on photography in America, a subject in which, knowing from personal observation the practical skill of American operators, we always feel considerable interest.

It afforded us considerable satisfaction, and was gratifying to our national pride, to learn that Professor Emerson, himself an accomplished amateur photographer, considered English photography in many respects in advance of that of his own countrymen. Notwithstanding their great skill in portraiture, there were many branches of the art to which they had given but little attention. To illustrate, we may mention that composition photography is unknown there. Two of the purposes the learned Professor had set before him in visiting this country were to see a composition photograph, and to procure a Dallmeyer's triple lens. Of the composition pictures we had the pleasure of showing him in our personal collection, Mr. Robinson's "Holiday in the Woods," and Mr. Brothers' memorial picture of the principal members of the British Association who met last year at Manchester pleased him most. With these he was much charmed, their excellence fully meeting the ideas he had formed of this class of productions.

In examining various instantaneous pictures, especially the magnificent transparencies of Mr. Breese, he remarked, that in this country we possessed a facility for the production of beautiful clouds and atmospheric effects of which the American photographer was entirely deprived, from the simple fact that such clouds do not exist there. During the greater part of the year nothing prevails but the clear blue sky, which, whilst it is favourable to photographic operations generally, deprives instantaneous pictures of one of their most charming features.

Hitherto the amateur photographic public in America has been decidedly limited, much more so than in this country. Since dry photography has begun to be appreciated there the number of amateurs has increased, and is, we imagine, likely to continue increasing at the termination of this unhappy war, which, by the way, Professor Emerson only regards as commencing, and contemplates the possibility of its continuance during ten years yet.

The dry process most used in the States is the tannin. Professor Emerson himself, who, as our readers know, practises that process, possesses the utmost confidence in it, and states that he never dreams of a failure. His experience confirms our own as to the increased sensitiveness gained by the addition of honey to the solution of tannin, without any loss of any kind, in keeping or otherwise, arising from its use. He lays especial stress upon the advantage of using a very old bromo-iodized collodion as pre-eminently well suited for tannin plates. A neutral bath he has generally found to confer greater sensitiveness, with these plates, as with the wet process, but with the drawback that it induces a tendency to fogging. Heat, as an aid to development, has also been successful in his hands in reducing exposures very materially.

Mr. Thompson's changing box, which, as we informed our readers last week, is simply one manufactured by Mr. Hughes, of Oxford Street, has been the admiration of all amateurs on the other side of the water, from its simplicity and convenience, and its delivering the plate from its dark chamber into its place in the camera, without any jerk or unnecessary shaking. Dry plate photography, not having being largely practised hitherto, the acknowledged mechanical ingenuity of our American brethren has not, as yet, been called much into action to meet its requirements. Double backs appear to be as yet unknown amongst them; and when we showed Professor Emerson our own portable stereoscopic camera, with its equipment of double backs, as manufactured by Meagher, he was inclined to regard it as still more convenient than the best changing box.

The problem of an instantaneous dry process continues to excite much interest in the States. Neither hot water, nor citric acid, nor ammonia, appear to have solved the question, on the other side of the water more than here. The editor of the *American Journal* remarks, in reference to this subject, that whilst many pretend to a fair solution of the question, the prints, and not the process, are shown, leaving the matter to rest on personal veracity only, which, he adds, "is a poor reliance: in England, we suspect, there are a few more Pounceys still left; and here, Rev. Hills."

Mr. Sutton, who appears recently to have awoke to the fact on which we have so long insisted, namely, the importance of two salts of silver in dry plates, appears to think that he has solved the problem by the use of iodide and bromide, in the proportion of equal atoms. He describes the process in a paper to be read before the British Association, at Cambridge, which we shall give in an early number. The plates are stated to be equal in sensitiveness to wet collodion. We shall heartily rejoice if it be so.

## ON THE EXPENDITURE OF SILVER AND GOLD IN PHOTOGRAPHIC OPERATIONS.

BY JOHN SPILLER, F.C.S.

In continuation of a series of analytical experiments upon the amounts of gold and silver expended in the process of printing upon albumenized paper, the general results of which were announced in the Photographic News of the 18th of July last, I beg leave now to furnish additional particulars in reference to some points which, at that time, had not been fully ascertained.

First, with regard to the actual consumption of the precious metals, it has already been shown that, in the preparation of a full-sized sheet of albumenized paper, floated for five minutes upon a 70-grain solution of nitrate of silver, 50 grains of the nitrate are ordinarily withdrawn from the bath, but that inasmuch as 40 grains and upwards of this amount may be recovered in the form of silver residues easily convertible, the quantity of nitrate actually expended may be estimated at about 10 grains (or one pennyworth) per sheet. The object of the chemical investigation now to be described has been mainly to determine the proportion of gold and silver fixed and retained in the finished proof, and to compare this amount with that already ascertained to have been expended in the ordinary mode of conducting the operation of photographic printing.

For the purpose of this enquiry, a number of prints, on albumenized paper, were taken, which were considered to be well toned, and to exhibit the relative proportions of light and shade ordinarily presented in landscape photographs. The subjects were various, and the depth of printing such as to render it desirable to arrange the pictures in two sets of twenty and twelve respectively, which should fairly represent the two limits between which the average amounts of silver and gold would generally range. The set of twenty may be said to illustrate the lighter style of printing, and the twelve darker subjects to express the maximum result. In order to ensure the thorough removal of traces of chlorides and soluble salts generally from these photographs, they were washed in three changes of warm distilled water as a preliminary precaution; they were then immersed for about twenty minutes in a hot solution of pure nitrate of potash, taken out and dried; the object of this treatment was two-fold: in the first place it facilitated the combustion of the paper and other organic matters in the next stage of the process, and by furnishing a small proportion of alkaline carbonate effectually prevented the loss from volatilization of any chloride or other salt of silver. The pictures were burnt in succession over a porcelain basin, and the ashes resulting were further reduced in bulk by the direct application of a blowpipe flame. The residual matter was then washed several times with pure boiling water, until all the alkali was removed, the solution being thrown away after it had been ascertained that no traces of the metals sought were contained therein. The fixed residue was then digested with nitric acid to dissolve out the silver and leave the gold, and after having separated, in this way, nearly the whole of the silver, the remaining ash was treated with warm nitro-hydrochloric acid to extract the gold, a trace only of chloride of silver being afterwards recovered from the silicious residue by the solvent action of ammonia. In order to estimate the amount of silver, the whole of the metal was precipitated from the nitric solution and weighed as chloride, and the gold being reduced from the second solution, by the aid of bisulphite of ammonia, it was easy to collect, wash, dry, and ascertain, likewise, its weight.

The twenty photographic prints, having an aggregate superficial area of 1,760 square inches, furnished 1·93 grains of chloride of silver, and ·63 grains of metallic gold.

The twelve darker copies measured, in the aggregate, 721 square inches, and gave of chloride of silver 1·22 grains, of metallic gold ·31 grains.

If, from these data, the amounts of metals be calculated upon the whole sheet of printed albumenized paper, estimated at 390 square inches, we arrive at the following results:—

| | Silver | Gold |
|---|---|---|
| I. Ordinary proof | ·321 grains | ·140 grains |
| II. Darkly printed | ·496 „ | ·167 „ |

It will be remarked how small a proportion of silver and gold is contained in the finished photograph, and that for the ultimate deposition of this half grain of metallic silver, no less than thirty-two grains of the metal (in the fifty of nitrate), have to be employed in the original preparation of the sheet of paper; or, by another mode of stating the results, 1·6 per cent. only of the amount of silver used is permanently fixed in the photographic print. What a wide margin for the exercise of economy in the collection of the residues, and what wonderful evidence of tinctorial power is here displayed! With regard to the amount of gold actually absorbed by the print in the operation of toning, it appears that one grain of the terchloride should in many cases be sufficient for three whole sheets of paper, if means could be devised for working the toning baths to exhaustion. The result of the experiments just now described proves in each instance that in the operation of toning the print the particles of reduced silver become superficially coated with metallic gold, but that this interchange does not ordinarily extend to the entire removal of the silver, and its replacement by gold as stated by Dr. Schnauss,* for in the series quoted above a much larger amount of silver than gold was detected. In order to set this question at rest, I have selected prints which, of an inky or bluish-black colour, would be described as "over-toned;" in every case I have detected silver in the print, and generally in proportion exceeding that of the gold.

Proceeding in the next place to enquire into the disposition of the silver and gold upon the surface of albumenized proofs. I have been somewhat surprised to find so much silver existing in the sky, and other perfectly protected portions of the print, an observation which led me to examine a large number of photographs, and cuttings removed from the same preliminary to mounting, also the productions of other operators besides the work executed by our own department, and in no instance have I failed to detect silver by the discolouration on moistening the albumenized surface with sulphide of ammonia, and allowing this reagent to dry upon the paper. But if prints on plain paper be similarly tested there is no evidence of any silver remaining in the white parts of the picture, nor on the back or unprepared side of albumenized prints, will any silver be found, a conclusive proof that the same treatment which effectually removes the whole of the silver from plain paper in the course of fixing and washing, is not capable of dissolving out entirely the silver from albumenized surfaces. As a confirmatory experiment, however, I sensitized plain salted paper and three different samples of albumenized paper in the same nitrate of silver solution, and, as soon as dry, they were, without exposure to light, all washed together in several changes of common water, then fixed in a newly-made solution of hyposulphite of soda (one ounce of the crystals to four of water), and again repeatedly washed as usual, until, after a twenty-four hours' interval and a plentiful supply of water, they were judged to have been sufficiently washed. When dry, the sheets of albumenized paper contained silver in quantity sufficient to give a dark stain with sulphide of ammonium, whilst the plain paper did not contain a trace. Since making this observation I have endeavoured to find some ready means of separating this last portion of metal from its combination with albumen, and have subjected the samples of paper to treatment with hot and cold salt brine, tartaric acid, the tartrates, and a variety of other salts, without any appreciable effect; a second immersion in hyposulphite of soda removes some of the silver, and iodide of potassium, and the citrates appear to dissolve out a larger proportion, but I am still in search of a solvent which is at once both cheap and efficient.

As to the disadvantages arising from the existence of silver in the pure whites of the photograph, it must be remembered that they are always liable to discolouration by exposure to an impure atmosphere, and likewise by the effect of sulphur contained in the albumen itself as a constituent, which, if liberated by incipient decomposition or other cause, would immediately unite with the silver, and give rise to those yellow appearances so commonly observed in the early stages of fading, and, at the present moment, so palpably manifest in the Photographic Gallery at the International Exhibition.

Royal Arsenal, Woolwich, *September* 27, 1862.

## The International Exhibition.

### BRITISH PHOTOGRAPHIC DEPARTMENT.

The history of the International Exhibition will be a history of grievances. Nothing is more irksome than the task of perpetually recording, in connection with such a magnificent undertaking, a series of reiterated follies and mistakes. The task, however, often becomes imperative, for the purpose of preventing misunderstanding. Here is the "Illustrated Official Catalogue," the shortcomings of which have been already so often pointed out, and dwelt upon. We had hoped to pass it by without mention; but we have had several enquiries regarding it, and have heard many comments upon it, from which we find that a large portion of the public, photographic and general, persist in regarding it as being what it really ought to be: an official catalogue with illustrations and descriptions of such objects as were worthy of especial attention, instead of being, as it really is, simply a grand advertising medium. It should be distinctly understood, then, that all the illustrations, and all the descriptions, are advertisements, prepared by, and paid for, by the contributor. The fact of the contributions of one house being specified in a single line, and of another occupying a page or two of illustrations, descriptions, lists of prices, &c., does not in any degree indicate that the one deserves greater prominence than the other; but, simply, that one paid for the advertisement, and the other did not. To dignify such a production with the title of "Official Illustrated Catalogue," is, in the last degree, contemptible. The *Times*, a few weeks ago, had some excellent remarks on the subject:—

"The first two volumes of the 'Official Illustrated Catalogue' have just been issued. As compared with the similar catalogue in 1851, or even regarded in the milder light of a common pictorial record of this Exhibition, it is a dull and most unsatisfactory book. In 1851, the 'Illustrated Catalogue' was a work of private enterprise, and, like any other book, had to be made as instructive and attractive as possible; and, both these conditions being admirably fulfilled, the work had so large a sale that the Commissioners, on this occasion, were tempted out of their legitimate province, and undertook the publication of the catalogue themselves. With a not unnatural distrust of its financial success, the cost of printing, publishing, &c., was secured in advance by charging so much a page to the exhibitors who wished to appear in it, leaving them to find the illustrations and the matter, and admitting nothing that was not paid for, and everything that was. The result is exactly what might have been anticipated. The official illustrated catalogue of 1862 is merely two volumes of tradesmens' advertisements. In vain we ransack its pages in search of anything that will remind us of the great triumphs of art manufactures collected at South Kensington. Amid its meagre rows of names and price-lists are thinly interspersed woodcuts of cheap beds, boots, kitchen ranges, saddlery, false teeth, &c.,—just such leaves, in short, as one turns over at the end of *Bradshaw*, during the tedium of a long railway journey. Scarcely an attempt is made to reproduce any of the fine English works, either in glass, porcelain, furniture, or precious metals, and, when they are attempted, as in the case of Elkington's, Hancock's, Hunt and Roskell's, or Harry Emanuel's, the attempts are worse than failures. It is said that the three volumes of the foreign portion of the Exhibition will make up for the deficiency in the English. This may, or may not, be so; but, even if true, it is no manner of excuse for the issue of these two volumes of mere trade advertisements, as the 'Illustrated Catalogue' of the contents of the English Exhibition. They are, *unquestionably*, the dearest and dullest volumes that have been published for some time, which is saying a great deal in a few words."

The paucity of information in any of the catalogues, except in the form of the advertisements referred to, and the fact, that apparatus is enclosed in glass cases, inaccessible to the public, somewhat interferes with the complete utility of the Exhibition. A full description of the contents of each case, with details of the especial intention of the respective articles, would have added materially to the value of the display. In making our own observations upon photographic apparatus, we have aimed, as far as possible, especially in relation to all novelties, to obtain opportunity for careful examination, with detailed explanation from the exhibitor. In reference to a large proportion of the apparatus, it consists, as we have before remarked of the ordinary instruments in every-day use, well known to photographers, and not needing any detailed description.

Messrs. Horne and Thornthwaite (3,100) contribute an excellent display of apparatus and chemicals. The latter have already been noticed in these columns: they are especially well worthy of the attention of photographers, as comprising some of the most carefully prepared and beautiful samples exhibited. A specimen of chloride of gold excites much attention from the extreme beauty of the crystallization. Amongst the apparatus are examples of various stereoscopic cameras, including the well-known and very portable Powell's stereoscopic camera. A camera for card portraits is exhibited, which has a neatly contrived back for square plates, holding four negatives, which are produced by two lenses. A clever instantaneous shutter, on the guillotine principle, and some other articles, complete a display of very excellent apparatus, but without any especial novelty which we have observed.

Mr. J. C. Leake (3,111) exhibits his portable tent, manufactured by Squire and Co. The example sent to the photographic department was, we believe, made at the last moment possible to secure admission, and having been made under these circumstances of imperfectly seasoned wood, and exposed during the first week or two to the full blaze of the sun, became very much twisted and warped. It is only fair to add, that we have one in our possession which has been subject to a good deal of change of temperature during the last two years, and is still perfectly free from warping, or injury. Notwithstanding the number of tents in the market, this remains the lightest and cheapest we know. It has not so many appliances as many, and is, perhaps, even with those it has, susceptible of some improvements, but its extreme lightness and portability are great recommendations. We subjoin a description of it, which has before appeared in our pages:—

"This tent comprises lightness, portability, simplicity, and cheapness, combined with efficiency, in a greater degree than most that we have seen. It consists primarily of a shallow box or tray, about twenty-two inches long, twelve wide, and two deep, the lid forming the top of the tent. Round three sides of this tray is secured the lining, of black and yellow calico, and a curtain of the same material wraps round the operator, and excludes light. The top is supported by two light iron rods, which are of sufficient length to keep the covering in a state of tension, thus insuring perfect rigidity. An aperture in front admits of sufficient light for convenient working, and a gutta-percha tray, with a flexible tube attached, carries off the waste water. The whole is attached to a tripod stand, of a height to suit the operator. When not in use, the covering folds into the box, which may be conveniently carried by the handle attached to the side. The weight of this tent, complete, is about five pounds."

## THE NEW METHOD OF PRINTING.

### ON THE USE OF GUMS OR RESINS INSOLUBLE IN WATER FOR POSITIVE PRINTING.

BY H. COOPER, JUN.

Notwithstanding the many good qualities of the paper prepared with benzoin, it has one serious disadvantage; that is, the oxidation ot the gum by exposure to the air, which will render the prints yellow after some time. I did not think of this before I sent my last communication; but I discovered it soon after, to my great mortification, as some paper that I had prepared a fortnight, the yellow had become deeper to an appreciable extent. I then set to work, to see if any of the gum resins that I had not tried would do as well as benzoin. After a few trials, I hit upon frankincense. This gum appears to possess all the necessary qualities, and, moreover, it does not oxidize by exposure. Frankincense is a resin very nearly allied to common rosin, which makes it very difficult to obtain in a pure state, as it is very often, particularly in the cheaper kinds, adulterated with the common rosin. Although no great objection to this latter gum would be apparent at first sight, as the resinate of silver is very sensitive to light, yet, upon a closer investigation, it will be discovered that it is liable to a great deepening of colour by oxidation. Therefore, one great point is to procure the frankincense perfectly *pure*, which can generally be done by applying to a respectable house, and paying a good price for it. As it has been often said, cheapness, in its common acceptation, is the bane of photography.

Upon preparing some paper with frankincense *alone*, I found that the prints, upon drying, became covered with a kind of cold bluish bloom, which was quite detrimental to depth and transparency; I therefore added a small quantity of chio turpentine, which had the desired effect—that of removing the bloom, and giving a warm tint to the picture. As I have received many inquiries as to the nature of benzoin, and other substances mentioned by me in last Friday's News, I will explain the nature of any that I may have to call attention to, so as to be sure of being rightly understood. Chio turpentine is a gum resin used in medicine. It is a solid, but soft and pliable, like india-rubber, except that it is not elastic. Like frankincense, it is easily soluble in alcohol, but insoluble in water.

Having made several experiments upon benzoin acid, I am very nearly convinced that it has no other action on the print than nitric or acetic acid would have.* It cannot act upon the silver, except by double decomposition; but Mr. Simpson suggested, that a trifling alkalinity in the bath or the paper itself might be sufficient to aid in forming a trace of benzoate of silver, which might have some peculiar action upon the image. I find that, although it makes the prints slower in printing and toning, it is rather desirable in a small quantity, as it is conducive to clearness and cleanliness.

Both frankincense and chio turpentine being soft resins, I recommend the addition of some harder gum, to keep the picture more upon the surface. Too much must not be used, as it would make it difficult to obtain an even layer of chloride of silver. I have employed a small quantity of "Sochnée" varnish, which seems to answer perfectly; but as I wish to make the formula as simple as possible, I intend trying mastic, a portion of which is easily soluble in alcohol.

The improved formula is as follows:—

| | |
|---|---|
| *Pure* frankincense ... ... | 1 oz. |
| Chio turpentine ... .. ... | 1 drachm |
| Sochnée varnish ... ... ... | 2½ drachm |
| Benzoic acid ... ... ... | 1 drachm |
| Chloride cadmium ... ... | 1½ to 2 drachms |
| Methylated spirit ... ... | 10 oz. |

Although I say 1½ to 2 drachms of chloride of cadmium it is very difficult to ascertain exactly how much is dissolved by the alcohol in which it is but sparingly soluble. My plan is to weigh out 1¾ drachms of the chloride, reduce it to a powder, place it in a capsule, with its weight of distilled water, then apply heat till it is dissolved, and continue the heat till it is about to crystallize, then add the 10 ozs. of spirit, stir it up and pour it into a bottle, in which shake it up every now and then for six hours, when only a small portion will remain undissolved. I then filter the solution and add the frankincense, chio turpentine, benzoic acid, and sœhnèe varnish, shake till dissolved and put by to settle.—Proceed in the preparation of the paper in the same manner as for the benzoinized paper. Print *deeply*, as the prints lose more than those prepared with gum benzoin.

I have been asked whether the soaking in warm water is necessary. It is necessary that the print shuld be thoroughly permeated by the water before toning; cold water will do, but it takes longer than warm. With *Papier Rive*, the soaking will only take from 10 to 15 minutes. As regards the respective merits of *Papier Rive* and *Saxe* I may add that

* Benzoic acid is a body resembling, in appearance, pyrogallic acid. It has a very faint acid re-action; and it is obtained by sublimation from gum benzoin.

I consider the latter most suitable for large pictures, and the former for smaller subjects.

One peculiar feature of the paper prepared with frankincense is the dull look of the prints when they are dry, but this appearance vanishes as soon as they are rolled, when the picture starts out in all its fineness and depth. A high degree of gloss may be obtained by rolling both before and after mounting. The appearance, as regards surface, of albumenized paper may be imitated by immersing the unmounted rolled prints in a weak solution of mastic; care being used to prevent streaks, &c.

In answer to several inquiries respecting the manufacture of the paper, should it succeed, I take this opportunity of stating that I have no intention of supplying it, as I only pursue the art of photography as an amateur, and that I shall not have the least objection to any gentlemen, who may feel so disposed, preparing it for sale. I am convinced, by the number of applications I have received, of the interest the publication of the formulæ has created. In fact, I was quite unprepared to supply more than a quarter of the number of samples required; I took every care possible in dispatching them to the respective addresses, but if, through any mistake, any gentleman have not received their paper, I should be glad if they would let me know, and receive the above as my excuse. I have only a few more words to add. In a thing of this kind it is necessary, to ensure perfect success, that others should repeat the experiments made and proposed by the originator.—Photographers! do not be disheartened by the failure of the first trial. Try again! and if the instructions I have endeavoured to clearly lay before you, are attended to, I do not doubt of your success. I shall be most happy to hear of the result of your experiment. I shall continue mine, and if I hit upon anything important in any of the points of the process, I will not fail to let you know through the medium of those pages from which I have myself derived so many useful hints.

## PRINTING AND TONING PROCESSES.*

Much of the progress of photography is so gradual that it is scarcely perceptible, and consists more in the gradual aggregation of the experiences of able men than in any marked or entire revolutions of the processes employed. The methods of printing now used, as judged by the results displayed at the International Exhibition, might suggest two very opposite conclusions: from the delicacy, richness, and tone of the prints exhibited great progress might be argued; whilst from the faded and yellow condition into which some of the prints have, in the course of a few months, fallen, the absence of improvement, if not retrogression, at least as regards permanency, might be deduced with equal conclusiveness. On more mature reflection, however, it will be seen that, whilst almost all the prints have improved in quality, some have remained permanent as well. The conclusion inevitably follows, that, if *some have* remained permanent, *all might* have done so, and that real progress has been made. It may be of advantage, then, occasionally, carefully to collate the methods used by able men, and re-state those which, by their theoretical truth or success in practice, may be relied upon as giving the best results.

The use of albumenized paper for photographic prints is now all but universal, and it is necessary to deal with such formulæ as have reference to its employment. The majority of photographers purchase their paper ready albumenized; but, for the convenience of those of our readers who may feel disposed to prepare their own, we shall briefly refer to the best methods in use.

*The Paper.*—The French and German papers are almost universally used for albumenizing in the present day. There has been for some time past an outcry amongst photographers, that good paper was difficult to obtain. Whether the quality of photographic paper has really deteriorated, or whether the increased demand offers the temptation to put worse or unsuitable samples in the market, or whether the methods of working now in use have introduced new troubles demanding a peculiar quality of paper for their removal, it is difficult with certainty to determine. The utmost that we can say here is, procure for albumenizing the best paper possible, selecting the French or German according to the results desired. The French paper, *papier Rive*, has the hardest surface, and gives the most brilliant prints, but it is more difficult to procure of good quality, more subject to spots and surface imperfections, and more difficult to manage in all the manipulations than the German paper. It is also very subject to blister in the processes of toning and fixing. These blisters, although they generally disappear on drying, sometimes leave traces of their presence which are very annoying. *Saxe* paper is more free from imperfections, and is easy to manage throughout; it yields softer prints than the *Rive*—with less of contrast; but with careful manipulation and a good negative, no lack of brilliancy need exist in the results. It is almost unnecessary to repeat the cautions as to the selection and marking of the smooth side of the paper, as it will be manifest that this is as important in albumenizing as it was with plain paper when that was used.

*Albumenizing and Salting.*—Wherever they can be procured, fresh eggs should be used for albumenizing photographic paper. The use of stale eggs, or the practice of keeping the albumen for a few days, has been recommended by some, on account of the facility it gives to the manipulating part of the operation, arising from the increased fluidity of the albumen. But the decomposition of that body, either before it is applied to the paper or after it is on its surface, is a prolific source of future troubles. The proportion of albumen must depend on the surface required. For small and delicate photographs, such as card-pictures, pure white of egg should be used, in order to obtain the highest possible surface. For larger pictures a less amount of glaze is desirable; and the proportion may be varied, according to taste, from three ounces of white of egg and one of distilled water to equal parts of each. It should be borne in mind, however, that the tendency of albumen is to give red prints; and the greater the proportion of albumen, the greater the difficulty in securing black tones.

The proportion of salt is a most important point, and one on which much discrepancy of opinion and practice exists. Some of the best authorities who have written on the subject recommend a very large proportion of salt. Mr. Maxwell Lyte says that in his experience three per cent. of chloride of sodium, or nearly 15 grains to the ounce of solution, is the minimum proportion which should be used, and that he prefers for his own use 4 per cent., or nearly 20 grains. Some other excellent photographers recommend 10 or 12 grains to each ounce of solution. The practice amongst professional albumenizers generally, however, is opposed to this large proportion, very few of them using more than 8 grains to the ounce. One large firm, which has a reputation for producing albumenized paper of very superior quality, recently informed the writer that, in their general practice with paper used successfully for card and stereoscopic pictures by many of the best photographers of the day, they used pure white of egg and 7 grains of salt to each ounce, half of which was chloride of sodium and the other half chloride of ammonium. Another large firm stated that they used 8 grains of chloride of ammonium to each fluid-ounce of white of egg. A well-known photographer, whose paper is prepared in his own establishment to the extent of something like 3 reams a week, states that he uses 4 grains of chloride of ammonium and 4 grains of chloride of barium to each ounce of pure white of egg. Mr. T. R. Williams, who stands first amongst photographic portraitists, and whose prints are irreproachable, uses practically less chlorine than any of these, his proportion being 10 grains of chloride of barium, which is equivalent to about 5 grains of chloride of sodium, to each ounce of solution.

We may remark, *en passant*, that, whilst the consideration

* From the *Photographic Journal.*

of the base of the salt used has reference chiefly to the proportion of chlorine with which it unites, yet a strong impression prevails amongst many photographers that it does exercise some influence on the final tone of the picture —the chloride of sodium tending to a cold tone, and the chlorides of barium and ammonium to a warm tone.

In reference to the proportion of chloride, it should always be remembered that the larger the amount used in preparing the paper, the stronger should be the silver bath. Mr. M. Lyte, when using 20 grains of chloride of sodium in preparing the paper, used 100 grains of nitrate of silver to the ounce of water in exciting it. Those who successfully use 15 grains of chloride, generally use a 75-grain silver bath. Stating the matter roughly and in round numbers, the chlorine in 1 grain of chloride of sodium will unite with the silver in 3 grains of nitrate of silver. When a 20-grain chloride solution is used, a 60-grain nitrate solution will be required to convert the whole of the chloride of sodium into chloride of silver; and where a 100-grain silver solution is used, 40 grains are left as free nitrate or in combination with the albumen. With a 15-grain salting solution and a 75-grain nitrate bath, about 30 grains are left for these purposes. With a 12-grain salting solution and a 60-grain nitrate bath, about 24 grains of nitrate and albuminate remain.

With the various commercial samples of paper in which the salt does not exceed 8 grains per ounce, and with which a 60-grain nitrate bath is generally used, the excess of silver as free nitrate and albuminate is much greater.

It is somewhat unfortunate that the importance of the relation between the strength of the salting solution used in preparing the paper and the strength of the exciting bath does not receive more attention. As regards the albumen, and the proportions in which it combines with the silver, still less attention has been given. The exact proportion of pure albumen present is rarely regarded, except so far as it affects the surface to be obtained; and the amount of silver combining with it, and the effect thereby produced, appears scarcely to have received a thought. That some free nitrate is necessary is practically well known, although what part it plays in aiding the vigour of the print is not so well understood. The most probable theory is that which supposes that a portion of the chlorine set free by the action of light upon the chloride of silver unites with some of the free nitrate present, forming fresh chloride of silver, which being reduced by light, in addition to the chloride formed in the usual way, thus adds to the amount of reduced silver and the consequent vigour of the picture.

A practical formula, giving very excellent results, stands as follows:—

| | |
|---|---|
| The whites of fresh eggs ... | ... 3 ounces |
| Distilled water ... | ... 1 ounce |
| Chloride of ammonium ... | ... 40 grains. |

The eggs must be beaten until the whole is converted into a froth: and for certainly perfect results, when it is again fluid the operation may be repeated. The salt should have been dissolved in the water, and added to the albumen before heating. If a higher surface be required, pure white of egg, without water, may be used, preserving the same relation between the salt and the solution, that is, ten grains to the ounce.

No addition of acetic acid or any other substance need be made. The addition of acetic acid causes the formation of acetates, which induce rapid discoloration of the excited paper and other troubles.

The process of albumenising should be performed in a room at a temperature of at least 70° Fahrenheit, as rapid drying keeps the albumen on the surface of the paper, and aids in producing brilliant prints. There should be plenty of solution in the dish. The sheets should be raised from the surface of the albumen, and suspended from two corners by the aid of American clips, without any turning of the sheet round, first holding by one corner and then by another in the way which has been recommended by some amateur writers, such a method tending to produce streaks. Practice only, and the exercise of judgment and skill, will enable the manipulator to avoid bubbles, and get an even surface, free from streaks and uneven waves of albumen. From half a minute to a minute will generally be sufficient time for each sheet to remain on the albumen; but the thickness and absorptive powers of the paper will, in some degree, govern the time; a thin and soft paper requiring less time than a thick or hard paper. The paper, when dry, will be improved by rolling. It should be stored in a very dry place, as it deteriorates if kept damp.

*The Exciting Bath.*—In the ordinary method of printing, a 60-grain nitrate bath should be used, with the paper prepared as above, without the presence of either free nitric or acetic acid. Three minutes' average floating will serve; but the time will be modified by the quality of the paper, just as in albumenizing. Some operators have recently recommended the use of an ammonio-nitrate bath for albumenized paper. The results are unquestionably very good when the process is successfully worked, but it requires great care throughout. A very strong bath should always be used in such a case; for a strong bath has another use besides those already indicated, namely, to coagulate the albumen rapidly, and thus keep the silver on the surface and preserve the brilliancy of the image. If the bath be at all alkaline, great strength is imperative, that the albumen may be coagulated before the ammonia has had time to dissolve it.

The formula most generally recommended is to make 20 ounces of a 80-grain solution of nitrate of silver; then take half of it, and add ammonia until the precipitate first formed is re-dissolved, in the usual way of making an ammonio-nitrate bath. This done, the solution is to be added to the remaining half of ordinary silver-solution; and about 2 ounces of absolute alcohol, or 1 ounce of ether, is to be added to the whole. Another method is to make an 80-grain ammonio-nitrate bath, and then divide it into two parts: to one of these add nitric acid until it has a very faint acid reaction. The two parts are to be added together, and the solution is ready for use. With either of these baths, the paper must be floated for a very short time, or there will be danger of the ammonia dissolving off the albumen in patches. A few seconds will suffice with some papers, and in no case should a minute be exceeded.

Another method is simply to add sufficient ammonia to produce a very slightly alkaline reaction, using also a strong bath and short floating. It is certain that a neutral or slightly alkaline bath makes the paper more sensitive and less liable to the irregular mottled toning called *mealiness*. The paper should be dried rapidly, and used as soon after exciting as possible.

*The Printing.*— A point sometimes overlooked is the is the importance of having the paper perfectly dry before placing it in the pressure frame. Sometimes, in his eagerness to get a batch of prints into the light, the operator will place the paper in the frame as soon as it is surface-dry, but whilst retaining some traces of moisture in the body of the paper. The result is, that the prints are drying and shrinking whilst exposed; and a blurred, imperfect image is the result. The most brilliant images are generally produced by printing in diffused light, which is to be preferred for all cases except where the negative is very hard and intense. Unless a negative have sufficient vigour to allow of a slight bronzing in the shadows, without over-printing the lights too much, it will be difficult to get deep-toned and rich prints.

*Toning.*—The prints should be washed in two or three changes of water prior to toning. If the first washing-water be distilled, it will frequently prevent the formation on the face of the prints of a thin film of carbonate, chloride, or other insoluble salt of silver, which, adhering very firmly, interferes with the toning-operation. It is desirable that, in the washing, each print be thoroughly soaked or permeated with the water, so that when it enters the toning-bath the action upon it may be even and regular.

Various formulæ for what is called the alkaline gold toning process have been proposed, and tried successfully. Those which have found favour with the greatest number appear to be that of Mr. Maxwell Lyte with the phosphate of soda, and that of Mr. Michael Hannaford with acetate of soda. The first stands thus:—

| | | |
|---|---|---|
| Distilled water | ... ... ... | 5 ozs. |
| Terchloride of gold | ... ... ... | 1 gr. |
| Tribasic phosphate of soda | ... ... | 20 grs. |

The second formula stand thus:—

| | | |
|---|---|---|
| Distilled water | ... ... ... | 5 ozs. |
| Terchloride of gold | ... ... ... | 1 gr. |
| Acetate of soda | ... ... ... | 30 grs. |

Experience has proved that either of these solutions gives better results, toning more evenly, and free from the mealy, mottled effect sometimes obtained, when they have been mixed a few days or even a few weeks previous to use. Should they, when thus kept, appear sluggish or inert, a few drops of a fresh solution of chloride of gold, of the same strength, will commence the toning-action, which will then proceed without interruption. If the prints have been sufficiently washed to prevent any decomposition in the gold bath whilst toning, the solution may be used over and over again, without disadvantage.

The prints should be kept moving about whilst the toning is going on, to prevent any irregular action. The operation should be performed in yellow light; but a glance now and then by the aid of daylight may be taken, to judge better of the exact tone, which should be a little deeper before removal than is required, so as to allow for loss in fixing. Over-toning should, however, be avoided, as it destroys the brilliancy of the print.

It may be important to remark that, whilst phosphate of soda and acetate of soda are both, theoretically, neutral salts, they generally possess a slightly alkaline reaction, which is in some cases sufficient to neutralise any trace of free acid in the chloride of gold. This is not, however, always the case: and in order to avoid the slightest risk of any free acid reaching the bath of hyposulphite of soda and causing decomposition there, it is desirable either to test the solution with litmus paper, and add, drop by drop, sufficient of a solution of carbonate of soda to neutralize it, or what is simpler and better, place each print into a dish containing a weak solution of carbonate of soda, as it comes from the toning bath, and allow it to remain a few minutes before fixing.

The methods of alkaline gold toning and subsequent fixing, are considered by the majority of photographers to be more philosophically correct, and to afford the best guarantee of permanency; nevertheless, it must not be denied that many excellent authorities have contended that the old methods of toning with hyposulphite of soda and gold, when conducted with proper precautions against sulphur-action were quite as trustworthy as regards permanency, and simpler in operation, than the new methods. Amongst these we may mention Dr. Diamond, whose prints are well known in the scientific world as amongst the most perfect and rich in tone, as well as the most permanent of those which have been fairly tested by time. His method is as follows:—To a pint of saturated solution of hypo, 4 grains of chloride of gold are added, and a piece of biborate of soda, about the size of a walnut. The prints are placed in this solution until they acquire the desired tone, and are then removed and left for a quarter of an hour in a fresh solution of hypo. Neither solution is ever used after the slightest evidence of decomposition is manifest, either by smell or by discoloration.

*Fixing.*—After toning by the alkaline gold bath, the prints are to be immersed in the soda bath, or rinsed and placed in fresh solution of hyposulphite of soda, four ounces of the salt being dissolved in every pint of water. It is somewhat difficult to state with accuracy the number of prints which may be perfectly and safely fixed in a given quantity of hypo solution, so many circumstances affect the question; but, as a general approximation, it may be stated that one sheet of paper may be safely fixed by each ounce of hyposulphite of soda, if care be taken to avoid any decomposition. As the material is cheap it is never worth while to run any risks. From ten to twenty minutes, according to the kind of paper will generally be sufficient time for the fixing operation. The prints should be kept moving about, and prevented from adhering one to the other. Imperfect fixing, whether from the use of weak or exhausted hypo solution, or too short immersion, or the prints sticking together, is quickly seen from the prints showing mottled patches of a dirty yellow or brown tint produced by the decomposition of hyposulphite of silver, which the fixing-bath was not strong enough, or had not opportunity to dissolve before the print was removed.

*Washing.*—The subject of washing has frequently been discussed, and there is little of importance to be added thereupon. It should be as rapid as is compatible with its thoroughness. Rapid changes of water, and each change as complete as possible, are important. A regular system of changing the prints into a fresh dish of clean water, draining each one for a few seconds before placing in the next dish, more readily removes the hypo than merely pouring water out of the dish where the prints lie, and, without removing the prints, filling up again. A little sponging of each print is very valuable. Four or six hours of such washing as we have described would be more effectual than six times as long with the prints sticking together, without draining or sponging singly. One or two final washings in tepid or warm water are valuable; but hot water is apt to injure the print, and removes the size from the paper. The idea that such removal was an aid to permanency at one time prevailed, but is now generally exploded.

Dr. Diamond attributes much of the permanency of his prints to the practice, which he considers important, of ironing each with an iron as hot as possible without burning the paper.

One or two precautions, sometimes neglected by amateurs, should be mentioned before concluding. First, the importance of conducting every operation, up to the washing, in yellow light. Many operators place the paper in the pressure-frame in daylight, and also examine the progress of printing by the same light; and some even tone in diffused light. The whites of the prints cannot fail to suffer from such habits. Secondly, it is very important to avoid handling the prints, especially with fingers which have touched other chemicals, and more especially still with fingers which have touched hypo, at any stage of the printing and toning. Stains inevitably follow such handling. It is not an uncommon thing to examine and touch prints in the toning bath with fingers which have just touched others in the hypo bath; this tends at once to decompose the toning bath, and to spoil the prints. In short, care, cleanliness, and judgment should be used throughout.

## A SHORT LESSON IN CHEMISTRY.—No. 4.*

Salts exist in three different chemical conditions; in the first place they may still retain an *acid reaction*, a state in which the acid preponderates over the base; secondly, they may be perfectly *neutral*, the natural and legitimate condition of a salt, as we are taught to understand by the definition of a salt; and thirdly, the base may preponderate over the acid, so that such a salt is said to have a *basic reaction*. In exemplification, we have sulphate of potassa, and again bisulphate of potassa, in the latter of which the acid is double in amount of that in the former, and acts upon bases as if it were free; this bisulphate is, in fact, a double salt, being the sulphate of the oxide of potassium + the sulphate of the oxide of hydrogen. Secondly, pure nitrate of silver is a neutral salt, that is, a salt producing no change either on blue litmus paper or on red litmus paper. Finally, subace-

* From *Humphrey's Journal*.

tate of lead is a salt which has a basic reaction, having in fact three times as much of the base (oxide of lead) as the acetate, this salt acts on red litmus paper like an alkali.

Acids, bases, and salts may exist either *hydrated* or *anhydrous*, that is in connection with water or without; not always, however, in either condition but sometimes in one, sometimes in the other, and sometimes in both. Thus we have anhydrous sulphuric acid, and hydrated sulphuric acid; anhydrous soda, and hydrate of soda; and (anhydrous) nitrate of silver. Furthermore certain salts exist either in an *amorphous* condition, or in a crystallized form; in the former condition they may contain water as an essential part of their constitution (constitutional water); in the second they contain an additional quantity of water which is essential to crystallization (water of crystallization). For example, sulphate of the protoxide of iron (protosulphate of iron) exists either as a green vitriol in a crystalline form, or as a white powder in an amorphous condition; the former salt contains seven times as much water as the latter.

Salts are denominated monobasic, bibasic, tribasic, etc., in accordance with the fact that the acid in such combines either with one equivalent of the base, two equivalents, three equivalents, &c., but the two equivalents of one and the same base, or three equivalents of one and the same base; may have their substitutes, giving rise to the interesting classes of compound salts, as for instance: Rochelle salt= tartrate of potassa and of soda: and microscopic salt= phosphate of the oxide of sodium, of the oxide of ammonium and of hydrogen.

In addition to what I have remarked in reference to chemical combinations, you must know that there exist very well defined compounds, acting in one case like metalloids and acids, and in the other like metals and bases; and that these produce, by their combinations with one another, or with either metalloid or base, a species of compound salt exactly analogous to simple salts. This cyanide of potassium is a compound of hydrocyanic acid (prussic acid or cyanide of hydrogen); but hydrocyanic acid=cyanogen and hydrogen; and cyanogen is a compound consisting of two equivalents of carbon and one of nitrogen. Sulphide of ethyl is composed of sulphur and a compound base containing four equivalents of carbon and five of hydrogen. Such combinations are very common in organic chemistry, and will become much more important when we begin to understand the precise reactions in reference to the science of photography.

I have mentioned the word *equivalent* more than once; it requires explanation. Chemical compounds are built up of equivalents, as distinguished from indefinite mixtures; they take just so much of either element in the composition, and neither more nor less. If we assume the weight of the lightest of all elements as the standard of unity, then the individual weights of all the rest of the elements will be multiples of this unit; and, consequently, the weights of compounds will, in like manner, be multiples of the same standard unit. These ratios or comparative weights of the constituents of any compound are called the *chemical equivalents*, or combining proportions of these constituents. For instance, hydrogen is the lightest of all bodies, and it combines with many of the metalloids; let us see in what ratio it combines with them. We may assume 1 ounce, 1 pound, 1 cwt, 1 part, &c., as a starting proportion of hydrogen which is to combine with each of the other elements, as with oxygen, bromine, chlorine, sulphur, &c. Now water is a compound of hydrogen and oxygen; and by the most refined analyses, often repeated, it has been ascertained that, for every *single* ounce of hydrogen, *eight* ounces of oxygen are required to form the liquid. Again, hydrogen and chlorine combine so as to form hydrochloric acid in the proportion of one ounce of hydrogen to thirty-five ounces and a half of chlorine. Hydrobromic acid contains one ounce of hydrogen to seventy-eight ounces and twenty-six hundredths of bromine; and hydrosulphuric acid contains one ounce of hydrogen combined with sixteen ounces of sulphur. Now the great beauty of chemical combination is manifest in this fact: if chlorine, bromine, and sulphur combine with oxygen, then the resulting compounds will have the ratio of weights: 8 of oxygen to 35½ of chlorine; 8 of oxygen to 16 of sulphur; or supposing such compounds do not exist, or that others exist also, then 35½ of chlorine may combine with twice, thrice, &c., of 8 ounces of oxygen, but never in fractions of eight; and so with all the rest of the elements. Take the combinations of chlorine and oxygen as an example:

| | Chlorine. | Oxygen. |
|---|---|---|
| Hypochlorous acid | = 35·5 and | 8. |
| Chlorous acid | = 35·5 and | 24, [3 x 8]. |
| Hypochloric acid | = 35·5 and | 32, [4 x 8]. |
| Chloric acid | = 35·5 and | 40, [5 x 8]. |
| Perchloric acid | = 35·5 and | 56, [7 x 8]. |

The number 8 is called the equivalent of oxyen, 16 two equivalents, &c. In like manner 35·5 is the equivalent of chlorine; 78·26 that of bromine; 16 that of sulphur; 1 that of hydrogen. Ammonia consists, however, of 14 parts of nitrogen to 3 parts of hydrogen; laughing gas contains 8 of oxygen to 14 of nitrogen; hence we see that ammonia contains 1 equivalent of nitrogen to 3 equivalents of hydrogen. Protoxide of iron contains 8 of oxygen to 28 of iron, whilst the sesquioxide contains 24 of oxygen to 56 of iron; the first therefore, contains one equivalent of either element; but the latter is a compound of 3 equivalents of oxygen to 2 of iron. Now the ratio of 3 to 2 is that of 1½ to 1, a ratio containing a fraction, which is obviated in all cases by doubling the whole number. In my next lesson I will show you the application of chemical equivalents to photography.

## SALTS OF SILVER, PHOTOGRAPHY, AND INDELIBLE INK.

The quality which salts of silver possess of becoming black by exposure to light lies at the very foundation of the photographic art. The chloride of silver is most sensitive to the action of light. It was discovered a long time ago by the old alchemists in their search after the "philosopher's stone," and was by them denominated "horn silver." It is formed from a solution of the nitrate of silver. The latter is made by dissolving metallic silver in aquafortis (nitric acid), then adding a solution of common salt to it. A white precipitate of chloride of silver is formed, which, when exposed to light for a few moments, changes from white to violet colour, and then to black. The blackening of this salt by the rays of light did not escape the attention of the old alchemists, and it led them to the opinion that light, as well as heat, was one of the great agents in the transmutation of metals. The action of light upon certain salts and substances, whereby they are decomposed and changed in appearance or colour, constitute the chemistry of the photographic art. Other salts beside the chloride will also turn black if exposed to the light, provided they are in contact with organic bodies. The action of light upon different substances is not yet well understood. This agent facilitates (in some cases) the combination of certain elementary bodies, and in other cases it hastens the separation of combined elements. The blackening of silver salts by light is an instance of chemical decomposition. In the form of chloride of silver it is a white salt; when it becomes dark by exposure to light, the black substance produced is simply metallic silver in a very finely subdivided state. A very simple experiment may be performed to establish this fact. Dip a slip of ivory into a solution of the nitrate of silver until it assumes a bright yellow colour, then place it in a tumbler containing rain water, and expose it to the direct light of the sun, and it will then gradually become black; but when dried and rubbed with an agate burnisher, the ivory surface will become bright, and resemble a slip of metallic silver.

Heat produces an effect upon the salts of silver analogous to light. M. Niepce de St. Victor heated a metallic plate by boiling it in water, he then placed the print of an engraving against it, and over that a sheet of paper prepared with the nitrate of silver and the chloride of gold, and he obtained a violet-blue impression on the paper of the dark parts of the engraving. If the paper is only prepared with the nitrate of silver, the light parts of the engraving are reproduced in metallic luster.

Long before photography was known or practised, the nitrate of silver was employed to colour the human hair, stain marble, and mark linen, and it is still employed, to a large extent, for the first and last-named purposes. The best indelible marking ink is made with nitrate of silver, aqua ammonia, a small quantity of cream of tartar, sugar, gum arabic, and the whole coloured red with carmine. About one part of the nitrate of silver is dissolved in twelve parts of water, and ammonia poured in slowly, until the solution appears free from precipitate. A very small quantity of gum arabic and sugar are required. This ink must be kept in a bottle screened from the rays of light. Although called indelible, this ink is easily removed with the cyanide of potassium, but it withstands the action of washing with soap and water.

Simple photographic paper for copying pictures and various objects, may be made as follows;—Prepare a solution of nitrate of silver by dissolving an ounce of the nitrate in twelve of water, and adding aqua ammonia gradually until the liquor becomes clear. Take a sheet of white paper, soak it in a solution of common salt and then dry it. After this, stretch it on a clean board, apply the ammonia nitrate solution to its surface evenly with a sponge, and dry it in the dark.
