To copy a print or a negative picture it is placed with its face upon the sensitive paper, and a plate of glass is placed upon its back, and the whole exposed to sunlight through the glass. The picture gradually appears upon the prepared paper, first in a bluish tinge, then black. When fully developed, the paper is first washed in soft water, then the picture is fixed by washing in a solution of the sulphide of soda.

Hair is stained black with a solution of the nitrate of silver and ammonia; or what is better, a solution of one part of the nitrate dissolved in six of water, is first applied with a sponge, then a solution of one ounce of the sulphuret of potassium dissolved in six of water is applied, and the hair then becomes quite black. A little rose water is applied afterward to neutralize the odour of the sulphuret. What an important part the solutions of silver play in the arts! They convert grey hairs into sable locks; and with the sun beam for his pen, the artist can transfer to his tablets the lineaments of youth and age, and the resemblances of insect, leaf, fruit, and flower.—*Scientific American.*

## Proceedings of Societies.

### Amateur Photographic Association.

A Meeting of the Council of the Amateur Photographic Association for the admission of members and subscribers, was held September 26th, at 26, Haymarket, the Right Hon. the Viscount Ranelagh, Vice-President, in the chair.

The minutes of the last meeting having been read and confirmed, the following members and subscribers were proposed and duly elected.

| | |
|---|---|
| Admiral Kellett, C.B. | Major-General Osborne. |
| The Hon and Rev. A. Campbell. | Robert Murray, Esq. |
| R. S. Newall, Esq. | A. W. Hume, Esq. |
| F. Ark, Esq. | Captain W. R. Houghton. |
| J. W. Weldon, Esq. | W. Drury, Esq. |
| Rev. R. Battiscombe. | Miss E B. Huson. |
| Robert Hunt, Esq. | Thomas Pryce, Esq. |
| R. F. Holle, Esq. | Captain A. Hoskins. |
| B. Willis, Esq. | W. Allen, Esq. |
| W. F. Tollemache, Esq. | S. Mortimer, Esq. |
| G. Farquhar Smith, Esq. | T. Woods, Esq., M.D. |
| Captain J. G. Sandeman. | Thomas Halifax, Esq., M.D. |
| Ben. Fagh, Esq. | Miss E. Gamlin. |
| W. J. C. Moens, Esq. | J. Vaughan, Esq. |
| F. H. N. Glossop, Esq. | The Commander of H.M.S. *Algiers.* |
| Lieut.-Col. C. Holder. | F. W. Pigott, Esq. |
| James Ferrier, Esq. | R. Staples, Esq. |
| Mrs. C. J. Osborne. | W. Sibbald, Esq. |
| W. H. Price, Esq. | C. J Setts, Esq. |
| John Yates, Esq. | Geo. Potts, Esq. |
| Charles Crookes, Esq. | J. W. Tillerton, Esq. |
| J. Proctor, Esq. | D. W. Hill, Esq. |
| T. J. Murray, Esq. | J. Morton, Esq. |
| Hugh McBean, Esq. | A. Hall, Esq. |
| F. E. Currey, Esq. | F. W. Hasenclever, Esq. |

The Secretary then laid before the meeting some very fine Egyptian negatives by Robert Murray, Esq., one of the newly elected members, which were much admired. The negatives are by the calotype process, and almost rival in sharpness and half tone the finest collodion plates.* Also some interesting copies of ferns, by C. S. Harris, Esq.

Several matters of detail, relative to the method of supplying the Association prints to members and others, having been arranged, the proceedings terminated.

A. J. Melhuish, *Hon. Sec.*

### American Photographical Society.

A regular meeting of this Society was held in the New York University, on Monday evening, September 8th, President Draper in the chair.

In consequence of a misunderstanding about the length of the summer vacation, a number of members thinking October the meeting month instead of September, the attendance was small. The minutes of the last meeting were read and approved. There being no reports of committees, communications and discussion came in order.

Secretary Thompson exhibited several negatives and prints therefrom, and some glass transparencies by the milk process. He explained at length the peculiarities of this process, and read an account of his manner of working. (The "milk process" is given in full in one of Secretary Thompson's former letters to the News.)

The President and others remarked the very thin and weak appearance of these negatives to the eye, and the exceedingly vigorous prints they produced; thereby showing that it is not dense opacity which constitutes a good negative, so much as a thin non-actinic colour.

Mr. Tillman expressed great pleasure in viewing these pictures, and admired the glass transparencies on account of their rich brown colour and tone. He moved a vote of thanks to Secretary Thompson, which was carried.

Secretary Thompson stated, in acknowledgment, that the glass transparent stereograph admired by Mr. Tillman was printed by gas-light in five seconds, and was a year old. The idea of the milk process was entirely due to H. T. Anthony Esq. He only claimed the manipulation, and carrying out of Mr. Anthony's idea.

The Secretary then gave the Society a short account of his waggon drive last May, from New York to Honesdale Pa. in search of the picturesque.

Professor Seeley referred to Professor Hime's recent paper on Stereoscopic vision. He agreed with his theory that the points of vision for each picture must be separated according to the object in view.—Thus the cameras for stereos must be separated several feet in taking a landscape, and in all instances more than the space between the eyes must separate the optic axes. He thought a person saw the same effect of distance and size with one eye as with two, and a single picture will have a stereoscopic effect if viewed through a convex lens with one eye.

Secretary Thompson thought Professor Seeley's arguments were contradictory, for if we saw the same solid effect with one eye as with both, why have any distance between the optic axes at all.—Why not print two copies from a single negative and place them side by side for viewing in the stereoscope? He had tried this by mounting two right eye pictures of a stereo, (the left being spoiled) on the same card, and of course lost all the effect.

Mr. Tillman thought the convergence of the optic axes should be about the same as the eyes are apart, to give a proper natural effect, but a greater convergence than that would exaggerate everything.

President Draper believed in the stereoscopic effect being produced by one eye. He mentioned the case of the birds and fowls whose eyes were on opposite sides of the head, and only one was used at a time, yet the fowl never fails to judge distance more accurately than we can who use both eyes. He asserted that in reading usually we use but one eye while we think we use both. Then there are many persons who can see no stereoscopic effect in the most perfect stereograph.

Secretary Thompson was reminded of the famous pictures of Jacopo Chimenti, and promised to bring copies of them to the next meeting, to afford any curious member the experiment on the causes and effects of Strasbismus, as contracted by viewing these pictures in the stereoscope.

* It may be some encouragement to hear that Mr. Murray taught himself entirely by a shilling hand-book, sent out to him in Egypt, having never seen a negative taken by anyone until after his return to this country.—A. J. M.

President Draper mentioned the recent comet, as seen through his large telescope. The appearance was a nucleus with a face-like tail. The nucleus seemed in motion like a mass of molten iron boiling with heat. He watched the transit of the comet's tail across a small star, and although the tail must be thousands of miles in thickness yet the star was not obscured by it.

On motion the Society adjourned to the second Monday in October. F. F. Thompson, *Secretary*.

## Correspondence.

### PRINTING DIFFICULTIES.

Sir,—Next to printing from a be-fogged and stained negative, nothing can be more offensive to the eye of an intelligent printer, than a well-manipulated plate spoiled by the inartistic arrangement of its details, which destroys all hope of anything like harmonious results in his finished work. How he longs to cast a soft, harmony-producing shadow over that obtrusive table, with its painfully sharp edges. How his feet itch to kick over that staring snow-white pedestal. And as a sum total of his desires, he would doubtless make a clearance of that heterogeneous heap of antique, out-of-place, ill-balanced accessories, as complete as Dickens's dwarf practised on the old curiosity shop, or "Womankind" bade fair to accomplish in the dusty chamber so fondly cherished by their eccentric antiquarian relative. Oh! Mr. Wall, resume once more your powerful pen, and clear away this too popular barrier, that obstructs the road leading to the goal which photography's votaries must reach ere they can successfully claim kindred with the fine arts. Teach them to see and feel, that they are working for the future more than for the present. Show them that a falsely designed picture is more unpardonable than a falsely written history, because man may err in his judgment, but the lens cannot make a mistake; and a large proportion of its present productions in the shape of portraiture, when handed down to posterity, will certainly induce them to believe the habits of their progenitors were anything but tidy, and their tastes far from the boundaries of refinement. But my mealy subject grows cold under this exciting topic. I must, therefore, hasten to select a negative from whence we may trace one more source of mealiness. It not unfrequently happens, whilst engaged in toning a batch of prints, we notice all the pictures obtained from a particular plate turn off mealy, when the slightest trace of that evil is absent in all the others. To explain the cause, we must examine the negative previous to intensifying, and by reflected light, we readily perceive a coarse granular deposit on the half tones and shadows. In the after-processes, each of these atoms will be strengthened by further deposits; and being beyond the influence of molecular cohesive attraction, there will exist interstices comparatively transparent, which admit a greater amount of light, and, consequently, a greater depth of printing power than can be obtained from the adjacent more opaque parts. Owing to the deposit of the "bastard albuminate," this inequality of colour is not perceptible until the print is exposed to the action of the toning bath. When pushing for dark tones, the parts least exposed to light are overdone before the required depth of colour can be secured; the remedy is obvious—be satisfied with a little less toning.

And now, we must get our frames in order, and commence printing operations, for our patrons are getting clamorous for their cartes de visites. Whilst I am toning, you will have my views on the requirements of this process, to meet the demands exacted by the toning bath. At present, I shall merely add, that he who starts on a day's printing with an intention of getting a large number of prints from an unmanageable number of negatives, will find that he must sacrifice quality for quantity. During the whole day, he is in a fever of excitement, jumping and hopping about like a street tumbler amid a shower of halfpence, until his physical powers and his paper are together exhausted; and he forgets that in the first washing there lurks another source of mealiness, and except he keeps the prints moving about, and changes them quickly into another water, the liberated silver will combine with the organic or other substances the first water contains, and cling to the surface of the print with a tenacity no after treatment can remove. Under the conditions given in my second letter, a long soaking is invariably required; with a stout horny paper, the water made warm is a decided advantage, because the pores of the paper are more readily opened; their distension loosens the molecules of reduced silver, thus giving free access to the reducing agents contained in the toning bath. I thank Mr. Cooper for endorsing the views I entertained on this subject by practical tests, as well as for laying open the secrets of his valuable discovery. It proves that he believes, to quote the words of Sir John Herschel, "the arts cannot be perfected till their whole processes are laid open." Again, he says, "Art is but the application of knowledge to a practical end; if the knowledge be merely accumulated experience, the art is empirical; but if it be experience reasoned upon, and brought under general principles, it assumes a higher character, and becomes a scientific art."—Yours respectfully, A Photographer's Assistant.

### IODIDES AND BROMIDES IN COLLODION.*

Startling as these results may appear, and utterly opposed as they are to the experience of photographers at large, I shall, I think, be able to show, to the satisfaction of all who will hear me patiently, that the presence of bromide could not be otherwise than productive of insensitiveness, and that it is only under certain circumstances that a simply iodized collodion, under pyro development, is superior to the same, or to bromo-iodized collodion under iron development.

First of all—as regards the loss of sensitiveness by the presence of a bromide—Mr. Hardwich, an universally respected authority, has shown that bromide of silver is ten times less sensitive than iodide of silver. In corroboration of this Mr. Sutton has shown that the exclusive use of bromide produces insensitiveness. Iodide of silver then being *the* sensitive medium, by what law of nature, may I ask, should a combination of the two salts shorten exposure, or give increased sensitiveness and prove superior to iodide alone? If, as it is maintained, that the presence of a bromide is the cause of increased sensitiveness, I ask that the following simple experiments be made. Iodize collodion with iodide of cadmium, and another portion with iodide and bromide of cadmium; also some with iodide of ammonium, and another portion with iodide and bromide of ammonium; after proper keeping, coat, sensitize, and expose plates, develop with iron, and mark the results. It will be found, as I have repeatedly done, that the iodide of cadmium collodion is superior in sensitiveness and intensity to the bromo-iodized cadmium collodion; and similarly the iodide of ammonium collodion is superior to the bromo-iodized ammonium collodion. If then the alleged addition of a bromide gives increased sensitiveness, why does it not in these cases?

I shall probably be referred to the results on bromo-iodide of silver in the Daguerreotype process, but I think it is pretty clear that the superior sensitiveness in that process was due to the *mercurial developer not to the bromide of silver.*

If, then, by experiments such as I have made, and by the dictum of so high an authority as Hardwich, iodide of silver alone is the most sensitive to light, and bromide productive of insensitiveness, how is it that the belief in the superior sensitiveness of a combination of iodide and bromide has arisen.

It will be seen, by a reference to the results of my experiments, that bromo-iodized cadmium collodion was inferior to simply iodized cadmium collodion, and bromo-iodized ammonium collodion to simply iodized ammonium collodion, and that on the addition of a portion of iodide of ammonium collodion to iodide of cadmium collodion, an

* Continued from p. 467.

immediate increase of sensitiveness, though no durability was obtained over the simply iodized cadmium collodion, and that sensitiveness, but want of durability, was also obtained by the addition of bromide ammonium to iodized cadmium collodion, but that the bromized ammonium plus cadmium collodion, was inferior in durability and sensitiveness to the iodized cadmium plus ammonium collodion.

The inference from the above is, *that the increased sensitiveness was owing to a molecular action set up in the collodion on the addition of the alkaline salt (whether iodide or bromide ammonium), to the acid salt cadmium, and to the consequent excitation produced in the collodion, towards a state of nicely-balanced equilibrium, an excitation hitherto erroneously attributed to the bromide salt, because an alkaline bromide has, in most cases, constituted a part of the bromo-iodizer, which is usually, mostly, or largely compounded of the cadmium salt.*

The same excitation may be inferentially assumed, as I have found it, when we have a potassium or ammonium iodide with a cadmium bromide.

But, although the use of a bromide is attended with loss of sensitiveness, the more appreciable as the quantity is large, compared with simply iodized collodion, yet its presence in collodion is very desirable, because of its established sensibility to coloured light, and it simply remains for operators to regulate the quantity according to requirements, remembering that there is scarcely a subject which will not benefit by its presence in suitable strengths. Of course, the iron developer must be used.

Although the simply iodized collodion, under iron development, has been shown superior to the same with the pyro development, yet there are many instances to prove the superiority of the latter over iron with simply iodized collodion, and the cause of this appears to lie in the use of the iodides. Experimenting with various iodizers, I have found that *collodion iodized simply with potassium or ammonium, is more sensitive under pyro development than under iron;* but starting from this point with both developers, and introducing *cadmium as a component of the iodizer, the superiority of iron became manifest when the proportion of the cadmium salt was at least half, and that inferiority increased with the increase of cadmium.* It must be remembered that sufficient age was given to the collodion in all cases where cadmium was used, so that the conditions of the experiment should be uniform throughout. From the above it is apparent that *the iron developer must be used when the cadmium salt is a component of the iodizer, and that it fails in proportion to the smallness of the quantity of cadmium, or where the iodizer is entirely ammonium or potassium.*

Pyro development and iodized collodion are slower than iron development and iodized collodion, in the cases shewn above, where cadmium constitutes at least half the iodizer, and they are slower in the same cases than iron development and bromo-iodized collodion made up like the simply iodized collodion, but having, instead of the compounded iodides, a small portion of them as *bromide. But simply iodized collodion, as above, and pyro development are faster than the iron and bromo collodion in question, when the proportion of the bromide is large.* One grain to seven or eight oz. is quite sufficient. An increase to one grain per oz. will give the superiority to the pyro development and iodized collodion in a marked and decided manner.

Before concluding, I will beg not to be misconstrued. One sample of collodion, one strength of developers, one description and strength of bath, as before implied, were used throughout. None were sensitive enough to give instantaneous results. Ross's stereo view lens was used, and the exposure was simply experimental—less for the desire of producing pictures, than for the sake of determining the respective merits of iodized and bromo-iodized collodion, *and of pyro* and iron development—so that the difference in results, between one case and all, was appreciable and notable, even *to seconds of exposure.* This would have been absolutely difficult, if the exposure had been in each case of such a character as to descend to difference in fractions of seconds! Now, it frequently happens with operators, that certain conditions of chemicals and light operate so at times, as to confer surpassing sensitiveness to their plates, and this is particularly true of instantaneous photography, which being, like photography in general, of a progressive character, will, doubtless, at no distant period, so shorten the time of exposure, as to make the presence of a bromide in large quantities an absolute necessity. For where results are reduced to a fractional scale, the differences of sensitiveness between iodide and bromide become of so infinitessimal a character, that the latter salt, from its superior sensibility to coloured light, may yet be preferred, even to the total exclution of the former. But I would submit, that in such a case it would be a difficult matter to pronounce an opinion either one way or the other, on the present question of iodide, *v.* iodide and bromide. And the difficulty would continue until the exposure was increased to some calculable period. I will, therefore, here object entirely to the instantaneous experiments of Mr. Blanchard, where a ten-thousandth part of a second of exposure, more or less, would possibly ruin his simply iodized ammonium or potassium plate, or complete his bromized one.

Another objection to instantaneous experiments is the circumstance that no two lenses are of absolutely equal power. Their difference of power is inversely as the given exposure, and it will probably appear in a magnified form when the exposure is a fraction of a second, and the result a phantom image for subsequent intensification, the more especially so when, as in Mr. Blanchard's experiments, half the plate is coated with a sensitive bromo-iodized collodion, and the other with an inferior iodized one.

None of the experiments, four in number, made by Mr. Blanchard are really fair. They were simply illustative of the circumstance that under certain conditions, which nobody should adopt, bromo-iodized collodion is superior under iron development to simply iodized collodion. Now it is not sought to learn the superiority of ammonium and cadmium, combined as iodides or bromo-iodides, over potassium or ammonium, as appears to have been done by Mr. Blanchard, and inferentially by other successful operators, such as Messrs. Fry and England (for their results are identical with Mr. B.'s), but rather to prove the general excellence of bromo-iodides over simple iodides, and for this reason they should have taken, as I did, and wish to have others repeat, simply as an *approach* to what has been apparently overlooked, viz., *equality of conditions in the iodizing and bromo-iodizing solutions, so as to bring the organic and inorganic developers to a par.* I say they should have taken proportions of the cadmium and ammonium salts, the former preponderating, for an iodizer; and for a bromo-iodizer the same salts in the same proportions, only substituting the bromide of ammonium for all or part of the iodide of ammonium. It will then be found that whatever the proportions used, provided the cadmium does not fall below half the quantity of the salts used, and provided that those proportions are uniform both in the iodizer and bromo-iodizer, it will be found that the simply iodized collodion under pyro is superior in sensitiveness to bromo-iodized collodion under iron only when the proportion of the bromide is large, and that simply iodized collodion under iron is superior in sensitiveness in all cases to bromo-iodized collodion under iron, in proportion to the quantity of the bromide salt. It will be found that 1 grain to 7 or 8 ounces will not appreciably affect sensitiveness; but as foliage and coloured lights and shades cannot be rendered without bromide in a satisfactory manner, its introduction is an absolute necessity. And, lastly, it will be found that simply iodized collodion under iron is superior in sensitiveness to the same under pyro development.

Trusting that you will not consider the length of this communication a fault, and that you will deem it worthy of a corner in the Photographic News, I remain, &c.,

*Meerut, N.W.P. India, July* 26, 1862. Augustus Webb.

## Talk in the Studio.

Photographic Exhibition at Dusseldorf.—We have recently received from Herr A. Gestewitz, of Dusseldorf, a long account of a series of photographic reproductions, now exhibiting in that city, in the Hall of the Society of Arts. These photographs are from the establishment of Mr. T. F. Michiels, in Brussels, and are all copies of oil paintings by such artists as Heubner, Hilgars, Lindlar, Lachenwitz, and others. They are stated to be superior to anything ever produced, as regards half tone and general artistic effects, and especially in the correct rendering of the various colours and shades of the originals. Herr Gestewitz has obtained an order from the "Cultusministirium," in Berlin, signed "Lehnert," for the protection of these photographs from piracy, a mark of appreciation never accorded to works of art of this kind before.

Mr. Robinson's new Picture.—Mr. Robinson is favouring the provinces with the first sight of his new composition photograph, "Bringing Home the May." From what we have seen of the design, and some of the early studies for the picture, we anticipate that it will be one of his best. The *Western Morning News*, noticing a recent art exhibition in connection with the Cornwall Polytechnic Society, says of this picture :—"The contributions by amateurs occupy a considerable amount of space in the left gallery, and decidedly the place of honour is occupied by Mr. Robinson's most beautiful photograph, 'Bringing Home the May.' This is an ornament to the gallery, and was admired by all who lingered to look at it."

Photographic Exhibition at Nottingham.—We have received a communication from Mr. A. G. Grant, 58, Long Row, Nottingham, in which intimation is made of an intended photographic exhibition in that City. Prizes are proposed, the value of which is to be raised by subscription amongst exhibitors. Fifteen prizes for the excellence in the following classes :—Photographic portraits, plain, black and white, water colour, oil, crayon or chalk, cartes de visite, collodion positives, coloured, animals plain, landscape views, stereoscopic views, portrait paintings, miniature ditto, landscape ditto, and animal ditto, are proposed. A meeting of those concerned is to be held on the 3rd. of October at Mr. Grant's residence. By whom the exhibition is proposed, or by whom it is to be managed, or who is responsible, we do not clearly understand, but we give publicity to all we know on the matter.

New Work on Photography.—Mr. Sutton has in the press a new three shilling work to be entitled "The Collodion Process, Wet and Dry." It will be published by Sampson Low, Son and Co., Ludgate Hill.

## To Correspondents.

J. B.—The paper to be used in the uranium-printing process is simply plain photographic paper, without albumen or other preparation, beyond that described. The chief defect in your card print is, want of definition in the face : it is not sharp ; otherwise, it is pretty good. The spot to which you refer is a metallic spot in the paper.

F. P.—The dirty-yellow stains in your print are, undoubtedly, due to imperfect fixing. Independent of your hypo being old, as you state, the prints have, probably, stuck together, and thus prevented the perfect solvent action taking place in every part of each one. The hypo should be new, and strong enough ; and the prints should be kept well immersed and moving about. When prints become mottled with a dirty yellow or brown, whilst washing, it generally indicates imperfect fixation. The insoluble hyposulphite of silver, which is formed, becoming decomposed, whilst washing, and producing the effect in question.

F. Vincent.—The texture of the canvas and painting will generally show, more or less, in reproductions from old paintings. The effect may be reduced by taking care that the light falls on the painting, in such a manner as to make the small excresences and texture give as little cast shadow as possible. It is a branch of the art requiring much judgment and experience to meet each particular case.

A.—The iridescent deposit formed between the film and the glass, is almost invariably the result of dirty glasses. However clean the glasses may have appeared to be, this is generally a proof that they have not been chemically clean. Other causes will favour this deposit, such as the use of a thin collodion, made with powdery pyroxyline, and under-exposure, followed by over-development or over-intensifying.

Phos.—The circumstance you describe is somewhat inexplicable. That negatives taken at the same time, with the same materials, treated in the same manner, varnished with the same varnish, placed in two new boxes, and kept in the same place, should in one box be spoiled with vermicular cracks, and remain perfect in the other, would appear to admit of one explanation only : namely, that one box was damp, and the other dry, or that one box was made of porous absorbent wood, and the other not. Unless there was some difference in treatment, this is the only explanation we can suggest. Possibly, without noticing it, some of the plates have been less thoroughly washed after fixing than others. Any trace of the fixing salts left in the film is an almost certain cause of such cracks. Perhaps a better thing in this case than finding out the cause, is the suggestion of a remedy. The plan proposed by Mr. Claudet, in such cases, proves, we know, in most instances, efficient. It consists, simply, in rubbing the cracked surface with powdered charcoal, which fills up the cracks, and makes their presence scarcely observable in the prints. Probably, powdered plumbago will do as well. The best security against future recurrence of such cracks consists in very careful washing, and drying, before varnishing ; in the use of varnish of known good quality, and in thoroughly dry storage. The quality of the negatives appears very good, and the subject pretty. Perhaps there is a trace of under-exposure. We think the plate is rather too narrow in proportion to its length for the best effect. The length is, within a fraction, of being double the width. An inch more in width would have added to the effect. The lens does its work very well, but you over-estimate the angle included. The plate is 7½ in., and the focus of the lens 7½ ; even if the plate were well covered to the edges, it would not include 55°. If about three-quarters of an inch of imperfect definition be cut off each end, you will have something less than six inches. But that, even, gives a very good angle with satisfactory definition. From what we have seen of the productions of the new Harrison lens, we have no reason to believe that it includes an extraordinary angle ; but, as we have never been able to ascertain the equivalent focus of the lens, with which the specimens we have seen were produced, we cannot speak certainly.

P. M.—The leather used for the bellows bodies of cameras, is what is known technically as "skiver," or perhaps with the best cameras "roan." It is always lined with black calico. 2. Make your toning solution, and before use test with litmus paper. If it be acid, add drop by drop of a solution of carbonate of soda, say 10 grains to the ounce, waiting a few minutes between each addition, until the red colour of the litmus begins to disappear.

A. B. C.—Parchment size is not suited for mounting photographs. Good glue, or freshly made starch should be used. 2. There are a variety of good positive developers : 20 grains of iron, 20 minims of acetic acid, and 2 minims of nitric acid, form a very good one. 3. We do not know anything of the advertized back ground to which you refer.

C. Bryan.—The constant addition of citric acid to your printing bath, will, by precipitating citrate of silver, weaken it. If no precipitate is formed, it is because there is free nitric acid. Test for acidity, and if present, neutralize it. But the probability is, your bath is getting weak in silver, in which case the remedy is simple. We will examine the glass and report upon it.

A Subscriber from the Beginning.—Your bath is evidently out of order ; probably with organic matter. The best remedy will be to neutralize and sun it. From the results you describe the collodion is probably simply iodized. Mix with it some bromo-iodized collodion ; the positive collodion of the same maker will do. This will rid you of the spots, comets, &c. The ordinary positive collodion process is used with Skaife's pistol camera, and ordinary good chemicals answer the purpose. It will not work instantaneously in a bad light. It is simply a lens of very great rapidity, and a camera for small pictures, with means for rapidly exposing. It is, of course, subject to the same conditions as other lenses ; and without sufficient light there is no working.

An Amateur.—The indistinctness is due to the negative. The subject has been badly lighted, and the exposure too short. It is not simply sufficient to have sunshine, but it must fall upon the landscape in a proper direction. Your plates must, however, have been very insensitive ; 20 minutes exposure of a tannin plate, with a Ross lens of 14 inch focus, and half inch stop, ought to have been more than sufficient. The image appearing on a tannin plate on taking it from the camera, is generally a sign of over exposure. If this were the case with the negative in question, you must have mismanaged the development, probably by adding too much silver, and getting general deposit all over the plate instead of regular development. You can become a member of the photographic society on being proposed by a member. We shall have pleasure in proposing you for election.

J. C. H.—Your progress is, on the whole, satisfactory. You will have a little more control in lighting with your new arrangements. One of the prints shows some trace of imperfect fixation. There is some fault in your oil-painted backgrounds if they crack on rolling. Take care to keep them sufficiently behind the sitter to be out of focus. The lens you name is very admirable for landscapes. You cannot do better than obtain it.

H. Smith.—Mr. Lacy used the collodion of various makers, and in various proportions, to suit the conditions required at the time, the state of the light, the condition of the bath, &c. No fixed rule can be laid down, judgment must constantly be used. At one time he used a mixture of Thomas's negative with usual iodizer, and Mawson's positive. Latterly he used chiefly Rouch's (Hardwich's) bromo-iodized, alone, or mixed with others. The print enclosed is a little hard, and the feet are very badly placed.

A. F. B.—No. 3 in the list given, without the slightest doubt.

F. P.—See a recent article on toning in No. 210 of the Photographic News, entitled "Toning Experiments." On adding gold to the toning bath, if it be acid, neutralize it. We have not tried keeping the toning bath made with citrate of soda, but see no reason why it should not follow the general rule. We cannot tell to what kind of strokes you refer without seeing them, but you are probably referring to defects in albumenizing. Dry plates prepared with milk, according to the process of our American correspondent, are not washed after the milk is applied. See report of American Photographic Society's meeting. There is no certain method of ascertaining, by its appearance, when a print is fixed. Sometimes, when imperfectly fixed, it may be seen by opaque patches appearing when the print is examined by transmitted light. There is no objection to the use of citric acid and carbonate of soda in the toning bath, if you prefer to use it.

A Subscriber.—The effects described are exactly similar to those which arise from supersaturation with iodide of silver, and are very apt to occur in a strong bath in hot weather. We should recommend adding some un iodized solution of not more than 30 grains to the ounce. We will write soon.

Dr. Saunders Van Loo.—The collodion received safe. We will make an early trial of it.

Frank Howard, J. G. Fuller, J. H. Redin, Janie, Fantail, J. C., Charles Derby, W. W., D. J., W. G. G., and several other Correspondents in our next.

Vol. VI. No. 214.—*October* 10, 1862.

## British Association for the Advancement of Science.

The British Association has just concluded its thirty-second annual meeting, for the third time held at Cambridge. Any remark on the certainty and rapidity with which science and civilization have advanced since the establishment of this Association would be the assertion of a matter so trite as to appear a mere platitude. We were struck, however, by a trifling remark of our companion in the railway carriage journeying back to London, himself a veteran man of science—Mr. Robert Chambers. He said, "When I last attended the Association in Cambridge, seventeen years ago, I rode outside a stage coach: there was no railway to Cambridge then." How far the efforts of the modern peripatetic philosophers, as they have been termed, have contributed to the rapid progress of modern years, is difficult to determine; but that an association including all the greatest luminaries of the day, with the expressed purpose of giving a stronger impulse and more systematic direction to scientific enquiry, to obtain more attention for the objects of science, and promote the intercourse of all interested in its advancement, must have an immense influence on the progress of mankind is a fact now admitted by all, even by those who for years flouted the Association as a worthless and foolish thing.

Our own art, in its various developments, has for years, past occupied a share of the attention of different sections of the Association, the subjects being generally divided, somewhat arbitrarily, between Section A, Mathematical and Physical Science, and Section B, Chemistry. In the proceedings of this year, although no photographic exhibition was formed, as on some former occasions, photography held in the sectional meetings and elsewhere a tolerably prominent position. The papers read on the subject were, in Section B, "Description of a Rapid Dry Collodion Process," by Mr. Thomas Sutton, B.A.; "On a Photolithographic Process, adopted by the Government of Victoria for the Publication of Maps," by Mr. J. W. Osborne; "On Some of the Difficulties arising in the Practice of Photography, and the means of removing them," by Mr. Maxwell F. Lyte, M.A., F.C.S.; "On a Simple Method of Taking Stereo-micro-photographs," by Mr. Charles Heisch, F.C.S. In section A, M. A Claudet, F.R.S., read a paper, "On the Means of following the small Divisions of the Scale regulating the Distances and Enlargement in the Solar Camera;" and a paper was sent by the Rev. J. B. Reade, on "Experiments in Photography with Colour." The whole of these papers will appear in our columns in due course. At the soiree on Tuesday night, M. Claudet exhibited, by the aid of the oxyhydrogen light, the enlarged images of the solar camera. Mr. Brothers' large group of twenty-two members of the Association, coloured in oil: some photographs and apparatus by Ross, and by Dallmeyer, and a magnificent display of Ross's microscopes and microscopic objects, were the chief attractions of the soirees.

Mr. Sutton's paper, from what we are able to glean from those who were present at the discussion—it was read before we arrived in Cambridge—scarcely gave satisfaction, want of explicitness and want of novelty being urged against it. A more important question to discuss is its efficiency. It appears to us as explicit as the limits of such a paper admit. As regards the question of novelty, its chief claim would consist in the use of bromide and iodide in the proportion of equal atoms. The principle upon which it is based, the necessity of having two salts of silver in the sensitive film, is not new; we have constantly urged its importance, as our readers know. As regards its efficiency, that is another question. We have before us a print from a panoramic negative produced by this process, with just the same exposure, we are assured by Mr. Sutton, as he would have given wet collodion, and indications have been obtained of still greater sensitiveness. On this subject we cannot do better than give a letter we have just received from Mr. Sutton:

Dear Simpson,—I enclose you a print from a rapid dry collodion panoramic negative, taken in exactly the same time as a good wet collodion plate. The process was that described in my paper read before the British Association.

You know me well enough to feel sure that I am not deceiving myself, or trying to deceive others, with the announcement that this is actually the much-wished-for solution of the rapid dry process. I have also taken breaking waves, clouds, &c., instantaneously, upon these plates. In the course of my experiments indications have occurred of dry plates six times as sensitive as the best wet collodion. When, then, is this to stop? I hope you will use your influence with your readers, and induce them to try this process, already so near perfection. Who will use wet collodion out of doors after this? The plates are as certain, and quite as easy to prepare. The print is toned with a new double salt of gold, which I have called calcio-chloride. It makes a permanent solution, and never fails in giving rich vigorous prints, such as I send. Minute particulars of the rapid dry process will be given in my book.

Yours faithfully, Thomas Sutton.

In the print received there is perhaps a trace of under-exposure, but it is a marvellous result for a rapid dry process.

Of Mr. Osborne's excellent paper we cannot speak too highly: it is unquestionably the most practical paper which has been published on the subject: we shall probably have a few observations to make on it shortly. Mr. M. Lyte's paper was, as it could not fail to be from his pen, very interesting. Some of the theories were, we fancy, untenable, but the practical suggestions were, however, decidedly useful, if not entirely new. The practice we have so often recommended, of washing the plate, after long exposures, with a little distilled water, so as to prevent stains arising from accumulated drainage, was endorsed by Mr. Lyte. His method of preserving the printing bath from discolouration is well worthy of attention.

Mr. Heisch's short paper on a method of obtaining micro-photographs for the stereoscope is at once novel and simple; so simple as to excite surprise that it has never been thought of before. M. Claudet's paper consists of a very clear description of a mathematical method of obtaining the exact conjugate focus by means of a scale for any degree of enlargement. The title of Mr. Reade's paper, "Experiments on Photography in Colour," will excite hopes which will be disappointed, and for the sake of his reputation, we wish he had not sent it. The specimen which accompanied the paper as an illustration of the results obtained, consisted of a collodion positive, the high lights of which exhibited that creamy tint, verging on a salmon colour, with a greenish tint, in the half tones, which every photographer has obtained a hundred times, and is, in fact, the colour commonly obtained in a certain class of negatives when just verging on solarization. Variety of colour, beyond this, there was none. All the lights of the picture were of one tint, and all the shadows of another, whether they pertained to flesh or drapery. When the paper was concluded, and the specimen examined, no word of comment was made, but each one passed the picture to his neighbour with an elevation of the eyebrow and a shrug of the shoulder.

Photographs were often made available in the illustration of papers in the various sections, and in the able inaugural speech of the President, Professor Willis, the application of the art in connection with meteorological, magnetic, and astronomical observation was fully recognised. In speaking of the objects of the Association he thus refers to its employment of photography :—

An example of its peculiar functions is given in the very last report for 1861, when it appears that an instrument contrived by Professor William Thomson, of Glasgow, for the photographic registration of the electric state of the atmosphere has been constructed by Mr. Beckley in the workshop of the observatory, with mechanical arrangements devised by himself, and that it has been in constant and successful operation for some time. Those who have experienced the difficulty of procuring the actual construction of apparatus of this kind devised by themselves, and the still greater difficulty of carrying out the improvements and alterations required to perfect it when brought into use, will agree that the scientific importance and utility of an establishment cannot be overrated, in which, under one roof, are assembled highly skilled persons, not only capable of making and setting to work all kinds of instruments for philosophical research, but also of gradually altering and improving them as experience may dictate. The creation of this peculiar observatory must be regarded as one of the triumphs of the British Association. As far as the Association is concerned, its maintenance has absorbed between £5,000 and £6,000, and the annual sum allotted to it from our funds has for each of the last six years reached the amount of £500. The construction of the photoheliograph may be quoted as an example of the facilities given by this establishment for the developing and perfecting of new instruments of observation. A suggestion of Sir John Herschell in 1854 that daily photographs of the sun should be made has given birth to this remarkable instrument, which at first bore the name of the solar photographic telescope, but is now known as the Kew photoheliograph. It was first constructed, under the directions of Mr. De la Rue, by Mr. Ross, &c. The British Association aided in carrying out this work by assigning the dome of the Kew Observatory to the instrument, and by this completion in 1857 in their workshop by Mr. Beckley, the assistant; but the expense of its construction, amounting to £180, was supplied by Mr. Oliviera. On the occasion of the eclipse in 1860 this instrument was conveyed to Spain, under the care of Mr. De la Rue, who most successfully accomplished the proposed object by its means, and was replaced at Kew on his return. But to carry on the daily operation to which it was constructed, requires the maintenance of an assistant, for which the funds of the Association are inadequate, although it has already supplied more than £200 for that purpose. Mr. De la Rue, in consequence of the presence of the heliograph at Kew being found to interfere with the ordinary work of the establishment, has kindly and generously consented to take charge for the present of the instrument at this observatory, and at his own observatory when celestial photography is carried on.

## DESCRIPTION OF A RAPID DRY COLLODION PROCESS.

BY THOMAS SUTTON, B.A.*

The problem which has most interested photographers of late years has been the discovery of a dry collodion process, by which plates can be prepared as sensitive as with wet collodion. In the wet process, the negative has to be taken and finished upon or near the spot from which the view is taken, and with wet collodion the tourist is, therefore, obliged to work in a van or tent, and carry a load of paraphernalia about with him, which is, of course, both expensive and inconvenient. To avoid this, he is compelled to work with dry plates, and hitherto no process has been published by which dry plates can be made as sensitive as wet ones. A rapid dry process has, therefore, been an important subject of investigation to photographers, because, during a long exposure of a plate, the shadows move, and figures sometimes alter their position. A man or horse, for instance, are likely to remain still for a few seconds, but not for ten minutes.

I have lately solved this problem of rapid dry collodion, and produced dry plates as sensitive as wet ones, which will, moreover, preserve their sensitiveness and good qualities for several weeks, and perhaps indefinitely. This process, and the principles upon which it is based, I will now shortly describe.

The rapidity of this dry process depends upon the accelerating effect of bromine in dry collodion, and in this respect an analogy exists between the Daguerreotype and dry collodion processes. In the former a silver plate, simply iodized, is extremely insensitive, but when submitted to the fumes of bromine its sensitiveness is increased a hundred-fold, the same thing happens in those collodion processes, wet or dry, in which the free nitrate of silver is washed out of the film. A collodion film, simply iodized, and without free nitrate, is as insensitive as an iodized Daguerreotype plate, but a bromo-iodized collodion film without free nitrate may be rendered as sensitive as a bromo-iodized silver plate. In the wet collodion process the most exalted sensibility is conferred upon a simply iodized film by the presence of free nitrate of silver; but you cannot retain free nitrate in a dry collodion film because it not only crystallizes on drying, but by becoming concentrated as the water evaporates, dissolves the iodide of silver, and forms a curious and interesting double salt, the exact properties of which have not yet been fully investigated. You cannot even retain a perceptible trace of free nitrate entangled in a dry collodion film without introducing an element of instability, and consequent uncertainty in your work. The principle, therefore, of preparing a rapid dry collodion plate consists in using bromo-iodized collodion, and removing all the free nitrate, which is the element of instability.

But the image produced upon a bromo-iodized silver plate, developed with mercury, is extremely thin and superficial, as may be proved by transferring it to a sheet of gelatinized paper. And similarly, the image developed by pyrogallic acid upon a dry bromo-iodized collodion film is thin, and too transparent to yield a good printing negative. It is necessary, therefore, to apply to the film a coating of some organic substance, in order to give density to the dark parts of the negative. Many substances have been used for this purpose, viz., gelatine, metagelatine, albumen, various syrups, gum arabic, infusion of malt, tannin, &c., &c.; and experimenters have, almost without exception, exhausted their ingenuity in varying these preservative coatings, as they are called, instead of seeking in the use of bromide for the true accelerating agent. The preservatives named have not all the same effect, and besides affecting the sensitiveness of the film, they also determine the colour of the finished negative, gelatine and gum giving a black, tannin a red, and albumen a yellowish colour to the deposit in the dark parts. Much, therefore, depends upon the selection of a proper preservative, when the most exalted sensitiveness is required.

One more difficulty remained to be overcome, and it is this. When a collodion film has once been allowed to get dry, and is wetted a second time, it is very liable to split and leave the glass; or if a preservative has been applied to it, it is very liable to rise in blisters, which spoil the negative. But this may be prevented by giving the glass plate a preliminary coating of india-rubber dissolved in kerosolene.

The operations in the rapid dry process are, therefore, as follow :—

1. Clean the glass plate, dry it thoroughly, and apply to it a solution composed of 1 grain of india-rubber dissolved in an ounce of kerosolene.

2. Coat the plate thus prepared with bromo-iodized collodion, containing an equal number of atoms of iodine and bromine, added in combination with cadmium. There should be about 5 grains of mixed iodide and bromide of cadmium to the ounce of collodion.

* Read before the British Association.

3. Excite the film in a bath composed of 30 grains of pure recrystallized nitrate of silver, slightly acidified with nitric acid.

4. Wash off all the free nitrate of silver, and pour over the film a preservative composed of 25 grains of gum arabic freshly dissolved in an ounce of water. Let it dry spontaneously, and before putting the plate into the dark slide, dry it again thoroughly before a hot flat iron.

5. Give the same exposure as for wet collodion.

6. Develop the picture by first wetting it with distilled water, and then pouring over it a developer consisting of 1 ounce of distilled water, 2 grains of pyrogallic acid, 2 scruples of glacial acetic acid, and a few drops of a weak solution of nitrate of silver. The image appears immediately, and very soon acquires the necessary intensity.

7. Fix the negative in the usual way with a saturated solution of the hyposulphite of soda or lime, and when dry varnish it with spirit varnish.

Negatives taken in this way are equal in every respect to those taken upon wet collodion plates, and the process is as simple as any of those which are now employed for slow dry plates.

At the termination of the paper some discussion followed, and much regret was expressed that Mr. Sutton was not present himself to elucidate the matter more fully and clearly. We had not the good fortune to be present at the time, but extract the following report of remarks on the subject by Mr. Maxwell Lyte, from the *Cambridge Independent* :—

Mr. Maxwell F. Lyte made some observations upon the subject. He said—"My experience having been somewhat considerable in the use of dry collodion, I venture to make a few remarks on the paper. There is no doubt of the fact that a combination of bromide with the idoide of silver is decidedly advantageous as an accelerator in the case of sensitive dried films ot collodion ; but that this introduction of bromine should in any way be looked upon as new, when employed in this manner, is a mistake. Bromides have been very long employed in landscape photography, as a useful adjunct, and have been alternately vaunted by various practitioners as accelerators, and the contrary. One thing seems certain, that where greens form one of the prevailing colours in the picture, their impression is most decidedly facilitated. The proportion of bromide proposed to be introduced by Mr. Sutton is, in my opinion, rather too large—one part in four of iodide being the proportion which I find to work best. The use of gum arabic as a preservative coating, combined, it is true, with a very small portion of honey, was mentioned by me in the journal of the Photographic Society of Paris many years since, but subsequently discarded as giving a tendency to fog ; but perhaps my decision in this respect may have been hurried, as I may not have washed the plate thoroughly enough, and certainly the proposed acid nitrate bath in which Mr. Sutton renders his plates sensitive, is likely to diminish this fogging tendency. This fogging it was which induced me to substitute the metagelatine for the gum arabic, which I subsequently did. Now, however, I am led to believe that the following modification of the resin process employed by the Abbe Desprats is the simplest and best process for dry collodion. Add to the collodion one-fifth per cent. of the resin of scammony, that which has been purified and bleached with animal black is to be preferred. Sensitize in a bath of seven per cent. nitrate of silver, slightly acidulated with acetic or nitric acid ; wash the plate most thoroughly in clean rain water, or in distilled water, to which has been added 0·1 per thousand of common salt or chloride of ammonium, and let the plate become dry in a place thoroughly free from dust. The exposure is less than that required with any other dry process with which I am acquainted, and is not above one-half more than that required for moist plates. The development should be performed by first moistening the plate with distilled water, and then pouring on a solution containing one part of pyrogallic acid, ten of acetic acid (glacial), and five hundred of water. Fix with a solution containing about one of cyanide of potassium to a hundred of water. It is not absolutely necessary to employ for the *first* washing bath distilled or rain water, with an addition of chloride, as in actual experience I have obtained very good and perfect results with spring water ; but, considering the varied nature of the salts found in spring waters, it is prudent to proceed as above recommended. The second washing should always be performed in water as pure as can be obtained—in distilled water if possible—and especially the presence of any bicarbonates is to be avoided. The present is only a sketch of what I propose to present hereafter in a more detailed form, and was only elicited from me by hearing Mr. Sutton's paper. The acceleration of which Mr. Sutton speaks may very probably depend on the action of the gum with which he coats the plate. Gum arabic is the lime salt of a very weak acid. In contact with nitrate of silver it is decomposed, with formation of the gummate of silver ; but no such double decomposition takes place when it is placed in contact with the bromide or the iodide of silver. The action of light, however, on these latter compounds is to eliminate their acid element and separate the silver, and the iodide and bromide set free would tend to fix themselves on the lime in the gum. If the washing be not thoroughly performed, however, gummate of silver will form, which blackens in contact with the developer, even without previous exposure to light. It is, therefore, with much propriety that Mr. Sutton insists on a careful washing of the plate after sensitizing, and previous to the application of the gum. In the preservative process of which I have given a slight sketch, I have chosen to employ the resin of scammony, as it is soluble in ether, and, from its friable nature, seems to more completely disintegrate the collodion, and render it pulverulent, a condition most essential to obtaining intensity on dry plates. The collodion I employ is prepared just as I have already explained in a paper published some time since in the *Photographic Journal* of London."

## ON A SIMPLE METHOD OF TAKING STEREO-MICRO-PHOTOGRAPHS.

BY CHARLES HEISCH, F.C.S., LECTURER ON CHEMISTRY AT MIDDLESEX HOSPITAL.*

The production of stereoscopic micro-photographs, which should give the effects seen in the binocular microscope, has been for some time a desideratum. Like many others, I have been engaged in attempts to meet the difficulties encountered in using the binocular microscope as the instrument to produce them. The use of this instrument for the purpose, at first sight seems very simple, but it presents several difficulties.

1st. The two bodies standing out at an angle to one another precludes the use of one plate on which to take two pictures.

2nd. The light of that picture which has been reflected by the prism, is always weaker than that directly seen, so that it is difficult to regulate the time of exposure. Under these circumstances I devised the following plan :—

A microscope with its eye-piece removed, is placed in a horizontal position, and fitted to an ordinary sliding back, single lens, stereoscopic camera. The ordinary adapter for the object glass being removed, its place is supplied by one carrying a tube which can be turned half round inside, by means of a lever from the outside sliding in this tube, is second furnished with a stop which cuts off half the pencil of light coming from the object glass, in fact, occupies the same place as the prism in a binocular microscope. The distance of this stop from the back of the object glass, is adjusted, experimentally, by sliding the tube which carries it in and out, till the image shown on the ground glass of the camera is equally illuminated in whatever position the stop may be turned.

The prepared plate being put in its place after carefully focussing the object, the first picture is taken. The plate is then shifted, the stop turned half round, and the second picture taken on the other half of the plate.

If the object be of considerable thickness, more effect may be produced by focussing the upper surface for one picture and the under surface for the other. The adapter for the object glass with its tube and stop I send herewith. It can be adapted to any microscope.

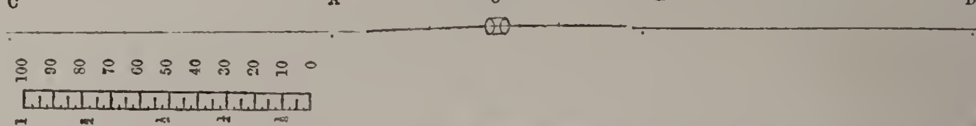
* Read before the British Association.

## ON THE MEANS OF FOLLOWING THE SMALL DIVISIONS OF THE SCALE REGULATING THE DISTANCES AND ENLARGEMENT IN THE SOLAR CAMERA.

BY A. CLAUDET, F.R.S.*

In a former paper, read before this Association, I have proposed a new method of measuring both the distances of the negative and screen, by means of a scale or unity, divided into 100 parts, and smaller fractions, if possible. By this method the distances are measured, not from the object glass *o*, fig. 1, but from the points A and B, being the focus for parallel rays. No object can be brought nearer the lens than A; and B being the focus for parallel rays there cannot be any focus nearer than B.

Fig. 1.



The scale, A C, is fixed on the table containing the optical apparatus, and an index connected with the frame holding the negative, being brought exactly on any division of the scale indicates the proportion and the distance of the image.

The whole arrangement would be very complete and satisfactory, if the scale were long enough to be marked with divisions sufficiently conspicuous; but the shorter the focus of the object glass and the smaller the divisions of the scale must be. Even for long focus object glasses it is very difficult to subdivide the parts of the scale to a degree which enables us to obtain, with the greatest accuracy, both the exact positions of the negative and screen.

The means I have adopted to reach the divisions with a greater precision and certainty, consists in constructing, on the table of the apparatus, an equilateral triangle, the base of which is the exact length of the unity of measure. Taking 8 inches, for example, as the length of the scale, we have a triangle, A B, fig. 2, the three sides of which are eight inches.

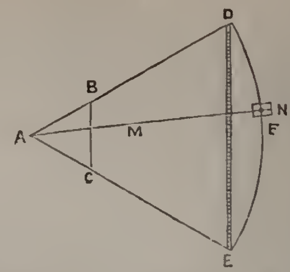
Fig. 2.

We can enlarge the base 3, 4, 5, or any number of times, by extending the sides A B and A C in the same ratio. So that if we want to enlarge the scale four times, we form the triangle A D E, fig. 3, the base of which is four times larger than B C, or equal to 32 inches.

If, instead of dividing B C into 100 parts, we mark these divisions on the base D E, it is evident that they are four times larger than if they were taken on the base B C.

Now if we take the lines A D, A E as the radius of a circle, the centre of which is at A, we may describe the arc D F E, the cord of which, D E, is the increased scale, and supposing that this radius is a metallic thin wire M fixed on a piece N sliding on the arc, it is evident that each division of the magnified scale which happens to be covered by the wire, will correspond exactly with an equal division of the scale B C. But as it would be very difficult to mark distinctly the divisions on the base B C, and if these divisions could be marked, still more difficult to see to read them, we may

Fig. 3.



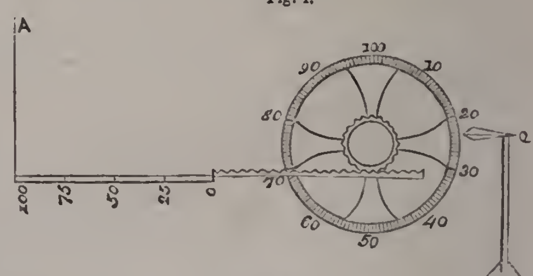
dispense with dividing B C, finding a greater advantage by establishing larger proportionate divisions on D E, the only thing to do being to fix on A C and A E the position of the unity B C, according to its length, by taking A B and A C equal to B C.

So that after having brought the metallic wire on the division of the scale D E, indicating the size of the required image, and the wire being fixed on the index moving with the frame of the negative, we shall bring the index exactly on any division of the scale B C, however small it may be.

Another plan suggests itself for obtaining the same result, which would consist in fixing the moveable frame of the negative A, fig. 4, on a rack as long as B C, which, acting on a pinion adapted to a sufficiently large wheel containing the required divisions, could produce a whole revolution of the wheel, and an index being fixed on the table, would indicate on the wheel the exact amount of the course effected by the negative on the scale B C, and by moving the wheel to the division required, this would bring the negative with the greatest accuracy to the distance corresponding with the division.

This system for focussing all camera lenses might be very advantageously adopted in photographic operations, and would be less subject to errors than the usual or visual way of focussing on the ground glass.

Fig. 4.



* Read before the British Association.

## DETAILS OF A PHOTOLITHOGRAPHIC PROCESS, AS ADOPTED BY THE GOVERNMENT OF VICTORIA, FOR THE PUBLICATION OF MAPS.

BY MR. J. W. OSBORNE, OF MELBOURNE.*

Towards the end of the year 1859 I read a paper in Melbourne, before the Philosophical Institute, now the Royal Society of Victoria, on a new photolithographic process, invented by me, and patented in the colony on the 1st of

* Read before the British Association.

September of that year. I have now the honour to bring this subject under the notice of the British Association, in such a form as to enable every one skilled in photography and lithographic printing to execute it with certainty and success.

The process I am about to describe has been for upwards of three years in active operation in the Department of Crown Lands and Survey, at Melbourne, the first map for sale having been printed on the 3rd of September, 1859, since which time many hundred maps and plans of all sizes, have been produced by its means. The Victorian Government has also recently erected an office suited to the requirements of the process, and offering every facility for its successful prosecution.

Before proceeding to give exact details, I shall sketch out the leading characteristics of this photolithographic method, with the intention of making more intelligible the object of the careful manipulations which are subsequently enjoined; premising, also, that the remarks embodied in this paper have reference only to the reproduction of drawings or engravings in simple black and white, without the gradual passage from dark to light, known as half tone, and peculiar to mezzotinto engravings, chalk drawings on stone, and in an eminent degree to ordinary photographs from natural objects.

A reproduction from stone being required of a drawing or print of the nature I have described, the first step is to obtain a negative on glass, bearing to it the desired relation as regards size. From this a photographic positive is printed by light in the pressure-frame, upon paper coated on one of its sides with a smooth surface, consisting of gelatine and bichromate of potash with an admixture of albumen. This positive is now covered with lithographic retransfer ink by passing it through the press, inverted upon a stone, which has been evenly covered with that substance by the printer's roller. The next operation is to float the paper with its inked side upwards upon a tray of boiling water, the effect of which is, in the first moment, to fuse the thick greasy ink, giving it thereby more homogeneity, and, subsequently, to coagulate the albumen in the coating, and, as the water cools, to swell and soften the gelatine which, protected by the opaque portions of the negative, has not suffered the well known alteration by the actinic influence in the presence of the chromium salt. As soon as the blackened print has remained a sufficiently long time upon the surface of the water a little gentle friction will be found to remove all the ink, save that in contact with the altered positive work upon the paper, and a subsequent flooding with boiling water, will sweep away every thing that is soluble upon the surface of the print, leaving behind the coagulated albumen only in the form of a smooth tenacious film under the design.

After this print is properly dried, it becomes what is technically known as a "positive transfer," and is, in fact, a photograph of the original in re-transfer lithographic ink, so constituted as to admit of the design upon its surface being transferred to a stone in the ordinary way known to lithographic printers. From the drawing thus obtained, the usual number of copies can be printed, the quality and permanence of the work upon the stone being in no way influenced by it photographic original.

To recapitulate, I would first draw attention to the negative, upon the quality of which depends the excellence of the works subsequently produced. Its characteristics should be extreme sharpness of definition, freedom from distortion of any kind, absolute transparency of the shadows, and considerable intensity. Unless these conditions are fulfilled it is impossible to produce photo-lithographic work which will compare favourably with that produced by hand. As may be expected, much will depend upon the lens employed, and in this respect I cannot do better than recommend the use of Mr. Dallmeyer's triplet, which I believe to be unsurpassed for copying purposes, and to the excellent qualities of which I gladly bear witness. The method I have systematically followed to produce negatives of the prescribed quality, is as follows:—Bearing in mind the fact that in copying, the photographer is, even under the best of circumstances, working in a weak light, owing to the near proximity of the original to the lens, and the small stop required, it will be found best to develop with iron, and to abandon the idea of getting sufficient intensity in the first instance. Intense clear negatives may occasionally be produced under favourable circumstances, fit for silver prints; but not as a rule in all weathers, or in the routine of daily work. I therefore recommend the use of intensifying agents, of which the most important is Major Russell's developer. Previous to its use, however, I have found it necessary to resort to a method of "clearing up," which will, I believe, be found new and useful. This consists in re-iodizing, to a very slight extent, the deposit in the film after fixing, by the use of free iodine, and then dissolving off the iodide of silver thus formed. In practice it will be found best to prepare a saturated solution of iodine, in a two grain solution of iodide of potassium. Pour a few drops of this into a developing glass, and dilute with water. Treat the fixed plate with this after very careful washing, until the liquid becomes colourless. The operator will then be assured that all the free iodine has expended itself upon the silver in the film, and by judging of the colour of the dilute solution he uses, a most accurate estimate may be formed of the amount and intensity of the change it will effect upon the negative. By proceeding in this way, the deposit, which in my opinion is always to be found upon the transparent shadows, even in the clearest pictures, is totally swept away, leaving them incapable of determining the precipitation of an additional quantity of silver. Major Russell's admirable developer for his tannin process, may now be used, and the development pushed to any desired extent, without fear of destroying the contrast, or dimming the shadows in the slightest degree. To obtain the necessary intensity by this method alone, would occupy too much time, the negative being invariably a very feeble one to begin with, in consequence of which it will be found well to wash the plate, when a certain amount of intensity has been obtained, and *immerse* it in a saturated solution of bi-chloride of mercury, in water acidulated with hydrochloric acid. Afterwards apply a weak solution of iodide of potassium, increasing its strength gradually, until the deepest yellow colour pervades the whole depth of the deposit; when the yellow may be changed to a dark olive with advantage, by flooding with a one grain solution of chloride of gold.

The glass for negatives treated in this way, should have the edges roughened for obvious reasons, and it is also very advisable to pour over the finished negatives, while wet, a solution of gum arabic, of such a strength as to leave no gloss when dry. This precaution will be found to prevent the peeling off of the film while drying, and to obviate the necessity for varnishing, as the plates will keep perfectly well if stored in tin boxes.

The next step in this process is the manufacture of photolithographic transfer paper. For this purpose introduce 800 grains of Nelson's opaque gelatine into a flask, add 440 grains of finely powdered bichromate of potash, and cover both with eight ounces of cold water; place the flask in a dark place for two or three hours, for the purpose of allowing the gelatine to soften and swell. After the lapse of that time its contents are to be melted by immersing and agitating it in hot water, after which the temperature must be lowered to about 110° F., and two liquid ounces of albumen added and thoroughly mixed. About 12 or 14 half sheets of plain positive paper of good quality, having been slightly damped for some time previously, are now to be coated with this solution in the following manner:—A small tin trough is provided, about 11 inches long, 3 inches wide, and 1½ inch deep, into which the gelatinous solution is carefully strained. The trough is made fast to one end of a board, upon which the positive paper is placed, and when the temperature of its contents has fallen to 85° F., the operator, laying hold of a sheet by two adjacent corners, draws it slowly over the trough, while an assistant presses it into contact with the surface of the liquid by means of a piece of wood of suitable form.

This is by far the best method of coating paper with gelatinous liquids, with which I am acquainted; it is economical, ensures great regularity, and enables the liquid used to be retained at the necessary temperature without difficulty. I believe it would be found useful by the manufacturer of common albumenized paper.

After being coated the sheets are to be hung up and dried in the dark; the room used for that purpose requiring to be artificially warmed in damp or cold weather. In preparing this paper, great care must be bestowed upon the quality of the albumen used; the eggs from which it is obtained must either be taken when but a few hours old, or they must be buttered with the freshest butter while yet warm, in which case they will keep, if taken care of, for about a fortnight. If this rule is not attended to no certain results can be looked for.

The positive transfer paper thus made, is, when perfectly dry, to be rolled or glazed in a press, so as to improve the regularity of the surface, enabling it to be brought into the closest contact with the negative. The average time required for its exposure in the pressure frame is, in Victoria, about half a minute; in this country I do not think it would exceed double that time. When the paper is taken from the pressure frame, it is inked by the printer in the manner already described; a somewhat stiff ink being used for the purpose. This should not be applied to the paper in too heavy a coating, but should just allow the stronger parts of the positive work upon the print to be dimly perceptible through it. To effect the coagulation and soaking, I have made use of tin trays of an inch and a half deep, and otherwise of dimensions to suit the size of the negatives. The water used must be actually boiling, and about a pint of it should be poured into the tray and then rejected, before the latter is filled for the reception of the inked print. This is done to prevent the cooling of the water used for coagulating, which, without it, would be so lowered in temperature as to effect its object with difficulty. The time required for the proper soaking of a print is variable, and must be fixed in every case by the judgment of the operator; but an hour may be named as the average interval which should elapse before the print is ready for "washing off." The general appearance of the blackened surface, the relative differences in elevation and gloss, which the positive portions present, as compared to the rest of the inked face, and the temperature of the water, are the guides which experience alone will make valuable.

The soaking having been completed, the print is placed upon a smooth board, and the requisite friction for the removal of the superfluous ink, applied with a clean and dense sponge moistened with water.

Here again, it is hardly possible to give directions which will ensure perfect success in the hands of one inexperienced in the process; but I may state that the amount of friction which the print will bear without injury, will not fail to surprise the operator who washes one off for the first time.

When the details upon the paper have acquired the greatest degree of sharpness of which they are capable, the washed off print is ready for "scalding." For this purpose it is attached to a flat board, and placed in an inclined position in a large trough. A very large quantity of boiling water is now poured upon it in such a way as to pass both above and below the paper. This is an important, indeed, an indispensable operation, its effect being to carry away every particle of soluble gelatinous matter, which, were it allowed to remain would inevitably "stop out" the work during the subsequent operation of transferring, and it is here that the albumen, by resisting the action of the boiling water, shows how admirably it is fitted for the part it has to play, namely to insure, by its sticky nature when damp the immovable adhesion of the paper to the lithographic stone, during the process of transferring in the press.

Finally, the scalded print is dried by floating it upon the surface of the water, which has been described as having just passed over it; a border of ink left on purpose round the edge of the paper, preventing the hot water from flowing in upon it, while the heat from below causes the evaporation from the albumen surface to be completed in a few moments.

By adopting this method the print dries perfectly flat without the formation of irregular corrugations upon its face, which would become receptacles for drops of water, containing, in all probability, gelatinous substances in solution.

This photographic print in greasy ink, or "positive transfer," as it is called, is given to the printer—after the drying of the back has been allowed to take place spontaneously—who transfers it to the stone in the usual way, treating it throughout as if it had been produced by the hand of a lithographic draughtsman.

I beg to lay before the members of the Association specimens of hand-drawing, both mathematical and artistic, wood-cuts, engravings, and lithographs reproduced from the stone by my method. Also a specimen of photo-zincography, and of transfer to the surface of waxed copper, as a guide to the engraver. And, lastly, I should remark, that several of the photolithographs here exhibited, are produced by joining two or more positive transfers, from different negatives, before laying them down upon the stone, the number joined in this way amounting, in one case, to eight; from which it will be seen that a large camera is by no means necessary for the production of a large copy; nor is there any limit, but the the size of the lithographic stones and press at command to that of the finished photolithograph.

In the course of reading his paper, and at its close, Mr. Osborne entered into further oral explanations and remarks. Referring to the usual process of photography, he explained that the printing surface consisted of an image in a greasy ink, which was either drawn upon, or transferred to, the lithographic stone, which consisted chiefly of carbonate of lime. The common opinion held was, that the ink was simply absorbed by the stone, but he held the conviction that an actual combination took place. The mere contact of grease and carbonate of lime could not, of course, effect this combination; but he thought it was probable that, in the processes of burning, &c., to which the materials were subjected in the manufacture of the ink, a portion of fatty acid might be liberated, which, acting upon the stone, produced actual combination. This was the more probable from the fact, that if the image were removed from the stone by means of a solvent of the ink, such as turpentine, there was still a tracing of the image left upon the stone, which, as lithographers well knew, could be "rolled up" again by applying fresh ink, with a roller, in the usual manner.

In exhibiting a variety of very beautiful specimens, consisting of maps and plans of Victoria, and of drawings, together with some transfers, &c., he explained that, for the satisfactory reproduction of the maps, it was desirable that a definite system should be used in the drawing of the originals, especially where the copies had to be made on a reduced scale, as, otherwise, the lettering would be so far reduced as to render it difficult to read. The economy of the process was made apparent by reference to some of the specimen maps, which, at one time, used to be issued at two guineas each, and by means of photo-lithographing they were enabled to reduce the price to three shillings each. Some of the large specimens were produced by taking several negatives, and joining the transfers obtained from each on to one stone, a process which materially facilitated the production of large plans.

In answer to a question from the President, as to any inaccuracy arising, either from the photographic image or the contraction of the transfer in drying, after the hot-water soaking, Mr. Osborne stated, that on one occasion the Surveyor-General, desirous of testing the process, unknown to him (Mr. Osborne), had a copy of a plan, which had been reproduced on the same scale as the original, printed from the stone on to tracing paper. This photo-lithographic copy, on tracing paper, was then laid on the original drawing, when it was found that the copy was absolutely coincident with the original. The chief thing to be observed was, that all the transfers to be joined should be printed on paper cut from the same way of the sheet, otherwise the contraction in drying would be unequal, and a perfect junction impossible.

Mr. Maxwell Lyte asked Mr. Osborne if his discovery was prior to that of M. Poitevin?

Mr. Osborne said it was not.

Mr. G. Wharton Simpson said, if he had rightly understood Mr. Osborne, the discovery claimed was not the origin of photo-lithography itself, but of producing the photographic image upon the lithographic stone by means of a *transfer*, by which all the difficulties, inconvenience, and imperfection of photographing direct upon the stone was avoided.

Mr. Osborne said the transfer was, in truth, the important part of his process, and that, by its means, other important advantages were secured, such as the impressing the image directly upon the stone itself, and incorporating it with the stone, as in the usual lithographic process. In M. Poitevin's, and some other processes, there was a layer of albumen, or gelatine, &c., between the image and the stone, and this layer quickly wore or broke away in printing, and left the stone useless. When he first read a description of the process in Melbourne, he had entered into an examination of M. Poitevin's process, amongst others, and had pointed out where they failed. That paper had been reproduced in at least three of the English photographic journals,* so that he need not enter further into the question.

Mr. James Wyld, M.P., asked Mr. Osborne if his process were not, in many respects, similar to that of Colonel James, and which of the two were discovered, or published, first?

Mr. Osborne said, that the two processes were in most respects analogous. Colonel James worked on zinc, to which a certain grain was imparted to make it bite, and he used gum with the chromic salt. He (Mr. Osborne) used the lithographic stone, and gelatine, and albumen; and, he believed, the advantage was decided in favour of the latter. Regarding the question of priority, his process was worked, and published, six months prior to that of Colonel James. The latter was published in March, 1860, whilst his (Mr. Osborne's) was patented in September, 1859.

Professor E. Emerson asked what method of focussing Mr. Osborne adopted?

Mr. Osborne said he focussed on a ground glass, with a magnifier. He was not, however, quite satisfied with the result, as the ground glass was too coarse, and there was an appreciable distance which the lens might be moved without any apparent change in the sharpness of the image. He believed, moreover, that a better lens still might be produced, and had been consulting with Mr. Dallmeyer, as to the making of a combination, in which the grinding would be effected by the method employed for astronomical object glasses.

Mr. M. Lyte said he had found that a collodionized plate plunged in the bath for a second or two, and then washed and dried, made a very good focussing glass, when a magnifier had to be applied, as the texture of the ground glass was thus got rid of.

Professor Emerson said that plain glass was better still. He used plain glass with a few diamond scratches on it, upon which to focus the magnifier. Although the specimens exhibited were very perfect, perhaps the finest he had seen; still, he thought, by absolutely correct focussing, more perfect results might be obtained.

* See Photographic News, vol. iv. p. 374, and 388.

The President remarked, that the plan to which Professor Emerson had referred was adopted by Professor Dove, in a microscopic photometer he had contrived.

Mr. Osborne said, he thought that the absence of fine lines, to which Professor Emerson referred, as the result of imperfect focussing, was rather due to the photographic negative, in which the finest lines were sometimes filled up with the deposit of silver.

After a few more words from Mr. M. Lyte and others, the discussion terminated.

On the subject of Mr. Osborne's paper, and the discussion which followed, Colonel James has addressed the following letter to the *Times*:

Sir,—In the report of the proceedings of the Chemical Section of the British Association, which appeared in the *Times* of yesterday, Mr. J. W. Osborne's account of the process invented by him at Melbourne, Australia, is given, and which he has named photo-lithography.

"In the course of subsequent discussion," the report says, "it was elicited that one of the principal claims to novelty involved, was the fact that Mr. Osborne's process was the first in which the image on the stone was effected by means of a transfer. The process of Colonel Sir Henry James, used at Southampton for the reproduction of Ordnance maps, was analogous to it in this respect, but was first used six months subsequently to the process of Mr. Osborne."

The inference which may be drawn from this is that I have adopted Mr. Osborne's process, or something very analogous to it, without any acknowledgment. If Mr. Osborne had only stated that my discovery had been made independently, and without any knowledge of the result of his labours, it would be unnecessary for me to address you on this subject, but the facts are, that an account of the process adopted by me is given in my report to Parliament for 1859, with the copy of a small deed printed by it; that Mr. Osborne, in a letter dated Melbourne, 16th January, 1860, which is printed in the *Photographic Journal* of April, 1860, says, "A positive is printed from this negative upon a sheet of paper so prepared, that the image can be transferred to stone," but he gives no information as to what the nature of the preparation is; and, in fact, he appears to have studiously avoided divulging the nature of his process in England, that he might be able to take out a patent for it, and only made it known when he found we had anticipated him.

I have been most anxious to do full justice to Mr. Osborne, as you will see by reference to the fifth page of the preface to the small work on photo-zincography, &c., which has been just published by Messrs. Longman, and of which I send you a copy.—I am, sir, your obedient servant,

Henry James, Colonel Royal Engineers.

*Ordnance Survey-office, Southampton, October 7, 1862.*

Without entering into the question of priority here, we may remark that Mr. Osborne made no intimation whatever to the effect that Colonel James's process was derived from his; but simply said, in answer to Mr. Wyld's question, that his own process was patented prior to the publication of that of Colonel James. Regarding the priority of publication we believe there is a doubt. We shall probably recur to this subject again.

## Scientific Gossip.

### Solar Phenomena—The Red Protuberances—Magnetic and Auroral Hypotheses.

Of late years the constitution of the sun has attracted considerable attention. Observers and speculators on its various phenomena were not wanting at any time, but the recent spectrum discoveries of Bunsen and Kirchhoff have endowed the subject with increased interest. To a photographer our central orb must always possess great attractions, both because it is the *fons et origo* of his art, and also because photography is peculiarly adapted to discover its hidden secrets. All our readers must remember the wonderful disclosures made by the camera on the occasion of the last great solar eclipse. The existence of the red protuberances, and their connection with the sun, were by that means placed beyond a doubt, and the photographic records then obtained have served as a basis for subsequent speculations and theories. In the last number of the *Philosophical Magazine* Mr. B. Stewart, M.A., F.R.S., has propounded a theory with respect to these remarkable appearances which appears to us to merit considerable attention. These strange and startling appearances have now been observed at least three times. The first of these occasions was during the total eclipse of the 7th of July, 1842, when their existence was revealed by the late Mr. Baily and the Astronomer Royal. The account of these philosophers was sufficient to rouse the attention of astronomers; so that during the next total eclipse, which happened on July 28th, 1851, there were assembled a large body of skilful and accurate observers well qualified to make the most of the few but precious minutes of darkness allotted them, in order, if possible to elucidate the nature of these striking appearances. From the observations of Mr. Airy and others it was rendered very probable that the red protuberances really belonged to the sun, while, from their vast magnitude, the idea of their being solar mountains was at once discarded. It seemed rather to be the impression among those assembled on this occasion that they were connected in some way with solar spots, some of which appeared on the sun's disc in places not far removed from those occupied by the red flames; and Mr H. Fox Talbot suggested that the latter might be heated vapours, which, rushing through the spots or openings in the sun's photosphere, ascend to the upper regions of the solar atmosphere in flames of immense elevation. The third and most recent occasion on which these protuberances were observed, was during the total solar eclipse of July 18th, 1860, which was attentively watched in Spain by eminent men from all quarters. It was on this occasion that Mr. De la Rue was enabled, by means of the Kew heliograph, to obtain a photographic representation of them; and from the very great care and labour which he has bestowed upon their reduction, no doubt can be entertained of the accuracy of his conclusions. By his labours, and by those of Mr. Airy and other observers, it is rendered certain that these prominences belong to the sun, and that they are not optical illusions, but represent actual changes of unknown nature, but stupendous magnitude, taking place in our luminary, and extending, in some instances, to a distance of 70,000 miles or more above the photosphere of the sun. It was also proved on this occasion that the light from the protuberances was unpolarized, and that it had very great actinic power. Many members also of the expedition supposed these appearances to be clouds in the solar atmosphere, to which idea they may have been led by the circumstance, that at least one mass, appeared to be floating quite detached, 14,000 miles away from the body of the sun. Mr. De la Rue also seemed to think that one of the most remarkable of the protuberances was connected in position with a mass of faculæ, which came round upon the sun's disc a day or two afterwards. These are the three occasions on which these phenomena have been observed; and it has been the nearly unanimous belief of all observers who have acknowledged their connection with the sun, that they represent great disturbances taking place in those regions of the solar atmosphere in which they manifest themselves. Since, therefore, argues Mr. Stewart, these are phenomena undoubtedly associated with our luminary, since, also, they extend to a distance of at least 70,000 miles above the sun's photosphere, and since we cannot well conceive them to exist without the presence of an atmosphere of some sort, however attenuated, we are led to the startling conclusion that the sun's atmosphere extends to at least this distance above its surface.

This result appears so strange that the mind can only admit it with reluctance; and, hence, Mr. Stewart has sought for an explanation consistent with the presence of a very attenuated atmosphere; and. guided by terrestrial physics, and looking to those phenomena which take place in our own atmosphere, at the greatest elevation above the surface of the earth, the aurora borealis will undoubtedly suggest itself, as an appearance which both observation and experiment, induce us to associate with the extreme limits of our atmosphere. There is, besides, another reason which might induce us to resort to this explanation: the observations of Schwabe and Sabine give us good grounds for supposing that the sun exercises a magnetic influence upon the earth. Now, Mr. Stewart, in papers which he has communicated to the Royal Society, has endeavoured to show that the terrestrial aurora is the induced effect in the upper regions of the atmosphere, of small but rapid changes, occurring in the intensity of the earth's magnetism which form what is known as magnetic disturbances, and occur simultaneously with auroras. It has also been shown, by General Sabine, that these disturbances have a daily period, thus proving their connection with the sun, and also a ten-yearly period coincident with that of the relative frequency of the solar spots. There is, therefore, little doubt left in the mind, that these changes in the earth's magnetism are due to similar changes in the sun's magnetic effect, and that both are connected directly, or indirectly, with those spots which appear on the surface of our luminary. Arguing on these grounds, Mr. Stewart, therefore, makes the suggestion, that those changes in the sun's magnetic effect, which, acting through the earth, produce an aurora in our atmosphere, exert a similar effect upon the atmosphere of our luminary, calling forth a simultaneous aurora there. According to this hypothesis, the red flames are supposed to be these auroras, and that this is not by any means impossible, the following points of likeness between the two will show. The extreme height to which the flames rise above the surface of the sun has already been adduced in favour of this hypothesis. It is strictly paralleled by the observed heights of terrestrial auroras. The great actinic effect which Mr. De la Rue showed was a characteristic of the red protuberances, is also another point of similarity, since Dr. Robinson and others have found the light of terrestrial auroras to possess similar chemical action. The red or violet colour of the solar flames is also in favour of the hypothesis. The light from each kind of aurora is likewise unpolarized; and lastly, some of the red flames present a curved appearance, similar to the auroral arch.

These coincidences are by no means very striking. Indeed, they can only be looked upon as points of likeness by physicists, who feel that any hypothesis is better than none at all, and that the solar phenomena, as recently exemplified by the red flames, and the willow-leaf appearances, are so startling that they warrant the indulging in strange and somewhat far-fetched theories. Several objections to Mr. Stewart's theory will at once occur to many of our readers. For instance, it is a necessary characteristic of terrestrial auroras, that they should be confined to the upper strata of the atmosphere; whilst in the case of the solar flames, they almost always appear to descend down to the photosphere; the above theory being, in part, built upon an isolated instance of one mass appearing to be floating quite detached from the body of the sun. Again, the sharp outlines of the red flames are scarcely comparable with the misty, uncertain, outline of an auroral display; and their position in respect to the poles and equator of the sun, can scarcely be reconciled to our terrestrial ideas of an aurora. However, as we said at the commencement, Mr. Stewart's theory merits considerable attention, as it is certainly the most satisfactory attempt at explaining these phenomena which we have as yet seen.

## NOTES ON ENLARGING PHOTOGRAPHS.

BY SAMUEL FRY.

The desire to produce large pictures is very general amongst photographers, whether amateurs or professionals. Many are deterred from attempting to work unusual sizes, from the expense involved, in the first place, by the purchase of the apparatus required; and in the next place, by the great labour involved in the operation when at a distance from home; for even when working 12 × 10, which is a very moderate size, a heavy stock of impedimenta is necessary, involving much expense and great labour. The specimens which have been exhibited of enlargements have been of a mixed character, many very good, and others unsatisfactory. The latter have arisen from several causes, amongst which may be named, choice of unsuitable subjects, carrying the amplification to an excessive degree, or having a poor or inartistic negative to start with. A small picture, inartistically treated, may be passed over amongst other prints, from the very fact of its smallness; but the same picture enlarged to 18 inches, and suspended in a room, is very undesirable, and tends to prevent the general use of a very beautiful and valuable branch of photography. The writer has been practically engaged in enlarging pictures for several years past, and on the announcement of Mr. Woodward's patent camera, he invited the attention of the proprietor to the process he was then using for enlarging photographs of the moon, and which had then been at work, with much success, for nearly two years. An idea is very generally prevalent, that large and costly apparatus is required for enlarging. This is a mistake; and it will be seen that with a stereoscopic camera and pair of lenses, and a little ingenuity from the operator, negatives of 18 × 15 may easily be procured.

The method we recommend, is that of obtaining a transmitted positive from a small negative, and then enlarging this positive to a negative. Two great advantages this method claims over the solar camera are, that a particular character of negative to commence upon is not required, any good, sharp, clean plate being suitable; and, in the second place, that sunshine is not required, or even desirable. The difficulties in this way of procuring a supply of solar prints are well known, and in dull seasons and in winter time, none at all can be done, or so few as to practically prevent commercial transactions being carried on. By the method about to be described, on the contrary, an ordinary moderately good light is always amply sufficient. In the City, at the writer's establishment, 20 seconds is an average exposure for enlarging from a negative plate 2¼ × 2 up to 15 × 12. The loss of sharpness is merely nominal, where the original plate is absolutely sharp; but where there exists only an approximate focus, the apparent loss is greater than might have been expected.

We generally obtain the transmitted positive by a long deal camera, having the lens in the centre, the negative in front, and the focussing screen at the same distance behind the lens that the plate is in front. We employ a Dallmeyer's Stereoscopic Lens for this part of the operation, and as it requires a very perfect positive, it is desirable to use a small stop, say three-eighths of an inch, and focus with extreme accuracy, pointing the camera at an angle of about 40 degrees towards the northern sky, from an open window, or, if the weather will not allow of that, placing the end of the camera very close to the panes of glass, which should previously be carefully cleaned, or much light will be obstructed.

It would be difficult to name a precise time for an average exposure, as everything depends on the density of the negative, and as great difference will be found in this as in printing on paper, where one negative may take 10 minutes, and another 10 hours, or 60 times as long. We develop the plate with protosulphate of iron, 10 grains, and acetic acid, 20 minims. The picture should appear very slowly, and the iron may be kept on, moving it constantly, until the minutest details are well out; then wash with extreme care, back and front, and finish with a little distilled water, as caution is necessary to prevent the slightest stain. The impression will probably require a little of a 2-grain solution of pyrogallic and acetic acid, with four drops of a 10-grain silver solution, to bring it to its full density; and it is here that considerable judgment is required, as upon this depends the success of the final operation. The very darkest portions should have their transparency unimpaired, as the tendency of the ultimate amplification is to produce rather harder lines than exist in the original; and by thus allowing a slight margin of softness in starting, we may attain to a very fine result in the end. We ought, by the way, to have specified, that it is extremely desirable that the original small negative should be fully exposed, and have the finest half-tones well indicated, or it will be clearly impossible to obtain a transparency having that proper balance of vigour and softness which go so far to produce the requisite rotundity in the print. It is well, before commencing to enlarge a series of pictures, to decide upon what will be the most convenient size, having reference to their ultimate destination.

Stereoscopic pictures, enlarged to 12 × 10, have a very pleasing effect; and one of this size, produced by the writer from a stereo negative, may be seen in the International Exhibition, by those who have the requisite temerity to ascend the threescore and ten steps leading to the "Photographic Garret." This picture is from the celebrated sculpture, "The First Cradle," by Auguste Debay, and is intended to illustrate the advantages of Mr. Swan's patent stereoscope. This picture defies examination as far as sharpness is concerned, and preserves in a remarkable manner, the style of the original negative, which was taken by Mr. Maddison, operator for Messrs. Negretti and Zambra at the Crystal Palace. For landscape subjects: a size of 14 by 12 mounted horizontally, is extremely pleasing and imposing , and a good sharp stereoscotive negative, to the corners and edges, will yield such a size easily, with gratifying results; but it is no use to attempt to work upon inferior, ill lighted, leprous, marky, inartistic pictures, however sharp they may be. Let the true definition of sharpness be what it may, we all know in these days of Dallmeyer, Ross, Grubb, Sutton, Voigtlander and others, what is meant by a sharp negative, and all admit that the second most desirable quality in a negative is sharpness, the first being always artistic treatment. Having now got up to the half-way house of the subject, the production of the transmitted positive, we propose in the next to consider the part requiring greater dexterity, and power of manipulation, and certainly as much judgment and skill, as that we have now touched on. At the risk of giving vent to heterodox views, we cannot but say that in our opinion, a good manipulatory powers, and sound judgment will in most cases be of more value to the practical photographer than profound chemical knowledge.

## Correspondence.

### PRINTING DIFFICULTIES.

Sir,—Although the fabric of photography appears to rest on a perfect system of toning being discovered, there is no brnach of the art where the chemical conditions of the solutions used are so imperfectly understood. Able men, thoroughly versed in chemistry, have, from time to time, endeavoured to solve the problem; but, after a volley of hard sounding words, attended by (what to the uninitiated appear) a long row of noughts and crosses, they have beaten a retreat, leaving us in the same amount of ignorance as before. I make no pretensions to the character of a genius, and, consequently, cannot be expected to undertake what others, whose road to the acquirement of knowledge has been less rugged than mine, have failed satisfactorily to elucidate; still a few points are left open, an examination of which may, in the absence of clearer light, prove a stepping stone to discoveries of a more important character—for the most mighty works extant are but accumulations of small things. Dividing, then, the toning bath, and examining its constituent parts, what have we?

first, water, then chloride of gold, followed by (say) carbonate of soda; let us now endeavour to ascertain the part each of these bodies has to perform in the process of toning; First, water, which dilutes and brings the remaining substances under control; secondly, chloride of gold, that imparts colour; and lastly, soda carb., which prepares the way for the last named agent to perform its part. But a difficulty here presents itself; carbonate of soda, except in contact with gold, refuses to act, still the gold of itself possesses no powers of reduction, neither is the soda capable of imparting colour; this question, apparently so perplexingly paradoxical, needs some explanation ere we can proceed further. Numerous experiments and close observation led me to believe that the soda partially decomposes the chloride of gold, $Au^2 Cl^3$; a portion of the chlorine unites with the soda, thus forming another compound, which prepares the surface of the paper for the reception of the gold; the remaining portion preserves the $Au^2$ and Cl, probably now standing $Cl^1$ in combination, that enables it to act, and its action seems to exercise a mechanical influence on the film of coloured matter that covers the high lights of the picture; but this influence can only be exerted when in contact with the primary reducing agent, a bath containing a few drops of hydrochloric acid with soda carb. to produce an alkaline reaction, without the assistance of gold, will clear the surface of the paper sufficient to secure even-toning, but this solution does not readily remove the coloured film spoken of. But if, instead of the acid, we employ chloride of gold with an excess of soda to destroy its toning action, the surface of the prints is cleared as effectually as can be accomplished by the usual method of toning, the action of course, being somewhat slower. This train of thoughts suggested the idea, that a paper given to mealiness, if submitted to the action of a newly prepared bath, with soda in excess, to render the gold inert so far as toning is concerned, it would prepare the surface of the paper and prevent mealiness when exposed to the action of a second toning bath, made in the usual way. On trial, I found such to be the case, although slow toning gave the best results; with a longer soaking in the first bath I have no doubt but a quicker toning might have been resorted to, although the second bath stand but very slightly alkaline; and this leads us to consider the conditions of the gold rendered inert by the decomposition above alluded to. I believe that so long as this substance retains a portion of chlorine, however small that quantity may be, a total decomposition cannot be effected; and when, by the addition of chlorine, either in combination with hydrogen or the precious metal, the balance is restored, it revives into new life, and works as vigorously as ever. I entertain a strong impression, that, if this subject was fully entered into by photographers enjoying the threefold blessing of time, talent, and money, they would be amply rewarded for their pains, for I believe those investigations would be the means of bringing about a complete revolution in our present system of toning.—Yours respectfully,

A Photo's Assistant.

## PHOTOGRAPHIC EXCHANGE CLUB.

Sir,—Twelve months having passed since the alteration of the rules of the Exchange Club, it may not be an inappropriate time to submit to the members, and likewise to the readers of your journal, a record of what has been done during that time.

In the first place, it is with great pleasure that, as secretary, I have to thank you for the great assistance you have afforded myself and the members of the Club by placing the columns of the Photographic News at our service; in advising and suggesting, at times when the Club was not working harmoniously, and in assisting at all times to promote what cannot fail to have afforded a great deal of pleasure to many amateur photographers.

Since undertaking the office of secretary, I have received communications, corresponded with, and received prints from exactly 50 gentlemen. I have received 1,801 photographs, of which the scrutineers passed about 1,450, which I have exchanged; about 250 were returned as unsuitable for exchange, and the balance I have in hand; the largest number received from one individual was 136. One gentleman sent 111, not one of which was from a bad negative, and were all most carefully printed. Another gentleman has sent me regularly 6 prints every month for some time past, amounting altogether to 62 prints, every one from a different negative, not one of which have been rejected.

Some of these details will be sufficient to show gentlemen who might wish to join, that both pleasure and profit may be obtained from good negatives that they may have by them, by joining the Club. As regards the merits of various processes, some information on that head is to be derived from inspecting so many prints, and may be of interest to the photographic world at large. The contributor last mentioned works dry plates, the collodio-albumen, the results speak for themselves. The member sending 111, works the wet, develops with iron, failures he appears to have none of. So much for wet or dry: now for dry processes. Surely, one could say, after the specimens of the collodio-albumen that bears off the palm, it does as to quantity, keeping in sight quality as well, until I come to mention a smaller contribution of 14 prints, from the far west of England, showing as good results with the Fothergill process; honey and gelatine come next as to results, and the last, both as to number and quality, is the tannin. As to the working of the Club, I trust that some satisfaction has been given. I am afraid I cannot say I am not aware of dissatisfaction having been expressed, upon one or two occasions, when prints have been returned. The great difficulty is still, as it used to be some two or three years ago, gentlemen will not look at their own productions with a sufficiently critical eye; half the labour would be spared the scrutineers, and all the unpleasant part of the work to the secretary, if this were done. Trusting that gentlemen, from whom I have not heard lately, will send me in some prints from the best negatives they have been taking this summer, as this last month or two we have languished a little, and several good prints are on hand waiting for equivalents; it is as I said would be likely to occur, two or three energetic good photographers send up month after month their good photographs, and bring me to a stand still for want of good material to send them back.

I will now conclude, with simply saying that members are contributors from all parts of England, Ireland, Scotland, and India, and that new members will be guaranteed that variety and novelty of subject abound if they should be desirous of joining the Club.—Yours respectfully,

Frank Howard.

10, *Lansdowne Road North, South Lambeth,*
*September 30th*, 1862.

## RESINIZED PAPER PROCESS.

Dear Sir,—In my last communication, there is a slight error in the formula, whether my own or the printer's, I know not. It should be one *scruple* of benzoic acid, instead of one *drachm*. I should be obliged by your inserting this note, as the latter quantity would make the prints very red, and very slow in printing.

As I promised, I have tried mastic in the place of Sœhnée varnish, and find it everything that can be desired. From half to one drachm to the 10 ozs. of spirit, according to the quality of the paper (a harder sample requiring less than a more porous one), is the quantity I would recommend.

The only thing that I am dissatisfied with in the process, is the chloride of cadmium, which is objectionable, not only on account of its expense, but also from the difficulty of ascertaining the quantity dissolved in the alcohol. It is, also, slightly deliquescent, which is another disadvantage. If any gentleman should think of any other chloride that would answer better than the cadmium, I should be glad if he would let me know. It must be pretty permanent in the air, and soluble to the extent of 15 grs. to the ounce in rectified spirit, provided that it contain as much chlorine as chloride of sodium; should it contain less, a greater quantity must, of course, be soluble in the alcohol.

I may as well here call attention to the fact, that methylated finish (which is very often sold for the methylated spirit, as the latter cannot be sold in less quantity than 12 gallons) contains a good deal of shellac, which would be detrimental in the resinized paper.—I am, dear sir, yours respectfully,

H. Cooper, Jun.

5, *Aberdeen Park, October 7th*, 1862.

P.S.—I had forgotten to state that the resinized paper will be prepared for sale by C. B. Francis and Co., 2, Upper Street, Islington, N.

---

Dear Sir,—Permit me, through the medium of the Photographic News, to thank Mr. H. Cooper, jun., for his new printing formulæ. It promises well, and doubtless will supersede albumenized paper. I enclose a print, also a piece of the prepared paper for your inspection.

The paper is a bad sample of Rive, that has been laid aside between three and four years, as useless for all other photographic purposes to which it has been applied previously. I have not followed Mr. Cooper's formula exactly, having substituted chloride of zinc for chloride of cadmium. The chloride of zinc is very soluble in alcohol. I will here state the particulars of my proceedings:—

| | |
|---|---|
| Prepared gum benzoin ... ... | 4 drms. |
| Prepared mastic in solution ... | 8 grs. |
| Alcohol 825 ... ... ... | 8 oz. |
| Chloride of zinc ... ... ... | 120 grs. |

Dissolve and filter into a dish, the paper is then drawn through the solution and dried in a warm room; sensitized on a 60-grain solution of nitrate of silver, very impure, containing 20 per cent. of lead.

I found it necessary to print *no deeper* than the finished print would be required when toned and fixed. The print enclosed remained 25 minutes in a saturated solution of hyposulphite of soda, and was then washed for half an hour in the syphon trough. I am inclined to think that it will tend to whiten the high lights, as I have never found the benzoin become yellow, but always black by exposure to light and air, when carefully selected and prepared.—I am, sir, yours most obediently,

H. R. Nichols.

2, *St. Jude Street.*

[The tone and surface of the print enclosed are highly satisfactory.—Ed.]

---

Dear Sir,—I have been much interested in Mr. Cooper's new printing experiments, with gums and resins, in place of albumen, and if it can be accomplished, will be an undoubted improvement on the old form; but it is my impression that varnishes darken by age generally, if not invariably, and will form an insuperable difficulty in the perfection of the process. Some method of producing a hard close texture in the paper itself I should prefer; is it possible to print on parchmentized paper? which seems to possess good physical qualities for producing prints.

The remarks on toning that have lately appeared in the News, tally entirely with my experience, although I have not before known the *rationale* of the action of various solutions. I have a long time employed the subcarbonate soda instead of the bicarbonate, and have been much more successful with it in getting prints free from mealiness; and its action, according to your correspondent's views, would be owing to its greater causticity and power of acting on the fibre and albumen of the paper. Whilst the hot water plan of development is so much practised to accelerate exposure, I cannot think why some do not try the use of an alkali in gelatine for dry plates, which, with cold development, is nearly or quite as rapid.—I am, sir, yours respectfully,

W. Bartholomew.

*Bentley, Hants, October* 8, 1862.

[Most resins darken more or less by exposure to the atmosphere, but some much less than others. The desideratum at present is to find that which, whilst suitable for the purpose, darkens the least. Mr. Cooper is inclined, at present, to the use of frankincense or mastic; some prints with the latter, which he has forwarded, are very good. The very small proportion of the resin necessary will not, we apprehend, except in the case of those which darken very rapidly, cause serious loss of purity in the whites.—Ed.]

---

## COMPTOIR INTERNATIONAL DES PHOTOGRAPHES.

Sir,—After some months standing, we are happy to have to announce to you, that through the favour and sympathy that has everywhere welcomed our project of a *Comptoir International des Photographes*, we shall be able, from the present time, to open our first International Exhibition of Photographs, in a locality in the centre of Paris, namely, at No. 97, Rue Richelieu, a few steps from the Boulevard des Italiens.

All persons who may desire to exhibit prints are requested to address to the Director, at our Office, 46, Rue Bondy, Paris.

Portraits will not be admissible for exhibition, as the chief object will be to effect sales. The prices should be sent with the prints.

Hoping, sir, that you will give your great publicity to this letter, I have the great honour to remain, yours, the Director,

Edmond Potome.

*Paris, September 24th*, 1862.

---

# Photographic Notes and Queries.

### Free Nitrate in Toned Prints.

Sir,—Having been away from home for a considerable time, I did not see Mr. Dawson's "Lessons to the Learned" till a few days ago.

Mr. Dawson appears to take it for granted, that the acetate of soda is the only ingredient in the toning bath recommended by him, which would decompose the nitrate of silver remaining in an imperfectly washed print. The chloride of gold would certainly be decomposed much more than necessary, and thus a considerable loss of this expensive material would be entailed.

His experiments are not at all convincing, that free nitrate of silver would remain in the paper after passing through the toning bath; for if any salt of silver be remaining, it would certainly be the acetate.

But whether nitrate or acetate of silver be present in sufficient quantity to induce sulphuric acid in the hyposulphite bath, it would be of very little consideration, as the sulphuric acid would be at once neutralized by the hyposulphite bath being, as it ought always to be, in a decidedly alkaline state.

If an unwashed picture be put into a toning bath of acetate of soda and chloride of gold, a milky precipitate will at once be formed. If this precipitate be *acetate* of silver, then the washing is not of so much consequence; but if it be *chloride* of silver, this must be formed at the expense of the chloride of gold, and hence the washing must be of very great importance.—Your obedient servant,

W. W.

*Bristol, September 30th*, 1862.

[There can be no doubt whatever of the propriety of careful washing; and no doubt has ever been raised. Mr. Dawson gave an untenable reason, however, for that washing, and has since defended that position by very inconclusive experiments; but it is not worth while to discuss the matter further.—Ed.]

## Talk in the Studio.

Conversazione of the Society of Arts.—The last conversazione of the Society of Arts of the season was held last night at the South Kensington Museum. It was intended to be a sort of farewell meeting to the many distinguished foreigners who it was supposed would be in London at the closing of the Exhibition. From the postponement of that ceremony, the foreign element last night did not so largely preponderate as was anticipated, though most of the foreign exhibitors and Commissioners where present. The company was received by Sir Wentworth Dilke, one of the vice-presidents of the Society, and by other members of the council. Of course, the noble collection of articles of vertu, antiquities, and relics which have been lent for exhibition by numerous noblemen, and gentlemen, both in this country and abroad, was the great centre of attraction. A cursory inspection of a few of these priceless gems of art enables the visitor to realise the soundness of the estimate which calculates the value of the articles thus lent for the gratification of the public at no less a sum than six millions sterling. The admirable bands of the 1st Life Guards, and of the Coldstreams, added considerably to the enjoyment of the visitors, by the capital style in which they performed a well-selected programme of popular and operatic music.

New Double Salt of Gold.—Mr. Sutton's new double salt of gold, the calcio-chloride, appears to answer well for toning purposes. In principle we apprehend it will form a solution very similar to that we recently described Mr. Lacy as using. The prints sent out by Mr. Sutton (for the double purpose of showing the quality of the sensitive dry process, described before the British Association, and of illustrating the difference between views of the same scene, taken by the ordinary view lens, and one by the panoramic lens), are toned by this salt. The tone is a rich deep sepia, which most people like. The subject is a rustic-looking old church in Jersey, which we remember very well.

Tannin and Honey.—A correspondent says "I have worked the tannin and honey process, with success, with very short exposures, from 5 to 20 seconds, but find they do not keep after exposure, as the image fades quite away in about 4 weeks." Mr. England has kept the plates many months before exposure without injury. It is a singular and unexplained fact that the latent image in very rapid dry plates has a tendency to disappear if kept long after exposure. This is the case with the rapid plates of Dr. Hill Norris. The same effect does not take place in the slow dry processes.

Illustrations of Enlargements.—At the closing soiree of the British Association at Cambridge M. Claudet exhibited by the aid of the oxyhydrogen light, the enlarged images of the solar camera thrown on to a screen. A number of *cartes de visite* were enlarged showing the great perfection of proportion and the natural expression which may be imparted to portraits when they are taken in a very short sitting, in order to show the working of the solar camera, it was placed in a room adjoining the great hall. M. Claudet exhibited in this manner pictures of persons enlarged to the size of nature, and some considerably larger from small *cartes de visite*. The effect was very striking and beautiful. He also exhibited some photographs, taken by the Compte de Montizon, of all the most curious animals of the Zoological Gardens, and some views of Java, taken by Messrs. Negretti and Zambra, with instantaneous views of Paris by Ferrier, showing the Boulevards full of carriages and people, as they are in the middle of the day. One of the principal objects of M. Claudet was to explain how it is possible to trace or draw with pencil on canvas those enlarged portraits when they are to be painted, and for this purpose how it is even more advantageous to apply the colours, not on a surface containing the chemical substances of photographic pictures, but on the usual medium employed by artists without the black shadows forming the delineation of photographs.

## To Correspondents.

J. C.—We do not see how a gutta-percha bath can be conveniently lined with india-rubber after it is made. The only plan we can suggest would be to make the lining completely first so as to fit inside the bath exactly; then drop it in and turn the top edges over. Sulphate of ammonia is an article commonly kept by most chemists, and sold at a penny an ounce. You surely must have made some mistake in asking for it.

W. S. C.—Volumes 1, 3, and 5 of The Photographic News are in print; their price is 8s. 6d., 11s., and 15s. each. The other volume is out of print.

Fantail.—The instantaneous dry plates recently referred to in a recent letter from Mr. Fowler were those of Dr. Hill Norris, with some peculiar method of development. 2. We cannot in this column enter into a description of an instantaneous shutter. There are various plans by which one can be made to open in the middle. Perhaps one of the best is that recently described in our pages by Mr. Mann, page 319, July 4th. 3. We do not know anything definite of the lens to which you refer. It is, probably, a pretty good second-rate lens. It cannot be more than that from the price.

J. H. Kedin.—The defect to which you refer arises primarily from defective lighting; the face is not sufficiently illuminated. There is also a little under-exposure, and the negative is too thin.

Annie or Janie (the name is not quite clear).—Water colours are very apt to work up when one is worked over another on albumenized paper. To prevent this, you will find the use of "Newman's Preparation" very valuable. A little of it, mixed with the colour first laid on, allows of washing or hatching over it, without fear of working up. In all cases the glaze of the albumenized paper is removed, more or less, when covered with water colours.

An Apprentice.—To obtain the silver from clippings of sensitive paper, first burn them; then take the ashes and place them in a crucible with a flux, such as borax, or carbonate of potash and nitrate of potash, &c., and subject the crucible for an hour or two to a bright, red heat.

Amateur.—Plain paper is excited by floating on the silver bath, in the same way as albumenized paper, but does not require floating so long. All the processes with plain paper may be managed in the same manner as with albumenized paper, and with the same negatives. To secure the best class of plain paper prints, the ammonia-nitrate silver bath should be used. Your glass shall be examined.

A New Subscriber.—Acetic acid once in a bath of nitrate of silver is very difficult to eliminate, and would be detrimental if present in the proportion you state, in a printing-bath, or one for collodion positives. If you neutralise it, acetate of silver is formed. This may be partially removed by placing the bath in a very cold place for a few hours, and then filtering. A portion of the acetate may be, by this means, removed, but not the whole. 2 The present volume of the News commenced at the beginning of the year.

Simple Simon.—Solutions of nitrate of silver may be reduced to the metallic state by various methods. The reason why the method of reducing it to a chloride first is generally recommended is, because the product is most free from impurities. 2. We will shortly give the method of precipitating a silver bath by means of bi-carbonate of soda, and re-dissolving with nitric acid in detail.

Cassandra —By filtering your turbid solution you lost a great deal of silver, as the brown turbidity was caused by oxide of silver. We have followed the same instructions with success, but there is a great tendency to the further precipitation of oxide of silver on adding the two parts together. We prefer the method recently described in our columns of making an ammonia-nitrate bath, and then adding nitric acid until it is nearly neutral. The result is a solution of oxide of silver in nitrate of ammonia, which gives very rich prints.

K.—We have not met with such a defect before. It is more likely to occur from some fault in the paper than from impurity in the nitrate of silver. The acidity may arise from acetic acid being added to the albumen, which is a practice with some albumenizers.

A Young Photographer.—The idea has often been considered: the chief difficulty consists in doing justice to the subject by means of wood-cuts to be printed with a newspaper. The subject shall be borne in mind, however.

James Drake.—Your washing apparatus has arrived, but having been at Cambridge during the last week, we have not had time even to unpack it yet. We will take an early opportunity of examining it and reporting.

J. F. L.—The method of preparing Dr. Hill Norris's extra sensitive dry plates is a secret, not a patent. His original method was patented, but whether the patent has been kept up or not we cannot tell: it is certainly not enforced. How the collodion is prepared we cannot tell, but it is certainly not simply iodized. We know this much from the Doctor himself.

Alpha.—If a suitable collodion be used, we do not think it is necessary to coat the glass with gelatine in the tannin process, especially for small plates An old and powdery collodion adheres best. It should always have a bromide as well as an iodide. 2. The object of preparing a concentrated solution of pyrogallic acid, and of citro nitrate of silver, is primarily convenience. Having these solutions at hand it is easy to mix them in a moment, in any proportions, and in any degree of dilution. It is always well to begin development with a very small quantity of silver. If the picture show signs of under-exposure, adhere to the small quantity of silver, and develop slowly; if, on the other hand, the image start out and show signs of over-exposure, the citro-nitrate may be added freely, to obtain the required density rapidly, and gain a well contrasted picture. 3. When there is any tendency in the film to leave the plate, it is well to varnish the edges of the plate. We have found Hughes's black varnish answer well for the purpose.

J. M. B.—You can belong to all, or any of the photographic societies, if you wish. You require to be proposed by a member. *The* Photographic Society of London, or rather of England, is the oldest. The subscription is a guinea a year, and a guinea entrance fee. If you join at the present time, you will only pay half a year's subscription, as the year commences in February. The meetings are held in Kings' College, from November to June, on the first Tuesday evening in each month. The North London Society meets on the last Wednesday but one in each month, from September to May, in Myddelton Hall; the South, on the second Thursday in each month, from October to June, in the City of London College. All the meetings are held at 8 o'clock in the evening. It is not absolutely necessary to be a member, in order to read a paper.

B. F.—You cannot precipitate the silver from your fixing solution as a chloride. It must be thrown down as a sulphide. We have repeatedly described the process.

Several correspondents in our next.

All Letters, Works for Review, and other Communications for the Editor, should be addressed to the Office, 32, Paternoster Row, London.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 215.—*October* 17, 1862.

## THE FUMES OF AMMONIA IN PRINTING.

The value of a solution of ammonia-nitrate of silver in printing is well known by all photographers of any experience. Paper prepared with it is more sensitive, and gives more vigorous prints, and richer, deeper tones than can be obtained with the plate nitrate solution. Notwithstanding the various formulæ which have recently been given for the use of ammonia-nitrate with albumenized paper, many photographers find a difficulty in using it satisfactorily.

We have just received from Mr. Penny, of Cheltenham, a suggestion for the application of ammonia in a different manner, which, if a simple method of effecting it can be found, will, we think, prove valuable. Mr. Penny says :—

"While experimenting upon fuming dry plates with ammonia, it occurred to me to try the effect upon sensitized albumenized paper.

"The result was that it increased the sensitiveness, the colour of the print, when taken from the printing frame, was better, and the shadows richer. The paper tones in the acetate bath, quite as readily, and to the ordinary colours; but if the paper be damp at the time of fuming, it is apt to blister in the subsequent processes.

"I have not been able to carry out a course of experiments, but the suggestion might possibly be useful to some during the approaching dark days.—Yours truly, G. S. Penny.

"*Cheltenham, October* 11*th*, 1862."

Before going further, it is only right to say that this idea, although manifestly original with Mr. Penny, is not entirely a new one. Very recently, a distinguished American amateur communicated it to us as a most valuable secret, which he could put us in possession of, for our own use; but as it was given to him, to some extent, under the seal of confidence, he did not feel at liberty to communicate it for publication. As the matter is now suggested by an independent discoverer, we need not hesitate to add the confirmation of its value, which our friend's experience enables us to give. The results were described as possessing a richness and depth entirely unattainable by other means, and the printing was said to be effected in half the time. The mode of applying the fumes of ammonia was as follows :—A little of the strong liquid ammonia is placed in a saucer; for convenience, a piece of cotton wool may be saturated with it. This is placed at the bottom of a box with a well-fitting lid. To the centre of the lid, inside, is attached a clip to hold the paper. A sheet of paper is then taken, and two diagonal corners brought together, and placed in the clip, so that the sheet hangs loosely folded, face downwards. The lid is then closed, and the excited paper is subjected to the fumes for a few minutes. A very short time is sufficient, and too long exposure causes the albumen to be attacked. The operation should be performed just before exposing in the pressure frame.

We fear that where printing is conducted on a large scale professionally, this process will be considered to involve too much trouble. But with those to whom trouble is a secondary consideration, compared to obtaining the best possible results, this plan is well worthy of a trial. We were informed by the gentleman to whom we have referred, in reply to a question as to whether ammonia in his dark room, did not interfere with his negative process and cause fogging, that although theoretically he had feared such a result, practically he had not found any kind of inconvenience. We have an impression, which we cannot at this moment verify, that some time ago the same method was mentioned in the letter of our Paris correspondent, who stated, that a French photographer had used it with success. Photographers will be obliged to Mr. Penny for the readiness with which he at once communicated the idea to his bretheren, not the first good idea, by the way, which he has published.

Whilst referring to ammonia-nitrate for printing, we may mention that we have been using it recently on albumenized paper, with great success. We made an 80-grain bath and added ammonia until the precipitate was redissolved. We then divided it into two parts, to one of which we added nitric acid until it had a decidedly acid reaction. We then added this to the other: the result was a solution slightly alkaline, consisting of oxide of silver in nitrate of ammonia. The paper is floated from thirty to sixty seconds, not more, and prints and tones very satisfactorily. We had a visit a few days ago from Mr. Carbutt, a photographer in Chicago, U.S., who showed us some very excellent prints, printed, as we were informed, by a very similar method.

## REPRODUCTIONS. CLEARING UP NEGATIVES.

In the paper on photolithography read by Mr. Osborne before the British Association, there is a hint upon what is termed the "clearing up" of negatives, which we conceive to be of great importance, and which, by some of our readers who are not sufficiently interested in photolithography to read the paper carefully, may easily be overlooked. One of the troubles experienced in reproduction, especially of engravings, and other similar subjects, where the presence of pure blacks and whites is of great importance, consists in obtaining sufficient density in the whites, and clearness in the shadows. A slight tint on the whites, is very common in reproductions of engravings. The difficulty arises from various causes, such as the near proximity of the object, the long focus of the lens, the small stop desirable, &c. The use of old collodion, and long exposure is an uncertain remedy. Intensifying for the purpose of getting sufficient density, is the usual method adopted for getting purer whites; but this often brings another trouble, which renders it only partially successful. It almost invariably happens, especially where a very sensitive collodion and iron development are used, that there is a slight, although sometimes almost imperceptible deposit on the shadows of the negative, which, whilst insignificant in itself, becomes the nucleus of further deposit in the process of intensifying. As we have repeatedly before observed, any deposit on the deepest shadows, becomes equivalent to a given loss of intensity on the dense parts of the negative, inasmuch as it renders so much darker printing necessary to get sufficient depth in the blacks of the print. In reproductions generally, this trouble is felt, and in photolithography must imperatively be avoided, as the slightest tint in the whites would be fatal.

To surmount this difficulty, Mr. Osborne resorts to the "clearing up" process. This consists in flooding the iron developed negative, which at this time does not possess more density than an ordinary collodion positive, with a solution of iodine in iodide of potassium, one grain of the former, to two of the latter in an ounce of water, or more dilute as may be necessary. The slight deposit of silver on the shadows is by this means converted into an iodide of silver, which, on being treated with a very dilute solution of cyanide of potassium, is at once dissolved and removed. After thoroughly washing, the process of intensification may be effected, and it is now found that the utmost density may be obtained without any further deposit being reduced upon the shadows, which remain perfectly clear and transparent, and thus facilitate the reproduction of pure whites and deep blacks in maps and engravings.

It is scarcely necessary to remark, that this process would be unsafe if applied to ordinary negatives, containing half-tone instead of lines, &c. In such case, the delicate half tones would run great risk of being dissolved, leaving a hard negative without gradation. In very careful hands, and if used with great judgement, the process might be employed for removing the coppery deposit which sometimes occurs in intensifying; the process involves much risk, and should be practised first upon a worthless negative, to gain experieuce before endangering a good one.

## PHOTOGRAPHY AND FORGERY.

In a recent article on this subject, we took occasion to refer to the photolithographic reproductious of engravings of Mr. Ramage, of Edinburgh, as the finest we had seen, and remarked that, by the same method and the same manipulator, Bauk of England notes might be reproduced with such accuracy as to defy detection. In this compliment to his skill, Mr. Ramage, or some one of his friends, discovers an impeachment of his moral character; because we stated the unexceptional excellence of his work, he thinks we imply that he is capable of employiug it for dishonest purposes. As we never dreamed of implying anything of the kind, we unhesitatingly give prominence to his remonstrance. Here is his letter :—

Dear Sir,—Having beeu from home, I have only just noticed an article, in your impression of September 19, on "Photography and Forgery," to which my attention has been called by some of my friends as placing me in a somewhat curious light before the public.

The writer, after a few important blunders (such as making *two* processes out of photolithography and photozincography, while they are the *same* process—the mere transferring to stone, zinc, steel, or copper, making no difference at all), says, referring to Col. James and Mr. Osborne, "these are gentlemen, it may readily be said, from whom there is no danger of forgery," while you have "*no hesitation whatever*" in saying "Bank of England notes might be produced by me, which would entirely defy detection."

Now what I complain of is, that while Messrs. James and Osborne you very properly hold as "iu no danger" of committing forgery, yet I am separated and spoken of as one who "might" do so, by either of *their* methods, although I practice neither.

Had I not found that many others, before me, had been surprised at the matter, I would have taken no notice of it; but certainly, iu writing on such a subject, some little care should be used in the selectiou of language, not to confound moral character with questions on art or science.—I am, sir, yours truly, James Ramage.

8, *West Brighton Crescent, Portobello, near Edinburgh, October* 9, 1862.

We think it must have been apparent to any discriminating reader that what we meant to convey was simply this :—The processes of Mr. Osborne and Col. James having been mentioned, it might readily have been urged that both the gentlemen and their processes were in the employment of Government, and any forgery from such a source need not be feared. But there were various private persons, unknown to Government, who were practising similar processes with equal skill, of whom Mr. Ramage was an able example. That there was, in short, skill enough in existence to produce forgeries which were beyoud detection. As to Mr. Ramage's moral character we never implied a doubt, as we have no reason to believe that he is less honest than he is skilful.

As to Mr. Ramage's parenthetical remark, it is he who makes a blunder. Col. James's photozincography, and Mr. Osborne's photolithography are *similar*, but they are not the *same*, any more than the calotype process and the collodion process are the same. Both are based on the same principles, but they differ in some points of material, manipulation, and results. If we confounded Mr. Ramage's method of working with that of others, he has only himself to blame, as he has not published the details of his process, the results of which are so excellent.

## ALBUMINATE OF SILVER AND THE ABBE PUJO.

BY GEORGE PRICE.

Some some time since, the photographic jouruals published an article, entitled, "Positive Priuting on Albumenized Paper, by M. L'Abbé Pujo;" as it has since beeu often alluded to by various writers, and always in terms of commendation, I cannot but presume that the statements contained in it have been generally accepted as *facts* :—whereas, the most important one of them, is so utterly at variance with truth, as to deserve being placed amongst the "fallacies of the scientific,"—of which, methinks, a singularly curious and voluminous collection might be made without much trouble.

The Abbé Pujo says,*—"Albuminate of silver plays a very important part in printing positive proofs. And, moreover, every normal sheet of paper passed over a salted albumen bath, imbibes a quantity of liquid which varies from 4 to 8 cubic centimetres (67½ to 135 minims). Now under ordinary conditions, 5 cubic centimetres of albumen solution, contain 9 grains of pure albumeu, and 3 grains of salt; so that when a dry sheet of paper is placed ou the silver bath, albuminate and chloride of silver are formed, about three times as much of the former as of the latter."

The Abbé's statement therefore is, that the albuminate of silver will bear the *same* proportion to the chloride of silver, as the dry albumen on the paper does to the chloride employed in salting it.

It does not require *much* knowledge to say that this assertion respecting the proportions of albuminate and chloride of silver is *erroneous*. If, after sensitising a sheet of albumenized paper, the albuminate of silver *bears the same proportion* to the chloride of silver, as the dry albumen did to the chloride employed in salting it, it follows as a natural consequence, that the *atomic weight of albuminate of silver must be the same as that of chloride of silver*, and moreover, that *albumen must be endowed with the extraordinary property of being able to alter its atomic weight, so as to become the same as that of the chloride employed in salting it.* Under no other conditiou whatever, can the albuminate of silver bear the same proportion to the chloride of silver, as the dry albumen did to the salting chloride; the Abbé Pujo's statement that they will do so, is, therefore, *a very great fallacy*, and so transparent is its falsity, that it is astonishing how it could ever have been entertained for a moment, and much more so, that it should have been deliberately published.

The Abbé also says,† "a proof when taken from the printing frame is formed of three superimposed images, the first furnished by the albuminate the second by the chloride, and the third by the nitrate of silver."

Passing over the extraordinary idea of *three superimposed images* as being wholly untenable, I will proceed to show the *extent* of the error in the Abbé's statement respecting the proportion of albuminate and chloride of silver; but, before doing so, it will be necessary to make a few observations. Feeling convinced, at the time it was published, that the Abbé's assertion would cause much misconception, regarding the quantity of albuminate of silver which a given formula would produce, I entertained the idea of investigating the subject, but could not obtain any informatiou as to the *atomic weight* of albumen. I read in the photographic journals that, being a complex compound, its atomic weight

* Photographic News, Vol. v. p. 291.
† Photographic News, Vol. v. p. 303.

was *unknown*; as I was but little versed in chemistry, I could not gainsay this assertion; and as a mere *approximation* to the truth would be sufficient for the purpose I then had in view, viz., to give the proportions, *somewhat* nearer the truth than I felt assured the Abbé had done, I resolved to attempt its calculation myself.

I had met with the following analysis by Mülder, of the percentage constitution of albumen: carbon 53·5, hydrogen 7, nitrogen 15·5, oxygen 22, sulphur 1·6, phosphorus 0·4. From this being given in various works, I naturally concluded that it was generally received as being correct. I therefore calculated the formula that would *represent* this percentage constitution, and finding that phosphorus (which was the lowest in amount) was represented by only an *eightieth* of its own atomic weight, I multiplied my formula for each of the constituents, by 80, in order to obtain a *whole* atom of phosphorus, instead of a fractional part. Where my formula, expressing the percentage of any of the constituents, had a fraction representing *more than half*, I took that fractiou *as a whole number*; thus:—Carbon $8\frac{11}{12}$ I considered as 9, oxygen $2\frac{3}{4}$ as 3: but those with a fraction expressing *less than half*, I multiplied as they were; after multiplying by 80, if any *produced* a fraction expressing more than half, I took the next whole number above, thus:—Nitrogen producing $88\frac{4}{7}$ I considered 89; this gave me the following formula:—C, 720; H, 560; N, 89; O, 240; S, 8; P, 1. Reflection, however, soon told me that this was, in reality, only a formula representing the constitution of 8,000 parts instead of 100, and, therefore, I had no right to assume that the number, 8,206 resulting from it, was the *atomic weight* of albumen; I was thus compelled to let the matter rest until I could obtain better information.

Some time after this, Mr. Martin gave an article on albumen, in the *British Journal*,* with the following formula for its atomic weight:—C, 400; H, 620; N, 100; O, 120; P,— S, 2. *One* circumstance respecting this formula I thought tended to prove its incorrectness; therefore, under the signature "An Ignoramus,"† after pointing out an error in the equivalent, which was stated as 5,412 instead of 5,444, I mentioned that the formula given was simply the multiplication, by *ten*, of the numbers, in the column headed "Atomic Weight," giving the percentage constitution of *proteine*, but the added phosphorus was multipled by *eighty*, whilst the added sulphur was increased by only a fractional part, viz., *a fourth*. I asked *why* these latter should be increased in *different* and *differing* proportions. In Mr. Martin's reply, no answer whatever was returned to this important question, as I consider it; I have, therefore, rejected his formula as wholly untrustworthy, for the following reasons:—

In a formula for the atomic weight of a compound, common sense dictates that its constituents should be so represented as to have, as nearly as possible, *the same relative proportions as they bear in its percentage constitution*; but in this we have C, H, N, and O increased *ten-fold*, P, *eighty-fold*, and S receiving merely the addition of *a fourth*. Notwithstanding this, I calculated the albuminate of silver from this atomic weight of 5,444; but the more I consider the subject, the more do I feel convinced that it is based on error. I have, therefore, re-calculated it from my own formula, giving 8,206.

That I may not be accused of *presumption* for so doing, I may as well state that I have recently met with Dr. Löwig's "Principles of Organic and Physiological Chemistry." In this, he quotes the following as having been given for albumen:—$20\ (C_{36}, H_{25}, N_4, O_{10}, +2\ H\ O) + 8\ (N\ H_2, S) + N\ H_2$, P; upon analysing this equation, it gives C, 720, H, 558, N, 89, O, 240, S, 8, P, I = 8,204; this *is exactly the same as my own calculation in every particular, excepting* H *being* 558 *instead of* 560. This extraordinary coincidence, as it must be deemed, when it is borne in mind that I have *very* little knowledge of chemistry, has induced me to prefer my own calculation of the atomic weight of albumen, to that given by Mr. Martin.

I have been thus explicit in describing my "pursuit of knowledge under difficulties," in order to prevent having to give reasons in a promised future communication, for preferring my own formula. I will now return to the Abbé.

Three grains of chloride of ammonium, produces 8 grains of chloride of silver, therefore, 9 grains of dry albumen should produce 24 grains of albuminate of silver, according to the assertion that the albuminate and chloride of silver will be in the same proportion as the dry albumen and salt were; 24 bearing the same ratio to 8, as 9 does to 3. Taking the atomic weight of pure albumen to be 8206, 9 grains of dry albumen will produce only $9\frac{765}{4103}$ grains of albuminate of silver, which is but little in excess of the chloride of silver instead of *three-fold*; the 9 grains of albumen by becoming albuminate *are increased but* $\frac{487}{24{\cdot}618}$ths *more than one-sixth of a grain*, instead of receiving an increase of *fifteen grains*; the increase which the Abbé Pujo states they will receive, is, therefore, more than *eighty times* too much—a pretty considerable amount of error methinks.

It will no doubt surprise many persons to be told that whether the atomic weight be taken at 8206, as calculated by myself, or at 5444, as given by Mr. Martin, it will make but a *very slight difference* in the quantity of albuminate of silver yielded by 9 grains; taken at the latter they give $9\frac{765}{2722}$ grains instead of $9\frac{765}{4103}$, the difference is therefore only $\frac{1{,}056{,}465}{11{,}163{,}366}$th of a grain.

## NOTES ON ENLARGING PHOTOGRAPHS.

BY SAMUEL FRY.*

We had arrived last week at the finish of the transmitted positive, from which the enlarged negative is to be produced. We should just add to that, that if on careful examination, any minute flaws, such as pin holes or black spots, exist on the original negative, and of course become transferred to the positive, it is better to defer any attempt at touching them out until the completion of the enlarged plate. When a plate is to be simply printed on albumenized paper, it is easy enough to remove such slight blemishes, but for subsequent enlargement the case is different, a probability arising that the marks of the brush end will create rough edges, round the spots, which, when enlarged, become circles of appreciable dimensions, and are in that state difficult to deal with, except by those well accustomed to the work. There are two courses open to us, either of which may be available for the operation of enlarging the transparent positive, either a large deal camera placed at a suitable angle to face the northern sky, and provided with the usual slides and ground glass; or a vertical arrangement, in connection with the dark room, consisting of an aperture in the roof, having the transparency on the top, and below that the lens, beneath it a focussing screen, consisting of a table on the camera stand principle.

It is this form of enlarging apparatus which we ordinarily employ, and with great success. The simplicity of the arrangement, no camera being required, is greatly in its favour, but it is, of course, only available when the peculiar position of the developing room admits of it. The focussing is a matter of extreme simplicity, as the manipulation being inside the room, door and window closed, all is dark, except the image projected on the screen, and which under these circumstances, presents an almost magical beauty. The rough adjustment is conducted with the rising and falling motion of the camera-stand table, and an approximation being obtained, the fine adjustment is regulated by the screw of the lens overhead.

Both theoretically and practically, the thing is correct, with a Dallmeyer No. 1 B, we can enlarge a carte de visite picture up to 20 inches, without loss of sharpness, and with

* *British Journal*, Vol. ix., p. 251.
† *British Journal*, p. 321.

* Continued from p. 489.

perfect freedom from that falling off at the sides and corners which is so prejudicial to photographs. Those who examine the image on the focussing screen of the camera we have just described, will, we feel persuaded, agree that it leaves little to desire. It has been strongly objected to this vertical form of enlarging camera, that the zenith light is not that most suited to the purpose, but our practice shows conclusively to the contrary, and our own results are so much better with it than with a camera adjusted at an angle, that we strongly recommend it, not alone on account of its simple inexpensive nature, but from its great efficacy, the details of the enlargement comprising little more than the ordinary negative work.

We employ for all sizes larger than 10 by 8, a flat ebonite tray, to contain the nitrate of silver solution, as being more convenient than a dipping bath, and requiring much less solution. Those who doubt this, can satisfy themselves that such is the case, by experiment, when it will be found that a pint of bath will suffice for 18 by 15 plates, but if a dipping bath were used, a gallon would be necessary at least. The difference in cost being that between 4s. and 32s., This is rather beyond a mere percentage.

We immerse the plate, collodion side *downwards*, placing it first vertically, and lowering it with a silver hook very steadily, it sounds like a nervous operation, but it is as simple as possible, and in all probability the first attempt will be successful.

It is very necessary to skim the bath before immersing the plate, to remove all dust which may have settled thereon.

We generally hold the plate by the silver hook for one minute, and then turn it over, face uppermost, the removal of the greasy appearance upon the surface of the plate is readily effected, by giving a vibratory motion to the side of the dish; then, when ready, raise it vertically, and drain it much more thoroughly than is done for ordinary collodion work, as were this not attended to, on placing the plate in the horizontal position it occupies whilst receiving the image projected from above, the free silver would run into pools and irregular forms on the surface, and give rise during the development, to serious blemishes of like conformation. We often hold the plate for as much as two minutes and a half, to ensure thorough draining.

This effected, place the plate in the spot where it is to receive the impression, the inner end of the lens having been previously covered with a yellow glass cap, in order, that whilst the image is still sufficiently visible, to place the collodionized plate in its position, no actinic light approaches it. Now close the wooden shutter, covering the yellow window of the developing room, take out your watch, and remove the yellow cap from the lens, carefully time it, stand perfectly still during the exposure, in order to avoid causing dust or vibration, which latter might give reason to think "your sitter had moved."

In developing, "proceed with caution," observing the same rules as in ordinary development, the usual ferro acetic developer may be employed, and pyro and citric acid to intensify.

Any good collodion is suitable for enlarging, but we prefer a bromo-iodized. We might have stated in reference to focussing the enlargement, that we have found it better to focus on a spot one-third from the edge of the picture, than quite in the centre. Those accustomed to copying will readily perceive that a more general focus is obtained by this than by choosing the centre of the picture as the spot of sharpest focus, which will probably produce blurred corners, and want of definition at the extremes of the picture.

Considerable judgment is necessary in choosing the subjects for enlargement; those in which a great variety of subject is combined, present most facilities, as the inclination to coarseness which parts may display, from being partially out of focus, is concealed to a great extent by the multitude of details.

We are free to confess that in our own humble opinion the "human form divine," is less suited to enlargement than any kind of picture. The question of whether enlargements will ever come much into fashion is a knotty one; there are many reasons to be urged in favour of them, but we must bear in mind that they can never be produced as our "cartes de visite," for the million, and at such prices as to be within the reach of more than a few. Much has to be done, photographers must labour unceasingly in the artistic department; learn to look at pictures other than as photographs; there are points of importance besides having clean plates, good collodion, and an orderly bath, too much time has been spent in arguing paltry processes, which have been the bane of the science.

Photographers are too much given to wordy warfare; a very small number of those who write and talk most, are known by their pictures: this year has been fraught with a strange mixture of good and evil for the votaries of the black art.

Rebuffed by the Commissioners of the Exhibition, they have in reality gained ground in public opinion by the prominence given to the naturally rather angry words that rose: to English practitioners, it was peculiarly galling to find those of their countrymen who had the destribution of space, so far behind the Continentals in their appreciation of photography.

The French display of photography is truly magnificent, and the space allotted very large.

Should another International Exhibition take place in our time, photography will undoubtedly be allotted an important department in the best situation.

## PHOTOGRAPHIC CHEMICALS:

### Their Manufacture, Adulteration, and Analysis.

*Baryta Salts.*—(Continued).—*Carbonate of Baryta* is valuable as a convenient means of removing sulphuric acid from solutions, which it does, owing to the great affinity which this base possesses for the acid. It is very readily prepared. If a solution of carbonate of soda be added to a soluble baryta salt, the carbonate at once falls down in the form of a heavy white powder, which only requires washing to free it from excess of soda salt, for it to be fit for use. There may, however, be some little difficulty in inexperienced hands, in freeing the carbonate entirely from soda salt by washing, and we therefore advise that photographers should prepare their carbonate of baryta. when they require it to be perfectly pure, from the caustic earth. If a solution of caustic baryta prepared as described in our last chapter, be submitted to the action of a stream of carbonic acid, or even if it be exposed to the air for some time, with occasional stirring, it is completely converted into the carbonate, which only requires filtering and drying to be perfectly pure and ready for use. Carbonate of baryta is a heavy white powder, insoluble in water and decomposed by all soluble acids. As mentioned above, its great use is to separate sulphuric acid from solutions, when this is required to be effected without introducing anything into the liquid. When, for instance, carbonate of baryta is placed in a solution containing a little dilute sulphuric acid, a decomposition takes place, owing to the powerful affinity which there is between the acid and the base, the carbonic acid escapes, and sulphate of baryta is formed.

*Sulphate of baryta*, is a perfectly insoluble powder, produced whenever sulphuric acid or a soluble sulphate comes in contact with a baryta salt. The affinity which baryta has for this acid is greater than that which it has for any other, and consequently sulphate of baryta is always formed in preference to any other compound, if the acid and base are brought together either free or in combination. It is important for photographers to recollect this point, for when chloride of barium is employed as a salting compound for positive paper the slightest trace of a sulphate in solution in the water will produce a decomposition, and give rise to a different effect to the one desired.

*Acetate of Baryta.*—In cases where a sulphate of a base is required to be decomposed, and a weak organic acid substituted for the powerful mineral acid, chemists make use of acetate of baryta. For instance, in the preparation of acetate of the protoxide of iron, for developing purposes, the best plan is to prepare it by means of double decomposition between acetate of baryta and sulphate of iron; upon filtering off the insoluble sulphate of baryta which will be precipitated, the acetate of iron is left in solution. Acetate of baryta is very easily prepared. Carbonate of baryta, or caustic baryta is mixed with a slight excess of acetic acid, and the whole evaporated to dryness over a water bath. The dry mass is then digested with hot water, and the liquid filtered from insoluble portions. The solution, which will contain the acetate of baryta, must then be evaporated again until it shows signs of crystallizing, when the heat is to be removed and the liquid left to cool. The salt separates in the form of flat foursided bevelled prisms, containing only one atom of water of crystallization, they effloresce in the air, but retain their form. They have a pungent odour, and produce a slight alkaline reaction with test paper. They dissolve in about an equal weight of cold water, but are scarcely more soluble in boiling water. Alcohol dissolves the salt but very sparingly.

The remaining baryta salts are of very limited interest, and do not require further description in this place. We therefore pass on to a much more important class of salts, those of lime. Unlike baryta, this earth in its caustic state is very common, and well known to all our readers. We may, however, give a few of the chemical properties of lime, which are not so well known as its physical qualities.

*Lime* is the oxide of the metal calcium. It is termed *quick lime* when free from water, and *caustic* lime when it contains no carbonic acid. It is prepared by heating the carbonate to redness. On a small scale, and if a pure result is desired, artificially prepared carbonate of lime should be used. This is packed in a crucible, heated to redness, then allowed to cool, moistened with water, and again heated for some time, to redness; by this means the last traces of carbonic acid are removed, being carried off by the steam. Lime on the large scale is made by igniting common lime stone (a native carbonate of lime) in kilns. When the lime-stone contains clay, the silica of the clay unites with some of the lime, forming a half fused compound, which prevents the mass from evolving heat when wetted with water. This is technically called "dead burnt" lime. Pure carbonate of lime, such as Carrara marble, does not become *dead burnt*, even if submitted to the highest attainable artificial heat. Pure lime is white, soft, and easily pulverised. It is infusable at any attainable temperature, and on this account has been employed by the French chemists as a lining for their oxyhydrogen furnaces, &c. When strongly heated, it emits a brilliant white light, which is so intense as to be employed for illuminating purposes, being known as the lime light. The ignited jet of combined oxygen and hydrogen gases, is used in this case as a source of heat. When a lump of quick lime is moistened with half its weight of water, this is at first absorbed by capillary attraction, into the pores which have been left in its substance by the escape of carbonic acid. The air contained in the pores is thereupon driven out with a kind of hissing noise, and in a few minutes combination between the water and the lime takes place, with evolution of great heat, the temperature sometimes rising high enough to inflame gunpowder, sulphur, or wood. The purer the lime the more rapid and intense is this heating. This phenomenon takes place even when ice is mixed with lime, and, therefore, cannot be explained by the passage of the water from the liquid to the solid state. The steam, which rises during the slaking, carries with it a considerable quantity of lime. When the phenomenon of slaking takes place in the dark a bright light is observed. The result obtained in these cases is a combination of the oxide of calcium with water in equal atoms, known as hydrate of lime. This hydrate, when formed by slaking quick lime, is a fine white powder, of an alkaline taste and reaction; it readily absorbs carbonic acid from the air, and becomes converted into carbonate of lime. It dissolves in water to a small extent, but is much less soluble than baryta. In order to prepare lime water for chemical or other purposes, it is advisable to wash the slaked lime once or twice with distilled water, in order to remove the alkalies, potash, and soda, which ordinary lime always contains. The best plan is to proceed as follows:—Place a small quantity of good slaked lime in a bottle, and fill up with water; allow it to stand for some hours in a cool place, shaking it occasionally during the time; then allow the excess of lime to settle, and pour away the pure supernatant liquid. Repeat the operation with a fresh quantity of distilled water, and then fill up the bottle a third time with pure water; and after allowing it to digest, in the cold, with frequent agitation, on the residuary lime for a day or two, filter the liquid quickly, and with as little exposure to the air as possible, into a well stoppered bottle, and preserve it in a cool place for use. We have specified the necessity for keeping the liquids cool in these operations, for the following reason:—Lime dissolves in 778 parts of water at the ordinary temperature, but requires 1,280 parts of boiling water for solution. Hence, lime water, saturated at the ordinary temperature, deposits, when heated to the boiling point, a considerable quantity of hydrate of lime, in small crystals. The mixtures known as *milk of lime* and *cream of lime* are prepared by stirring up slaked lime and water to the requisite thickness. They consist of mechanical mixtures of hydrate of lime and lime water.

## PHOTOGRAPHIC MANIPULATION. VARIOUS HINTS.

BY J. C. LEAKE, ESQ.*

When I undertook to provide a paper for this evening, I had no doubt but that I should be able to persuade some of our friends to come forward and place at your disposal, a paper on some subject of a far more novel and interesting character than I can hope to produce. In the absence however, of anything else, and rather than the meeting should go empty away, I will endeavour to make a few remarks, in the hope of raising a discussion which may elicit some useful information from those gentlemen present who are so well qualified to give it.

It has been said of photographers, and truly, that they are in most cases ignorant of the theories of their art. That this is so, is a fact much to be regretted. Yet, let a man be ever so good a theorist, he will in all probability be in the habit of doing a number of odd things from fancy, and if asked why he did so and so, his reply would be, "I fancy it is better," but can give no reason for thinking so.

This being my unfortunate condition, I propose stringing together a few of my photographic whimsies, and recounting them to you, if you will kindly listen for a quarter of an hour.

Beginning with plates. I have a prejudice against everything but the best polished plate glass. I have tried sheet and crown of almost every description, and in all cases have failed to produce satisfactory results. In fact I believe it to be impossible to produce as much fine and delicate detail upon either of the two last named varieties as upon the former. If, after development, a picture upon a piece of sheet glass be examined, it will be found that a film of reduced silver is deposited between the collodion and the glass. This being the case it is evident that some reducing action is set up, and that this is independent of the development, may be proved by taking a piece of sheet glass, exciting as usual, and after allowing it to remain in that condition a few minutes, fixing it, *without development*.

* Read before the South London Photographic Society, on Thursday, October 9, 1862.

In almost every case in which I have tried this experiment, a film of reduced silver has completely covered the plate. Glass of this description is therefore unfit for photographic purposes, and pre-eminently so for dry plates, which have to be kept a long time in a sensitive condition. I know many amateurs use sheet glass from motives of economy, and often fail through so doing, and I would certainly advise them to throw away all such plates, and betake themselves to patent plate, which will serve them better. Another subject upon which I entertain views which may be regarded as peculiar, is the preparation of the nitrate bath for negatives. I cannot make a bath work to my satisfaction without the addition of carbonate of soda. I have tried fused nitrate of silver, oxide of silver, and most other substances which have from time to time been recommended for making and mending baths, but in my hands none have been so successful as the addition of a small quantity of the carbonate. In making a new bath I proceed as follows—Having dissolved the nitrate of silver in the water, I add to each ounce of solution about a couple of grains of carbonate of soda, and a small quantity of the iodizing solution, with which the collodion to be used is iodized. Let the solution stand about twelve hours, filter, and it will be ready for use.

Negatives taken in a bath prepared in this manner, are of a rich creamy tint, very full, and deep in colour, and, what is of the greatest importance to the portraitist, the half tint and shadows of flesh are rendered with great perfectness. In a conversation with Mr. Blanchard, whose street views are now so well known, he informed me that his own experiments in this direction had led him to the conclusion that this method of preparing a bath was by far the best, giving a better quality of negative, and producing it in a shorter time than when the ordinary modes were used.

In connection with sensitizing, I have another whimsy, viz., that as a rule, plates are removed from the bath before the sensitizing process is completed. The time usually recommended, two or three minutes, is scarcely sufficient. I would prefer to allow five or seven. On immersion in the bath, the plate becomes coated with iodine, first in lines corresponding in direction with that of the dip. If the plate be taken out of the bath before these lines are removed, and an even coating obtained, the picture will be streaked, as the lines will appear in the finished negative. It is often said that the plate if left too long in the bath will become streaky, and this will certainly be the case if it be removed from the bath too soon.

I am a believer in long exposures. In my humble opinion, a large proportion of the cartes de visite offered for sale in our shop windows, are very considerably under-exposed. I know it is desirable to make the exposure as short as possible for many reasons, but nothing can justify the principle of so shortening the exposure as to make the resulting negative hard, with sooty shadows, and crude chalky lights.

The best results will be obtained by giving a lengthy exposure and a somewhat short development. If the development has to be pushed, the result is rarely satisfactory. It is far better to let the light act so long upon the plate, as that you have some energy to spare, and so can stop the development rather short.

I consider a picture under-exposed, unless the whole of the detail in the flesh and hair is distinctly and well rendered. Let the shadows of the flesh be well given, above all things. It is to this I look alone, in portraiture, dress and all must (if necessary), be sacrificed to this, as no beauty of detail, or brilliance of effect can compensate for a want of gradation in the flesh tints.

Another fancy of mine, is with respect to the iron developing solution. This I prefer to mix at least twenty-four hours before use. In the first place, this is better, because it will allow the sediment to deposit itself, and so save filtering; and secondly, and what is of more importance, the negatives will be finer in texture, and consequently softer. As far as I can ascertain, the particles of silver constituting the image, are much smaller than when the solution is freshly mixed.

As to intensifying, after all, I prefer the old system of "pyro," and silver, and of finishing the negative at once. If the exposure be correctly timed, and the bath, collodion, and developing solution in order, but very little will need to be done to obtain sufficient intensity, and what *is* wanted will most readily be obtained by this method. It has been argued that this method of intensifying is apt to clog up the fine lines and destroy the sharpness of the negative. Perhaps, if carried too far, it does, but, carefully done (as everything in photography should be), it will give very fine results, and I believe it to be, on the whole, the best method of intensifying.

For fixing, I always use hyphosulphite of soda. In the first place, because it is easier to use. I keep a dipping bath full of solution at the end of the developing table, and after the plate is intensified, just pop the plate in and leave it until the iodine is dissolved. A few minutes in excess will not hurt it. Secondly, it is cheaper, not costing a quarter as much as cyanide of potassium. And thirdly, and most important of all, it does not affect the health of the operator. If however, cyanide *be* used, it is better to use it strong enough to fix the picture quickly, for if a weak solution be used and the action be continued for a long period, the peculiar bleaching action will render the image grey, and the light will, in printing, permeate every part, and the resulting print will be flat and wanting in brilliance.

So much for negatives, now, if you are not tired, for a few whimsies about printing. And first, as to paper. When the disease known as "cardomania" set in, photographers were, of course, driven to use a paper upon which as much detail and brilliancy as possible could be obtained, and the variety known as rive, was at once acknowledged as the best, on account of its superior hardness and fineness of texture. For small pictures, it is undoubtedly the best; but I hope the day is not far distant, when, for everything above whole plate pictures, a paper will be used which has not the offensive gloss of albumen. Until however, we can prepare a paper, producing the same amount of depth and brilliance as albumen, we must perforce use it. Nevertheless, the gloss *is* a nuisance, and I recommend the subject—the production of a paper, giving the depth of albumen without its gloss, to the attention of those gentlemen present, who have time and inclination to experiment in that direction, and also to the Experimental Committee.

Starting with rive paper, then, I will proceed to state what I consider the best method of producing prints upon it. Always bearing in mind that I am considering printing portraits only. In sensitizing, don't be afraid of the silver. To produce the best results, from seventy to ninety grains to the ounce may be safely used. I have a fancy for using a bath of, say one hundred grains, and, instead of floating three or five minutes, floating only two. And I believe this to produce the best results, the print being more on the surface of the paper.

As soon as the paper is surface dry, it should be thoroughly dried by artificial heat, and the solution should *not* be allowed to soak into the paper. I think it will be found that most portrait negatives, good ones especially, will print best in the shade: the action is slower and more regular; and generally more satisfactory results will be obtained, than by direct sun-printing, Mr. Thomas to the contrary notwithstanding.

All having gone on satisfactorily to this point, I am inclined to think that here most printers commence the work of spoiling what they have hitherto done. Instead of quick and careful washing to remove the nitrate of silver, the prints are pitched into a pan, and left to soak for, perhaps, half an hour or more, during the whole of which time, the nitrate of silver is soaking into the pores of the paper, and laying the foundation of future mealiness and uneven toning. I believe it to be of the utmost importance to remove the whole of the nitrate of silver from the surface of the proofs; and that the more rapidly this is effected, the better. Quick and careful washing for ten minutes, will do more good than soaking the prints for half an hour. After a thorough washing in the manner mentioned, the prints may be considered ready for toning without any further treatment with acetate of soda, or chloride of sodium, which I am inclined to consider as unnecessary complications. Nearly twelve months since, I wrote a short paper on printing and toning, in which I stated my preference for the acetate of soda toning bath. During the last year, I have conducted a somewhat lengthy series of experiments, on the various substances used for toning, but I have not found cause to alter my opinion, and still believe the old formula, of thirty grains of acetate of soda, to each grain of gold, to be the best. One thing is imperative; the bath must be mixed at least twenty-four hours before use. A useful "dodge," however, if a bath be wanted to work at once, is to double or even treble, the amount of acetate. If this be done, a bath may be used as soon as mixed: and the action will be more rapid than if the bath has been kept. On the whole, however, I would not recommend this process, as, if great care be not taken, the prints will redden to a fearful extent in the hypo, and the whole process has more of uncertainty in it, than when the first-named bath has been used. As soon as the toning is completed, the prints should be well and quickly washed, before fixing.

Many persons do not think this important; I do. I have seen proofs taken from the toning bath, and placed on a plate of glass to drain, till some thirty or forty had accumulated; when the whole batch was placed in the hypo in a mass, and separated in the solution. I think nothing can be more dangerous than this method of procedure; and would recommend that the proofs be *well* washed before fixing, and placed in the hyposulphite solution singly. The usual strength, six ounces to the pint, will be found strong enough for this solution, and I would recommend that it be used fresh *every day*, and unmixed with either chloride of gold, or nitrate of silver, as has been recommended.

On removal from the fixing bath, each proof should be washed, back and front, on a glass plate under a tap, before being placed in the larger dishes to soak.

I have to apologise for having nothing more novel to offer you; but I hope I have said something from which many of you will disagree *in toto*. This being the case, my end will be attained, and we shall have a long and interesting discussion on the points you may think proper to dispute.

### ON SOME OF THE DIFFICULTIES WHICH PRESENT THEMSELVES IN THE PRACTICE OF PHOTOGRAPHY, AND THE MEANS OF AVOIDING THEM.

BY F. MAXWELL LYTE, M.A., F.C.S.*

MANUFACTURE OF PYROXYLINE ONE CAUSE OF DECOMPOSITION.

One of the principal causes of the spontaneous decomposition of pyroxyline seems to be a remnant of acid left by imperfect washing.

In this condition pyroxyline, and especially that which has been prepared in weak acids, is very prone to decomposition, and possesses, moreover, another disadvantage, viz., that it produces a collodion which, when iodized, turns very red, and soon spoils the nitrate bath in which it is used.

It has been proposed, as a remedy, to add to the last washing water a few drops of liquid ammonia. Now, whenever this has been done, I have always found that much of the pyroxyline became insoluble, and that the portion which dissolves only produces a rotten film, easily broken in washing.

Another mistake in making pyroxyline is attempting to add too large a proportion of the material, whether cotton, paper, or flax, which it be intended to be converted. The proportion should never exceed 10 per cent. of the nitric acid employed, beyond this point, a further addition is nearly sure to involve failure of more or less of the product; and this is reasonable, for, in proportion as pyroxyline is formed, nitric acid disappears, and is substituted by the elements of water, or, what is the same thing, H is substituted by $NO^4$ and HO is produced. A point is, consequently, arrived at where the mixed acids become too dilute to produce any further action. Up to the addition of 7 per cent. the conversion of the pyroxyline is nearly simultaneous with its immersion, but for the remaining 3 per cent. of lignine added the conversion is more gradual, requiring four or five minutes to complete it, so that if we add rather more material the effect is distributed over the whole quantity, and a large portion remains insoluble.

The only sure plan is to add not more than 10 per cent. of the weight of the nitric acid employed, and instead of removing the last traces of free acid with ammonia, I am in the habit of adding a few grammes of an alkaline acetate to the last washing water. In this water I allow the pyroxyline to soak for a night, and then withdraw it and wash again and dry it. Pyroxyline so prepared is very stable, and if the temperature of the mixed acids has been correct, and their strength accurately examined before use, the pyroxyline will be found perfectly soluble, and will remain so for years.

SOURCE OF HALF TONE.

Much has been said about different samples of collodion producing one better half tones than another.

I believe the whole, or nearly the whole gist of landscape photography on collodion, as far as the obtaining of gradation of tint goes, to consist in obtaining the thickest possible film. My theory on the subject is as follows:—Iodide of silver is a yellow salt, and offers more or less resistance to the passage of the actinic rays. The greater, then, the body, so to speak, of the film, the longer the time which the rays require to produce their effect through its entire thickness. Now, in what consists the excellence of a positive print? Why, in possessing fine gradations of half tone blending insensibly into the deep shades and high lights. No sudden and severe contrasts exist, as a rule, in nature.

Now, we know by experience, that if a plate is over-exposed the high lights become solarized, as it is termed, and become transparent, printing through and destroying the brilliancy of the positive. While, on the other hand, if a plate be under-exposed the half tints never appear at all. Now, in landscape we have often, at one and the same time, deep greens or red rocks in the foreground, the details of which must be given in order to produce a harmonious picture; and blue distances, which must be given in order to give character to the landscape.

The reproduction of such a combination is looked upon by many photographers as a complete paradox, but use a thick film and the difficulty is solved. The yellow iodide of silver offers the necessary resistance to the actinic rays to impede solarization in the high lights while we are enabled to expose the plate sufficiently long to impress the details of the deep shadows. Our choice should then fall on that quality of pyroxyline of which we can introduce the greatest proportion without rendering our collodion too glutinous, and, in this point of view, I find that prepared from paper to be much superior to any other, as I have remarked in other papers on the same subject.

CAUSE OF SOLARIZATION.

Having mentioned the subject of solarization, I may be excused for venturing a new view as to its cause. We all know that by various degrees of exposure the sensitive atom of iodide or bromide of silver, whichever it may be, assumes successive tones of colour, in which one or more of the primary colours prevail. Now, may it not be that the superposition of these various tones of colour, as would obviously

* Read at the British Association.

occur in a plate where the actinic influence had not penetrated too completely the collodion film, and produced the ultimatum of effect, should produce opacity, whereas, if the ultimate effect had traversed the entire thickness, a yellowish or reddish transparence might be the result; or, in other words, when the molecules of reduced silver are all in one and the same position, they may become capable of transmitting certain luminous vibrations, when their position is variable they cut every vibration off.

UNEQUAL DRYING OF FILM.

In hot climates a difficulty presents itself, the means of obviating which it may be useful to describe. When we attempt to work in a tent under the influence of a hot sun, the collodion on the upper part of the plate dries before that on the lower part, from which the collodion was last poured, is sufficiently set to permit its immersion into the bath. To obviate this, I observe carefully when the collodion at the lower part will permit the plate to be turned upside down, without flowing back, so as to cause a return ridge. By then turning the plate so that the part least set is uppermost, the heavy vapour of ether, given off as the film dries, falls on to the part of the plate already getting too dry, and slightly moistens it again, and so equalises the degree of dessication all over the plate.

The plate also is frequently found to have become so far dry on removal from the dark slide, that when we attempt to pour on the developer it flows unevenly, and the finished negative shows rings of unequal development, and it often happens, under the same circumstances, that the nitrate of silver solution accumulates at the lower edge of the plate, and, mixing with the developing solution, flows back in streaks over the plate and produces dark lines and marblings. Further, it frequently happens that in our attempts to obviate these defects, the developer is thrown too suddenly on to the plate, and, washing off all the nitrate, produces a transparent spot where it falls, and often a sort of mark on the centre of the plate as if a fine comb or a brush had been passed over it.

Now, in order to obviate these defects the best mode of proceeding is to pour over the plate a little water, to which has been added a small dose of acetic acid, say 0·1 per cent., and when the plate has been thoroughly washed with this solution to then apply an iron developer. The nitrate of silver having been for the most part removed, a very feeble image only appears, but on the application of a solution of pyrogallic acid with addition of a little free nitrate, the image comes out in far finer detail than by any ordinary treatment that can be used, and with a harmony of effect which is quite surprising. In the top of the tent in which I work I have a sort of chimney of linen, into which I stuff a tuft of grass, or of fern, and which, while it effectually bars the entrance of light, allows a free circulation of air.

PER-ACETATE OF IRON SOLUTION.

I find that the protosulphate of iron, which is somewhat reddened by the presence of a persalt, is that which answers best for the development of negatives, and with this view I keep a solution of the peracetate of iron by me, which I add to my iron developer if the protosulphate with which it has been made be of too pure a nature.

VARNISHES.

It has always been a problem among photographers to find a good varnish. The amber varnish, which is decidedly the best hitherto described, is faulty in many respects.

1st. It is very expensive to use, both on account of the primary cost of the materials, and of the extreme volatility of the ether and chloroform which form the solvents.

2nd. The negatives varnished with it are liable to crack in frosty weather should the slightest condensation of moisture take place in the box in which they are stored, and the same effect often arises where they are placed in contact with a sheet of positive paper not perfectly dry.

The solution of gum benzoin in alcohol is liable to cover the negative with minute pinholes from the crystallization of the benzoic acid it contains. The crystals breaking up the film in numerous minute points, and, lastly, the solution of bleached lac is inadmissible, as, in a hot sun, it becomes tacky and sticks to the positive paper.

The same defect belongs to the varnish of Sœhnée, freres, of Paris. In the South of France, where I work, I have lost many fine negatives through each of these causes. I now use a varnish, which I consider perfect in every respect, made by dissolving 10 to 12 per cent. of the purified resin of jalap in alcohol of 95 per cent. This varnish, while it does not seem to have as great a liability to chill as some other varnishes, is hard and resistant, and gives a body to a negative such as few others will give, and it never adheres to the positive paper under the influence of the hottest sun.

PRINTING.

Now, as to printing positives, I wish to draw your attention to one or two points, but time will not allow me to do more. I wish to speak, in the first place, as to the necessity of adjusting the strength of the nitrate sensitizing bath to the amount of chloride contained in the paper which is to be prepared upon it. The moment the paper is laid on the nitrate bath, it decomposes the nitrate of silver on the surface of the solution with which it comes into immediate contact, with formation of nitrate of sodium and chloride of silver. The solution of nitrate of sodium thus formed possesses a far less specific gravity than the nitrate of silver below it, and does not so easily mix with it as might be supposed, and, consequently, forms a film on the top, which, lying between the surface of the paper and the nitrate of silver below, forms a sort of carrier which dissolves out the salt without decomposing it, and disintegrates and dissolves the albumen instead of coagulating it. Under such circumstances a white precipitate of chloride of silver often renders the bath turbid, and the finished proof has a dull, grey, cold tone. This defect is only to be remedied by so proportioning the nitrate of silver in the bath to the chloride in the paper, that the paper shall find enough nitrate in the part of the bath into direct contact with which it is brought, to convert all its chloride into chloride of silver, and even leave a small excess.

By adding to the albumen about 0·1 per cent. of the crystallized phosphate of soda—$2NaO\ HO\ PO_5 + HO$—it will be found that the discoloration by albumen is nearly entirely prevented, and if the bath ever becomes coloured, it may always be completely discoloured by adding to it a solution of a mixture of the crystallized carbonate of soda with crystallized phosphate of soda in about the proportion of 2 to 5 and dissolved in water in the proportion of 7 per cent.; for every 10 grammes of such a solution added 1 gramme of solid nitrate of silver must also be dissolved in the bath in order that it may not become weakened, and the bath filtered till it becomes clear.

At the conclusion of the paper

Professor Emerson, of Troy Univerity, U.S., said there were some points in Mr. Lyte's paper of the correctness of which he was not certain. In the first place, as to the advantages claimed by a thick film, he thought the theory could scarcely be maintained, and in his own practice he had obtained equal gradation with a thin alcoholic collodion as with a thick one, and for the tannin process he preferred it. The method of preventing stains by first treating the film with a little distilled water he could cordially endorse, having practised it himself with success. As to the preparation of the nitrate bath so as to suit different samples of paper, he had given great attention to the subject; but had come to the conclusion that actual experiment with each fresh sample of paper was necessary, as manufacturers varied so much in the proportion of salt they employed. The best plan, in his hands, of keeping the printing bath clear was to add from one-fourth to one-third its bulk of alcohol.

Mr. Lyte said that he had found alcoholic collodion gave a film too rotten to bear washing, and the image was not so delicate; but, so far as his theory was concerned, he thought the experience of Professor Emerson had confirmed it, as alcoholic collodion, even when thin, had generally a good deal of body. In reference to paper, it would be a great advantage to photographers if manufacturers generally would state the proportion of chloride employed in the preparation of their paper. In the absence of such information a very simple rule might be adopted. If a 20 per cent. silver bath were used, and one sheet of Saxe paper excited upon it, if the amount of silver withdrawn from the bath were found to be four grammes, then the paper had been prepared with 4 per cent of chloride. Taking this as a standard, calculations for other proportions could be easily made.

Mr. Wharton Simpson asked if in this calculation Mr. Lyte had taken into account the varying quantity of albumen present, and the proportion of silver it absorbed.

Mr. Lyte said he uniformly used albumenized containing the same quantity of albumen. It is very highly albumenized.

Mr. Simpson said, had he then ascertained the combining proportions of albumen and silver, and the amount of silver required by the albumen of his paper, independent of the chloride.

Mr. Lyte said that this was an interesting and important point, but he had not yet examined it.

## EXPERIMENTS ON PHOTOGRAPHY WITH COLOUR.*

An abstract only of this paper was read before the sectional meeting. It commenced with an extract from Sir David Brewster's recent article in the *North British Review*, in which a hope was expressed that natural colours might be produced, and intimated that they were a ligitimate object of scientific research. Proceeding, then, with a theory derived from Dr. Young's Bakerian lecture, to the effect that radiant coloured light consists in undulations of the luminiferous ether, and that all material bodies have an attraction for the ethereal medium, by means of which it is accumulated within their substance, and exerts its influence upon them. This theory led to the conviction that it was within the the laws of physical science to suppose that the collodion film might retain within itself the varying undulations of the coloured objects whose images they receive, and communicating those undulations to the ethereal medium without them, thence transmit colour to the eye. The writer then adds:—

"In the course of the present week, I happened to obtain unusual traces of colour in photographic portraits. The chief difference in manipulation was a slight excess of the iodizer in the collodion, and the addition of acetic acid and acetate of soda to the bath. And in order more fully to test the effect of the cadmium and bromo-iodizers, I increased the quantity until natural colours ceased to be strengthened. The final proportion of iodizing solutions gave the portrait which illustrates these few remarks. The general warm colours of the forehead and face of the sitter are fairly represented, and the varying tints of the hirsute ornamentation correspond with the original. The tone of the shooting coat is also correct. I have also obtained coloured pictures of buildings, and a good representation of autumnal tints."

The specimen exhibited was a collodion positive portrait, the tone of which in the lights was of a buff tint, but in the opinion of most present, so far as could be gleaned, and certainly in our own opinion, before expressed, was in no sense a reproduction of natural colours as usually understood.

## AUTOGRAPHS OF THE SUN.

Professor Selwyn showed and described (Section A), several photographs of the sun, described as autographs, taken by Mr. Titterton, of Ely, with his "heliautograph," which consists of a camera and instantaneous slide, by Dallmeyer, attached to a refractor of $2\frac{3}{4}$ inches aperture, by Dollond; the principle being the same as that of the instrument made, at the suggestion of Sir J. Herschel, for the Kew Observatory. The autographs are of July 25, 26, 28, 29, 31; August 1, 2, and August 4, 10.15 a.m., and 11.30 a.m. (a series of bright days coincident with a large group of spots); August 19, 20, 23 and 25, where the same group reappears much diminished; September 19, 23, 26 and 30, in which is seen a group of 118,000 miles in length. On the 23rd three autographs are taken, two of them with the edge of the sun in the centre of the photographic plate, showing that the diminution of light towards the edges of the disc is a real phenomenon, and not wholly due to the camera. In the two of the 4th of August, where the great spot (20,000 miles in diameter) appears on the edge, a very distinct *notch* is seen, and the sun appears to give strong evidence that the spots are cavities; but eye observations and measurements by the Rev. F. Howlett, and others, tend to show that this evidence is not conclusive, for there was still a remaining portion of photosphere between the spot and the edge. The phenomena shown in these autographs appear to confirm the views of Sir J. Herschel, that the two parallel regions of the sun where the spots appear, are like the tropical regions of the earth, where tornadoes and cyclones occur, and those of Wilson in the last century. The *faculæ* seem to show that the tropical regions of the sun are highly agitated, and that immense waves of luminous matter are thrown up, between which appear the dark cavities of the spots, whose sloping sides are seen in the penumbræ, as explained by Wilson and others. Other analogies between solar spots and earthly storms were pointed out, and reference was made to the glimpses of the structure of the sun, exhibited by Mr. Nasmyth as confirming the above views.

* Read before the British Association.

# Proceedings of Societies.

### South London Photographic Society.

The first meeting for the present session of this society was held on the evening of Thursday, the 9th instant, at the City of London College, Leadenhall Street. The Rev. F. F. Statham, M.A., F.G.S., President of the Society, in the Chair.

The Chairman, referring to the open air meetings of the summer, regretted that he had been unable to attend any of them himself. Some of the meetings, he understood, had been very successful, one at Charlton especially. He called the attention of members to some excellent photographs taken on that occasion by their Secretary, Mr. Harman, which, both from the scenery and the number of portraits they contained, were very interesting. The Society's annual dinner, at Dulwich, had been a very pleasant meeting, he only regretted that more gentlemen were not present. He called the attention of members to some excellent photographs by Mr. Martin, taken during a tour in North Wales, and in the neighbourhood of Liverpool. These prints Mr. Martin had presented to the folio of the Society, a practice he commended to members as worthy of imitation. The prints were $7\frac{1}{4}$ by $4\frac{1}{2}$, and described as taken by Horne and Thornthwaite's panoramic lens.

Mr. J. C. Leake, Jun., then read a paper on "Photographic Manipulation" (see p. 497).

After a vote of thanks had been passed to Mr. Leake—

Mr. Harman, examining the negatives produced as illustrative of the effects of the different baths, said he thought the difference in colour must be accounted for, rather by difference in exposure than by difference in the baths. He objected moreover, to the use of carbonate of soda for neutralizing a bath. He always, in making a new bath, used oxide of silver, followed by a little nitric acid, and thought the plan was most philosophical and effective.

Mr. G. Wharton Simpson said, the use of either carbonate of soda or oxide of silver, should only be resorted to as a remedy for something wrong. It was manifestly an error to regard the use of either of them as always necessary in making a new bath. If pure nitrate of silver were used, no such application ought to be necessary. If the bath were not in good working order, the application of a remedy was necessary, and the selection depended upon the condition of the bath. If it simply contained too much nitric acid, then the addition of oxide of silver was the simplest, and best method of neutralizing it, as nothing was added but the proper constituents of the bath. But there were cases in which carbonate of soda was valuable, as performing another office besides neutralizing any free acid. It was well known, that the formation of an insoluble precipitate in any solution, had a tendency to throw down other particles of matter present, in suspension, or even in solution. In preparing metagelatine, for instance, the solution always retained an opalescent turbidity, which no filtration would remove, until cleared by a method of this kind. The addition of a little white of egg, and then boiling, at once rendered the solution clear and transparent. The coagulated particles of albumen were thrown down, and with them, the matter which caused the opalescence. It was so, he apprehended, with the addition of bi-carbonate of soda to the silver bath. Traces of organic impurity, which unfortunately, were sometimes present with commercial nitrate of silver, were precipitated with the insoluble carbonate of silver formed, and thus a bath was sometimes very easily purified by the use of bi-carbonate of soda. In reference to Mr. Leake's remarks on albumenized paper and the importance of getting a substitute to supply its place for large prints, he cordially agreed with him, and might take this opportunity of calling attention to a dozen or two of the early experimental prints, taken by Mr. Cooper, on resinized paper, an account of which members had doubtless read in the pages of the Photographic News.

Mr. Harman said that reference had been made to some slight yellowness in the paper. By artificial light they could not see the exact tint. He asked Mr. Simpson if that were insurmountable.

Mr. Simpson said that in the benzoinized paper that tint was apparent. But in some subsequent experiments with frankinsence and mastic, immunity from yellowness had been secured.

Mr. Price had some of the prepared paper by him, which he was keeping in order to test, and it remained perfectly white.

Mr. A. H. Wall had hoped to have brought with him a solar camera picture, taken on resinized paper, which would have illustrated its value. He thought it was a most important process, especially in an artistic sense.

Mr. Price said, in reference to the yellow tint in benzoin, he believed the first gatherings of the "tears" were quite white. If these were kept separate instead of being mixed with the darker portions subsequently gathered, they would answer the purpose well.

After some further conversation on the subject, in which several members spoke very hopefully of the promise of the resinized paper,

Mr. Frank Howard said Mr. Leake's paper was a very valuable one, dealing as it did with many minor points of importance. There were some parts of it, however, in which he could not entirely agree with Mr. Leake. One was as to the use of plate glass. In his own practice he had used the crown glass for stereoscopic and other negatives, up to 5 by 4, without experiencing any of the disadvantages to which Mr. Leake had adverted. Again, as to adding to the bath a little of the iodizer of the collodion intended to be excited in it, he thought the plan was inconvenient and unnecessary, and in some cases, where the nature of the iodizer was a secret, impossible. He thought there was no readier and simpler means of making a bath than that recommended by Mr. Simpson. He dissolved one ounce of nitrate of silver—always weighing it himself—in twelve ounces of common water. This of course caused a precipitate. To this quantity he added one grain of iodide of potassium, and after agitating at intervals for half an hour, he filtered through two thicknesses of paper, and found the bath ready for use without further waiting. There was another point he would name in reference to exciting paper. A suggestion which appeared a short time ago in the News he had found most valuable. It was to the effect that if the paper were drawn very slowly from the surface of the silver bath there would be scarcely any waste of the solution, as the paper would come away without bringing more than a drop or two of solution running down its surface. He believed a saving of 25 per cent. might be effected by this method.

Mr. Harman remarked that, if the drainings were caught in dishes it did not matter, as they were then saved.

Mr. Simpson suggested, that Mr. Harman was looking at the matter from the professional photographers' point of view, his operations being conducted on a large scale commercially, whilst Mr. Howard was looking at it as an amateur. It would scarcely answer the purpose of the amateur who was about to print, perhaps, a score of prints, to place dishes to catch the drippings from a few pieces of paper.

Mr. Wall thought many mistakes and many discrepancies of opinion arose from the cause just adverted to: the difference between amateur and professional opinion. Take the question of glass, for instance. He (Mr. Wall), for economy, had thought he would get crown, and test it, as he had seen recommended, in the pressure frame, before using. Unfortunately, such a test was not always trustworthy, as he had found to his cost; for he had lost four or five guineas, only recently, by the breakage of a negative, on common glass so tested. He (Mr. Wall) thought professional photographers, to whom negatives were money, would find their account in using plate-glass.

The Chairman asked to what such breakages were due?

Mr. Harman said, invariably to unequal pressure, from some cause. If the glass were quite flat, and perfectly even, no matter how thin it might be, there was no danger of breakage.

Mr. Fitch said he used common glass up to whole-plate size, and never had breakages.

Mr. Simpson said that, even if plate-glass were used, there would always be a certain percentage of breakages from various causes, where much printing was done. The fact, therefore, that a certain negative, or negatives, had broken and caused loss, was not, necessarily, an impeachment of crown glass.

Mr. Foxlee said, that he thought the film on common glass, to which Mr. Leake had alluded, was caused by the effect of smoke condensed on the surface in the manufacture. He had found that, in cleaning glasses, this smoke could only be removed by mechanical action. If well cleaned with tripoli he (Mr. Foxlee) thought the flattened crown was as good as patent plate.

Mr. Simpson said, in reference to this foggy deposit, alleged to be caused by common glass, he (Mr. Simpson) thought it must be due to other causes, and for this reason:—Flatted crown was the glass universally used by positive operators for collodion positives, and, as was well known, the slightest fog or deposit in the shadows of a picture was far more fatal to its excellence than it would be in a negative, and much more easily detected. But collodion positives of the utmost brilliancy were constantly taken on flatted crown.

Mr. Price said, that plate glass was not always of an even thickness. He (Mr. Price) had seen a piece of plate glass double as thick at one edge as the other.

After some further conversation on the subject,

Mr. Harman, in answer to the Chairman, said, that intense negatives required to be printed in the sun, and weak ones in the shade.

Mr. Wall said, that he had recently prints from the same negative—printed one in the sun, one in a diffused light, and one in the shade in a room; the last was decidedly the best print.

Mr. Simpson said, he thought it was well understood by practical photographers, that an intense negative required printing in direct sunlight, and a weak one in diffused light. But, other things being equal, it was generally a better class of prints which was produced in the shade. The reduction was slower, and the molecules of reduced silver seemed smaller. The print produced was more delicate in its detail, and even sharper looking.

The Chairman asked, if the effect of temperature on printing had been observed?

Mr. Leake thought it did not make much difference.

Mr. Martin said, since heat augmented the energy of most chemical reactions, he thought it would only be fair to assume that it had some influence in printing.

Mr. Howard said it was evident it had, as excited paper decomposed much sooner in warm weather than in cold.

Mr. Price said he believed that sun-printed pictures were the first to fade. That opinion was put forth by the editor of one of the American journals some time ago—Mr. Snelling, he believed, the paper was published some time ago in the News—that some prints were like over-quickly cooked steaks, the outside was done before the rest was perfect, and he believed that a want of permanence was the result.

Mr. Howard referred to the causes of mealiness, which he believed to be carelessness and haste in the washing before toning. Washing in luke warm water he found beneficial in preventing it.

Mr. Fitch preferred very slow toning, which was analagous in principle to the plan Mr. Howard had described.

Mr. Harmer thought very thorough but rapid washing was important, the shorter the time prints were in the first washing water the better, as otherwise a film of insoluble carbonate or chloride, adhered to the surface, and caused irregular toning.

Mr. Wall has found that keeping the toning solution before use, was the best remedy for mealiness.

After some further conversation on the subject,

Mr. Leake briefly replied to various objections. He thought that notwithstanding all that had been said, a microscope examination of the surfaces would prove the superiority of plate glass. As to toning, he believed the best results were obtained by using a bath made some time, but if it were necessary, to use it as soon as mixed, a large excess of acetate of soda would give similar results to age. As to the use of carbonate of soda in the toning bath, he believed it to be the worst thing which could be used.

After some further conversation,

Mr. Wall, referring to the process of printing on resinized paper, thought that societies might with propriety, at times, step out of their routine, to thank individuals for liberally giving to the public valuable processes, through other channels than their own meetings. He therefore begged to propose a vote of thanks to Mr. Cooper, for the account of his process published in the Photographic News. The vote of thanks was passed by acclamation.

Mr. Simpson exhibited a panoramic picture taken by Mr. Sutton on one of his dry plates, with just the same exposure as he would have given to wet collodion. The picture gave general satisfaction. Mr. Simpson also showed a variety of charming card pictures, by Window, Robinson, and Southwell.

Mr. Carbutt, of Chicago, showed an album with many very fine card pictures, which were much admired.

Messrs. Schnadhorst, J. Chaplin, and W. Chaplin, were elected members of the society.

The proceedings then terminated.

## Correspondence.

### IODIDES AND BROMIDES IN COLLODION.*

Dear Sir,—Since writing to you a few days ago, I have more closely examined the "Proceedings of the South London Photographic Society," published in the Photographic News of the 16th May, 1862.

I shall remark, categorically, on Mr. Blanchard's experiments, the results of which were then laid before the meeting. Without intending anything in the way of offence, I must record my opinion that the publication of the results, backed by Mr. Blanchard's reputation, have caused, doubtless, much heart-breaking and vexatious disappointments to all those who have taken them as conclusive. And conclusive they must have been considered, especially when you and Mr. Fry endorsed those results.

In the first experiment of Mr. Blanchard, the necessary equality of conditions in the iodizing and bromo-iodizing solutions, insisted on in my preceding letter, has not been observed. In the one case the salting solution is 3½ grains; and in the other 5½-grains, a little less than double. Now I ask Mr. B., in all fairness, how the result could be otherwise than in favour of the 5½ grain collodion, even if there had been no bromide in the latter? And if, as I understand him, 2 distinct samples of collodion were used, how could the results of the one be reasonably arrayed against the other?

In the second experiment the error is repeated—no less that 6½ grains in one case, and only 3½ in the other—but no mention either is made whether only one collodion or two were used. Irrespective of the great difference in results, this matter alone would cause—an iodide of potassium is selected against a sensitive bromo-iodizer! Now if Mr. Blanchard had taken the iodides of potassium and cadmium in equal proportions for his iodizers in the one case, against his bromo-iodizers of ammonium and cadmium (by way of approach to equality of conditions), he would have found the results very difficult of decision one way or the other. Nor does he say how much cadmium was in the 4½ grains of ammonium and cadmium of his bromo-iodizers, for the more cadmium the more sensitive the collodion. In short, by a still further consideration of the matter, the amount of bromide is so large, that the proposed iodizer of half potassium and half cadmium would have proved superior to his bromo-iodizer.

In experiments 3 and 4, if, instead of taking potassium only for one half the plate, he had added 1¼ grains iodide of cadmium to it, and arrayed its results against those of the bromo-iodized half plate, he would have found them run parallel to each other, for there would have been intimate equality in the two solutions. And indeed my own experience would point even to a superiority of the iodized collodion over the bromo-iodized one, simply on account of the excess of bromide.

Experiment 5 proves simply the correctness of Mr. Sutton's experiments, that bromide alone is insensitive to light, or rather causes insensitiveness. But if Mr. B. had been aware of the principle of excitation propounded by me in my previous letter, he would have been fairer to poor bromide. He would have not used bromide of cadmium alone, but a mixture of the bromides of ammonium and cadmium, and the resulting produce would not have been quite so feeble as it turned out.

Although the result of experiment 6 was not produced at the meeting, Mr. B. has given sufficient particulars regarding it. Like the preceding ones, I must, at the risk of a charge of rudeness, pronounce it utterly unfair. No approach to equality of conditions in the iodizing and bromo-iodizing solutions are observed. If, instead of simply 3½ grains of potassium in the one case, he had added 1¼ grains of iodide of cadmium to the same, and then developed with pyro, he would have found the result superior to the bromo-iodized half plate: for the proportion of bromide used is too large to array against the said simply iodised collodion, although the latter were under pyro development. Still less would it have stood against the same iodized collodion, if iron development had been used with the latter, as in the iodizers of the preceding five experiments.

And now, as regards the whole of these experiments conjointly, the marvel is, how the coating and developing of these plates was satisfactorily done. There must have been a hitch somewhere. The coating first—how were the two collodions applied? if simultaneously, how was the excess poured off, and a proper uniform coating given? and under any circumstances the two collodions, whether of one sample or not, being differently iodized, and having therefore different setting properties, how was this part of the process regulated, so as to ensure the necessary amount of setting to each half of the plate? if lowered into the bath by one of the long ends downwards to allow of this, how was the excitation regulated? And in the case of the last experiment, how were the iron and pyro developers prevented from running into each other, and the necessary amount of development given each half of the plate.

It occurs to me that the experiments in question should have been performed with *one* sample of collodion, *variously iodized and bromo-iodized, as required, and with the necessary equality of conditions for a fair trial*, with *separate* plates with *one bath* and one strength of developers.

Trusting that you will find a corner for this letter also—I remain, dear sir, yours truly, Augustus Webb.

*Meerut, N. W. P. India, 29th July*, 1862.

## Photographic Notes and Queries.

### Resinized Paper.

Dear Sir.—By correcting an error, in the 23rd line you will oblige. As I have never found the benzoin become yellow, but always *black*, it should be *bleach or whiten by exposure to the light and air*. I am proceeding very satisfatorily with this process. I have also much improved the formula, or I may say remodelled it, as the salting solution is not in the substance of the paper, but entirely on the surface. The finished print much resembles ivory. I shall forward results and particulars at my earliest opportunity.—I am, sir, yours obediently

21 *Jude street.* H. R. Nichols.

## Talk in the Studio.

Dagron's Micro-photographs.—The Abbé Moigno gives a most enthusiastic account of the new method of preparing and exhibiting micro-photographs invented by M. Dagron. After describing a process by which a series of the minute sun pictures are taken in rapid succession, he proceeds to inform us that a number of "cylinders of common or flint glass are prepared in advance, about five or six millimotres long and two thick. The second extremity of these cylinders is spherically rounded in a hollow, to transform it into a magnifying lens. To one extremity of the cylinder a microphotograph is fixed with Canada balsam, and the edges ground by an optical tool to efface the marks of the union. 'This is the photo-micrographic cylinder, one of the most delightful conquests of science and art. * * * If we look at the plane end of the cylinder we see the picture with great difficulty as a black almost imperceptible point, and M. Dagron was naturally led to do for the second extremity what he had done for the first. He fastened on a second picture with Canada balsam, he rounded the glass in another hollow, and he obtained a cylinder which twice performed the functions of microscope and object holder.'" In other cases, he fixes the picture so that it can only be seen when the glass is held at a particular angle. As the originality of these methods was disputed, and their merit referred to, Sir D. Brewster, who gave some similar hints, the Abbé Moigno obtained a letter from that philosopher, vindicating M. Dagron's claims to the invention.

Photozincography.—Mr. Osborne has addressed the following letter to the *Times*, in answer to one from Col. James, which appeared in our last:—Sir,—On my return from Cambridge, yesterday evening, I observed in your columns, a letter from Colonel Sir Henry James, referring to a notice in *The Times* of my paper on Photolithography, read before the British Association, in which he expresses the fear that a wrong construction may be put upon your report of the discussion which ensued upon that occasion. As to what transpired in the Chymical Section, I have simply to remark that my paper was a dry detail of facts, bearing exclusively upon my own process; but, that in answer to a question by Mr. Wyld, M.P., I made the statement published in *The Times*, and not contradicted by Colonel Sir H. James—that mine was six months antecedent to the Southampton process. I did not in any way imply that the latter process was based upon mine, nor did any other person present, both question and answer having reference solely to priority of invention. Trusting that this explanation will satisfy Colonel Sir H. James that the originality of his process was not impeached by me, I remain Sir, yours obediently,

J. W. Osborne (in charge of the Photographic Office, Survey Department, Melbourne).

Chanter's Collodion Pourer.—Mr. Solomon has recently manufactured the most perfect collodion bottle we have seen, the invention of Mr. Chanter, of Southsea. About half way down the bottle is a funnel-shaped partition, extending nearly to the bottom of the bottle. Through the small orifice of this funnel all particles of sediment fall, and when the bottle is turned up, for the purpose of pouring, these particles naturally fall to the side, and, instead of being poured out with the collodion, are stopped at the point where the edges of the wide mouth of the funnel are attached to the inside of the bottle. A stopper, at the bottom, can be removed to permit the occasional removal of all sediment.

Photographic Allegory.—Mr. Rejlander has recently executed a very fine allegorical photograph entitled "A Vision from Aspromonte." The champion of Italy's liberty and unity is reclining wounded and desponding on the ground. He is supported by a female figure of classical outline, evidently intended to typify hope, one arm holding an anchor, pointing to the distance, through which dimly looms the dome of St. Peters, and we see that she points to Italy. Garibaldi is personated by the artist himself, to the likeness of whom he bears as we have before observed, a strong resemblance. The picture is a whole plate, but is reproduced in card size for publication.

## To Correspondents.

Amateur has forwarded a piece of glass for examination in the spectroscope. It is of a deep orange colour, and cuts off all the chemically acting rays in a very perfect manner, and may safely be employed in the window of a photographic laboratory.

C. Bryan.—The specimen of glass sent is of a pale yellow colour, and is only a little less transparent to the chemical rays than is common window glass. For photographic purposes it is valueless.

M. R.—Mr. Lovell Reeve publishes the *Stereoscopic Magazine*, illustrated with stereographs. The price, if we remember rightly, is half-a-crown monthly. The object of the News is to circulate photographic information, not photographs. Most of our readers take pictures for themselves.

G. S. Penny.—We do not know of any place in this country where the solidified milk can be purchased; but it is not improbable that some of the emigration outfitters to be found in the neighbourhood of the docks may keep it. Mr. Thompson describes it as simply fesh milk and sugar, boiled down to the dry point, and then boxed up for keeping. The plan of making the coating for dry plates, he recommends, is to fill a convenient bottle one-eighth full of ground white sugar, and then add seven-eighths of fresh milk, and shake until the sugar is dissolved. The solution is then ready for use. 2. Kerosolene is simply a hydro-carbon, similar to benzole. Either chloroform or benzole, will answer the same purpose as a solvent for india-rubber. It is a somewhat singular fact that all samples of india-rubber do not equally dissolve. Dr. Diamond showed us some a few days ago, which has simply swelled up to a spongy mass, instead of dissolving.

A. D. J. states that he has found an old solution of acetate of soda added to fresh chloride of gold prevent mealiness. We fear that he arrives at conclusions from insufficient grounds. Isolated facts are insufficient data for generalization.

Excelsior.—The partition must be in its place in the camera whenever you take stereoscopic pictures. 2. The facility to separate the lenses further is thought an advantage by some photographers, but it is not absolutely necessary. Suitable compound lenses may be used for views with advantage. 3. The rusty tone of your print arises from the negative lacking intensity, which does not permit the print to be printed deeply enough; and without sufficiently deep printing you cannot get deep toning. Nevertheless, by toning a little deeper, you would get better results.

E. A. R.—Information on glass-rooms, generally, is scattered through the pages of each volume of the News. You will find, however, a specific article on their construction, on p. 73 of our third volume, No. 59.

Phos.—The negatives are, fortunately, still in existence. We will leave them at the office, addressed to you.

Fred. Davis.—Your experience is somewhat inexplicable. Fifteen minutes' exposure in sunshine, for a tannin and honey plate, ought to have given an over-done negative, instead of one with scarcely a trace of an image. Have you not mismanaged the development in some way? Do you adhere to the method described by Major Russell? Your next difficulty we have met with. If any trace of free nitrate remain in the film, the plate will often turn brown in patches. The remedy is, more perfect washing. Some samples of collodion retain the silver after very long washing. The powdery and permeable kind is best. Wash in a series of dipping baths, without ever removing the plate from the dipper, as recommended by our American Correspondent (Mr. Thompson). Iron may, sometimes, be used for developing dry plates; but, as a rule, pyrogallic acid is better. Mr. Bailey is a manufacturing chemist, at Wolverhampton.

Joseph Lewis.—We believe you may practise, for your own amusement, any patented invention, without risk. But we are not sure that the law gives you that permission.

D. M. A.—If you wish to intensify before fixing, use 2 grains of pyrogallic acid, and 1 grain of citric acid, in an ounce of water, and add a few drops of a 15-grain solution of silver. The same solution may be used after fixing, but it will work better if, prior to applying it, the plate be flooded with a solution of 1 grain of iodine and 2 grains of iodide of potassium in an ounce of water. In all these cases wash the plate very thoroughly before applying each fresh solution.

St. Denis.—Photography is used in various Government departments, but we cannot tell you how to obtain a Government situation as photographer. 2. You may, with propriety, use the bromo-iodized collodion of either 1, 4, 5, or 6; and probably of the other makers, but we have not tried them.

H. V. R.—A good thick coating of shellac varnish, or, better still, a thin lining of sheet gutta-percha will preserve your zinc tray from the action of various solutions.

Beta.—Your specimen is not bad; but there is room for improvement. A little more perfect definition of the head, and, indeed, throughout; a cleaner background, and warmer tone, are required for good results.

F. Vincent.—The varnish to which you refer, has proved sticky in our hands and spoiled us one or two negatives. It is a somewhat difficult thing to get a good varnish. The Sœhnée varnish, which used to be so good, has lately often been tacky. Amber varnish, when good, is very good; but it cannot always be relied upon. The varnish recommended by Mr. Fitch, which you describe as running unevenly and drying must have been too much diluted with spirit. The irregular flowing and dull drying indicate too much alcohol. We have not tried Ponting's varnish. The print is in many respects very good; the definition is very satisfactory, and the print is free from mealiness. The bright leather covering of the chair reflects too much light, and disturbs the harmony of the picture a little.

D. A.—An ordinary quarter-plate portrait lens is not well suited for full length standing card portraits. Your only plan to improve the definition will be to use a small stop.

Phist.—Photographer by all means, not photographist. Both analogy and euphony forbid the latter.

R. G.—A little thin gum-water should be mixed with lamp-black for painting on negatives. Or the cake lamp-black of the artists' colourman may be used. Letters addressed to Paternoster Row reach us the same day they arrive, or the following day. Communications to reach us at once may be sent to our private address, 18, Canonbury Park South, N.

Photo.—Mr. Sutton's new book on photography is not yet published, but will be shortly we believe. Kerosolene is a fluid analogous in its character to benzole. The latter may be used in most cases for the same purpose.

Justitia.—The defect of which you complain arises from the collodion, which is not sufficiently limpid. A more highly alcoholic collodion would give an even film with less trouble, but some samples of a pyroxyline will give a collodion of that character with almost any proportion of solvents. The difficulty may be got over, to some extent, by skilful manipulation, but it requires tact and skill. Pour a large quantity of collodion upon the plate, so as to get it covered rapidly, there is less danger of setting in those unequal ridges in such cases. Another sample of collodion is the best remedy.

H. Regnier.—We are obliged by your offer of back numbers, but have some copies of those you name. No. 79 is not yet reprinted.

Buchanan Smith, A Photo's Assistant, E. E. L., and several correspondents in our next.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 216.—October 24, 1862.

## BROMIDES IN COLLODION.

We once more recur to this subject, although we think it is, in the minds of the majority of photographers, a settled question. In recent numbers of the News we have published two very long letters from Mr. Augustus Webb, some of the arguments and conclusions in which were, in our conviction, so persistently wrong, that but for the earnestness and manifest honesty with which they were written, and our desire to do all sides of all photographic questions full justice, we should not have felt justified in giving them publicity.

We are not now about to follow Mr. Webb throughout his various experiments and arguments; but just to point out one or two errors he makes, and one or two plausible fallacies of which he is guilty.

In the first place, in reference to his remarks upon Mr. Blanchard's experiments, detailed at a meeting of the South London Photographic Society, a few months ago, Mr. Webb entirely misappreciates their avowed character. Mr. Webb is angry with them for not being what they did profess to be. Mr. Blanchard very carefully guarded his position, by stating that his engagements had prevented him from preparing a paper of any completeness on the influence of the bromides, but that he would place before the meeting the results of some of his experiments in the crude form they then possessed, these experiments having been made with reference to questions which had recently excited attention. On the general question they were not put forth as conclusive. But they were held to be tolerably conclusive as to this fact, that bromides and iodides in combination were more sensitive than either bromides or iodides alone. Again, Mr. Webb appears outraged at Mr. Blanchard's unfairness in having in one experiment, tested collodion with a simple potassium iodizer against a sensitive bromo-iodizer, and urges that to give the simple iodide fair play, it should have had a cadmium base, or cadmium and potassium mixed. But Mr. Webb altogether overlooks the fact that the experiment in question was made simply for the purpose of testing a theory often reiterated by more than one photographic authority, to the effect that a potassium iodizer gave by far the most sensitive collodion, an opinion which used to prevail, indeed, amongst all the advocates of a simple iodide.

The next error Mr. Webb commits is an amusing, although by no means an uncommon one. He states his own experiments, and draws his conclusions therefrom with the manifest conviction that they are unchallengeable. In referring to Mr. Blanchard's experiments, however, he unhesitatingly challenges both the experiments and conclusions. He disputes the fairness of what is explained, and surmises the unfairness of what is not explained. As regards the mode of manipulating he is convinced that "there must have been a hitch somewhere." He says:—

"And now, as regards the whole of these experiments conjointly, the marvel is, how the coating and developing of these plates were satisfactorily done. There must have been a hitch somewhere. The coating first—how were the two collodions applied? if simultaneously, how was the excess poured off, and a proper uniform coating given? and under any circumstances the two collodions, whether of one sample or not, being differently iodized, and having, therefore, different setting properties, how was this part of the process regulated, so as to ensure the necessary amount of setting to each half of the plate? if lowered into the bath by one of the long ends downwards to allow of this, how was the excitation regulated? And in the case of the last experiment, how were the iron and pyro developers prevented from running into each other, and the necessary amount of development given each half of the plate."

These questions are asked with so much *naïveté*, that although the method of manipulating in such experiments appears simple enough, we are tempted to explain them for the benefit of others wishing to repeat the experiments, and feeling any uncertainty about the mode of doing so. We cannot say with certainty how Mr. Blanchard went about the matter, but we can describe the mode in which we have gone through the same and similar experiments dozens of times. We use for testing collodion, a binocular stereoscopic camera, with a pair of lenses of ascertained uniformity of action. One half of a stereoscopic plate is coated with one collodion, and the other half with another; the two are then excited together, exposed together, and developed together. Under these circumstances, however, it follows that one collodion is set more than the other before it is plunged into the bath. It is necessary, therefore, to repeat the experiment under exactly the same conditions, simply reversing the order in which the collodions are poured on to the plate, in the second experiment coating first with the collodion which before was last. This principle should always be observed: wherever varying conditions necessarily arise, the experiment must be duplicated, to give to each sample of collodion its trial under each phase of variation. If, in such experiments, one collodion requires a longer time for setting than another, it is obvious that such collodion should be poured on first. In using one half of a plate with an iron developer, and the other with pyrogallic acid, it is simply necessary, before coating the plate, to make a diamond cut down the centre. This will not interfere with the manipulation until it is required; and then, before development, it is simply necessary to apply the proper pressure to divide the plate into two pieces, each of which can be easily developed with its own solutions, without the fear of mixture which Mr. Webb anticipates. Wherever it is possible, simultaneous exposure is highly desirable, as removing one or two fertile sources of error—unsuspected inaccuracy of timing, and unperceived variation of light.

Mr. Webb further says:—

"It occurs to me that the experiments in question should have been performed with *one* sample of collodion, *variously iodized and bromo-iodized, as required, and with the necessary equality of conditions for a fair trial*, with *separate* plates with *one bath* and one strength of developers."

In making comparative experiments, the first step will necessarily always be, to maintain equality and uniformity in all the conditions, in all points except those under trial; the same pyroxyline in the same solvents, and in the same proportions; the same bath, lens, light, exposure, developer, and manipulation. This is all very necessary, and will satisfy Mr. Webb's demands; but is by no means enough, and will not satisfy ours. It is not simply sufficient to test two different collodions under the same conditions; but they should be tried *each under its own best conditions*, and these will not always be the same for both. A bromo-iodized collodion, for instance, works best with nitric acid in the bath; to a simply iodized collodion this would be fatal. In maintaining, as we have steadily done, the advantage of bromides, we have done so from conviction based upon very numerous experiments, tried not only under the same conditions, but under every varying condition likely to give an advantage to either iodide or bromide. We have repeatedly admitted, that a simply iodized collodion, under its own best conditions, is as sensitive as can be desired, but that these conditions are difficult to secure and impossible to maintain; and that they are frequently accompanied by a host of troubles in the shape of spots, streaks, and comets, which have often well-nigh driven the photographer frantic; whilst a bromo-iodized collodion is more uniformly rapid in action, almost entirely free from speck or spot, and more harmonious and satisfactory in general result.

We do not attempt here to enter into some of the theoretical questions raised by Mr. Webb. We are content to look to the facts. Bromo-iodized collodion and iron development are now almost universally used by professional photographers, who are generally tolerably quick to perceive in which direction their interest lies. We receive almost every week letters from able and experienced amateur photographers, stating that they have renounced pyro and the simple iodide, and henceforth swear by iron and a bromo-iodizer; and not a few thank us for our persistent advocacy, which has induced them to change their faith and practice in this respect. We repeat, as we have often done: let all who have time try each method, each under its own best conditions; and let those who have not time for experiment look to the results in the works of the best operators. In either case there will remain little room for further indecision.

## Scientific Gossip.

For some months past a paper war has been waged in periodicals more especially devoted to pharmacy, respecting the employment of methylated spirits in the preparation of tinctures and extracts, one party advocating its use and urging the proper authorities to legalise its introduction for this purpose, whilst other sections of the disciples of Esculapius indignantly protest against such an innovation, and prophesy every imaginable evil as the result of employing such methylated medicaments. It is doubtless well known to all our readers that methylated spirit, which is allowed to be sold duty free, is spirits of wine, to which a small portion of methylic alcohol, or wood naphtha, has been added. This was originally done at the recommendation of several eminent chemists, who were engaged to report on the subject to the chairman of the Inland Revenue. Wood naphtha is very similar in chemical properties and behaviour to wine alcohol, being, in fact, the alcohol next below it in the series; it has, however, hitherto been believed to possess an odour and taste peculiar to, and inseparable from, itself. This being of a somewhat nauseous character, and the problem of separating the two bodies being at that time unsolved, the Excise authorities felt themselves secure in permitting the untaxed sale of ordinary alcohol which had been mixed with the methyl compound; "in fact," write Messrs. Graham, Hofman, and Redwood, in their report on the subject, "the more highly purified the naphtha is, with which the spirit is mixed, the more difficult will it be to effect the alteration of the mixture, in the way contemplated, by any chemical process." In the notices of the photographic chemicals, in the Exhibition, at South Kensington, we drew attention to a case of "potable wood naphtha," exhibited in the Eastern Annexe, and pointed out several applications for which this material would be useful in photography. In connection with the subject of employing methylated spirits in pharmacy, this specimen of wood naphtha is of considerable interest, in fact, much of the discussion could not have taken place had this purified spirit previously received the attention which it deserved. The subject is of almost equal importance to photographers as it is to druggists, and we are, therefore, glad to be enabled to lay before our readers a few additional facts respecting this spirit. The spirit has been recently chemically examined by Mr. Harry Draper, who obtained specimens of the liquid large enough to serve for several experiments. It is reported as being colourless, its odour suggesting nothing but alcohol, and its taste but the very faintest suspicion of pyroxylic spirit. It has a specific gravity of ·805. When diluted, both the scent and taste of wood spirit become more perceptible; but, so little so, that the slightest addition of an aromatic essential oil is enough to conceal them effectually; and, it is certain, that there is no single tincture in the pharmacopœia, which, if made with this spirit, could be distinguished from the officinal preparation by its sensible properties. This spirit was prepared under a patent taken out during the present year. Mr. Draper gives the following outline of the patentee's method of "treating wood, and other vegetable spirit," premising that the specification offers no evidence that the patentee considered wood spirit as anything but some very impure form of ordinary alcohol, which, like that prepared from beetroot and madder, it would be desirable to render potable. Specimens of beet and madder spirit are, in fact, exhibited in the same case.

The specification states that the wood spirit is first diluted with from 75 to 80 per cent. of water, allowed to repose for twenty-four hours, and then passed through a succession of filters containing coarsely-granulated wood charcoal. The only novelty claimed by the patentee is, the very ingenious arrangement of the filters, which are so placed that the spirit in the process of purification shall continually come in contact with cleaner charcoal, and that one, the first of the series, can be replaced, when foul, by a new one, not in its place, but as the last of the series. After purification, the spirit is, of course, distilled. On the small scale, and with a series of seven filters instead of fifteen, as recommended by the patentee, a spirit was obtained nearly as free from taste and smell as that exhibited at South Kensington, and there is little doubt that even this latter can be still further deodorized.

Here, then, is proof positive, that the mixture containing but ten per cent. of methylic alcohol can be successfully purified, and that wood spirit itself, as found in commerce, can be made to so closely resemble wine alcohol, as to be when undiluted, indistinguishable from it, save to the most sensitive and tutored smell and taste. Not only is there a specimen in the Exhibition, which upsets all the calculations of our revenue chemists, but the published specification of the patentee, details minutely the process of manufacture which can be successfully repeated by any chemist. Whilst this discovery promises to interfere somewhat with the revenue derived from wine alcohol, it has especial interest for the lover of science, in that it points to a new chemical truth. Mr. Draper says that it is impossible to avoid the conclusion, that the body which is described by chemists as methylic alcohol, *plus* a minute quantity of a strongly odourous hydro-carbon (probably the same which exists in the crude wood spirit to a large extent, which has so great an affinity for the alcohol, that not only does the ordinary process of purification by dilution with water and distillation, fail to remove it, but that the most powerful oxidising agents are equally unsuccessful. If the dilution however, be followed by an interval of repose, and the fluid be then percolated through charcoal, at a low temperature, and in such a manner that the partially purified filtrate shall not re-dissolve the separated hydro-carbon, the result is a body, which, while we can no longer attribute to it the peculiarities of taste and smell, by which methyl alcohol is now recognised, and which it is described by chemical writers as possessing, is still methyl alcohol in all its chemical characteristics and reactions.

If this purified wood-naphtha can be prepared by the patentee, at a price at all approaching that of wine alcohol, it could not fail to be of great value to photographers. Its high volatility—exceeding that of alcohol, would enable a great saving to be effected in the consumption of ether, in collodion, and we cannot imagine that a collodion prepared with so pure a methylic spirit as this, would be any less sensitive a photographic agent than when made with ordinary alcohol.

## PHOTOGRAPHY IN AMERICA.

*New York, October, 7th*, 1862.

My Dear Sir,—I imagine you, as you see this letter among the rest on your morning table waiting to be opened, saying with a frown, "Monsieur Tonson come again! Confound that Thomson, he is an unreliable, irregular fellow, I wish we could depend on him or get rid of him." All I can do is to doff my hat very meekly, and like a sorry school-boy, say "I can't help it."

We are in a very bad way this side of the Atlantic, my dear sir. We think no more of killing off five-thousand men per diem, for ten days at a stretch, than you would of killing off red ants.

Our President calls for a fresh million of men as coolly as he does for a dinner; and those who don't volunteer, are drafted into the ranks, so it all ends the same. Our Congress passes tax laws that leave Old England away back in the shade. Our Secretaries issue paper money of all kinds without limit. A man having a gold coin, preserves it in his family as an ancient relic, and a silver half-dollar is a curiosity. But yet we all jog on, and of course, money being manufactured by the simple power of a thousand printing presses, we are richer, more prosperous, and busier than ever. We Yankees adapt ourselves to anything; like the eels, we get used to being skinned. Some old fogy fellows look ahead, and say "where are we drifting to?" I acknowledge I am one of the old fogy kind. We will quell rebellion without a doubt, but at what a cost! We will totally extinguish slavery, that curse of our country, but what seas of blood must be the element of purification. Every family in our land has a member in the army; every person can tell you of a friend buried on the battle field, or what is worse, the Chickahominy swamp fever. Do you wonder when I say that photographic interest is somewhat drowned by the continual tramp! tramp! tramp! of armed men, and the sharp rattle of the drums through our streets? Do you blame me if I turn with disgust from amateur photography, or any other amusement, when I hear the now hourly sound of the muffled roll, and the solemn dead march, as the close platoons of soldiers with reversed arms, follow some gallant officer to his last home?

My own regiment having returned to this city, I hope to be more regular in writing to you hereafter, although we have received orders to draft our ranks full again, and stand ready to move at ten hours notice.

Now about photography,—I enclose herewith a print by H. T. Anthony; it is one of the gems of the Club, and as a sample of the *milk process* fully sustains the superiority of those plates. The vignetting of this picture is done in a very simple and easy manner, by pasting on the back of the negative several layers of white tissue paper, each one overlapping the other towards the centre, and a whole piece over all the rest. The general shading is finished with blue water-colour washed over the edges of the vignette with a soft camel's hair brush; or this vignette can be made on a plain piece of glass, and used to lay over the negative in printing. This is the most convenient vignette I know of and is worth a trial.

I also enclose a couple of my own pictures, to show you a new method of toning I have discovered. It is done by the usual alkaline gold bath. Having added to the soda solution some *nitrate of brass* (if there be such a chemical), that is to say, I dissolve some brass filings in nitric acid, and add this solution to my bi-carbonate of soda bottle. The acid is neutralized with great fermentation, and a clear blue liquid is left. This I use with one half the usual quantity of chloride of gold, and a bath is the result which tones almost instantaneously, and of a beautiful colour. I omitted to state that I add a pinch of common salt to each half pint of toning bath, which seems to preserve the surface of the paper cleaner. *A half-grain of chloride of gold used in this way wi l tone sixteen stereo prints.*

The fixing bath is: one part hypos. sodae, one part, 95° alcohol, and five parts water. I never use this bath a second time. When my prints are toned and washed, they are put into the alcohol and hypo. bath, where they do not change colour at all, as in the old fixing bath, but retain their brilliancy throughout. The whites are excessively clean, and the shadows very transparent. But you judge by the prints herewith. This is not the first instance where *brass* has passed for *gold*. It is an every-day occurrence, elsewhere than in the Photo's chemical den.

That dry-plate changing box I have in my possession, has done wonders on this side of the ocean, in converting old, and making new amateurs. Perhaps since Sellers has described it so well, the English maker will recognise his work, and let us know him.* Such deserving ingenuity ought to be made public. More from me soon.—Yours respectfully,

F. F. Thompson.

## MR. SUTTON'S RAPID DRY PROCESS.

BY MAJOR RUSSELL.

The process which Mr. Sutton described at the meeting of the British Association, is one with which I am quite familiar, as I worked a good deal with it between 2½ and 3 years ago. It is doubtless a good method for some kinds of subjects, but, as far as I can judge from my own experience, it will scarcely justify Mr. Sutton's sanguine expectation. A plate prepared with gum arabic is no doubt a trifle more sensitive than if tannin had been used on the same collodion. My principal reasons for preferring tannin for general use were the following:—

It is difficult, when gum is used, to prevent loosening of the film; a thin coating of india-rubber did not always produce sufficient adhesion, and a thicker coating was apt to crack when the negative was finished and dried; a substratum of gelatine did not always answer; it was, therefore, necessary to use collodion in a particular condition, or to have a previous coating of coagulated albumen, which involved great trouble. I found the plates prepared with gum to produce most excellent results with great certainty, when the subject included little or no sky, but otherwise fogging or reddening all over the upper parts almost always appeared, especially when any objects were near and dark enough to require a rather long exposure. Again, if the gum was not thoroughly washed out, it usually made the developing liquid turbid.

I found, by many comparative experiments, commenced nearly 3 years ago, that the use of bromide in about the same proportion which is now recommended by Mr. Sutton greatly accelerates dry collodion, and for 2 years I have used and recommended it, but I do not find that it gives nearly as much sensitiveness as can be obtained with wet collodion.

Mr. Sutton's theory that an equal number of atoms of iodine and bromine, gives the greatest sensitiveness, may very probably be right, but practically no great nicety is required, as little difference can be perceived in different proportions, between one part of bromide to two of iodide, and equal parts of each. I have generally used from two-thirds to three-fourths.

Finding that the sensitiveness gained by the use of bromide was not so great as was desirable, I have been for a long time endeavouring to find means of increasing it, until very recently, with but little success, but at last have found a method of developing, which will bring out a picture after a much shorter exposure than usual, and which promises other advantages. As, however, nothing is easier than to make mistakes in such matters, I delay publishing the method, until there has been time to test it further, and to find out the best way of working.

## IMPROVED APPARATUS—A FEW HINTS.

BY JAMES L. LANE.

Sir,—I have great pleasure in forwarding you the enclosed

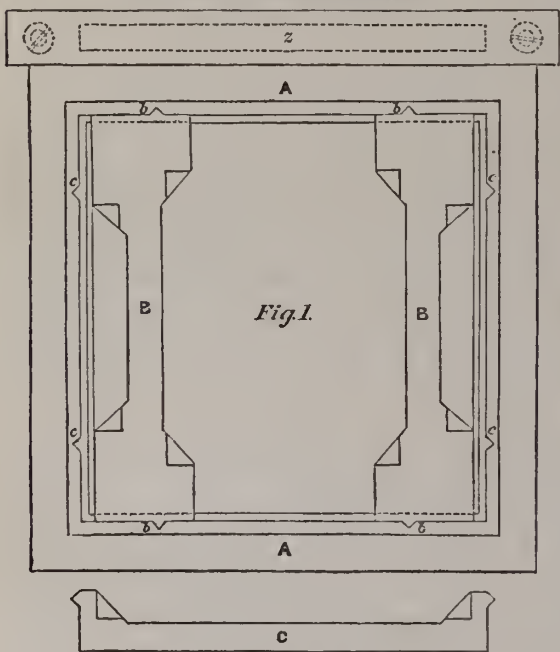
* Our correspondent will have learned ere this that the Englishman is found.—Ed.

diagrams, and particulars of some improvements in photographic apparatus, and to indulge in the hope of a space in your valuable journal, should they be worthy of your notice.

Four years ago I commenced operations as an amateur photographer, with a common made French camera, having the carriers of the ordinary description, except that the corners of the glass were made to rest on pieces of bone, which were secured to the back of the carrier with *iron* screws. Now, the nitrate of silver which drained from the glass, coming in contact with the screws, produced very ugly stains on the collodion film, and very quickly destroyed the screws, and allowed the pieces of bone to drop off, and the mitres becoming disunited, rendered the carriers perfectly useless. In this dilemma, I was compelled to contrive something in lieu of them, when I hit upon the following cheap and simple contrivance, which has answered the purpose exceedingly well, and can, in cases of emergency, be constructed with a penknife. They should be made of hard wood, and coated with shellac varnish. I do not consider silver rests necessary, as I have not been troubled with stains since I have had mine in use. I trust the annexed diagram will explain the plan I propose.

A A fig. 1 is a collodion back of a quarter-plate square camera. B B, pair of my carriers for glasses $3\frac{1}{4}\times2\frac{3}{4}$ and

BACK FOR A QUARTER SQUARE CAMERA.

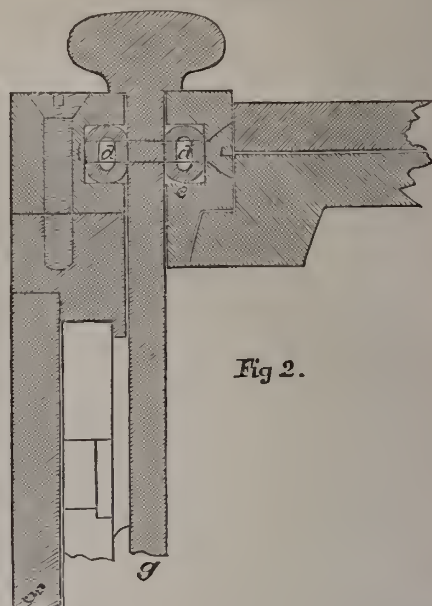


*s* Groove for Gutta Percha Tubing.

$2\frac{1}{4}\times2$. To take plates of the latter size, the carriers have only to be reversed. They have a projection at each end to fit the notches *b*, to prevent them from shifting. C, one of a pair of carriers for glass $4\frac{1}{4}\times3\frac{1}{4}$, these are to be inserted in place of the above; these have projections at the ends, which also fit the notches *b*. The plates can be placed horizontally for views or groups, by placing the ends of the carriers in the notches, *c*.

The next modification is in the sliding shutter of the camera back, to obviate the "stars and comets" which most photographers complain of, and, I believe, attribute chiefly to the dust caused by the friction from the working of the sliding shutter, which I have found to be the case if it fits tight enough to exclude the light from the camera. Fig. 2 represents what I suggest. The shutter should be french-polished, and made to work perfectly easy through the groove; then, in a recess on each side of the shutter, is inserted a piece of vulcanized india-rubber tube, about 5-16 outside diameter, and, to protect them from friction, they should be covered with silk ribbon of the required width, so that the edges nearly come together. Their elasticity causes them to press the shutter, allowing it to work

SECTION OF NEW IMPROVED BACK.



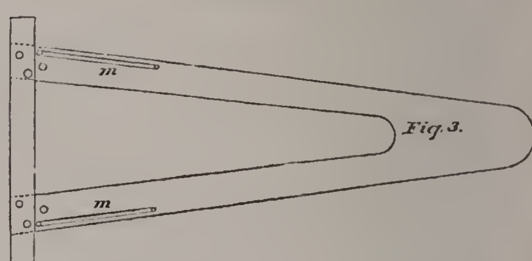
*d* Gutta Percha Tubes. *f* Door. *g* Sliding Shutter.

very soft and easy, avoids friction and dust, and effectually keeps the light out of the camera. I prefer the shutter without a hinged joint, especially in small cameras. The piece, *e*, which contains one of the tubes, is secured with a screw at each end, so that the tubes can be taken out occasionally, and freed from any dust that may have accumulated.

The tubes may be applied to any ordinary back, by enclosing them with strips of wood outside the frame.

Fig. 3 is a half-plate dipper, which answers exceedingly

WOODEN DIPPER.



*m* Silver Wire. *o* Wood Pins.

well; it is made of hard wood, coated with shellac varnish, on the projecting piece at the bottom are two silver pins, to keep the glass from wearing off the varnish; and I should also recommend two pieces of silver wire to be laid on the stems, extending upwards, say two inches from the projecting piece of wood, and the ends taken through the stems and rivetted.

Small dippers may be made of the usual shape, and the projecting piece at the bottom dispensed with, simply having the two silver pins projecting to support the glass.

Want of experience, or even carelessness, may have been the chief cause of all my mishaps and failures; but if they have been overcome by contrivances which may prove serviceable to any of your numerous readers, no one will be more gratified than myself.

*The Grove, Battersea Rise.*

## ELECTRICAL THEORY OF TONING.

Sir,—When we seek for an explanation of many of the most common, but little understood phenomena attending photographic operations, we find it difficult, if not impossible, to explain them by any known action of chemical affinities or decompositions. Were we, however, to pay more regard to the many careful observations of skilful experimentalists, it would be less difficult to trace a more intimate connection, than is at present admitted, between the electrical and chemical sciences.

It is to the first of these sciences, that I have long believed we owe the success of that part of our operations, known as "toning," in those cases where the tone is obtained by the deposit of a metal, and the facts recently brought forward in your excellent journal seem to me as so many proofs tending to a confirmation of this opinion; that what we call "toning" is not, as is usually stated, a process of substitution, but is really a process of electro-gilding, in which the gold of the toning bath is deposited by *electricity* in a minutely divided state on the ready formed image of *metallic* silver. This would, I believe, explain the fact that an addition of free acid, or solution containing free acid, renews the action of the toning bath, by setting up anew the electrical current, which has been *gradually* overcome by the addition to the bath of a negative element, for although the bath may appear neutral to such tests as we possess, experience teaches us that the effect of adding alkali is not so immediate as the test paper would lead one to believe. To point out all the known facts that would appear to lead to a confirmation of this view, would occupy too much of your valuable space; but it will be remembered that with the old hypo bath and the sel d'or bath, in which the acid was rarely, if ever, neutralized, we never had so many difficulties in toning proofs, to any desired tone or colour, evidently showing, with recent observation, that the presence of free acid in some form is an important element in easy toning, and which will, I believe, be found to arise from the power possessed by acid solutions of conducting currents of electricity.

The addition of an alkali I take to be simply a means of checking or regulating the rapidity of the deposit, for if the acid be in excess and the gold, consequently, deposited with great rapidity, it will be found that the lights as well as shadows of the proof will become coloured, and this in cases where there cannot possibly be any sulphur present. But if there be an alkali present, the deposit will take place only on those parts where the electrical affinities are strongest, *i.e.*, on the shadows of the proof, and the photograph will be toned before the feeble affinities that may exist in the lights can overcome the presence of the detergent.—Yours respectfully,

E. E. L.

P.S.—By this theory also we may explain one of the most troublesome amongst the numerous difficulties that beset the process. We well know, from experience, how hard it is to maintain intact the tone and strength of the proof until it shall have passed through the process of fixing.

Now, currents of electricity passing through solutions invariably decompose some small portion of the fluid through which they pass into their orginal elements, such action taking place in the gold solution would set free minute quantities of oxygen, hydrogen, chlorine, &c. Chlorine and silver, having such strong affinities, the small portion of the former set free (and it would be freed in proportionate quantities to the activity of the bath), would seize on the equivalent of silver not yet acted on by the toning, which would be in great measure the lighter tones of the proof, always last to be acted on by the gold bath, and would form with this untoned silver, chloride of silver; and as every photographer now knows, chloride of silver being soluble in hyposulphite of soda, we can easily perceive why the proof suddenly loses much on immersion in the fixing bath.

We may observe that this theory does not in any way interfere with the many suggested or proved causes of failures in printing, since I have only taken the proof in a state of perfect readiness for the toning process, and the suggestion that foreign salts are formed on the surface that interfere with toning, only strengthens this theory, since electricity will only form deposits on clean surfaces.

## LIGHTING THE SITTER.

Sir,—I do not wonder at the perplexity felt by those unacquainted with art, at the conflicting statements that appear in the various journals devoted to photography, respecting the lighting a glass room, or in other words, lighting the subject. To artists generally, there can be no difficulty attending it, it being well known to them, that the most beautiful effects are produced by the principal light falling on the object at an angle of 45°, or thereabouts, on the *side*-front. Want of time only, prevented me writing in confirmation of your remarks, No. 3 of the reply to questions put by "H. G. B.," in the September 19th number of the Photographic News.

After thirty years practice in giving lessons in drawing and painting, and in rooms as variously lighted as the residences entered, I am quite prepared to say that a *front* light will never produce a pleasing effect, any more than light falling particularly from the top will do it. It will be easy for anyone, however uninstructed in art, to satisfy themselves, at the cost of a shilling or two, laid out in the purchase of a moderate sized plaster bust, and placing it where the sitter should be, and trying it in various positions, lighting it in various ways, and occasionally hanging a white blind or sheet at a little distance from the shaded side, to give reflection. It is a pity, with such easy means at disposal, that so much uncertainty should prevail. In a paper I read on the subject, when a member of the Greenwich Photographic Society, I illustrated what I am now advancing, by shading in chalk, on a large scale, a ball, a cube, and a cylinder, in three characters of light and shade, viz., *front*, *top*, and side-front light; and it required no other confirmation than comparing one with the other, to show that the light falling on the side-front, at the angle mentioned, was the most pleasing, as well as the most effective.

I hope I have been sufficiently plain in what I have written, for, in pity to the bewildered, I would do all I can to help them; and as I think, if one can make himself understood, the *less* verbose the better, I will conclude, hoping the subject will be satisfactorily determined by each one for himself.—Yours truly,

Buchanan Smith.

*Blackheath Park.*

[We cordially endorse the advice of our correspondent. Let readers try the experiment for themselves. Wherever the attempt is at all practicable, no matter whether in chemistry or art, our advice is: make the experiment, and inform yourselves of the result. But remember, that in matters of art, the eye wants educating. The eye can only see that it brings with it the power to see. But this is a reason for perseverance, careful observation, and art culture; not for indifference or despair.—Ed.]

## PHOTOGRAPHIC DELINEATION OF MICROSCOPIC OBJECTS.

BY GEORGE S. BRADY, M.R.C.S.*

To be able to produce with rapidity and faithfulness representations of such objects and phenomena as are visible in the field of the microscope, is a matter of great importance to the labourer in almost every branch of natural science. Some observers are content to discard all adventitious aid, and to draw from the microscope in the same way as they would from an unmagnified object, relying for success on their own skill as draughtsmen. But though this method

* From the *Intellectual Observer.*

when well practised gives results, perhaps more spirited and life-like—more artistic in short—than any mere camera drawing can do; it is evident that the skill required is greater than can be brought to bear by the greater number of microscopists, and, moreover, in the best case it offers no unquestionable guarantee of faithfulness. To obviate these difficulties, to lighten the labour on the one hand, and to ensure perfect accuracy, at least of outline, on the other, the instruments in common use are the camera lucida of Wollaston and the steel disc of Sömmering. These are adapted to the eye-piece of the microscope, and by throwing the image down on to the table, so that its outline may be easily traced on a sheet of paper, they offer very great advantages. But even with these appliances, when the object to be drawn is very elaborate in its details, the labour involved is great, and in the case of living organisms their movements are a source of great perplexity, as an unlucky twitch of a limb may in a moment render useless the work perhaps of hours. Photography of course very early suggested itself as the remedy for all these hindrances, and a very encouraging amount of success attended the first attempts which were made in this direction. Mr. Shadbolt, many years ago, published, in the *Microscopical Society's Journal*, one or two very good photographs of microscopic objects, with an account of the process which he adopted, but it does not appear that any great practical results have followed so auspicious a beginning. For a long time, indeed, the cumbrousness of photographic appliances was a sufficient bar to any general use of them. In the midst of microscopic investigation, to have to busy oneself with preparing sensitive plates, and going through the whole processes of exposure, development, and fixing, was more than could be tolerated; but now that iodized plates can be kept always ready for use, and after exposure may be left any length of time for development, there is very little to be urged as to the *unhandiness* of the process, which is indeed exceedingly simple.

The body of the microscope being brought to the horizontal position must be inserted into the front of an ordinary portrait camera, from which the lens has been previously removed. In the absence of a special adapter, the aperture round the tube must be stuffed with some convenient material so as to exclude light. The image of the object is then to be accurately focussed on the ground-glass by means of the ordinary coarse and fine adjustment-screws of the microscope.* After focussing, however, it will be found necessary to make a trifling alteration in the adjustment, for the object-glasses being made with an "over-correction," in order to compensate for the "under-correction" of the eye-piece, their visual and chemical foci do not correspond; and thus the actinic rays are brought to a focus slightly beyond the visual rays. On this account the object-glass will need a certain amount of depression varying with the power, and the higher the power the less alteration will be required; usually, with a quarter of an inch objective, the chemical and optical foci are so nearly coincident, that the difference may be overlooked in practice. The amount of depression required for each lens can only be ascertained by repeated experiment, but the following data which apply to my own object-glasses (Powell and Leland's) may be taken as an approximation. The one inch glass requires a depression amounting to one turn and a half of the fine adjustment screw (about one seventy-fifth of an inch). The half inch requires about half a turn of the same screw.

The most satisfactory illumination is a strong sunlight, reflected directly upon the object by the concave mirror. Light reflected from a white cloud opposite the sun, will indeed answer the purpose, but the time of exposure is necessarily greatly increased, and the impression, when obtained, is much inferior in point of brilliancy and distinctness.

The "collodion" process is doubtless the best that can be used for microscopic purposes. Indeed, if the direct sunbeam be employed as the illuminating agent, no good result can be obtained with a less sensitive material, for the situation of the image on the prepared plate is continually altering with the altering position of the sun. The time of exposure must differ considerably according to the intensity of the illumination, the medium in which the object is mounted, and the nature of the object itself. When using the direct rays of the sun I have generally found from fifteen to forty-five seconds sufficient for a collodion negative.

Recent discoveries, by means of which sensitive plates may be constantly kept ready for use, have, as previously stated, removed one great impediment to the prosecution of microscopic photography. The point to which attention should now be directed, is the attainment of some simple method of artificial illumination. The illuminating agents now in common use are all greatly deficient in actinic power; and though photographs have been taken by their light, they are practically unavailable. It is evidently impossible that this application of photography should become at all general so long as it is entirely dependent on a brilliant sunlight, or on such agents as the electric or oxyhydrogen light, but if some easily produced flame, rich in actinic rays, could be devised, then we might reasonably look for a very extensive development of this branch of the art. It could then be practised in all weathers, and at all hours, and there are few objects which could not be represented successfully by its means.

* It is not the aim of this paper to explain the details of ordinary photographic manipulation. For information on these points, the reader must consult some one of the numerous manuals of photography.

## CURE FOR A FOGGY BATH.

BY F. B. GAGE.

[We repeat the following, which appeared in *Humphrey's Journal* some time ago, because we have been repeatedly asked to give the details of this method of purifying a disordered bath]

Put the foggy solution into a strong bottle, about three times larger than the bulk of the solution; then pulverise and add pure bi-carbonate of soda, until the silver is all precipitated to the bottom, in the form of carbonate of silver. If there is any acid in the solution, the soda must be added with caution, (stirring mean while, with a glass rod), as the soda will dissolve "fuming," and boil up and run over to your loss. After you have added soda until the silver is all precipitated,* fill the bottle with soft water, stir it up thoroughly with the glass rod, then let the precipitate settle. When it has done so, pour off the water, as closely as you can, without letting any of the precipitate escape.

Repeat this six or eight times, so as to be sure of washing off all the free soda. Now drain off all the water as closely as possible.

It would be well to use distilled water for the last washing, or the kind that you intend to make your bath with. After having drained it as closely as possible, proceed to add chemically pure nitric acid, to dissolve the precipitate, add it stirring with the glass rod at the same time, and with some caution, as it will fume strongly; continue to add until the precipitate is nearly, *but not quite, all dissolved.*

The solution at this point of the proceedings will probably be opaque and almost inky-black. This need not cause any alarm, as it will filter out clean and pure. Then take a quantity of clean cotton in your hand, hold it under water and squeeze and work it in your hand until it is thoroughly saturated, then press out the superabundance of water, put it into a funnel and filter the solution through it, test it with the hydrometer, and add water until it is of the right strength, wash your funnel, and put in some clear cotton, filter it again thoroughly, and it is right for a negative bath. For positives, it is only necessary to add one drop of nitric acid, chemically pure, to each three ounces of the solution. Baths for negatives treated in this way work decidedly clearer, better, and quicker than in any way I have ever tried. It also gives better delineations in positives. The experimenter, by this method, will be astonished at the amount of black or green matter that will be found in the funnel after filtering the first time, and will be able to see what fogged his pictures.

* Add the soda until you are sure the silver is all thrown down. Any excess of soda will be carried off in the subsequent washings, and will do no harm.

There are some points of importance to be attended to in this process. They are these:—

1st. That the bi-carbonate of soda be pure.

2nd. That the resulting precipitate be well washed, to free it from all soda that is not absorbed and combined with the silver.

3rd. That the precipitate be *not all dissolved* before it is filtered. If this part is not attended to, you will lose your labour. The theory of this is, that the *organic matter* in the bath is *soluble in acid* and cannot be filtered out while the bath is acid. There need be but very little precipitate left in, as the least amount undissolved will leave the bath perfectly neutral.

## ON THE SENSIBILITY OF IODIDE OF SILVER.

BY M. MC. A. GAUDIN.

Having resolved to study the German language, in order to be able to translate the valuable articles on Photography which appear in that language, the first chapter which I endeavoured to decipher was that published by Mr. Sutton, "On the Sensibility of Iodide of Silver;" and the attention I was compelled to give to it forced me to examine into the matter, and induced me to reply to his statements.

According to M. Monckhoven and Mr. Sutton, iodide of silver, by itself, is entirely insensible to light, while nitrate of silver, on the contrary, is very sensitive by itself, and a combination of the two will give the maximum of sensibility. I do not believe this theory to be true; and as the subject deserves examination, I, in my turn, proceed to discuss it.

First, I maintain that pure nitrate of silver, that is, free from organic matter, is insensible to light. Everyone may have remarked that this salt, kept for many years in a white glass bottle, invariably retains its purity, and that if, in some cases, it blackens, it is on the surface of the crystals, when the organic matters in the atmosphere have been deposited upon them. If ordinary paper which has imbibed nitrate of silver shows itself very sensitive to light, it is solely the effect of its sizing; for unsized white paper, in the same condition, is insensible. I believe, therefore, that all pains taken to guard this salt of silver from light, either in crystals or in solution, are of no use. Having left a bath of silver uncovered for many months, exposed to the dust, I evaporated it to dryness; after diluting it with water, and filtering it, I found it to possess extraordinary sensibility, and gave me proofs in which the details of a meadow were perfect, and without the direct rays of the sun, for the sun was not yet risen. I mentioned, long ago, these remarkable results.

To prove the insensibility of iodide of silver to light, M. Monckhoven relies upon the persistence of its natural colour. In this respect it is distinguished from the chloride and the bromide, but its transformation exists none the less. I have satisfied myself that there exists three iodides of silver; one white, another bright yellow, and a third of a fawn colour, which is the most sensitive to light.

To prove that the iodide of silver is insensible to light, Mr. Sutton produces it by decomposing nitrate of silver with an excess of iodide of potassium. This is exactly what he ought not to have done, as he must know that iodide of potassium possesses the property of *reducing, in presence of light, the iodide of silver already impressed by it*, even in contact with nitrate of silver; and he even admits, that notwithstanding the most careful washing, he finds some free iodide of potassium, which is inevitable. Experiments thus made can have no value. If it be desired to experiment with iodide of silver thus prepared, the whole of the iodide of potassium must be saturated beforehand, by boiling the washed iodide with a slight excess of acetate or nitrate of lead; then only will all trace of the iodide of potassium have disappeared, and the iodide of silver will be accompanied by a minimum quantity of iodide of lead, forming a body inert under the action of light.

Mr. Sutton has not been happier when he wished to remove the objection so clearly resulting from the effects of the daguerreotype, which for a long time rested exclusively upon the sensibility of iodide of silver alone to the action of light. This process permits, in fact, of our preparing a film composed entirely of iodide of silver, without the intervention of any salt; and this film has always shown itself endowed with sensitiveness. To remove this important objection, Mr. Sutton argues, that the polished silver is black and not white, and consequently, is *oxidized*. This is only a play upon words; the silver plate, transformed into a mirror, has taken, as we say commonly, a black polish; but if we view it reflecting a sheet of paper, it is perfectly white. According to Mr. Sutton, it contains oxide of silver, and this oxide, by intervening during radiation, performs upon the iodide of silver the same office as the nitrate of silver in the actual process; but that cannot be, for it is well known that the free iodine displaces completely the oxygen of the oxide of silver, and this oxide remaining upon the plate, there will remain no trace of the first action of the iodine upon the surface of the polished silver. It is certain, nevertheless, that the iodide produced upon a silver plate is in an exceptional condition, being engendered by a kind of cementation, which establishes a peculiar tension between the atoms; but I have proved the sensibility of iodide of silver in quite another way: by exposing silver foil to the vapour of iodine, it is transformed into semi-transparent pale yellow pellicles. This iodide, rubbed upon paper with a tuft of cotton, adheres to it with the greatest regularity; and if, after having thus prepared a sheet of paper, it is exposed to diffused light under a negative, we may afterwards produce a picture by developing in the usual manner; thus, the iodide of silver is sensitive to light without the intervention of any other compound of silver.

It is true, that in the daguerreotype, and in the case just instanced, the sensibility is very far removed from that which constitutes the basis of photography upon collodion; but it must be remarked, that here we operate upon dry iodide, that is, entirely exempt from water of combination, which is more than can be said of the iodide of wet collodion, or even of that of dry collodion. And, in fact, the intervention of water is supreme in photography, as in the great majority of chemical re-actions of an entirely different order.

This question is important, inasmuch as it connects itself directly with future improvements in collodion. It will be very useful to know if iodide of silver, rigorously deprived of nitrate of silver in excess, is as sensitive as that which is impregnated with the silver bath. Everybody denies it, and the great disproportion in sensibility which manifests itself in dry collodions prepared by different processes, and even by similar processes, which are attributed to the more or less perfect elimination of the nitrate of silver in excess, may rather depend upon the more or less complete impermeability of the collodion to the reducing agent.

The production of iodide of silver with excess of nitrate of silver, which takes place in ordinary practice, is a perfect means of having no earthy or alkaline iodide in excess; for, inasmuch as iodide of potassium, in presence of light, destroys the impression already undergone by an iodide, it is very probable that all the other soluble iodides produce *analogous* effects; that is to say, that if they cannot destroy, in presence of light, an impression already effected, they can at least, by their presence, prevent this impression from being produced. All the solvents of this iodide are in the same position; consequently, chloride of sodium itself, if employed to saturate entirely the nitrate of silver in dry collodion, will not fail to destroy the natural sensibility of the iodide of silver; and also, in a higher degree, do hyposulphite of soda and cyanide of potassium.

Accordingly, the best means, at present, of eliminating the nitrate of silver in excess, to work dry collodion, is a prolonged washing in water; the more perfect the washing, the better the plate will keep; and after all that has been written and tried to increase the sens*ib*ility of collodion, it appears very probable, that it is not so much in leaving free nitrate, as in having a collodion which does not become impenetrable, and transformed, in drying, into a *compact horny* substance. Albumen appears to act in this direction, and also tannin, and the addition of resinous substances; the employment of warm water has the effect of opening the pores of the collodion, and bringing it to a soft or permeable condition.

I conclude that the nitrate of silver is, by itself, insensible to light. We cannot say the same of iodide of silver. Although the presence of nitrate of silver is indispensable to effect the development, nothing has yet proved that the part of the nitrate of silver is the same during exposure in the camera. For my own part, I believe it goes for nothing at that moment, and that we shall soon arrive at knowing how to prepare a dry collodion, without albumen or tannin, as sensitive as wet collodion, by employing means susceptible of softening the collodion, and permitting the nitrate of silver to penetrate it as completely as at the moment of sensitizing.—*La Lumière.*

## Photographic Tourist.

### A PHOTOGRAPHIC TRIP TO THE PITCH LAKE, TRINIDAD.

BY W. TUCKER.

The Island of Trinidad, as yet, is but little known to the non-commercial European world; although from its geographical position and the fertility of its soil, it is one of the most valuable colonies belonging to the British in the West Indies. Commercially, the island is known to produce the finest cocoa for home consumption. Its area is about 2000 square miles, it is well watered and covered with magnificent virgin forest, even to the summit of its mountains, the highest range of which stretches along the whole of the northern coast, being the continuation of a spur from the South American Andes, and separated from them by the narrow mouths (*Bocas*) leading from the Carribean Sea into the Gulf of Paria. Only one eighth of this fine island has been brought into cultivation, although, from its position, it will eventually become one of the principal depots of agriculture and commerce for this part of the world, commanding as it does, the mouths of several rivers, the principal of which is the Orinoco; and a large section of the Venezuellan coast. Not only from its position will it become more known, but its natural products, viz., coal, recently discovered near the surface, valuable timber, and its still more valuable and wonderful—lake of asphalt.

In July 1861 I readily accepted the offer of Mr. C. F Stollmeyer to join him in a trip to the Pitch Lake for a few days. This gentleman is commercially engaged with the lake, and understands its, as yet, discovered uses; and is thoroughly acquainted with everything that is interesting and curious on or about its surface. The trip offering a good opportunity to take a few photographs of this really natural curiosity, I prepared the requisites for taking a few stereo pictures by the wet collodion process. We embarked from Port of Spain on board the steamer *William Burnley*, at 7 a.m., on Saturday, 13th July. This vessel plies daily to and from the next important town in the island (San Fernando), and twice every alternate week past La Brea or Pitch Point.

The steamer on her departure from town, took a southerly direction, coasting along within two miles of the shore, stopping first at Chaguanas, where a boat awaited her, some distance from the land. Several passengers disembarked, and we proceeded. Next called at New Bay, boat waiting as before; here cultivation first appears; up to this the coast is low and covered with forests of mangroves. From this point to San Fernando, sugar estates appear in succession, and present many picturesque spots, from the undulating nature of the land. Before reaching San Fernando, we partook of a hearty breakfast, considerable zest having been given to our usual appetite by the cool morning breeze, and the easy movement of the steamer over the tranquil Gulf of Paria. Arrived at the San Fernando jetty at 10 a. m. The town as seen from the gulf, forms a pretty picture; the houses built on the hill-sides appearing over one another, topped on one side by a Masonic lodge, on another by the hospital, and wholly backed by the Naparmia Hill. On this hill the first trace of asphalt is said to appear. After leaving San Fernando, the coast takes an abrupt turn west; and the low point seen in the distance is our destination. On reaching opposite the Point D'or estate, before reaching the point, a strong smell of pitch is first noticed. We passed over a pitch bank, where a thin scum of petroleum was observed floating on the surface of the water. Rounded point La Brea at about 11 o'clock. Mr. Stollmeyer's boat was in waiting, and we were safely landed on the village beach. Truly, pitch is the prevailing element here—landed on pitch rocks—the beach formed of pitch pebbles—the huts pitch-floored, and, in some cases, pitch-roofed. Pitch roads, and to a stranger, the very atmosphere smells pitchy. La Brea village is about 27 miles south of Port of Spain, in a direct line by water, and consists of about fifty huts, or rather tropical village houses, Roman Catholic church, and police station; and derives its name and importance from the Pitch Lake in its vicinity (Lac du Brea). The inhabitants are mostly fishermen; some cultivate small patches of ground, and raise provisions for their own use, and work for wages as pitch-cutters and boatmen. The principal resident of the village is a negro named Nimrod, who, since the export of pitch, has been Mr. Stollmeyer's foreman and contractor. Point La Brea, a few hundred yards north of the village, is a deposit of pitch, fifteen feet deep, extending over seven or eight acres. Its surface is covered with small trees and shrubs, nourished by the earth formed by the pitch being exposed to the action of the elements, which causes it to lose its oily and carbonaceous nature, and forms earthy matter, the same as that formed in partial combination with the raw asphalt. From this point, and not from the lake, pitch is at present shipped; consequently, a large portion of the point has disappeared. The pitch from the lake is less suitable for shipment in bulk. On the south side of the village, the Paris Asphalt Company have erected works near the beach, where the pitch from the lake is refined for exportation. During the prevalence of northerly winds, a high surf runs on the beach, and makes landing difficult. A few days before our visit, several large boats were wrecked on this spot. We rested in Nimrod's house, in the principal room of which—half shop, half bed-room and parlour—we partook of refreshment, prepared by our host's *married* wife—a fine-looking creole woman. After purchasing at a Chinese shop, eggs, fowls, &c., to complete our provisions, we started in a boat for Mr. S.'s country residence on Point Rouge, about two miles south of La Brea. This was our head-quarters during the sojourn. After leaving the village, the beach regained its sandy appearance, and at Point Boyer we came to the first pitch-nugget, or boulder, projecting into the sea. These continue along the coast, at intervals of twenty or thirty yards, to Point Rouge. The coast, although now covered with fine forest trees, was, some thirty years ago, cultivated sugar estates, all traces of which have now disappeared, and nature resumed her sway even to the producing of goodly trees on the bare pitch-boulders. Point Rouge is a perpendicular cliff, washed by the sea, and formed of different layers of clay, which have undergone the action of subterraneous heat, and become burnt to the consistency of soft brick of a bright red, and, in some places, of a yellow ochre colour. In some of the layers semi-jaspers have been found. We reached the house, which is situate on the top of the point, about one hundred feet above the gulf, at 6 p.m. From this spot we command a splendid view of the opposite coast of Guapo. The stillness of the water in the bay below, formed by the point, recalls to mind the small lakes of Switzerland.

The coast of Guapo (site of the observations taken of the eclipse of the sun on the 31st Dec., 1861), covered with dense forest, where men hardly ever penetrate, present pictures worthy of the best landscape painter, or photographic tourist. A few hundred yards from the land, and in the bay, lies a cluster of peculiar rocks, rising a few feet above the level of the water—formed by a combination of pitch and sand into stone, exceedingly hard. These rocks are at all times covered with numerous pelicans. Early on Monday morning we returned to the village, and my operations commenced with taking a view of the village from Pitch Point; one of the points and another of the village looking towards Point Boyer. Nimrod obtained for us men to take up the requisites for the day to the lake—he condescending to escort us—assuming the command of the party.

The road from the village to the lake is about 1¼ miles long, and has an appearance resembling a flow of pitch the whole length, and certainly favours the popular opinion of an anterior eruption, and overflow of lava from a pitch crater, leading all in one direction, in the form of a broad river, to Point La Brea. This view is not adopted by the Government geologists, who lately made a survey of the island. They regard all the pitch, though identical in its nature with that of the main lake, as independent nodules, or pitch-nuggets.

On the sides of the roads, and on the pitch, high, rank, grasses grow; and every dry season these so-called savannahs are burned off. The earth farmed here is similar to that of the Point La Brea; and produces the cushew and pine-apple, yams and manise in perfection. On reaching the top of a rising bank we enter upon this wonder of nature. The lake now before us, 131 feet above the level of the sea, completely surrounded by forests, contains upwards of 100 acres of asphalt, millions of tons of which is applicable to many useful purposes. To visitors, the first appearance of the lake is disappointing, they generally expect to see something *exceedingly wonderful and curious*, and are surprised to find it only a lake of hard black pitch, which, indeed, they very seldom venture upon, although it is quite hard, and will bear standing upon for several minutes before making an impression. Loaded carts often pass over parts of its surface. From this spot I took a view. Nimrod now informed me that as I wished to cross the lake and retain dry clothing, I must doff my nether garments and wade through the fissures which intersect the lake in all directions. Lady visitors, however, are generally supplied with a plank to form a bridge over the numerous cracks, and which is carried by one of the attendants, and, of course, used by the whole party. This was not used in our case. The probable cause of these cracks or fissures is owing to the gradual evaporation of water, which is in large quantities mixed up with soft pitch, it then contracts, sinks, in the centre, forming convex sides, and meeting at a point two or three feet below, and leaves a basin for rain water, the width of which, on the surface, is from six to twelve feet. In the dry season the water in the smaller crevices evaporates. I tasted the water contained in these fissures, it has a saline acid taste, not altogether disagreeable, and somewhat the taste of mineral water. It has a dark-green hue, but perfectly clear when taken up in a glass, and has been recommended for ablutions to persons deceased of the skin. I observed, in some places, many bubbles rising to the surface of the water. This proceed from gas which blows from small holes below in the pitch. Whilst crossing the lake we passed several several groups of Negro women, almost in a nude state, busily engaged washing clothes in the larger fissures, chanting their wild "*Belle airs*," and keeping time by beating the clothes on the pitch, as they usually do on large stones in the running streams in other parts of the island. My friend managed to keep, but with great difficulty, one of these groups sufficiently still to enable me to take a photograph. Every step on the lake causes a popping sound, from the breaking of some of the numerous gas bubbles formed on the surface. As the weather now looked threatening, we left the lake and proceeded to Point Rouge, overland by the Guapo road, which skirts the lake on the eastern side, and leaves it at the south eastern point. Before leaving, Nimrod had every article used on the lake stowed away in the brush near the road, and covered with the leaves of the wild banana.

(*To be continued.*)

## Correspondence.

### PRINTING DIFFICULTIES.

Sir,—In a former letter I had occasion to remark, that an excess of soda carbonate being added to the toning bath for the purpose of preventing mealiness, is a source of difficulty not easy to overcome. An explanation renders it necessary for a reference once more to be made to the subject of decomposition, produced by the alkaline agent when brought into contact with chloride of gold; and having a few moments of leisure before me, I propose entering somewhat minutely into the chemistry of this interesting, and, to photographers generally, most absorbing topic. My last hastily written letter was intended to meet the requirements of the general reader. I now write for the benefit of those whose tastes lead them to dip beneath the surface of hidden mysteries, effects of which are visible, whilst the causes remain concealed from the eye of a superficial observer.

Chloride of gold, in the symbolic language of chemistry, is stated thus: $Au_2\,Cl_3$; which, in plain English, means, two atoms of gold in combination with three of chlorine. Carbonate of soda is a compound substance, in symbols given thus: $NaO\ CO_2 + {}_{10}HO$; that is to say, an atom of sodium, one of oxygen (that forms plain soda), with carbonic acid one atom, and water 10, in combination, the whole forming the substance known as carbonate of soda. The chlorine introduced with the gold has a great affinity for sodium. In the case before us, oxygen is liberated to make room for the chlorine, whilst the oxygen enters into a new combination with the hydrogen, which most samples of gold in combination with chlorine doubtless contain. The produce of this connection is HO, or water. Now, let us suppose eight or more ounces of water, holding in solution 10 grains of soda carbonate to two grains of chloride of gold; taking it in rough numbers, we have about five equivalents of sodium, ready to unite with an equal number of chlorine, and five parts of common salt, Na Cl, will be produced by this process of decomposition, leaving but one equivalent of chlorine to form, in connection with the gold, a subchloride of that metal. By the addition of more soda, a further demand for chlorine is created, and the gold, deprived of its sustaining power, speedily decomposes. This process of decomposition, where the quantity of gold and soda are well balanced, appears to proceed slowly; and I am strongly inclined to believe, that the agitation (if I may so speak) excited by the disunion, although not perceptible to the eye, exercises a caustic or bleaching influence, that prepares the surface of the paper for the reception of the gold, which, being thus rudely torn asunder from its associate, seeks refuge with the subchloride of silver, access to which has been opened up by the agency of soda, whilst engaged in deadly combat for the possession of the slowly advancing chlorine. Arguments are not wanting to support this somewhat novel view of the subject. If a caustic agent alone could remove the "surface impediments," my theory immediately falls to the ground; but, as I have before observed, a solution of soda, minus gold, cannot accomplish the work. Hydrochloric acid improves, but its action does not produce the marked effect caused by the soda when in contact with gold. Why? because, in the former case, decomposition is effected too rapidly, the hydrogen yielding up chlorine without a struggle, to unite with the liberated oxygen, for which it has a greater preference, as the following symbol may prove. The results of this union and disunion may be rendered thus: $HCl + NaO = HO$ and $Na\,Cl$ (without naming the various atoms, the meaning is this: hydrochloric acid, in contact with soda decomposing, forming water and common salt). We have reason to believe that gold separates from the chlorine more tardily, and if the soda is saturated with chlorine produced from another source, the gold is left untouched. Professor Hyme has proved this fact by his interesting discovery. He has shown, that if, by reason of an excess of soda, a bath refuses to act, although abundantly supplied with gold, by acidifying with hydrochloric acid, and again rendering alkaline with soda, toning proceeds with renewed vigour. How is this change brought about? A large excess of soda rapidly deprives the gold of its chlorine; with but just sufficient of this agent to prevent total decomposition, it remains inert, and when the acid before named is added, it takes its fill of chlorine; but no action ensues, because the sodium is also saturated. Having dismissed its late companions in favour of chlorine, it has now become a new substance, viz., Na Cl. By once more adding soda in sufficient quantity, chlorine again tardily removes from gold, and toning recommences. An objection here suggests itself: if an excess of soda deprives the gold of the greater portion of its chlorine, why does it not at once take possession of the whole? In the first place, the soda loses power in proportion to the quantity of chlorine it has absorbed; the gold, on the contrary, acquires power in proportion to the amount of chlorine it has lost; therefore, as a subchloride, it is enabled to resist, for a considerable time, the power exercised by the remaining small portion of undecomposed soda. But this agent finally proves the conquerer. The gold, released from its last tie, decomposes, and no doctoring can revive its exhausted powers. I shall conclude this part of my subject next week.—Yours respectfully,

A Photographer's Assistant.

## IS MR. J. W. OSBORNE AN INVENTOR OF A PHOTO-LITHOGRAPHIC PROCESS.

Sir,—It may be of interest to you to know how Mr. J. W. Osborne's so-called discovery of a photolithographic process, was received by photographers and others, at Melbourne. As soon as Mr. Osborne announced, by advertisement, his intention to apply for a patent, Mr. G. W. Perry (a highly respected gentleman, and the best photographer in the colony) doubting the originality of the process, went, accompanied by a friend, to the office where the specifications of patents are kept, to learn what Mr. Osborne claimed as his own discovery or invention, intending, if there were sufficient grounds for so doing, to oppose the granting of the patent. They were not allowed to see the specification; and not knowing what Mr. Osborne claimed, they felt that it would be a waste of time and money to oppose him. In due time the patent was granted. Having thus secured the exclusive right to the use of photolithography in the colony of Victoria, Mr. Osborne was still far from satisfied. Backed by his friends, particularly by the Surveyor General, such representations were made to the Government as to induce the Treasurer to put down in the estimates a thousand pounds as a reward or recompense to Mr. Osborne, on account of his (?) great invention of a photolithogrophic process. Mr. Perry again took action, for having then read the specification of Mr. Osborne's patent, he (Mr. Perry) knew that Mr. Osborne's process was the same *in principle* as M. Asser's, of Amsterdam, a notice of which having arrived in the colony *before* Mr. Osborne advertised his intention of applying for a patent, convinced Mr. Perry that M. Asser's *principle* had been adopted by Mr Osborne, and that he was, therefore, not entitled to the honours and rewards of an independent discovery. Mr. Perry wrote to the colonial Treasurer, and to other influential gentlemen, and was the means of having the grant of money delayed, and ultimately of having a Board appointed to enquire into the advantages the public service was likely to derive from photolithography, and, also, into "the merits, originality, and value of Mr. Osborne's invention." Mr. Perry then called a public meeting of photographers, lithographers, and others, which was numerously attended. After hearing a lengthy statement from Mr. Perry, the meeting unanimously resolved that, in its opinion, Mr. Osborne was not an original discoverer, and that the time had come for the formation of a photographic society, in order that photographers in a body might be ready at all times to resist all such false claims to originality as that put forth by Mr. Osborne. Mr. Perry also received full powers to act for the newly-formed society, as he might think fit, in resisting and exposing Mr. Osborne's claims as a discoverer, before the Board. I may remark here, that it is known too well that Government Boards and Commissions are not the best of modes of getting at the truth. They too frequently know at the beginning of their labours what verdict they have to return at the close of them. This Board was no exception, for, ostensibly appointed by the President of the Board of Land Works, but really by the Surveyor General (Mr. Osborne's particular friend and patron), consisted mostly of persons holding Government situations, and others who were more or less predisposed in Mr. Osborne's favour. Of course such a Board reported in Mr. Osborne's favour, and recommended the Government to give him a thousand pounds. The Legislative Assembly, on being told by the Treasurer that Mr. Osborne's process would be the means of saving a large sum annually to the Surveyor-General's department, by Photolithography, at once voted the money—not caring at all whether he was the inventor of the process, or merely the introducer. Mr. Osborne saved the country's money—that was enough for honourable members—he was worthy of reward on that account. In reading the Report of the Board, no one can fail to see by the substance of the questions put to the witnesses for and against Mr. Osborne, that the Board knew they had to return a favourable report. The manner of some of the Board towards some of the witnesses (especially towards Mr. Perry), was at times neither courteous nor civil. Now, sir, as you have the Report before you, I shall not quote much from it. Although I believe it to be impossible to prove *absolutely* that Mr. Osborne is not the original inventor of the Photolithographic process he has patented, yet, on such kind of evidence as has often hung men in the absence of *real* proof (I disclaim any desire to hang Mr. Osborne on any kind of evidence or proof), I think that I can show that there exists strong presumptive proof that he is not the inventor. In all the papers Mr. Osborne has written on the subject of his Patent, and in his evidence before the Board, he has much to say about Mr. Poitevin's process, which differs from his; but of M. Asser's, which is the same in principle as Mr. Osborne's, he says but very little. Indeed, I believe Mr. Osborne kept a profound silence about M. Asser's process, until the sitting of the Board, when being questioned thereupon, he answered in an off-hand sort of way (*vide* question and answer No. 19, of the Report), and said as little as possible. Is it not strange, is it not suspicious, that Mr. Osborne when reviewing in his published papers, what had been done prior to, or contemporaneously with his own discovery, should have omitted all mention of a process, of which Mr. Hardwich says ("Photographic Chemistry," sixth edit., p. 252): it (M. Asser's) "in its essential features resembles that of Mr. Osborne?"

For some months, Mr. Osborne was prosecuting experiments in Photo-galvanography, trying to work out the process from the particulars of it scattered throughout the various journals and books. His endeavours led to no other result than to familiarise him with such experiments, the great value of which he would probably feel on taking up M. Poitevin's Photolithographic processes, for his success therein seems to have been very rapid. It is necessary now to pay particular attention to the dates. Mr. Osborne says, that on the 8th of August 1859, he first turned his attention to Photolithography, and that on the 19th he produced his first result with the *transfer* paper; so that he would have us believe that in *eleven days* he worked out M. Poitevin's processes, found out their great defect, and supplanted them by the invention of the *transfer*, which you are aware is the important part of his process. Quick work, that! He declares positively that the accounts of M. Poitevin's processes did not suggest the idea of a transfer to him. Strange, that Poitevin's processes should suggest the idea of a transfer to others and not to M. Osborne, for the following extract from the Report, will show that another gentleman at Melbourne, did, by Poitevin's processes *and the transfer*, produce a Photolitbograph contemporaneously with Mr. Osborne's first announcing his intention to apply for a patent. Mr. Perry is the gentleman under examination, and he is asked, Question:

"1097. You do not know that Poitevin's processes have been done in the way that Mr. Osborne's process is, that is, taking the picture on bi-chromate of potash paper, and transferring it to the stone—are you aware of that being done? Yes.

"1098. By Poitevin?—By Poitevin's process.

"1099. At what time?—Last year, by Mr. Himan, at the Government railway lithographic office.

"1100. At what time?—About this time last year (early in Sept. 1859), previously to the publication of this patent. I have an impression produced by him, a Coat of Arms. I was in communication with Mr. Himan a short time since, when, in fact, the very subject we are alluding to just now, was brought under discussion. I put the question in such a way, that if there had been any doubt about it, his answer must remove it, for I asked him if he did not coat the stone with gelatine, he said, "No, decidedly not, I produce the impression on the paper, grease it with ink, and *transfer* it to the stone.'"

I know Mr. Himan to be a very respectable man, and that his interest lay rather in making out a case favourable to Mr. Osborne. I saw the coat of arms (which was used on a Government document) which was quite equal to any photolithograph Mr. Osborne had at that time done. Here, then, was a man who had no means of knowing what Mr. Osborne was doing, who had worked out M. Poitevin's processes about the same time, in the same way, and with as successful a result as Mr. Osborne, but with far less means at command, and who had taken the idea of the *transfer* from one of the different published accounts of Poitevin's processes; and yet Mr. Osborne asserts that he did not get the same idea from the same source, but that he invented it! Is it not incredible that two men should be studying the same subject from the same books, and that one of them finds therein all that is required to lead him to success; but the other only finds a part, and has to invent the other and most important part? and invented it so rapidly too! From the foregoing it appears that M. Poitevin's processes really contain or hint at all that was necessary to lead Mr. Himan to do successfully, and in the same way, that which Mr. Osborne patented as his own invention. Although Mr. Himan never claimed the least originality, but openly stated that all his information had been derived from books and journals, yet great merit is due to him for having successfully worked out Poitevin's imperfectly described processes. But I will now quit M. Poitevin, and take up M. Asser.

In the report of Mr. Perry's examination before the Board, you will see that he stated that the first notification of M. Asser's process appeared in one or more of the English journals, of May, 1859; well, the mail that took those journals to Melbourne would be due there about the 8th of August, the very day that Mr. Osborne says he began his photolithographic experience. But most likely the mail was a few days late (it generally is), and that it arrived about the 11th or 12th. Mr. Osborne would then have been 4 or 5 days employed on Poitevin's processes; he had succeeded in printing the negative in lithographic ink, direct on the stone; but as that method would give prints with the right side of the map on the left, and the left on the right, he would be again brought to a standstill. Whilst in that dilemma, just in the nick of time, the May mail from England arrived, bringing the journals containing a notification of the *principle* of M. Asser's *transfer* process. Supposing that Mr. Osborne had not taken the idea of the *transfer* from anything he had read in the accounts of Poitevin's processes (as Mr. Himan did), is it not natural that he would seize upon Asser's idea with avidity, and that he would immediately set about working it out? in which he quickly succeeded, for, on the 19th, just eleven days from his first experiment in photolithography, he says he produced his first result with the *transfer* paper. Bearing the foregoing in mind, is it likely that in *eleven days only* he worked out the best known photolithographic processes, but finding them deficient, that he *promptly invented* a new process, that is generally allowed to be superior to all others. Can you believe it? I can't without positive proof. There are other statements of his equally doubtful; for instance, he says he obtained his first result with the *transfer* on the 19th of August, and yet twelve days afterwards he was still working Poitevin's process of printing direct on to the lithographic stone, for I have seen a map marked in his handwriting as his fortieth experiment, and dated August 31, which was done in this manner, as the sides were reversed, the names of the towns, &c., being backwards. Why should he continue wasting time and materials in experimenting in a useless process for twelve or more days after he had invented the new transfer paper process? The two assertions won't agree. (See question and answer of the Report, 1129.)

I have seen Mr. Osborne twice or thrice, and perhaps should know him again. A photographer at Melbourne for a considerable time used to borrow my photographic books and journals, as I thought for his own perusal, but on asking him to return them two or three times, he said he had lent them to the Surveyor-General, if he had said to Mr. Osborne, it would have been more correct (see Question and Answer, 1327.) When I heard that Mr. Osborne by his patent, would prevent me from using the very same information that he had taken from my books, I did feel some indignation, but that soon passed away, for I had no intention nor desire to enter into Photolithography. Therefore his patent did not interfere with me in the least. No personal feeling can possibly be imputed to me in this matter; it is solely in the cause of truth and justice that I have written this statement. I could have written it before, but I felt it would be unfair to oppose the claims of a man fifteen thousand miles off, who could not reply until months afterwards. But Mr. Osborne's presence in England removes my hesitation. I think I have now laid before you strong presumptive proof of Mr. Osborne not being the inventor of a Photolithographic process. In assigning him a place in the annals of Photolithography in Australia, I should place him in a lower degree, in much the same honourable position that Caxton occupies with respect to Printing, in England, namely, as the practical introducer and improver, but not in the higher position of an inventor.—Melbourne.

P.S.—Mr. Osborne says he sent the first account of his process to England, by the mail, which left Melbourne on the 17th September, 1859, to a Mr. William Dowden, of Cork, hoping to be able to fetter the process with a patent in this country. He heard that Mr. Dowden communicated the discovery to some one, for that gentleman "instantly wrote to me, stating that my process was anticipated, and therefore was not capable of being patented." (See Report, 23 to 27.) Of course, the publication of the *principle* of M. Asser's process, in May, 1859, was a complete *settler* to Mr. Osborne's intentions of taking out a patent in England. Let us be thankful to M. Asser for having saved us from another man's gross selfishness. There is plenty of this latter article scattered throughout the Report. Again, he could not say that Colonel James could not have been acquainted with his (Mr. Osborne's) process at the time Colonel James was conducting his own experiments. Now, I should have thought that the date on which secresy was removed from his specification at Melbourne, would have made him *sure* that Colonel James could *not* have known his (Mr. Osborne's) so-called discovery, unless he would have us infer that the secret passed from his own friend, Mr. Dowden to Colonel James, a most unlikely thing. He also fully believed (this was on the 28th August, 1860), that Colonel James would give up his own process in favour of Mr. Osborne's. (See Report, 110, 111, and 112.)

## Photographic Notes and Queries.

### Preventing the Silver Bath from Discolouring.

Sir,—In last Friday's News, I noticed a paragraph, among the "Answers to Correspondents," about the discolouration of silver printing baths, as to whether one made with common pump water, added to another made with distilled water, would discolour. I find it does *not*. About three months ago, I added 10 ounces of silver solution (90 grs. to the ounce), made with common *hard* water, to 20 ounces of an old printing bath, which was originally made with distilled water, and was of a very deep colour; on mixing, shaking up, and allowing to settle, the whole became quite colourless. After each time of using, I do the same, and the bath is now as clear as when first made.

I cannot understand some parts of Mr. Harmer's paper in your last issue; the mode of printing vignettes with brown paper, and then black paper; if the print is the proper depth at first, why is it to be printed deeper? I cannot make it out at all. Would you or Mr. Harmer kindly help me? for I am very partial to vignetted pictures.—Believe me, sir, yours obediently, W. G. G.

*September 30th*, 1862.

[If you state your difficulty more clearly, we will try to explain, or Mr. Harmer will doubtless be willing to do so. But we do not quite see where your difficulty is, as you state it.—Ed.]

### Cure for Negatives Breaking in the Printing Frame.

Sir,—My method consists in simply cutting off the four corners with a diamond. The plate thus rests in the frame on eight corners instead of four. I have had no broken negative since I adopted this plan. If it has not been published before, it will possibly help some brother photo. D. M. A.

## Talk in the Studio.

Photographic Portraits and Pen-and-Ink Portraits.—It is said that the photographic portrait of Victor Hugo, the celebrated author of *Les Misérables*, is not like the original. Photography is capricious, and sometimes favours most the most worthless subjects. The long beard, it is said, looks rough and spare in the photograph; the hair, which he wore short at that time, gives an unusual character to the head; the face seems without muscular firmness, and the eyes have no brilliancy. The following is the pen-and-ink portrait sketch by M. Theodore Banville, taken at the Brussels banquet:—"The fine head is now in its zenith of expression—when he rose to speak it was magnificent. The hair is longer than in the photographic portrait; its wave is crisp and vivacious, and yet it is as fine as silk, and *d'une blancheur auguste*. But the whiteness inspires admiration rather than respect or veneration, for the determined carriage of the head is expressive of the hardy combatant, who has still many a struggle to encounter. The forehead is fuller and more thoughtful than of old, and the increased prominence of the eyebrows conceals their sparseness, and adds firmness to the general expression. The eyes are full of will and energy, but sometimes assume an expression of tenderness and pity for all that suffers. The complexion, once so pale, has become hale and boldly coloured, and the outline of the face is robust. The winds of the sea, and the snows of the north, and the suns of the south, have left their traces upon it. The nose has assumed a bolder, and, as it were, a kind of imperious character, and the mouth has an expression that is at once that of resignation and joyousness. There is an occasional smile, half *spirituel*, half ironical, seen under the shade of the broad silky moustache, which is still brown, while the beard below is white; the beard itself undulating in fine masses like the beards in ancient sculpture." The sketch is rather elaborate, but there is no doubt that it beats the photograph both in truth and spirit.—*Literary Budget.*

South London Photographic Society.—The open-air meetings of this society were concluded by an excellent dinner at Dulwich, when the Rev. F. F. Statham, M.A., F.G.S., occupied the chair, and Mr. Frank Howard officiated as vice-chairman. Loyal toasts, photographic speeches, fun, and good fellowship prevailed during the evening. From several letters we have received we ascertain that the recommencement of the society's winter session has not been generally known. We would call the attention of members to future meetings, on the second Thursday in each month, until next June, at eight o'clock in the evening. The meetings are held in the City of London College, late Sussex Hall, Leadenhall Street. The address of the secretary, Mr. Alfred Harman, is 3, Albert Cottages, Hill Street, Peckham.

## To Correspondents.

A Blockhead.—If your painting be an original one, and it was not sold before the 29th of last July, you can secure the copyright, which will involve the sole right to photograph it and publish the prints, by registering at Stationers' Hall, which will cost one shilling. See The Photographic News, August 8th and 22nd 2. A picture the same as Landseer's, with the substitution of a stump of a tree in the place of a few stones, is, we fear, simply a colourable imitation. You had better not publish it. 3. We have seen very fair pictures taken with Moule's photogen; but not, of course, equal to those produced by sunlight. 4. If a negative have been sufficiently exposed, and well developed, it may be intensified after fixing, without disadvantage.

E. A. R.—We do not know any builder who devotes himself especially, or exclusively, to building glass-houses. Mr. John Cundall, architect, of Leamington, has given a good deal of attention to the subject, and is, at present, superintending a very perfect structure of the kind for Mr. H. P. Robinson.

Anxious.—The pictures have many good qualities. The tone is very excellent; perhaps a little deeper printing would be an improvement in some instances. In No. 1, 2, and 3, the vignetting is a little too regular and formal. The lighting of No 1 is best; in the others there is a little excess of front light, so that the figures are illuminated too evenly all around. No. 5 is the best lighted figure of those in the new room. 2. For lenses, A. in our judgment.

N. H. Harrison.—We referred to Ponting's usual collodion in recommending the addition of bromide for dry plates. You may safely add a grain to each ounce, and try it. Use, in that case, the bromide of ammonium. If you have time to wait, add it direct to the collodion and agitate well. It will require a few hours to dissolve, and a few more to settle. Or it may be dissolved in the smallest quantity of alcohol, and added in that way. 2. We have not observed much difference in the photographic results of the different bromides. The chief difference is the degree in which they are respectively soluble in alcohol, and also in the effect on the fluidity of the collodion. Cadmium is more apt to make some collodions gelatinous than ammonium. 3. The method of developing we recommended gives great latitude as to exposure. 4. We prefer the bi-lens-[illegible]scopic camera. It will always give the same relief which is pre[illegible] eye in nature. Relief should be secured by some foregroun[illegible] be required. 5. Preliminary coatings do not affect the definiti[illegible] all. 6. We have not tried it, but in damp weather it might be desirable to warm the plates. 7. The collodion we recommended contained iodide of cadmium, as well as iodide of potassium. If a collodion contain iodide of potassium only, and bromide of cadmium be added, at all freely, a precipitate of bromide of potassium is apt to fall, especially if the solvents be very highly rectified. You need not apologize at all for asking advice.

C. J. W.—You may procure a lens which can be used for taking card portraits, and also small landscapes. We cannot recommend a maker by name in these columns. A good one for the purpose you name will probably cost £5 or £6. The method of taking small negatives, and, subsequently enlarging them, is an attractive process, and will, at some time, probably, come into general practice. But there is still room for improvement in it before that time comes. At present you cannot do better for large landscapes than use dry plates. We have not yet tried Mr. Sutton's process, but have seen good results.

Cornish Chough.—We generally use kaolin; but we cannot undertake to say which is the best plan. Some prefer citric acid, some salt. It is somewhat a matter of taste. 2. We do not quite understand what you mean as to paper being greasy. It should not be so, unless it have been handled, which ought never to be done. 3. There is no objection, that we know of, to the use of pure fused silver for the printing bath.

R. Hanks.—The reticulated cracks are probably due to the presence of too much water. The solvents have not been sufficiently rectified. Some samples of pyroxyline also favour the same result. Try keeping the plate longer out of the bath, and letting it set well, before immersion.

Subscriber.—Any unused gold in the toning bath may be thrown down by means of protosulphate of iron. The iron remains in solution, and the gold is thrown down as a dark powder, which may either be sold, or may be redissolved in nitro-muriatic acid and formed into chloride of gold. The silver and gold in the hypo bath may be precipitated with liver of sulphur as we have often described. 2. We cannot give you the recipe of any negative varnish, which we can verify by personal experience as quite perfect.

N.—We are obliged for the hint. We have seen the small picture by Ghémar to which you refer. It is very exquisite. The glass ware in the Zollverein we have not yet examined, but will do so. The tilting dishes or baths of Elliot and Co. we noticed some months ago, before we saw them in the Exhibition. Our attention was drawn to them by Bland and Co., the agents. They are admirable for exciting plates with a small quantity of solution, and, therefore, especially valuable for experimental purposes. Some of our friends use them in the laboratory constantly for wet plates.

J. Peakman.—That to which you affix number 2, by al lmeans.

J. F. N.—We cannot, of course, be answerable for the ability of those who advertise in our columns. The specimen you enclose is unquestionably very poor. We saw, on the other hand, some very fine tinting indeed a few days ago by another advertiser, and on the same terms. We regret, however, that we cannot charge ourselves with the responsibility of either recommending or condemning particular artists. 2. The best light for your glass-room will be a combination of top light and side light. We shall always have pleasure in helping you.

W. G. G.—Mudd, or Brothers, both of St. Ann's Square.

J. Jones.—When the prints require so long a time before they acquire sufficient depth, the activity of the solution may be slightly increased by adding a few drops of a fresh solution of chloride of gold. We have never noticed discoloration at the back, except when the paper had been excited a few days.

Calx—Two cameras may be used for enlarging in the way you describe. The only doubt which exists, in our mind, is as to the suitability of your stereo camera. We fear that it will not extend sufficiently. You have not stated the equivalent focus of your lens; but, suppose it be six inches, then, in order to get a transparent positive the same size, both cameras will require the bodies drawing out to the extent of twelve inches. If your small camera will not allow of the required extension, the only plan will to take an enlarged transparency, and then an enlarged negative of just such proportions as you can.

A Royal Enthusiastic Amateur, Secunderabad.—The black powder precipitated by the iron from your toning bath is finely divided metallic gold, which, by the addition of aqua regia may be converted into chloride of gold. 2. Crystal varnish may be applied to positive prints, or a varnish made by diluting Canada balsam with turpentine. 3. Ordinary spirits of wine, in rather larger proportions may be added to the nitrate bath in place of ether or alcohol. 4. We regret that we cannot with certainty recommend any especial varnish that will not become tacky under the heat of an Indian sun. A coating of albumen or gum arabic, applied before drying the plate will resist its action best. 5. Either of the lenses will answer the purpose, but the latter gives the greatest freedom from distortion.

Joseph Lewis, of 29, Dane Street, Dublin, writes to state that he is not the Joseph Lewis who asked in last weeks News if he might practise a patented invention for his own amusement, and adds that he would consider such amusement to be felony. As the letter we received last week is superscribed with the same address as the present, but in a different handwriting, we are a little puzzled as to the purpose of this complication.

W. D.—The top design is best. Six feet over head opaque, each end opaque, you will then avoid direct front or top light. All the rest, top and both sides, glass. This, with a good arrangement of blinds, will give you a well-lighted room. 2. We have had many complaints of bad varnish lately. We have not tried the diluted white hard carriage varnish, but have heard good accounts of it. We cannot tell you the exact amount of dilution it will require. It is probable that different samples will vary. We will examine the jalap resin. 3. The foggy deposit on the shadows may proceed from a variety of causes, all, or the majority of which are treated of in an article on p. 361 of the present volume.

Philos.—Number 2 on your list, decidedly, so far as our experience and information go.

A Photographer.—We do not know any one in London who enlarges negatives. If you require enlarged prints, we do not, at this moment, remember any one who uses the solar camera in London, but Mr. Sydney Smyth, George-street, Euston Road. There are several houses in London who undertake printing, such as Cundall and Downes, and McLean and Melhuish, Wellings, and others. See our advertisement columns.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 217.—*October* 31, 1862.

## PHOTOGRAPHY AND THE CONTEMPORARY PRESS.

Photographers always read with interest the criticisms of the general press on the productions of their art; and they have, on the whole, reason to be satisfied with the estimate in which it is held. Now and then a truculent outburst of spleen, probably, as it has been suggested, from some gentleman whose counterfeit presentment as produced by the camera is not flattering, does find vent; but on the whole, the press as well as the public, estimate the art with tolerable fairness. A notice of British Photography in the Exhibition which recently appeared in the *Times*, and which we reprint in another column, is for the most part appreciative and satisfactory. There are, it is true, a few errors of omission and commission. Some names are not mentioned which are deserving of high praise, and there are a few blunders: but these are not serious. We have, for instance, the touched specimens of Mr. Mayall, which are so worked up in neutral tint, as to leave scarce any trace of the photograph, set before photographers as standards of excellence to which they should endeavour to attain. Doubtless this class of work answers Mr. Mayall's purpose, and we have nothing to say against it, except that it is not photography, and that Mr. Mayall does not, in exhibiting it, do justice to the really excellent photographs which are thus obliterated in the process of retouching; but we must, nevertheless, protest against pictures which are covered up with pigment, however skilfully applied, being held as models of perfect photography. We have next a somewhat amusing blunder, in which the excellence of the admirable untouched portraits of Williams is regarded as due to his "exquisite method of printing." The printing is, doubtless, exquisite, but without the equally exquisite negatives; it would serve but little purpose. There are in the article one or two other technical errors, but it will, nevertheless, be read with interest and satisfaction.

The *Athenæum*, which has generally been distinguished by its intelligent criticism on photography, is, in a recent notice of the British department at the Exhibition, less than usually appreciative, and, except where it is unjust, more than usually uninteresting and commonplace. The notice presents some such extraordinary specimens of bad writing, that it is a charity to suppose that the matter had been trusted to some incompetent subordinate during his chief's autumnal holiday. Here is a sample in which ill-nature and bad English culminate :—

> Mr. H. P. Robinson illustrates, more completely, perhaps, than anything else can do, the fallacy of expecting a mental operation, such as the results of pictorial art are, from a chemical process. In this case the operator has placed some models (children and others), according to a pictorial arrangement, in the hopes (*sic*) of making a picture. His "Holiday in the Wood" (131), and others here, with their set of portraitures, stiffness, and fixed smiles on the models' faces, are miserably depressing to the spectator. This failure of intention is the more observable, seeing that the operator has taken great pains to obtain a contrary result.

Of course the critic has a right to his opinion on the subject; but we might desire some consistency in that opinion. Now in the same journal, some time ago, we find the same photograph described as "most successful and effective," and as possessing a "sunniness beyond the reach of art." However, let that pass: and let us ask what the critic means by telling us, that "the results of pictorial art are a mental operation?" We fear the mental operation of which this criticism is the result, was not of a character so exalted as it was ill-natured. The bad English and bad humour are "depressing" enough, and the writer should remember, that a stereotyped sneer may be more offensive than even a fixed smile in a model. Mr. Robinson may take heart of grace, however; his work is not entirely bad: Here is another remark in the same article :—

> Mr. H. P. Robinson's "Album Photographs" show exquisite taste in toning, and choice of theme.

Mr. Robinson received the only medal awarded for card pictures. How satisfied he must feel to think that it was due to his "exquisite taste in *toning!*" The article presents some other choice specimens of lucidity in style; for instance :—

> The Earl of Caithness's Snow Scenes (100) are fine and broad in choice of effect, clear and well toned.

Now, what is a "broad choice?" Breadth of effect we can understand, but a broad "choice of effect" puzzles us. A paragraph in a more recent number of the same journal treats Mr. Rejlander with about the same amount of consideration as the above sentences treat Mr. Robinson, as though two of the most artistic members of the photographic guild were selected for especial slight. There is, moreover, an insufferable air of patronage and *knowingness* which is very offensive. Here is the paragraph :—

> Mr. O. G. Rejlander is a good manipulator, and we have sometimes found ourselves able to praise his photographs; but he must be told, in very plain words, that the English public will not tolerate his tricks. He must not try to pass, as portraits of Garibaldi, studies from an artist's model, paid for playing the hero of Marsala at fifteen pence an hour. The "Vision of Aspromonte" now in the shop-windows, is a nuisance. The woman is not an Italian. The man is not Garibaldi. The drapery is indecent, and the composition is bad in taste.

To speak of Rejlander simply as a "good manipulator," is to credit him with skill in one of the very smallest departments of the art, whilst his real excellence is displayed entirely in its highest and most artistic branches. Besides, there is no attempt to pass off the picture as a *portrait* of Garibaldi; nor is Mr. Rejlander, who, in the allegorical sketch alluded to, personates the hero, an artist's model at fifteen pence an hour. We were not aware that the figure representing "Hope" required to be an Italian, nor that there was anything indecent in drapery which loosely, and in ample folds, covers the figure from head to foot. There may be differences of opinion about the taste of the composition, but there can be none as to the bad taste and unnecessary snarling of the criticism.

We are glad to be able before closing to cull from the *Athenæum's* notice one paragraph we can agree with. It is as follows :—

> The folly of touching upon photographs was never more strikingly shown than in Mr. J. E. Mayall's *Portraits* (152), most of which, originally excellent, have been fairly spoilt by handling, that, however careful, is never an improvement to such things, —a fact it requires but a moment's consideration of the nature of a photograph to make palpable to the observer. A bad photograph is not worth keeping, and a good one is infinitely beyond the power of manipulating to improve.

This remark is worth saying, and is well said.

## ON THE CONSTITUTION OF THE DARKENED CHLORIDE OF SILVER.

BY JOHN SPILLER, F.C.S.

In the course of some experiments on the action of phosphorus upon metallic solutions, I was incidentally led to observe a chemical reaction, which appears to throw some light upon the nature of the decomposition effected by the sun's rays on the white chloride of silver. If a current of phosphoretted hydrogen gas be conducted through an aqueous solution of chloride of mercury, there is formed an orange yellow precipitate of somewhat doubtful constitution, but containing the elements phosphorus, chlorine, and mercury, in the proportion required by the formula $PHg_3$, $3\,HgCl$; and described in Gmelin's "Handbook of Chemistry" under the name of "phospho-chloride of mercury." This product having been collected on a filter, and purified by washing, was transferred to a test tube, and acted upon by a neutral solution of nitrate of silver, when the compound immediately became white, and underwent a succession of changes in colour, exactly corresponding to those observed when the white chloride of silver is exposed to sunshine; and by varying the conditions of the experiment—using the silver in larger or smaller amount, and employing a gentle heat—it was possible to control the rapidity of the change, and to produce the slight variations of tint, violet, sometimes tinged with red, at other times with blue, which are constantly noticed in practical photography.

With regard to the chemical changes accompanying this alteration of colour, it is probable that the first action consists merely in the conversion of the chlorine in the yellow mercury compound into white chloride of silver, the mercury at the same time entering into solution; a moment later the reducing action of the phosphorus in the compound begins to be exerted upon the remaining nitrate of silver, the result of which is, that particles of metallic silver are formed, and gradually accumulate within and throughout the entire mass of the white chloride, and to the production of this metallic precipitate is attributed the darkening and general alteration of colour observed during the progress of the experiment. If this explanation of the phenomenon be correct, there is a well sustained analogy in regard to the constitution of the darkened chloride of silver, whether prepared under the reducing action of sunshine, or by the power of reduction originating in the phosphorus contained in the mercury salt employed. In confirmation of this view, it may be stated that the violet substance produced in the manner indicated becomes grey and metallic by treatment with ammonia, hyposulphite of soda, or cyanide of potassium; and with nitric acid and other chemical reagents behaves exactly like the product formerly examined by me, and described in a contribution to the *Philosophical Magazine* for March, 1860.

*Royal Arsenal, Woolwich, October* 28, 1862.

---

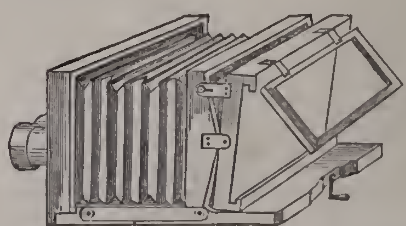
## The International Exhibition.

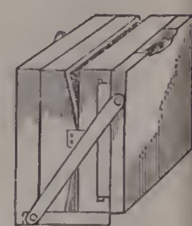
### BRITISH PHOTOGRAPHIC DEPARTMENT.—APPARATUS.

We find the last days of the Exhibition approaching before the amount of time and space at our disposal has allowed us to complete our notices. We now hasten to proceed with further brief remarks on the apparatus.

Messrs. M'Lean, Melhuish, & Co. (3,120), exhibit some excellent samples of the especial apparatus for which they are known, such as the Metal Camera, giving a maximum of rigidity, lightness, and durability; the Universal Objective, &c., &c. Especially deserving of notice is the "Simultaneous Camera," the conception we believe of Lieutenant-Colonel Shakspear. This is a square trunk camera, fitted with four lenses for card portraits. Its specialty consists, however, in the use of a fifth lens which acts as a finder. By the use of such a lens the sensitive plate may be placed *in situ* with the slide drawn, and all ready for exposure at a moment's notice, the right time being ascertained by the aid of the finder, with which the focussing of moving objects is also effected; the finder having, of course, the same focus as the other lenses, and the camera being so arranged that the focussing of one regulates all. For instantaneous effects, andfor portraits of children, &c., the use of this application will be manifest.

Mr. Meagher, Coppice Row, has a very well arranged display of photographic apparatus, chiefly consisting of cabinetwork. Mr. Meagher received his allotment of space at so late a moment that his name does not even find a place in the Catalogue; his contributions, begun and finished within a few days, were moreover placed immediately beneath the skylight, subjected to a heat which we hope apparatus has rarely to withstand even in the tropics. The perfect condition, however, of every article at the present moment illustrates their suitability for the Indian climate, for which a good deal of the apparatus exhibited is designed. A large trunk camera of Spanish mahogany, is a very handsome piece of cabinet work, and would be an ornament to any operating room. It has all the modern appliances of swing back, endless screw, &c., and having a focal range of from 6 inches to 30 inches, is available as an excellent copying camera. A new binocular stereo camera, manufactured by Mr. Meagher, and designed some time ago by ourselves, is exceedingly complete and convenient, and having now used for some time the first one made, we are well satisfied that it forms one of the most complete equipments possible for the amateur or professional photographer. It is arranged so as to be suitable for stereoscopic pictures, or views 7½ inches by 5 inches, having a moveable central partition and extra front. It extends from 3½ inches to 10 inches, admitting thus of the use of stereo lenses of short focus, and a single lens of longer focus for the larger views. In our own we use a Dallmeyer's, No. 1, triple, and a pair of his stereo lenses, which form a very complete equipment. The camera has a bellows body, and hinged tailboard, which folds up and reduces the camera to the smallest compass. It has also swing back, screw focussing adjustment, &c., stereo inner frames, and card portrait inner frames, &c., and when packed up with three double backs in the leather case provided for it, forms a convenient and very portable parcel for the hand. We subjoin an engraving of the camera extended and packed up.





Brass bound and other Kinnear cameras with modern improvements, a folding binocular stereo camera, which may easily be carried in the pocket, *carte de visite* cameras, revolving cabinet stereoscopes, various ornamental cases for stereoscopic slides, water tight baths, stands, printing frames, and various minor matters, complete a very handsome case of photographic cabinet work.

Messrs. Murray & Heath (3,128), have a fine display of apparatus of the very best quality, and designed with much judgment to meet the various wants of photographers. Prominent in their case is a noble copying and enlarging camera, with double bellows body, and extending several feet. It has a screw adjustment working from either end. A graduated scale is attached which enables perfect focus to be obtained for any degree of enlargement with absolute accuracy, without even looking at the ground glass. This is the arrangement described by Mr. Heath at the Photographic Society some months ago, in his paper on enlargement. The multiplicity and excellence of the contributions, and especially of the various clever contrivances, would require much more space to do them full justice than we can spare; we must, therefore, content ourselves with a brief enumeration of some of them. A modified Kinnear bellows camera possesses a strong and simple mode of giving firmness to the front, and the screws, &c., are packed so as to avoid loose pieces; it is very convenient. A neat binocular stereoscopic camera with dark slides for eight dry plates, forms, when packed complete, a rectangular box measuring outside 11 × 9 inches, and weighs only 7½ lbs. A compact camera especially adapted for stereoscopic, *carte de visite*, or single views, 7¼ × 4½ inches. It extends for focussing, from 3½ to 10 inches; a box front forming a sunshade for the lenses. It also possesses an instantaneous shutter. An ingenious registered stereoscope, convex reflector to properly illuminate the whole picture, with rack and pinion adjustment for length of focus. An improved reflecting stereoscope for large pictures, on the principle of Helmholtz's stereotelescope. The pictures are here seen in their true position, instead of reverse, as in the ordinary reflecting stereoscope. Smartt's admirable dark tent which we have before described, and with which almost all photographers are familiar. A useful and clever instrument for varnishing the edges of dry plates to give a uniform edging of varnish. A tripod stand with legs made of cane, giving the utmost degree of tightness compatible with rigidity. A water-tight travelling bath, with the top fitted so as to stand at the back of bath when in use. A new form of field box containing all the requisites for working 12 × 10 plates wet, and measuring only the same as a 12 × 10 dozen plate box. This is a very complete equipment. There is also another field box with some additional appliances. A bellows camera with double swing back, so contrived as to occupy no more space than an ordinary camera. These, with a variety of minor articles, such as plate drainers, collodion pourers, dropping bottles, improved pneumatic holders, &c., complete a very perfect display of apparatus.

T. Ottewill & Co., (3,133) contribute some cameras and other apparatus, of first-rate material and workmanship. These comprise the various requisites for the studio and the field in most general use. Mr. Ottewill has not aimed at novelty in his contributions, but rather exhibits those articles of such approved form and design, and such excellence in quality, as he is well known for producing. Some of theglass dishes which were used years ago, consisting of plate glass fixing into a frame work of wood, and which for many purposes have not been surpassed, are exhibited in this case.

The following notice of the British Photographic Department appeared recently in the *Times*:—

There is scarcely a class in the Exhibition which does not profess, with more or less of truth, to have its peculiar grievances and hardships. Not one, however, has such just grounds forcomplaint as the contributors to Class 14 (photography), and from none have fewer complaints and remonstrances been received. Not that photographers have been at all indifferent to the slights they have received, or the way in which their once superb collection has been treated. As a body they were among the first of the many whom the Commissioners unfortunately managed to offend, and their association, therefore, early withdrew from co-operating in bringing about an exhibition which they knew was not only to be located in a place where few would see it, but exposed to such influences as would destroy their chances of successful competition with their foreign brethren. We would venture to say that only a very small per centage of the visitors to the building ever found by their catalogues that there was such a thing as a photographic collection in the Exhibition, and of this small number only a smaller number still have been tempted to scale the weary flights of stairs which give access to the room where the photographs are almost hidden away.

For the information of those who may wish to see the little that yet remains worth looking at in this collection, we may state that the room is built above the brick tower of the Cromwell-road entrance—a height very nearly equal to the roof of the nave itself. A worse place than this could not possibly be given to it. The glazed roof, for a long time left unscreened, made the heat here during the summer quite unbearable. The heat peeled the pictures off their mounts, cracked and warped their frames, and the glare of the sun's rays ruined the tints of some of the finest specimens exhibited. Add to this that the whole space given was inadequate to the requirements of the class, and that more than half even of this little had to be shared with the maps and school-books of the education class. It must give foreigners (if any penetrate up here) a curious notion of our ideas on education to find that great dolls and cases full of the commonest kinds of children's toys are thought more worthy of exhibition as educational objects than the artistic and beautiful results of one of the most important scientific and chemical discoveries of the age. It may possibly be due to this state of things that the collection is by no means divided or arranged with proper effect, and that the Catalogue is therefore far from being as good an assistant as the purchaser has a right to expect.

Photography in 1851 had no class of its own, and, in fact, was scarcely represented at all except by a few Daguerreotypes and Talbottypes, which, with their apparatus, were exhibited among philosophical instruments. The collodion process, to which is due the development which has taken place since, was then not known. In the present collection all the photographs, with very few exceptions, are by the collodion process, and include, of course, every variety of specimens of the art—large and small portraits, *cartes de visite*, landscape views, instantaneous and otherwise, towns and buildings, stereoscope, and positive transparent pictures on glass.

Compared to what might have been expected, only a small number of portraits are exhibited, and of these collections only three call for any remark; viz., those by Mayall, Williams, and Watkins. Mayall very wisely makes every spectator a judge of his perfection in his art by exhibiting the likenesses of such personages as Lord Palmerston, Earl Derby, Mr. Gladstone, and others whose features are familiar. The art with which he has transferred the features and expressions of these statesmen is something almost marvellous even for photography. The portraits of the two first named peers might be set before all photographers as models of the excellence which they should aim at in such works. Mr. Williams, among untouched photographs, only shows one very well-known face—that of Mr. Gladstone, of which we cannot say more than that it is as good a likeness as that taken by Mr. Mayall, with all the additional advantage derivable from Mr. Williams's exquisite method of printing. His other portraits are chiefly those of less known individuals, but one has only to look at them to see that the same success has been obtained, especially with the likenesses of ladies. Mr. Watkins shows a fine series of portraits of Ristori in all her chief characters. It may be that these have suffered somewhat from exposure, for their printing is scarcely up to the high standard usual with this photographer. In coloured portraits Claudet and Williams are the chief exhibitors in point of merit. Some of the former's enlarged portraits are really wonderful efforts, as are also Williams's photographic portraits painted in oils of the late Primate and the Earl of Malmesbury. Some very admirable likenesses, which can neither be said to belong to the plain nor coloured series, are exhibited by Mr. Eastham. These are taken upon opal glass by the tannin process. Several of these, from the peculiarly soft and delicate tone given by the glass, are exceedingly effective. Caldesi is, as usual, first in his photographs from paintings and miniatures.

Of views and landscapes there is great variety. The place of honour in this class, whether for the wildest mountain scenery, for towns or buildings, for interiors of grand old minsters, likenesses of quaint old country inns or ivy-covered ruins—in short, for perfection in all that relates to out-door photography in its wildest and highest sense, belongs to Francis Bedford. Many landscape artists show in this collection, each of whom in his own peculiar walk may equal what Bedford does of the same kind in that branch, but he stands alone in being the only one who can equal all, no matter how long they may have practised, or how peculiarly their own they may have made any single department of landscape photography.

Let the visitor look at Ludlow Castle, the Feathers Inn Ludlow, Raglan Castle, Tintern Abbey, and the interior of Wells Cathedral, and then turn to such views as the Cheddar

Cliffs, Pont Aberglaslyn, and the Pass of Llanberis. With the wild, solemn, stony grandeur of the latter, with its pile of overhanging cliffs and rugged crags, he fails, as all photographers have and must do, when they cope with mountains of this class; but the Pont Aberglaslyn is wonderfully rendered in all its endless variety of rocks and pines, and the Cheddar Cliffs are equally good.

Mr. Rouch exhibits near these views a beautiful series of instantaneous pictures of Ventnor and Bonchurch, Isle of Wight. These, especially some of the latter on the beach, are exceedingly good in the minute clearness of their detail, from the first ripple of the inshore wave out to the regularly marked, though distant, undulations of the sea in the background. Of the same kind, and equally praiseworthy, are those shown by Mr. Wilson. Than his small view of Land's End there is nothing better in the collection. The picture of the Cambridge at gun exercise, with the smoke wreathing out of her heavy broadside, is also very commendable, and the result, we presume, either of a wonderful piece of good luck or else very carefully timed preparation. Mr. Stephen Thompson shows some remarkably well-developed cathedral pictures; and in the small but very good display made by the Amateur Photographic Association will be found some of an excellence which well-to-do professionals might envy.

Conspicuous among the amateurs, though not exhibitors under the Association, are the pictures of the Earl of Caithness, Lady Jocelyn, Sir A. Macdonald, &c. The Earl exhibits many very good views indeed, one of the best being a snow-scene, though in this, as is usually the case in the effort to secure detail in the light flaky effects of the new fallen snow, all other objects are rendered of an intense blackness. Lady Jocelyn's pictures are conspicuous for their clear detail, though some appear to have been rather over-printed. Messrs. Sidebotham, Robinson, Mudd, and Piper each send a careful selection of their best effects in landscape and other views, all of which are remarkably good, and some, especially those of Mr. Mudd, are not to be surpassed in their way by any in the gallery. Mr. J. Spode also shows some good views of Stoneleigh Park, which make one wish for more of the same kind. Mr. Vernon Heath exhibits very largely, and what is more, everything he shows is of the best description. There are views in this collection which are equal in clearness, softness, and detail to any shown by Bedford himself, and which are as exquisitely printed as the portraits of Williams.

Sir Henry James, the Director-General of the Ordnance Survey, exhibits a process known now as photozincography, by which photographs can be transferred to a zinc plate, and thus reproduced in common printer's ink to any extent. This process is used by the Government in the production of maps and plans, either enlarged or reduced in the camera, and a great saving is effected by it. Specimens of it, including a modification of the process called photopapyrography as well as photolithography, and showing its adaptation to the reproduction of printed matter, engravings, and, above all, MSS. (whether old or modern), are exhibited. For MSS., or for maps and plans, these zincographs are admirably suited, but the more ambitious effort of copying engravings is far less successful.

Mr. Paul Pretsch calls to the aid of photography the electrotype process, producing thus not only the engraved plate, but blocks for surface printing. The prints, however, especially of portraits, no matter how carefully done, are coarse and thick. The minute detail of a photograph, which an electrotype just as faithfully reproduces, is far too much for the action of such a thick, viscid agent as printer's ink. No doubt this obstacle will be overcome in time, but at present it is still a desideratum.

The London Stereoscopic Company, as usual, carry off the palm for stereoscopes. Negretti and Zambra exhibit a very beautiful series of positive transparent pictures on glass. For a long time this process was exclusively practised in France, and it was believed to be the *forte* of French photographers till Negretti and Zambra entered the field and latterly distanced all competitors. Their series includes some of the stereoscopes taken for them by Frith in Egypt and Nubia, and their book published on the antiquities of Egypt, the first of the kind ever issued with stereoscopic illustrations, and the forerunner, we believe, of many valuable works of the same class.

Mr. Breeze also shows some excellent transparent pictures, among which is one of a statue taken by moonlight. Even now, after all the ill-usage the collection has experienced from atmospheric influences, there is still more than enough left to show how well our photographers have maintained their reputation against all comers. Few, however, have visited it without feeling that they deserved better at the hands of the Exhibition authorities than having their works huddled away in such a remote and almost inaccessible corner of the building.

## Critical Notices.

INSTANTANEOUS VIEWS OF LONDON. Photographed by Valentine Blanchard. London: Eliot, Aldermanbury.

The task of photographing London under any circumstances has been one fraught with much difficulty, and hence it has happened, that a city comprising more photographers amongst its inhabitants than any city in the world, has been less photographed, probably, than any other large town. Not for want of objects of interest, as every one who knows what noble old buildings are almost hidden in it can testify. The difficulty has consisted in the soot-begrimed colour of its edifices, the murky atmosphere, and the crowded streets, interfering with the work. If there were difficulties in the way of ordinary photography, from these causes, what must have been the difficulties of instantaneous photography, in which the busiest thoroughfares, in their busiest moments, are portrayed? Despite all these difficulties, and the superadded trouble of a very unfavourable summer, Mr. Blanchard has succeeded in producing some of the best and most interesting instantaneous slides which have yet been issued; pictures which are brilliant, despite the smoky atmosphere, well-defined, in spite of the constant and rapid motion, and well-detailed and soft, in spite of the poor light and instantaneous exposure.

Here is "Oxford Street, looking east," No. 196, an admirably perfect picture from a most telling point of view, forming a most satisfactory composition. Cabs, omnibuses, and pedestrians, in motion, some right in the foreground, all perfectly defined, the one exception being a Hansom cab crossing the field of view, which is slightly blurred. The pace of a pedestrian, even still more in the foreground, was not, however, sufficient to produce a blur, a man wheeling a barrow across the road being perfectly caught with uplifted foot as he proceeds. Here are several views, from different points, of Trafalgar Square, by far the most effective of any we have seen of this noble site. Several views of the Strand, from different points, give an effective idea of this crowded thoroughfare; one with Temple Bar in the distance is especially excellent as a picture, and perfect in its rendering of moving vehicles which are quite in the foreground, whilst the effect of distance, and London atmosphere, are finely rendered. To describe and characterise faithfully every picture before us, would require many columns, but it is sufficient to say, that various views of Westminster, with Westminster Abbey and the Houses of Parliament, of the International Exhibition with its surrounding crowds of people, of St. Martin's le Grand, of the interior of Covent Garden, of the New Cattle Market on a market day, of Regent Street, &c., &c., are all equally good. The especial excellence of this series depends on a combination of causes, in reference to all of which, the very best conditions have been carefully studied and secured. The most effective views have been chosen irrespective of the difficulty of obtaining them; the best point of view, and the most telling period of the day for each subject have also been selected; and whilst, in each case, the most effective view of the place has been seized, regard has been had, in most cases, to the production of pictorial effect besides. As pictures, they are brilliant and harmonious, and as accurate portrayals and valuable souvenirs of the daily street life of the busiest metropolis of the world, we have seen nothing at all to equal them.

We have amongst the series, a few more of our *premiers amours*—Mr. Blanchard's marine and river scenes, which, with their varying effects of water, and shipping, and cloud, to us, possess a charm, that never palls or wearies. Here is "A study of the Thames, looking to London Bridge, with St. Saviour's Church in the distance," not one of the most effective as regards atmospheric effects, but which we commend to the attention of young students of composition, just for the purpose of pointing out how valuable a small sloop in the left hand corner of the picture becomes in completing the composition and balancing the picture. Again, both as a composition, and as a picture of wondrous poetic beauty, let us commend attention to No. 146, "Evening; the Port of London." The tranquil river illumined with an evening sun; forests of masts in the distance; a brig and various barges in the foreground; and, nearer still, portion of the hull, masts, and cordage of a large vessel looming heavy and black against a sky covered with grand clouds, the edges of which, are gilded by the sun, which is descending behind them. The scene is one which rivets and charms, and is well worth studying.

We have said little about the mechanical qualities of the series, as our attention has been absorbed by higher qualities. But we may remark, that the photography is excellent, and that the results here shown, furnish a recommendation, stronger than any words, of the excellence of the bromo-iodized collodion with which they were taken, and which, from announcements in another column, we see Mr. Blanchard now manufactures for the public, as well as for his own use. The tone and general quality of the prints, is not only uniform, but uniformly good, and, altogether, satisfactory.

## THE PHILOSOPHY OF POSITIVE PRINTING UPON ALBUMENIZED PAPER, IN CONTINUATION OF "ALBUMINATE OF SILVER AND THE ABBE PUJO."

BY GEORGE PRICE.

IN my last communication,* I stated that as the Abbé Pujo's paper entitled "Positive Printing on Albumenized Paper," was always spoken of in terms of commendation: I could not but presume that the statements contained in it were generally accepted as *facts;* now the acceptance of an error as a fact, retards the advancement of truth, and when that error relates to a subject that is but little understood, its acceptance as a fact is the more injurious. Having in that communication, shown the fallacy of the Abbé's assertion respecting the proportions of albuminate and chloride of silver, which will result from a given quantity of dry albumen and salting chloride: I will now resume the subject.

However humiliating the confession may be, I think every candid mind must acknowledge, that very little, if anything, is known respecting *one of the most important branches of the art*, viz., "The Philosophy of Positive Printing upon Albumenized Paper." Notwithstanding this ignorance, it seems to be the universal opinion of photographers, that chloride or nitrate of silver, alone, is *incapable* of producing good results, but that a conjunction of both is necessary; and also that the superior vigour and brilliancy of prints upon albumenized paper, is due, not so much to the *glaze* given by the albumen, as to the addition of the compound it forms with nitrate of silver, and which has been termed the *albuminate* of that metal.

As Nature *invariably* works by fixed laws,—there must be a certain proportion which the chloride, albuminate, and nitrate of silver should bear to each other, in order to produce the best results under the same conditions of light, &c., and above or below which proportions, we have no right to expect anything but deteriorated effects. We must readily concede that our knowledge of the exceedingly delicate and complicated actions and reactions which take place in positive printing, is not sufficiently advanced for us to state as a fact, what these proportions ought to be; and thus, we are necessarily compelled to proceed by guess, from not having, as yet, undertaken a series of well conducted experiments with the view of endeavouring to ascertain them.

* Page 494.

As tending *somewhat* to elucidate the intricate subject of "The Philosophy of Positive Printing upon Albumenized Paper," I have analysed the albumenizing formulæ of various photographers, and will now proceed to show the extremely diversified proportions of chloride, albuminate, and nitrate of silver which they offered. To prevent all misunderstanding, I may as well state, that when I use the word albumen, *without any prefix*, white of egg in its normal state is to be understood.

The tables which I shall append, show the percentage of salt to albumen; the proportion of dry albumen to one of the salting chloride; the quantity of *each* in grains which a sheet of paper will contain, after being albumenized and dried; the amount of chloride of silver, albuminate of silver, and free nitrate of silver produced by its being sensitized upon a 70 grain bath; and the quantity of nitrate of silver required to form the chloride and albuminate of silver. A cursory inspection, even of these tables, will, I fear, show such extraordinary diversity, as to fully warrant the sarcasm, that photographers but too generally work by "rule of thumb."

It will easily be understood, that in albumenizing paper, the *proportion* which the salting chloride bears to the dry albumen in the sheet, is not in any way affected by the *water* which is added for dilution, as it merely serves the purpose of causing the paper, when dried, to be surfaced with a greater or lesser proportion of dried chlorided albumen, according to the greater or lesser quantity of it which may be used.

With respect to the percentage of salting chloride to the albumen in the albumenizing moisture; Maxwell Lyte says,* "The proportion of salt added to albumen must not exceed two per cent." As he does not state *what* salt he means, the naming a percentage is of no use whatever; for the same percentage of different chlorides will yield more than double the amount of chlorine in one, to what it will do in another. In his own formula, he uses 5 grains each of chlorides of ammonium and barium to $\frac{3}{4}$ oz. of albumen. Estimating the two chlorides simply as 10 grains, we have $2\frac{7}{9}$ per cent.; estimating the ammonia as its equivalent of barium, we have these 10 grains equal to $16_{18}$ grains, which is $4\frac{53}{96}$ per cent.; estimating the barium as its equivalent of ammonium, we have these 10 grains equal to $7\frac{8}{41}$ grains, which is $1\frac{737}{738}$ per cent. When we bear in mind, that these varying percentages all yield *the same amount of chloride of silver*, we see the futility of naming a percentage without stating the chloride to be employed; and we have here a fair sample of the indefinite manner in which many photographers write what is intended for information, but which, when analysed, affords none at all.

As chloride of ammonium seems to be at present more generally used than any other salt, I have given Maxwell Lyte's percentage in its equivalent of ammonium; and the same whenever barium is used, but when sodium is employed I have given its own percentage.

In the first column of table No. 1, instead of the symbols of the chlorides, I have given So. for *chloride* of sodium, Am. for *chloride* of ammonium, and Ba. for *chloride* of barium; and when in any formula, barium is used, either alone or in conjunction with another chloride, the percentage is reckoned in the equivalent of that which is placed *within a bracket*; the same also when *any two* chlorides are employed.

I have taken as a basis for my calculations, the *maximum* number of minims which the Abbé Pujo states a sheet of paper will take up, viz., 135. For the quantity of salting chloride which surfaces the paper when dried, I have calculated the number of grains contained in the 135 minims, according to the more or less dilution of the albumenizing

* Vol. v. p. 159.

mixture. For the quantity of dry albumen, I have taken Stockhardt as an authority that white of egg leaves on evaporation only *one-eighth* of solid albumen, the rest being water; this being $12\frac{1}{2}$ per cent, and just midway between the statement of others, that good white of egg should yield on an average from 10 to 15 per cent. of dried albumen, is not likely to be far from the truth; therefore, after estimating the quantity of albumen contained in the 135 minims according to its dilution, I take $\frac{1}{8}$th of it for the quantity of dried albumen surfacing the sheet. The proportion of dried albumen to 1 of chloride, is estimated according to the quantity of it which each ounce of albumenizing *mixture* will produce, and the amount of chloride it contains, but when no more than just sufficient water is employed than will dissolve the salting chloride, I have considered the albumen to be *undiluted*.

With respect to table No. 2, which is headed "after sensitizing;" Mr. Spiller states* that a full sized sheet of albumenized paper ($17\frac{1}{2}$ by $22\frac{1}{2}$) abstracts from 48 to 50 grains of silver from a 70 grain bath; I have, therefore, estimated the quantity of nitrate of silver which the dry albumen and salting chloride in the sheet, require to form albuminate and chloride of silver, this, deducted from 50 grains, gives the quantity of free nitrate in the sheet. For estimating the amount of albuminate of silver, I have taken the atomic weight of pure albumen at 8206, and as the albuminate of silver is said to be a compound arising from a chemical combination of albumen with nitrate of silver, I have considered that they combine as elementary substances. If it be objected that 8206 is the atomic weight of *pure* albumen, whereas the dry albumen on the paper, has all the impurities which existed in the white of egg; I reply that for all practical photographic purposes, dry albumen may be considered as pure albumen; and moreover, those *impurities* as they are called, will, in all probability, but little affect the quantity of albuminate of silver which is formed, but rather tend to increase the quantity of chloride of silver; this, however, will be to such an infinitessimal extent, that it may safely be disregarded.

The parts of a grain are given in simple fractions, instead of decimals, as being generally better understood; besides, fractions give the *exact* fractional part, which decimals *seldom* do. I need scarcely, perhaps, state that the construction of these tables has involved much time and trouble.

The following are the various formulæ which I have analysed, and the sources from whence they have been obtained.

Nos. 1 and 2, "Dictionary of Photography," Photographic News, vol. iv. p. 260. "About half an ounce of water to an ounce of albumen will give a very good surface. To each measured ounce of the mixture, add from ten to fifteen grains of chloride of ammonium or chloride of sodium." I have taken the two extremes, No. 1 is ten grains, and No. 2 fifteen grains.

No. 3. Mr. Sutton, *Photographic Notes*, vol. vi. p. 236. Twelve grains of salt to every ounce of albumen, with only sufficient water to dissolve the salt. This is also the proportion in Mr. Fry's formula, Photographic News, vol. v. p. 411.

No. 4. Mr. J. C. Leake, junr., Photographic News, vol. iv. p. 245. "Albumen 15 ounces, water 5 ounces, chloride of ammonium, 300 grains."

No. 5. Mr. Charles A. Long, "Practical Photography," 4th edition, p. 66. Published by Bland and Co. Albumen 6 ounces, water 12 ounces, chloride of barium 270 grains.

No. 6. Mr. Maxwell Lyte, *British Journal Photographic Almanac*, 1862, p. 59. "Albumen $\frac{3}{4}$ths of an ounce, water $\frac{1}{4}$th of an ounce, chloride of ammonium 5 grains, and chloride of barium 5 grains."

No. 7. M. Alco, Photographic News, vol. iv. p. 101. "To every 100 parts of albumen, add 5 parts of a soluble chloride (that of ammonium is best), first dissolving it in as little water as possible."

* Vol. vi. p. 339.

No. 8. Mr. G. Wharton Simpson, "Photographic Teacher, 7th edition, p. 25: published by Squire and Co. Chloride of ammonium 20 grains, water 1 ounce, albumen 1 ounce. These are also the proportions in the formula of Mr. Hardwich, as given in his *last* edition of "Photographic Chemistry."

No. 9. Mr. Edwin Musgrove, Photographic News, vol. v. p. 532. "To each ounce of albumen, add 10 grains of chloride of ammonium or sodium, dissolved in a quarter of an ounce of water."

No. 10. Mr. Hardwich, "Photographic Chemistry," 2nd edition, p. 197. "Chloride of ammonium or pure chloride of sodium 15 grains, water 1 ounce; mix any number of ounces according to the above formula, and add a third part by measure of the whites of new laid eggs." In the following page, Mr. Hardwich proves himself to be *a very bad arithmetician*, by saying. "The solution made according to the directions will contain exactly *ten grains* of salt to the ounce."

No. 11. Mr. T. Cadby Ponting, "Photographic Difficulties," p. 88, published by Bland & Co. "Albumen 15 ounces, water 5 ounces, chloride of ammonium 120 grains."

The following have been kindly furnished me by Mr. G. Wharton Simpson.

No. 12. as being that of Mr. T. R. Williams, 3 parts albumen to 1 part water, with 10 grains of chloride of barium to each ounce of solution.

No. 13, as that of Mr. Hart, (Bourquin's albumenizer.) 7 grains of chloride of ammonium and 1 grain of chloride of sodium to each ounce of albumen.

No. 14, as that of M. Marion, $3\frac{1}{2}$ grains of chloride of ammonium, and $3\frac{1}{2}$ grains of chloride of sodium, to each ounce of albumen.

Without investigating the subject, most persons would be apt to imagine, that as albumen is a complex organic compound, and its atomic weight, therefore, necessarily high: the albuminate of silver must also be high in proportion to the chloride of silver in a sensitized sheet of paper, because the quantity of albumen largely exceeds that of the salting chloride in the albumenizing mixture; but such is not the fact, for the following reason: Taking 8·206 to be its atomic weight, the dried albumen, by conversion into albuminate of silver, is increased by the exceedingly small fraction $\frac{795}{4103}$, whilst the salting chloride, supposing it to be ammonium, by conversion into chloride of silver, is increased two-thirds more than two-fold.

The proportion in which a substance chemically combines with others, *is in inverse proportion to their atomic weights;* therefore, the atomic weight of pure albumen being 136 times and $\frac{21}{30}$ths *higher* than that of chloride of sodium; 151 times and $\frac{26}{27}$ths *higher* than that of chloride of ammonium; and 66 times and $\frac{88}{123}$rds *higher* than that of chloride of barium; any quantity of dried albumen will require 136 times and $\frac{23}{30}$ths *less* nitrate of silver to form albuminate of silver, than an equal quantity of chloride of sodium would require to form chloride of silver; 151 times and $\frac{26}{27}$ths *less* than an equal quantity of chloride of ammonium; and 66 times and $\frac{88}{123}$rds *less* than an equal quantity of chloride of barium. Thus the quantity of nitrate of silver required to form the albuminate of silver, is exceedingly small in proportion to that which is required to form the chloride of silver.

It must be distinctly understood, that I do not give the foregoing tables as affording *exact* estimates of quantities yielded by the formula I have analysed, as, independent of the uncertainty respecting the atomic weight of pure albumen, the more or less absorbtive power of the paper will affect the results; I merely give them for as near an approximation to the truth as the present state of our knowledge will allow us to obtain. However, it is perfectly immaterial whether the atomic weight I have chosen be correct or not, for, supposing it be very wide of the truth, it will only affect the proportions of each *individual* formula; but the disproportion existing between the *different* formulæ will not be affected in any way, as the same error (if error there be) will equally affect them all.

*Tabulated Statements of Results given by the Albumenizing Formulæ of Various Photographers, &c.*

Dr. Löwig says,—"With the proteine substances, it is as yet clearly impossible to determine even an empirical formula with but an approximation to exactness, not alone from the difficulty of obtaining them in a pure form, but also on account of the want of positive compounds of the same, and because of the ease with which they decompose.

From the analytical results presented, the most different formulæ may be calculated with equal probability. In the present state of our knowledge in respect to these bodies, we must abandon every formula by which their atomic constitution is said to be expressed."

If this be true (which I have not the least doubt of), the quantity of albuminate of silver, which is formed by using any particular albumenizing mixture, can only be ascertained by delicate and careful experiment as to the combining power of dried albumen and nitrate of silver.

As an inspection of the tables I have given suggests many important questions, I must defer their consideration to a future time.

## NEW METHOD OF PRINTING.

BY H. COOPER, JUNR.*

Though I hope the time is not far distant when resinized paper will take the place of albumenized, yet there is a good deal to be done in the former process before it can accomplish the wished-for result. I have the honour to lay before you this evening a few specimens of my progress; and if you will kindly listen for a few minutes, I should like to make a few remarks on the different methods I have employed, and on the disadvantages and drawbacks at present existing in the process, as I think that it is a better way to remove them, than to forget the faults, and point out the beauties. A good many faults arise, not exactly from careless manipulation, but from a want of knowledge of the peculiar requirements of the process. For after having gained a little skill in the processes we employ, we are apt to wonder why we cannot succeed all at once with a new one; forgetting, for the moment, all the difficulties and disappointments we met with in that which now appears so easy. For instance, after I had printed some dozens upon resinized paper, I lost numbers by not printing deeply enough. And what is more vexing, after a hard day's printing, and that to all appearances successful, than to see all the batch becoming gradually faint in the toning bath, without a hope of preventing it? The prints should be left in the printing frame till a good part is quite green with bronzing; and even if the lights become faintly tinted, it will be of no consequence, as they will become quite white again in the toning. Many will say, "But that is a great disadvantage; look at the time a print takes to get bronzed like that, why I shall only be able to print one half the number from the same negative!" But you must not forget that the resinized paper is very sensitive to light, and that as many prints may be produced upon it in the day, as upon albumenized paper. I have received many enquiries whether the bath should be acid, neutral, or alkaline. I recommend a strong bath very slightly acid with nitric acid, hardly sufficient to be detected by litmus paper. My reason for this is, that a very unstable salt is formed in the paper, which causes it to decompose very quickly, and the more alkaline the bath, the sooner the paper becomes spoilt. In very warm weather, the paper should be sensitized and fixed within twelve hours; but if it be very cold, twenty-four hours may elapse. I have also received complaints from several, that they have not been able to get warm tones. Sensitizing on an alkaline bath is very apt to render the prints cold, as well as to decompose the paper. The use of a new toning bath is also conducive to blueness. I find that a bath prepared as I recommended in the first instance—acetate of soda and chloride of gold made at least twenty-four hours before using—is the best to obtain rich warm tints. The prints prepared with chloride of cadmium seem much poorer than those prepared with a more soluble chloride such as calcium or magnesium. On this account, 10 grains is about the quantity of chloride of cadmium soluble in alcohol of 8·35°; this is equal to a much less quantity of chloride of sodium, as the chloride of cadmium has a much higher equivalent of its base than sodium. Being moreover locked up in a resin it does not, in my opinion, form as much chloride of silver as it would if it were employed in albumenized paper; by increasing the quantity of chloride of silver in the paper, the prints become much more vigorous. To effect this, I have employed the chloride of calcium and magnesium, which, as I have just remarked, are more soluble in alcohol. There is another advantage over cadmium in the two mentioned chlorides, they are very soluble in water, so that any that remains in the paper undecomposed is easily removed. The prints before you marked calcium and magnesium, contain 15 grains to the ounce. Some of the specimens, as you will see, are salted only on one side. I thought of this method when I was endeavouring to get more vigorous prints; but since using chloride of calcium I have discarded it, as it is much more trouble than the formula I gave at first; but as you may like to know the details, I will shortly run over them. The paper, to begin with, is immersed in a solution of frankincense and mastic, made according to directions given in The Photographic News for October 3rd. with the exception of the chloride, which must be omitted. When the paper is quite dry, float for two minutes or more upon a 15-grain solution of chloride of sodium. Float on the nitrate bath for three to five minutes. After the prints are finished they should be immersed, before mounting, in the resin solution that was used in the first preparation, to thoroughly encase all the particles forming the image. I would recommend that all prints on resinized paper should be immersed in a weak alcoholic solution of mastic. This does not give the prints a varnished appearance; but they will glaze much finer in the rolling. I have found an application of enamel to the prints, after they are mounted and rolled, is very efficacious in giving depth and transparency to the shadows; but it has also a disadvantage of causing the prints to assume a highly glossy appearance, which is highly inartistic and very like albumenized paper; it also slightly injures the whites. The want of transparency and brilliancy is one of the points I would call your attention to in the resinized paper. Another is the peculiar granular appearance of the prints after rolling, particularly *papier Saxe*. The cause of this is obvious—the uneven thickness of the paper. The resin is, as it were, in little hills, and when the paper is passed between the rollers, the tops of them get crushed down and polished, leaving the valleys untouched. With a thin sample of *papier Rive*, that I had some little time back, it was hardly perceptible. From the pieces of prepared paper now before you, you will perceive that *papier Saxe* possesses the granular appearance in the first instance; this also is caused by the uneven texture of the paper. The flat appearance of some of the specimens is owing to the want of depth in the shadows to which I have called your attention. To better show the failings of the process, I have brought a few prints on albumenized paper from the same negatives. As regards printing by development, about which I was very sanguine at first, I have not been able to get on at all well, the proofs being very motley. I have not had much time to devote to this branch of the process, but I hope, during the next few weeks, to resume my experiments in this direction. One fact with regard to it worth mentioning is, that the paper when prepared with a chloride, and a small quantity of a neutral citrate, receives the actinic impression very rapidly, so that it has to be exposed a much less time, than is usually requisite for this method of printing. Only the faintest trace of an image should be visible. I bring two proofs which have been the most successful at present. After removal from the pressure frame they were soaked for one hour in distilled water, and then developed in the following. Saturated solution of gallic acid one ounce, distilled water half ounce, acetic acid 5 drops, and 10 drops of a 30-grain solution of nitrate of silver. They were then toned and fixed in the usual baths. You will not be astonished at the stains on the back, when you hear that upon

* Read at a meeting of the North London Photographic Association, on October 22nd.

removal from the hypo-bath they were placed in a dish of water, separate from the other prints, and, being forgotten, left there for five days. All the specimens are *absolutely untouched*, with the exception of one which is marked. As I could not well understand from writing, how Mr. Harmer produced his prints, I have brought some of the masks used in printing the fancy ones now before you.

I have now only one or two cautions to add. 1. Let the solution of resin for the first preparation of the paper be perfectly clear and bright before using. 2. Whilst preparing the paper, be careful that there are no particles of dust or other matter flying about in the room. 3. Use a strong nitrate bath, and after having sensitized one piece of paper, agitate it before placing another upon it. If this be omitted, the bath will become turbid, for the reasons mentioned by Mr. Lyte. The nitrate of the base of the chloride in the paper will remain upon the surface of the bath, and dissolve out the chloride before it is decomposed. 4. Dry the paper by artificial heat as quickly as possible to prevent the free nitrate, which is so essential to the production of brilliant prints, sinking into the paper. Of course a quarter of an hour or so must elapse before placing it in the printing frame. 5. After printing wash very rapidly, and then soak before toning. 6. Only use the hypo bath for one day, as a curious compound appears to be formed in it, which rapidly eliminates the sulphur. Although I only use my hyposulphite once, I do not waste it; as it is used, I throw it into a large jar, and when sufficient quantity is obtained, I evaporate it down to saturation. I then add a little acetic acid, allow it to stand for twenty-four hours, filter it and employ it for my negatives; I dare say this will appear a great deal of trouble, but I do not find it so in practice. My last caution is, wash the proofs after fixing quickly; the whites will be kept much purer by it. I do not think I have anything else to mention, and I hope that in what I have said I have not proved tedious. But should any questions occur to you, I shall be very happy to give you any information in my power.

## NEW METHOD OF PREPARING IODIDE OF CADMIUM.

BY DR. MONKHOVEN.

Iodide of cadmium is usually prepared by putting into a glass retort, placed on a sand bath, a mixture of water, iodine, and metallic cadmium, at a temperature of 122° Fah. When the liquid becomes colourless, it is a solution of iodide of cadmium, which is next evaporated to crystallization.

The purity of the metal cadmium varies with the source from which it is taken; It is frequently contaminated with copper, zinc, and lead. Frequently iodine is also impure; it often contains chlorine, but in so small a quantity, that the iodide shows scarcely any traces of it. If the iodine be obtained by precipitation, it contains iodides, bromides, and chlorides of potassium, sodium, and magnesium. Iodine is much purer when sublimed, still it always contains a little iron which communicates a light yellow tint to the iodide of cadmium. We know that there are two methods of preparing iodine; the one consists in precipitating it from iodide of potassium by means of chlorine: the other consists in preparing it by sublimation on heating a mixture of iodide of potassium, peroxide of manganese and sulphuric acid.

In commerce, *iodide of potassium is cheaper than the iodine it contains*. It is upon this fact, and upon the ordinary impurities of cadmium, that we have been led to consider another method of preparing this iodide, which possesses the advantage of yielding a very pure iodide of cadmium at a lower price than now obtainable. The method to be followed, is as follows, carefully adopting the proportions given :—

Into a large porcelain retort placed on a sand bath, put 5 parts of water and 1 of sulphuric acid, then throw in the granulated cadmium.

The granulated metal is obtained by heating to a dull red heat a clay crucible, into which one or more ingots of cadmium are placed: care must be taken not to carry the heat too high, else the cadmium will be burned. The crucible is removed with tongs from the fire, and the melted metal poured from a height into a vessel of water: it is thus divided into grains which offer an extended surface to the action of acids. The action of the acid upon the cadmium is very feeble, but if heated, the cadmium is rapidly dissolved. When no more hydrogen gas is disengaged, the liquid is left in contact with the metal several days: the metals less oxidisable than the cadmium, especially the copper, are precipitated. Copper is often found with cadmium: it gives a reddish colour to the iodide, but only when it is completely dry.

Crystals are frequently deposited as the liquid cools; but of these we need take no notice.

If the cadmium be pure, or at least if the solution be colourless, and not bluish, the liquid is filtered while warm, and evaporated in a porcelain capsule.

Upon cooling, white crystals of sulphate of cadmium are formed, whose formula is $CdO, SO^3, 4 HO$. They are put into a funnel, well drained, and dried upon a porous stone covered with a sheet of bibulous paper. To the mother-liquor we add one fourth of its weight, or one seventh of its volume of fresh sulphuric acid, and proceed as before.

On the other hand, we may buy iodide of potassium from the large manufacturers of iodine. This iodide is sufficiently pure; it only contains a little chloride; in 1000 parts of iodide of potassium, about 5 parts of chloride, and 10 of iodide of sodium and of magnesium. These products do not materially alter the purity of the iodide obtained by our new method, and are in so small a quantity, that the iodide of cadmium obtained is as pure, or more so, than that prepared by the old method.

The atomic weight of the two substances is, iodide of potassium, 166·20. Sulphate of cadmium, 116.

$$\begin{array}{rcl} K & = & 39{\cdot}20 \\ I & = & 127{\cdot}00 \\ \hline & & 166{\cdot}20 \end{array} \qquad\qquad \begin{array}{rcl} Cd & = & 56 \\ O^3 & = & 40 \\ S & = & 16 \\ 4\,HO & = & 4 \\ \hline & & 166 \end{array}$$

The relation between 166 and 116, or more simply 83 and 58, enables us to recognise the quantities to be employed in preparing iodide of cadmium.

To this end take 116 parts of dry sulphate of cadmium, and dissolve it in as little boiling water as possible. Then dissolve 116 parts of iodide of potassium in their weight of warm water, and mix the liquids together. A *crystalline* precipitate of sulphate of potassa is immediately formed. (If cold solutions are employed, this precipitate will be pulverulent, and much more difficult to wash.) The mixture is left standing one night; abundant crystal of sulphate of potassa will be found attached to the sides of the vessel. In collecting the liquid, reverse the vessel, allow it to drain, and wash the crystals with a little cold water, to remove the last traces of iodide.

It may be perceived that the reaction is based upon the great solubility of iodide of cadmium, and the insolubility of sulphate of potassa. We have, however, in the liquid, a small quantity of sulphate of potassa, which must be removed; not that this salt can injure the collodion in the least degree, *for it is completely insoluble*, but we must render the product saleable.

To this end the liquid is evaporated to dryness in a flat capsule placed in a stove; the white substance is scraped up with a plate of glass, removed, and placed in a glass receiver. Upon 100 parts of this substance dried, pour 300 parts of ordinary alcohol, boiling; and after shaking it a few minutes to facilitate solution, filter it. Upon cooling, the iodide of cadmium is deposited pure in a crystalline state.

The alcohol is decanted and heated, and will serve for new preparations upon the addition of a little fresh alcohol. In a word, persons familiar with chemistry, will see that the operation is continuous, and that it may be practised, economically, on a large scale.

From 166 parts of iodide of potassium employed we obtain :

$$\begin{aligned} Cd &= 56 \\ I &= 127 \\ \hline &183 \text{ parts of iodide of cadmium.} \end{aligned}$$

We recommend those persons who make this preparation for their own use, to make use of the liquid dried in the stove, but not treated with alcohol. The quantity of sulphate of potassa which is thus mixed with the iodide of cadmium is so small, that it may be neglected in formulæ; and, moreover, the sulphate of potassa is completely insoluble in the liquid of which collodion consists.

The purest cadmium is that of the Vielle Montagne (Belgium). That from Silesia frequently contains copper. The price, in quantities, is 3s. to 4s. per pound; by retail that price is doubled. The price of iodide of potassium varies from 8s. to 9s. per pound. The price of cadmium is about 8s. or 9s. per pound. These prices are much higher when sublimed iodide is employed. When iodide of cadmium is prepared with precipitated iodine, it is always yellow, and contains many impurities.

Bromide of cadmium may be prepared in the same manner; but the old method is preferable, because bromine separates much more readily. We must, however, not omit to observe that bromine as now prepared, almost always, contains much chloride, in the shape of chloride of bromine, a substance which so much resembles bromine, that a chemical analysis is required to detect it. In such case the bromide of cadmium necessarily contains much chloride; but this chloride, somewhat less soluble in alcohol and ether than the bromide, separates at the expiration of a few days.—*Le Moniteur de la Photographie.*

## Proceedings of Societies.

### North London Photographic Association.

The usual monthly meeting of this Association was held on the evening of Wednesday, the 22nd, inst. at Myddelton Hall, Islington, Mr. G. Shadbolt in the chair.

After the usual routine proceedings, the following gentlemen were elected members of the society: Messrs Paigetor, Fisk, Layte, and Whiting.

Mr. G. Dawson then read a paper on the causes of fading in photographs. The chief cause he held to be the action of sulphur, and recommended the very careful washing of prints, and final immersion in salt and water, before toning and fixing, so as to eliminate every trace of free nitrate, because either that salt, or carbonate, or acetate of silver, would decompose the hyposulphite and set up sulphur action. He also endorsed the announcement which recently appeared in our pages, to the effect that silver was to be found in the whites of all albumenized prints, no matter how they had been treated, but expressed a conviction that the compound existing was insensitive to light, and that as yet it was not proved to exercise any detrimental influence on the permanency of the picture.

A conversational discussion followed in reference to the prints which had faded in the International Exhibition; the haste with which many of them had necessarily been prepared being alleged as one of the causes of fading, while such a cause was entirely disallowed by other members.

Mr. Hill said he had been troubled lately with a brown stain frequently occurring at the back of his prints for which he could not assign a cause.

Various suggestions were offered as to the probable cause, such as the use of dirty clips, the action of bits of bibulous paper when placed to assist in drying the excited sheet, touching with fingers which had come in contact with hypo. Mr. Hill did not think that any of the suggestions met his case.

Mr. Seeley asked if maintaining the hypo fixing bath in a decidedly alkaline condition, would not prevent the generation of acid from free nitrate, &c.

Mr. Dawson said that if nitrate, acetate, or carbonate of silver were introduced into the hypo bath, no matter whether it were alkaline or not, decomposition would ensue, and sulphur be liberated. He recommended that all free silver should be at once converted into chloride before toning. It was not important how much salt were used, if care were taken to have plenty.

After some further conversation on the subject, in which the Chairman, Mr, Dawson, Mr. Simpson, Mr. Hill, and Mr. Seeley took part,

The Chairman referred to the allusion made by Mr. Dawson to Mr. Spiller's recent statement in our columns, to the effect that the whites of fixed albumenized prints contained silver, and stated that he (the Chairman) had since corroborated, by experiment, the statement.

Mr. G. Wharton Simpson said, in reference to Mr. Dawson's statement, that the compound of silver and albumen thus left in fixed prints, was not acted upon by light, that he thought the non-sensitiveness was not satisfactorily ascertained. He had recently had an opportunity of examining a number of vignetted albumenized prints, which presented a large surface of white. That part of the whites which had been submitted to the action of strong light, was slightly discoloured, having something of a yellow or creamy tint, without, however, any signs of fading. The portions of the same prints which had been protected by a mount or passe-partout, remained perfectly white. He thought it was probable that this change of colour was, probably, due to the action of light on the trace of a silver compound left in the print.

Mr. Dawson said it was possible that the continued action of a strong light might affect the compound. He had only tried it in a test tube, and with a short exposure.

The Chairman referred to the fact that in some thick plain papers, especially when sized with animal size, he had, on applying the hydrosulphate of ammonia test, found traces of silver.

After some further conversation on the subject,

Mr. H. Cooper, jun., read a communication on "Resinized Paper" (see p. 524). At the conclusion of the paper he exhibited a number of very fine prints, the results of different experiments. Some of these were fine specimens of the effect to be obtained by double printing, and Mr. Cooper gave some explanations of his method of proceeding to produce the various effects. (A paper on the subject, by Mr. Cooper, will appear in our next.)

Mr. Dawson asked if the use of resin gave a better tone than Iceland moss, or Irish moss. Some of the finest tones he had ever seen were produced by these additions to the salting bath.

Mr. Cooper said the resin gave a better tone, and one which he preferred, and it gave more vigour. The prints now exhibited were, many of them, experimental prints, and by no means examples of the best possible results.

The Chairman thought there was not sufficient brilliancy to render it likely that albumenized paper would be superseded.

Mr. Cooper thought that for large prints it might be.

Mr. Hill thought for some subjects the effect was better.

A discussion then followed on the tendency of resins to become yellow.

The Chairman believed that all resins had this tendency.

Mr. Cooper said the specimen of frankincense he had used was perfectly white, and it had been five years in the hands of the retailer. How much longer it had been in wholesale hands he could not say.

Mr. Martin believed that all resins on exposure oxidized and turned yellow.

In answer to a question

Mr. Ross stated that Canada balsam, exposed in a bottle to the sun bleached and became whiter.

Mr. Martin said that, in that case, it was protected from oxidation.

Mr. Dawson said he was afraid that oxidation was a convenient term often applied to effects of the real nature of which we knew nothing.

After some further conversation on the subject,

Mr. Seeley said that he had recently been informed that in the photographic department of the South Kensington Museum they were only using a 30-grain silver bath for printing, and using, at the same time, a paper less freely salted.

Mr. Simpson said the plan had often been proposed and often tried, and, under some circumstances, and with some negatives, it doubtless answered; but as the general experience of photographers it had been found desirable to adhere to the use of stronger baths.

The Chairman said he did not put much faith in anything coming from South Kensington.

Some prints by Messrs. Hill, Fenn, Seeley, and others, and a copy of Col. James's new work on "Photozincography," by Mr. Simpson were then exhibited, and after votes of thanks to Mr. Dawson and Mr. Seeley, the proceedings terminated.

A paper on "Washed Collodion," by Mr. Hislop, was promised for next meeting.

## Correspondence.

### PHOTOLITHOGRAPHY IN VICTORIA.

Sir,—In your journal of Friday last I find an anonymous communication casting a doubt on my originality as inventor of the photolithographic process which bears my name. Had this letter been published in Melbourne, it would be quite unnecessary for me to reply, but under present circumstances I may venture to make a few short statements which will serve to show that your correspondent is in error, and but very partially acquainted with the facts about which he writes.

The only statement of importance contained in "Melbourne's" letter, is one to the effect that I obtained the first idea of my process from M. Asser of Amsterdam. If this were so it would matter very little, for both Col. Sir H. James's method and mine differ quite sufficiently from M. Asser's to entitle them to be regarded as distinct and new. Such, however, was not the case. M. Asser's process was not published in England until some time in December 1859, that is, more than three months after mine had been in active operation at the Survey Office, Melbourne. The notice of it to which reference is made by "Melbourne," appeared in your journal in May 1859, and consisted of the bare statement that M. Asser exhibited certain positives transported to stone in lithographic ink, adding, at the same time, that the specimens were far from perfect. This notice, such as it is, might have come to Melbourne about the period when I began photolithography, but not only did I neither see nor hear of it then, but I have never seen it yet, every exertion of mine while in Melbourne to obtain that copy of the "News" having proved unsuccessful.

At the time I speak of, the "News" was a journal but little known in Melbourne, and I never heard of any person possessing the number in question but Mr. Perry, from whose printed evidence alone I obtained the first knowledge of this early notice of M. Asser's experiments.

The fact is Asser's process was not known or talked of in Melbourne for months after mine had been introduced, and it was assumed by those who thought it right to oppose me, that I had imitated M. Poitevin of Paris, Mr. Perry himself supplying the information which he imagined would be conclusive for that purpose. It was about six months after the date of my patent that the December number of the "News" reached Melbourne, and it was then that attention was directed towards it for the first time.

Be that as it may, the paragraph in question was laid before the Photolithographic Board appointed by Government, as well as before another tribunal to which I shall presently refer, and supported by all the arguments which a strong feeling of opposition to me could suggest, notwithstanding which the Report was distinct in pronouncing my originality.

"Melbourne" informs you that Mr. Perry called a public meeting of photographers and others. He founded the Photographic Society of Victoria; became its president; set forth, in a lengthy statement, the evil I had done, and received power at that meeting to act for them, and to resist and expose, as he might think fit, my claims as an inventor. This was actually the fact (and I am sorry to say, that it is almost the only statement in "Melbourne's" letter, respecting which he and I do not differ); but what subsequently took place he has not told, and this information it is incumbent on me to supply.

Before I joined the society, notice was given, and a motion carried at the next meeting, in virtue of which a committee of seven members, elected by *ballot*, was appointed to enquire into my claims to originality, the utility of my process, &c. Pending the enquiry undertaken by these gentlemen, a motion, of which notice had been duly given, was carried at an ordinary meeting, to the effect that Mr. Perry's address, referred to by "Melbourne," as having been delivered at the formation of the society, should be cancelled and expunged from the minutes (upon which it had been entered verbatim), as unbecoming and personal.

Finally, after about six months' work, the committee brought up their report, having examined every witness who had, or thought he had, any information calculated to throw light upon the subject of their labours. Their *unanimous* decision was, that my process was *perfectly original, and superior to any other then known.* At a very full meeting of the society, this report was adopted without a dissentient voice, the president, who was in the chair, having the good sense to remain silent on that occasion, and a copy of it was ordered to be sent to the leading journals, in which it appeared, more or less fully, on the following morning (4th of June, 1861).

I shall abstain from disproving other erroneous insinuations to be found in "Melbourne's" letter, not from want of the material or the power to do so, but because I believe that enough has been said, and that to go into the subject at greater length would involve explanations of a nature hardly interesting to the readers of your Journal.—I am, Sir, yours obediently,

J. W. Osborne.

28, *Lorrimore Square, Kennington Park, S.*, 27 *Oct.*, 1862.

[We shall have a few observations on this subject in our next.—Ed.]

## Photographic Notes and Queries.

### Clouds in Landscapes.

Dear Sir,—Can you inform me of a good illustrated work on clouds? Artistic photographers have, we know, been long dissatisfied with universally white skies in landscapes. Now, their desire to increase artistic effect, has produced an *attempt* at something better than a mere shaded sky, and though the results are, with few exceptions, any thing but satisfactory, they indicate a growing ambition for something better, which should be encouraged. Our exhibitions show how imperfect and unsatisfactory are the various mechanical dodges for putting in skies. Good effects may be obtained where the sky in the negative is transparent enough to print through, which is now the rule instead of the exception, by printing clouds upon it.

But to render such effects truthfully, and in harmony with the rest of the picture, the eye and hand of the painter are required, and even that is insufficient unless the painter be also a photographer, or at least accustomed to study negatives with a view to their printing capacities.

My impression, is that it would be a great inducement to amateurs to practise their hands at putting in these aërial touches, if they had some good examples of clouds to study from, drawn, or what would be better, photographed from nature.

I imagine a series of sky and cloud studies, taken during the photographic hours, showing their characteristic forms, more common combinations, with the disposition of light and shade upon them, as seen by the eye of the camera, though too often obliterated on the plate, could be obtained of a moderate size, say with Dallmeyer's small triplet, by many of our photographers, those living by the sea-side having the advantage as regards site, in the course of twelve months.

I am persuaded, moreover, that there are some amongst us who could make such a work of very general interest, by adding valuable information, artistic and meteorological, to the illustrations; and even render it remunerative in a commercial point of view, if that were a consideration.

In hopes that these, not altogether disinterested suggestions, may be supported by others feeling the same want, I beg the favour of your publishing this letter, and remain, yours truly,

G. S. Penny.

*Cheltenham, October 25th*, 1862.

[We do not at this moment remember any work solely devoted to clouds. There are some excellent hints on the subject, with illustrations, in a little work on marine painting, by Carmichael, published by Winsor and Newton, a little work which will well repay perusal. We should strongly recommend, however, photographers to make their own cloud studies.

There are many occasions when magnificent studies of clouds might be obtained by almost every operator, even when nothing else could be secured. A good work on clouds, well illustrated with photographs, would be one of the most interesting and valuable which could be produced.—Ed.]

### Carbonate of Soda in the Toning Bath.

Dear Sir,—Not long ago you stated that having admired the productions of a certain gentleman, whose name I have forgotten, you solicited his formula, which he complied with; the toning bath was carbonate of soda. I had never tried this, but then made up one, and to my taste the result was far preferable to acetate. Judge then to my surprise on reading the account of the South London Society's meeting the following sentence of Mr. Leake's: "As to the use of carbonate of soda in the toning bath, he believed it to be the worst thing which could be used."

I have enclosed a few cartes toned by carbonate; what is your opinion of them? if the colour is not good, I will leave it off; but it is what my connection prefer; if, therefore, it is injurious, I should feel glad if you will state in what particular, that I may be on my guard. There are numbers of photographers who have gone back to carbonate, and who are no doubt surprised at Mr. Leake's opinion. I am not aware if the latter gentleman is an amateur or a professional photographer; but it is to the former the latter are indebted for very valuable information; to the professional photographer, whose business requires the aid of several assistants, certain formulæ are absolutely necessary; and when he has one he likes and pleases others also, how vexatious to hear others whom he relies upon, so conflicting in their opinions! I should, therefore, feel obliged if any of your numerous readers will state, whether they have found carbonate decidedly injurious in the toning bath.

Hoping you will excuse the liberty of requesting space for this, I am, dear sir, yours truly, E. T. Brooks.

*Newbury, October* 18th, 1862.

[Nothing could be better or more brilliant than the tone of the prints received.—Ed.]

### Photogenic Properties of Walnut Rind.

Sir,—Having discovered that the extract of the outside, or green shell, of walnuts has some of the properties of nitrate of silver, and having no convenience of testing it further, I now leave it to your numerous readers to bring it into some use in photography. If you think this communication worth your notice, you will oblige yours truly, J. W. H., *Herbalist*.

*Canterbury, October* 11, 1862.

P.S. If a piece of plain paper is placed in the extracts, in the dark room, it will not change its appearance until exposed to the light, when it will turn the paper quite as dark as the nitrate of silver solution.

[That the juices of walnuts and various other fruits and vegetables are darkened by light is well known; but this property has not been utilized hitherto.—Ed.]

## Talk in the Studio.

Silvery White Positives.—The following solution for developing positives, was given by Mr. Dawson at a recent North London meeting, with the statement that it gave glass positives of exquisite silvery whiteness. Three ounces of protosulphate of iron dissolved in one pint of water; to this was added three ounces of a saturated solution of gallic acid, and then nitric acid was added drop by drop until the solution was clear. It might be placed in a dipping bath and used over and over again.

Photographic Society.—The first meeting of the London Photographic Society for the winter session. will be held at King's College on Tuesday evening next at 8 o'clock.

Coloured Portraiture.—The rage for card portraiture, which at one time threatened to drive all other phases of photography out of the market, has not quite ruined the colourists, the majority of whom, are, we believe very busy. We had recently submitted to our notice some very good colouring in oil, by Messrs. Sawyer and Co. of Newcastle-on-Tyne, in which the photography and painting were alike excellent.

## To Correspondents.

*** Agents or subscribers having copies of the following numbers of the present volume, which they can spare, will confer a favour by forwarding them to the office, where they will be exchanged or bought at full price: Nos. 174, 187, and 196 to 203.

W. D.—The sample of resin received is jalap resin, but, not *purified* jalap resin. By passing an alcoholic solution of the resin sent through animal charcoal, you will deprive it of its colouring matter, consisting of one-tenth of its weight. The purified resin of jalap, or the jalapine of the pharmacopœia, is nearly colourless, very hard; but slightly hygrometric; that is, when powdered the (common form in which it is kept) it absorbs damp, and sticks together in clots, a circumstance which would appear to militate somewhat against its suitability for a negative varnish. The testimony of an able photographer and good chemist like Maxwell Lyte, to the effect that it is good, renders it well worthy of a trial. We fear that it will be too expensive for common use. Jalap is at the present time worth six shillings a pound, and it only contains one-seventh of resin, and this loses in one-tenth in purifying, so that the purified resin will cost six or seven shillings an ounce. This price need not, however, be a barrier to its use for negatives, should it prove really valuable for the purpose, as one ounce of the resin will probably serve for ten or twelve ounces of varnish.

A New Subscriber.—The best distinct work on the Talbotype process was that of Mr. Sutton, which is now out of print. Some of the best articles on the subject to which we can refer you, will be found in our first volume, especially on pp. 38 and 51, in Nos. 4 and 5; an excellent article on the subject by Dr. Diamond, who is a most skilful calotypist, appears in the first volume of the *Photographic Journal*. Turner's paper is generally preferred. Either floating or spreading with a glass rod may be used; the latter is preferred by many. Some spread the solutions with a Buckle's brush.

R. H.—We believe you will have reason to be satisfied with the action of a battery of 60 double plates of carbonized iron and zinc, arranged in three or more troughs in the same manner as the Cruikshank's battery of copper and zinc. The plates may be about 5 by 8 inches, those of zinc being about twice the thickness of the iron plates, and soldered to the latter. The existing fluid is a saturated solution of salt with one-third of sulphuric acid. The distance between the compound plates is about half-an-inch. It is preferable to amalgamate with mercury the zinc side of the compound plate, to reduce the consumption of metal.

R. F., Kennington.—Many of the matts and preservers used for photographs are imported from America. Those of English make are manufactured in Birmingham.

J. C. J.—It is probable that the clearing up process used by Mr. Osborne will not be so applicable to dry plates as to wet ones, but you may easily try on a plate of small importance. If your negatives are already intensified, but not sufficiently so, you may obtain a great accession of density by applying a solution of iodine and iodide of potassium, and then, after washing, apply pyro and silver; or by simply applying a solution of bichloride of mercury, followed by hydro-sulphate of ammonia. The latter is the method used in the Ordnance Map Office at Southampton, and it is always applied after the plates have been dried.

J. C. Wilson.—One thickness of yellow calico will not be sufficient to keep out actinic rays. The colourless sheet glass has rarely a surface sufficiently perfect to enable good collodion positives to be taken thereon.

James Ramage.—It is unnecessary to discuss the differences, or identity, between photolithography and photozincography; the inventors of the respective processes known by these names regard them as similar, but not the same; but anyone is, of course, at liberty to regard them as the same. Mr. Fox Talbot at one time tried to prove that the collodion process and calotype process were the same. They both consist of a film made from vegetable fibre, as a vehicle for iodide of silver, which receives a latent image from the action of light, and is developed by a reducing agent. But the nature of the film is slightly different, and the results widely different. Your statement on the coagulation of dry albumen by heat is perfectly correct. The fact has been more than once pointed out in our pages, that dried albumen cannot be so coagulated. But we go further than you, and affirm that it cannot be coagulated by alcohol, ether, &c. &c., as generally supposed. One of our correspondents, Mr. Price, pointed out, twelve months ago, that heat would coagulate dry albumen. Since then we have carried the experiments further, and have, at the present time, an article and another communication on the subject waiting for insertion, when we can find space. In reference to Mr. Osborne's experience, there would appear, at first sight, a discrepancy; but his explanation, in answer to a query on the subject, in a recent conversation we had with him was to this effect: the dry albumen is not coagulated by heat; it is not until the albumen has again become softened and moistened by absorbing water, that the heat coagulates it as he describes. That it is coagulated then, he says, is a simple fact.

Seaside.—It will be a very simple plan for each reader desiring his Almanac bound, to get it done for himself. Or it would be found a good plan to have made a reading case of the right size, which might be used for each year's issue. However, your suggestion shall be submitted to the publisher.

L. F.—It is frequently expedient, before proceeding to intensify a negative after it is dry, to varnish the edges. This materially lessens the chance of losing the film. Some collodions require this treatment, as there is great danger otherwise of losing the negative by the splitting of the film. Experience alone can teach you when to make the application, and when to neglect it.

Farringdon Lane.—We will examine the glass, and report thereon.

A large number of communications, in type, are compelled to stand over until our next, amongst which are articles on the following subjects:—"Double or Fancy Printing," by H. Cooper, jun.; "The Theory of Alkaline Gold Toning;" "A New Photolithographic Process;" "The Influence of Chlorides and Bromides in Collodion;" Report of the Marseilles Photographic Society," "Photographic Chemicals," "Ammonia as a Developing Agent," and several others.

All Letters, Works for Review, and other Communications for the Editor, should be addressed to 32, Paternoster-Row.

Vol. VI. No. 218.—*November* 7, 1862.

## HALF TONE IN PHOTOLITHOGRAPHS.

The great desideratum in photolithography has hitherto been, *half-tone*, or gradation of tint, without lines or points, hatching or stippling. This has not been satisfactorily produced by any of the known processes. Col. Sir Henry James has just announced it as an accomplished fact. The following letter appeared in the *Times* of Tuesday last.—

"PHOTOZINCOGRAPHY.

"Sir,—I shall be glad to be allowed to announce, through the columns of the *Times*, that we have accidently made the important discovery that the paper prepared with bichromate of potash and gum only, as described in the work on Photozincography lately published by Messrs. Longman and Co., will, if only kept for a week or ten days in the dark, yield half tones, and consequently give us lithographic or zincographic prints from any photograph.

"I enclose two copies of a print produced in this manner, which, although not so perfect as we can undoubtedly make them, will prove that the object so long sought after has now been attained.—I am, Sir, your obedient servant,

"Henry James, Colonel Royal Engineers.

"*Ordnance Survey Office, Southampton, November* 3.

Mr. Pouncey in a letter, an extract from which we give in another column,* announces similar progress, and challenges examination at the meeting of the Photographic Society. On Tuesday night he was present at the meeting, and produced several specimens, some of which were photographs, and others impressions in printers' ink, produced direct from the negative. They were not received very favourably by the meeting, a spirit of distrust on the one hand, and of antagonism on the other, seemed to prevail, and a general dissent from Mr. Pouncey's assumption, that they were equal to silver prints, was expressed.

For our own part, we feel some difficulty in expressing an opinion on the subject. We have every disposition to do Mr. Pouncey full justice, and we feel the difficulty of doing so without having silver prints from the same negatives, with which to compare his specimens. They were certainly not good pictures, and appeared to be from somewhat hard negatives; but they certainly possessed some gradation. His proposition to take any negative submitted to him, and produce from it a photolithograph, or an image in any printer's ink, which might be brought for the purpose, as perfect in half tone as any silver print from the same negative, certainly appears a fair one, and should, we think, be met. On the other hand, we would suggest to Mr. Pouncey, and we do it with every wish to avoid offence, since he holds the conviction that he has been ill-used by photographic societies and the photographic press, that, however unintentionally, he seemed to approach the meeting in a spirit of antagonism, and that begets antagonism. That, moreover, he contravened the custom of the society in wishing it to deal with a secret, or, at least, an unrevealed process. And that, further, he had, on former occasions—with the best of motives it might be—issued prints as the result of one process, which were produced by another; and this circumstance might explain some distrust. We believe, however, from what we saw of his results, on Tuesday night, that they are worthy of further attention, and shall be glad to see more of them. And, personally, we may add that we shall have pleasure in allowing him to select a portrait negative, from which to produce a photolithograph for comparison with a silver print.

In an interview with Mr. Maxwell Lyte, just before his return to France, he entrusted us with a verbal description of a method, by which he suggests that half tone might be produced in photolithographs. It was his wish that we should have described it to the meeting on Tuesday night; but the protracted character of the meeting, and a severe hoarseness under which we were labouring, induced us to publish it in this form.

Mr. Lyte proposes to obtain half tone in photolithographs, by taking advantage of the method adopted by M. Fargier, for obtaining half tone in carbon prints. M. Fargier, believing that the difficulty in obtaining half tone in carbon prints arose from the fact, that the action of light upon a film of gelatine, bichromate of potash, and carbon, failed to penetrate in the half tones much further than the surface, and that thus, when the sheet of paper on which it was spread was immersed in water, the unaltered gelatine underneath the half tones being readily washed away, carries off at the same time, the slightly altered portions which really constitute the half tones. The deep shadows being more perfectly acted upon by light, are, of course, less soluble, and remain. The result is a black and white picture, without proper gradation. The same fact will obtain in photolithography from the same causes.

M. Fargier overcomes the difficulty, by applying the film of gelatine, carbon, and bichromate of potash to glass, and after exposure, coating the surface with collodion. The film is then removed from the glass, and the unaltered gelatine, &c., dissolved. By this mode of manipulating, the delicate half tones are preserved, and remain attached to the collodion, instead of being, as in the other method, washed away.

Mr. Lyte proposes to apply this method to photolithography, with this difference to suit the case: instead of carbon in combination with gelatine and bichromate of potash, he proposes to use powdered bitumen, and after treating the plate after M. Fargier's method, he would transfer the image so obtained, to a lithographic stone, by the aid of heat. The half tone which is produced by this treatment, in a carbon print, would, he conceives, be thus secured on the lithographic stone.

So far as the production of a properly graduated image on the stone is concerned, this method appears very promising. How far prints with half tone would be obtained, remains to be tried. The experiment is certainly well worthy of attention.

## ON THE PERCEPTION OF RELIEF.

BY PROFESSOR EDWIN EMERSON, OF TROY UNIVERSITY.

[We have been favoured by the courtesy of Professor Emerson, and the prompt and courteous attention of Professor Silliman to his request, for early proofs of the following interesting contribution, which appears in *Silliman's American Journal* for November. We especially commend attention to it as a lucid explanation, of the not generally understood difference between two distinct phenomena, relief and perspective.—Ed. Photo. News.]

"Professor Cima of Turin, has sent us the description (says the editor of the *Cosmos*) of a stereoscopic experiment which is not without interest. He takes the picture of a front view of a human head, executed either in crayon or lithograph or copper plate, and which is three or four centimetres in height; this he cuts into two parts along a line which coincides with the vertical axis of the nose; he takes one of these halves in each

* An article in type, on "Photozincography, Photolithography, and Photoengraving, and their Inventors," is compelled to stand over until the next week.

hand, and holding them in the same perpendicular plane, he brings them before the eyes, at a distance which is less than that of distinct vision; he then allows the optic axes to converge, and thus causes the drawings to approach or recede until he is able to see two pictures of each half, and until the two middle ones overlap, so that they make the impression of an entire countenance. When one makes this experiment for the first time, says Professor Cima, he will see with astonishment that the full face which is produced by the overlapping of the two halves makes, in a high degree, the impression of a solid body; the half tones melt and mix together as in a modelled figure; the nose rises well from the face; the eyebrows, lips and chin stand out very well; and the entire figure raises itself from the ground upon which it is drawn, and assumes, in a remarkable degree, a living expression. The necessary distance of the two half-pictures from each other and also the proper distance from the eyes of the observer for the production of the greatest effect, can only be ascertained by trial. The more steadily one gazes at the pictures, the more the sensation of relief is strengthened."*

The foregoing extract from The *Cosmos* has been reproduced in *Pogg. Annalen*, bd. cii. p. 319; in *Il Nuovo Cimento*, vi, 185; in *Die Theorie de. Schens und räsmlichhen Vorstellen*, bei Dr. Cornelius Halle, 1861; and in *Monographie du Stereoscope*, par Blanchére, Paris, 1862. Seemingly endorsed by such a high authority as Moigno, the alleged fact passes through scientific treatises unquestioned, and is now apparently regarded as established. We consider it, therefore, important to refute the conclusions involved in the experiment as described by Professor Cima, and at the same time point out some analogous mistakes as to the perception of relief.

When the experiment of Professor Cima is carefully performed and analyzed, it will be found that the right eye sees the right half of the middle picture, and the left eye the left half, now as these two dissimilar masses are not superposed upon each other, as in the case with the dissimilar complementary figures in ordinary vision, but are merely joined together at the line passing through the centre of the resultant picture, it is evident that if such an effect is realized as that "the nose rises well from the face," or that there is any "sensation of relief," we have here an experiment which refutes the established theory of binocular vision, and leaves the effects of the stereoscope without any adequate explanation.

The fact is, however, that in Professor Cima's experiment there is no real perception of relief. All that is really seen is the perspective, which is mistaken for relief or solidity. To prove this—let the observer, while looking at the two half-pictures in the mode alleged to produce the effect of solidity, close one eye, the right for instance, the right half of the picture dissappears, but the left retains exactly the same appearance it had before; it loses no appearance of solidity, simply because it had none. Or, let the observer join the two halves together, and closely and continuously observe them with one eye, the effect will be the same as in Professor Cima's experiment. Or, to vary the test, take a *single* photographic picture, for instance, the right-hand side of a stereograph, cut it in two by a vertical line through the centre, and place the halves the proper distance apart in a stereoscope, so as to unite them readily into a whole, the same effect, claimed by Professor Cima to be a sensation of relief, will be observed: that it is not relief will be most manifest by comparing it with a stereograph of the same scene.

But the reader will very naturally inquire—"How did Professor Cima, and those who have unquestioningly quoted his experiment, fall into this error with regard to the presence of relief?" This reasonable question we will endeavour now to answer.

The ability to perceive relief, or solidity, is a natural one. To those who have the proper use of their eyes, and can walk, it is an intuitive faculty, we cannot help seeing solidity, where it exists, if we try, no more than we can help hearing sounds or seeing colours. The common idea that this faculty is the *result* of experience, and is, therefore, acquired, is opposed by the whole analogy of our being. The infant does not learn to hear; it hears, intuitively, if it is a perfect child, but learns as it grows to know what it hears: it feels a blow, but may be too young and feeble to know what that blow is; so it has but to open its eyes and the scene enters, it is painted properly and instantaneously upon the retina, but it may require a long education before the child will have an intelligent idea of what it sees; indeed, it may go through life and never be able to give more than *one* name to a great variety of very different colors, such as red, vermilion, scarlet, orange and crimson. It is unphilosophical to confound a faculty with its use. We have the natural faculty of seeing solidity; but the acuteness with which it is employed, depends greatly upon the intelligent attention with which it is exercised.

It is no answer to this to say that we can analyse the optical conditions upon which the perception of relief depends. This has been splendidly done by Wheatstone, Dove, and others, and is beautifully illustrated by the stereoscope; but this has no necessary connection with the question before us. When I say—we hear intuitively—it is nothing, in the way of refutation, to explain to me the acoustic conditions upon which hearing depends, or to assert that Mozart had no intuitive perception of melody and harmony, because the laws are fixed by which a melody ought to proceed, and harmony, to be such, must be according to the formula of Thorough Bass, whereas the child Mozart could not know all this. So with the matter in question; all men see solidity who have the proper use of their eyes; very few, indeed, know how it is effected, or are able to distinguish acutely between the perception of binocular relief and the perception of mere perspective, or the appearance of distance without relief.

The perception of *relief* depends upon the angle formed by the rays which proceed from any object of sight to the right and left eyes respectively; the larger this angle the more relief is apparent, provided the eyes can unite the dissimilar images; but when, by reason of distance, this angle becomes nothing, practically, and the rays are parallel as they enter the eyes, relief vanishes.

The perception of the *perspective* depends upon very different conditions, such as the direction of the lines that compose a view, the light and shade, the apparent size, the tint, &c.

When we consider the matter, it is not surprising that these two modes of perception should often be confounded. True relief diminishes so gradually, and melts so gently away, leaving perspective entirely master of the field, that the essential difference between them is likely to be lost sight of. That this is the case may be shown by the following examples:—

It requires a series of very careful experiments to determine how far, under ordinary conditions, we can perceive relief. Experiments of my own lead me to believe that the distance is under three hundred yards. The only reason a good painting, whose foreground is represented as it appears at the distance of two or three hundred yards, is not a complete illusion when seen under favourable conditions, is, that we can change our point of view; and motion to one side or the other will impart the idea of relief in nature, but as there is no relief, properly so called, in a painting, as soon as we shift the point of view, we detect this, and the illusion is at an end. Hence, paintings ought to be observed by one eye and from one point of view, to obtain the maximum effect. Hence, also, stereographs of scenes which lie at a distance of over three hundred yards from the observer, will give no stereoscopic effect, will not *give the impression* we are able to get with our eyes, assisted by our capacity to move from one point of view to another; they ought, therefore, to be photographed from stations more or less distant from each other, but always exceeding considerably the distance between the eyes.

Persons *not accustomed* to experimenting with the stereoscope cannot distinguish readily between stereoscopic and pseudoscopic effect; they are also constantly imposed upon by views which have no stereoscopic effect whatever; I have repeatedly mounted two identical or right-eye views of the same scene, side by side, as though they were right and left eye views, and have never failed to get the verdict that they exhibited stereoscopic effect; which was impossible of course. Not only are ordinary observers thus mistaken, but they constantly manifest an opposite peculiarity, being unable to see the greatest relief when it is exhibited in an unusual manner. In *Das Stereoscop*, C. G. Ruete, Leipsig, 1860, Dove's illustration of this point is republished in such a way as to destroy the object in view, showing that this commentator had not a fine perception of relief.

A remarkable instance of the uncertainty attending the perception or non-perception of stereoscopic relief, even in cases where we might suppose there could be no want of knowledge, is shown by the controversy now going on in Europe over the *Chimenti Pictures*. Sir David Brewster thinks he has in these

* *Cosmos*, vol. ii, pp. 353.

pictures a specimen of real stereoscopic drawings, produced about the middle of the 17th century: and this opinion is endorsed by Professor Tait, Professor M'Donald, and others, in decided terms. I have made a careful examination of the photographs of these pictures, and the truth is, that the trifling stereoscopic and pseudoscopic qualities about them are evidently accidental. To prove this let any one execute a pen-and-ink sketch; and then let him make as perfect a copy of it as he can without careful measurements; now place these two drawings in the stereoscope, and you get the same kind of effect seen in the Chimenti drawings, and for the same reason; the drawings will vary more or less from each other; all that is necessary then to impose upon ordinary eyes, is to find out which way the sum of the variations preponderates; mount the drawings accordingly, and, *mirabile dictu!* you have produced a stereoscopic picture (the pseudoscopic portion being overlooked) drawn by hand; you have done that very thing that Sir David Brewster has repeatedly declared was quite beyond human skill! If Professor Wheatstone gets no heavier blow than this, his fame as a discoverer is secure.

As a further confirmation of our views, we may point to the fact that but few persons can properly locate the optical position of reflections from curved surfaces, and, in particular, the images from concave surfaces.

During the last year or two large assemblages have been drawn together in our principal cities, to see with delight the effects produced by what is called *the Stereopticon*, which is merely another name for a Magic-lantern of good quality, with *one* side of a glass stereograph for a slide. Nearly all in these large assemblages have agreed in believing that they saw, what they were told they saw, excellent stereoscopic effect in the single picture which alone is exhibited. The truth is, they made the popular mistake; they saw nothing but perspective.

Stereoscopic effect on a large scale may be obtained by exhibiting the right and left pictures of a glass view side by side, by the magic-lantern, and then uniting the magnified pictures by means of prisms. This I have recently demonstrated by experiment. The idea was also suggested some years ago, by Dr. Wolcott Gibbs, to Mr. Pike, of New York, but not put to the test.

We conclude, then, from the foregoing—

1. That Professor Cima's experiment is only another instance showing how easily we can mistake one thing for another, and induce others to do the same.

2. That intuitive perception of relief may be indefinitely increased in degree by exercise; showing that this sense follows the same law under which we employ our other faculties.

## PHOTOGRAPHIC CHEMICALS:

### THEIR MANUFACTURE, ADULTERATION AND ANALYSIS.

*Lime Salts* (continued).—Caustic lime, both in the anhydrous and slaked condition, is in constant requisition in the photographic and chemical laboratory. Slaked lime is invaluable for neutralizing acids, which may have been accidentally spilt on the floor. Where these corrosive liquids are much in use it is scarcely possible to avoid such occurrences; sometimes in these cases the very worst thing that the operator can do is to mop it up with a cloth, and in many cases throwing cold water upon it will also do more harm than good. A handful of slaked lime should be sprinkled over the spot; this will immediately unite with the acid and convert it into a harmless non-corrosive compound. Now will be the time to add water, when the whole may be mopped up without the slightest danger to the operator or his clothes. The acid neutralizing properties of lime are likewise valuable in other directions, owing to this, its powers as a disinfectant are very great. Sulphuretted hydrogen and other deleterious gases are rapidly absorbed by it, and hence the value of slaked lime in sewers, drains, &c., where foul smells are generated. The dark room in which most of the photographic manipulations are conducted should always have the walls lime whitened; the layer of carbonate of lime which in this manner is exposed over such a large surface to the atmosphere of the room, tends very greatly to purify it from acid vapours, and keep it in some measure free from close and disagreeable odours. The coating should be renewed at least once a year.

In its unslaked caustic state, lime is likewise of great value. In the hydrated state lime is of value on account of its property of absorbing and neutralizing acids; in the anhydrous state it is chiefly of use on account of the great affinity which it possesses for water. A most ingenious and valuable application of this property has been made by Mr. Spiller; he uses it to dry the atmosphere in which sensitive photographic papers or plates are kept; their preservative properties being in this manner increased tenfold. The apparatus is very simple, and may easily be constructed out of an old box. The only requisites are that the lid should fit tight upon it, so as practically to exclude air. The box may be of any size, but the most convenient dimensions are such that a full sized sheet of paper may be laid in it without folding. A tray about six inches deep is placed at the bottom of the box, and a sheet of perforated zinc placed on the top of the tray; the latter is now half filled with lumps of good well burnt quick-lime, and the perforated zinc is covered with one or two sheets of white blotting paper. Upon closing the box the lime will rapidly absorb all the aqueous vapour, carbonic acid, sulphuretted hydrogen, and other impurities which might have been present in the atmosphere, and will protect any photographic paper or plates which may be put in the upper part of the box from contact with anything likely to be injurious. With a well fitting lid this drying box may form part of the furniture of the dark-room, and foggy dark days on which no other work can be done, may be conveniently employed in replenishing it with paper. If a box of this sort is to be made by a carpenter, a few alterations, as originally proposed by Mr. Spiller, will be advisable, although for general purposes, where little expense is desired, the above arrangement answers very well. Thus the portion containing the lime may be constructed as a drawer, which may be removed from the outside so as to avoid the possibility of lime dust getting into the upper part where the paper is held. It would also be a convenience if that part which is to hold the paper were likewise constructed drawer fashion, proper communication being effected between the lime and the paper by means of holes in the sides and bottom.

Lime water is sometimes of value as a cheap and convenient substitute for potash or soda in neutralizing acid liquids. The hypo-bath may thus be neutralized with it when old and acid, and it has this advantage over potash and soda, that the sulphate of lime formed is practically insoluble in water, and may be removed by filtration. Moreover, in neutralizing acid liquids with lime water, a slight excess of lime may be added without danger, as upon exposure to the air the surplus lime absorbs carbonic acid, and becomes precipitated as an insoluble carbonate; these two properties render lime water a very valuable substitute in many cases for the alkalies proper. Lime water is also usefully applicable to another purpose which may be of interest to the photographer. Formed into an emulsion with oil, it is one of the best materials for cleaning polished brass, &c. About half fill a corked bottle with lime water, and then add a little less than the same quantity of olive oil; shake them violently together, and the mixture will instantly assume the consistency of thick cream, it will keep any length of time, and merely requires to be well rubbed on to the metal with a woollen cloth, and afterwards polished with a leather. We may also mention in passing, that this same mixture of olive oil and lime water is the very best application for a severe scald or burn; it is to be thickly spread on a piece of cotton wadding, and laid on the injured part, when it removes the pain at once, and causes the part to heal very rapidly.

When caustic lime is exposed to the air in the hydrated condition, it quickly absorbs carbonic acid, and becomes converted into *carbonate of lime.* This compound is too well known for us to give its physical properties; the native compound occurs in several different forms, as chalk, marble, calc-spar, arragonite, &c. These are all identical, chemically with one another, although they differ greatly in their physical characteristics. Marble is constantly employed in the laboratory as a source of carbonic acid, and chalk is also frequently used for neutralizing acids. In this respect it may be used in the same manner, and for the same purposes as caustic lime, but it has the objection not possessed by this latter, of liberating an immense volume of carbonic acid during the operation. *Prepared chalk* is an artificial variety of carbonate of lime formed by precipitating a solution of chloride of calcium with carbonate of soda, and well washing the product; it is a fine white amorphous powder, the uses of which are too well known to require further allusion. Carbonate of lime, although insoluble in water by itself, becomes soluble when an additional quantity of carbonic acid is present. For instance, if lime water be placed in a glass, and a current of carbonic acid be passed through it, the first effect will be to precipitate carbonate of lime. As the gas continues to pass the precipitated carbonate gradually redissolves, and ultimately a clear solution is obtained of what is commonly, but erroneously, termed bi-carbonate of lime. The lime in this liquid is held in solution by the additional quantity of carbonic acid, and if the latter is removed in any way will be immediately precipitated. Hard water, especially in chalky districts, is a solution of this kind. By boiling, the extra equivalent of carbonic acid is driven off, and the carbonate of lime is precipitated. This occasions a deposit in culinary and other vessels in which such hard water is heated, and as the deposition takes place somewhat gradually, the carbonate of lime, especially if a little sulphate is present at the same time, is precipitated in the form of a hard stoney mass, which sometimes accumulates an inch or more in thickness. Many have been the plans proposed for remedying this inconvenience, but none of them are sufficiently effectual or practicable on the small scale to be of any use.

## The International Exhibition.

### BRITISH PHOTOGRAPHIC DEPARTMENT.—APPARATUS.

Mr. T. Ross (3149), displays a large collection of excellent apparatus and lenses, prominent amongst which, are several complete panoramic equipments for pictures of different sizes, together with some fine specimens illustrating the angle which can be obtained. We have so frequently described the panoramic lens and its products, that it is unnecessary to refer further to the subject here, except to remark, that no attention is spared in obtaining perfect results, every fresh set we see exhibiting some improvement in the mechanical appliances, curved porcelain baths instead of gutta percha, being the latest addition we have noticed.

There is a large collection of lenses of almost every kind, for every purpose. Portrait lenses, with two different back combinations, the object being to secure, when required, the utmost perfection of definition, with its accompanying curvature of field; or a flatter field with slight sacrifice of definition. There are also a variety of lenses for *cartes de visite* of different focal lengths, so as to suit glass rooms of various sizes. Portrait lenses of various sizes, of large aperture in relation to focus, suitable for instantaneous effects, of various kinds. Orthographic, triplet, single, stereographic, and other lenses for portraits and views, complete this part of the display. Mr. Ross also adopts the plan to which we have before referred, of illustrating the qualities of his lenses, by a number of very fine specimens produced by their aid, thus affording practical evidence of their excellance.

In addition to lenses, Mr. Ross exhibits some excellent cameras for different purposes and other apparatus. Amongst these, is a convenient bi-lens camera for stereoscopic views, or two card portraits, and, on removing a central partition, for views 8 inches by 4½ inches. This camera extends from 3½ inches to 11 inches, having a double means of extension, consisting of sliding body and bellows body. It has also a simple swing back movement, and instantaneous shutter. Some other good apparatus, and ingenious contrivances, complete the contributions in this case.

Mr. W. W. Rouch (3150), exhibits a handsome case of apparatus, and chemicals. Attracting first attention amongst these, is the Registered Model Tent of Mr. Ernest Edwards. This is one of the most complete and conveniently contrived tents, which we have yet seen. As conveying a better idea than a long description, we subjoin an engraving of a section, so drawn as to show the interior, with the operator at work.

It will be seen that a great convenience is gained, in giving as much space as possible over the head of the operator, so as to avoid the sense of suffocation so common in tents. Another convenience consists in the use of a small water-tank placed outside, and having a flexible tube and spring tap inside, the water being carried off by another pipe. The general arrangement secures the greatest convenience within the least space. Altogether, we believe that it would be impossible to get greater convenience combined with more portability.

The "Model" Carte de Visite Camera, may be used for stereoscopic as well as for card portraits, and has a moveable partition, so as to allow of its use with one lens of larger focus, for views, the full size of the plate. In this camera, the part to which the lenses are attached, is that which travels, it is worked by a rack and pinion, giving the utmost accuracy, and is altogether an excellent camera. There is also the "Universal," and other cameras, a clever instantaneous shutter, in which as one lid opens another closes by a simultaneous movement, and a variety of other good apparatus and convenient contrivances. The excellent chemicals we have before noticed.

Mr. H. Simpson (3154), exhibits a Photographic Cabinet, forming a complete operating room, which is thus described in the Catalogue:—

"The Photographic Cabinet, when extended, forms a complete operating room, when closed, it has the appearance of an ordinary closet or wardrobe, and will contain all chemicals, cameras, portable tent, and other apparatus, thus avoiding all photographic litter. It can be extended in one minute, and will then form a dark chamber, about four feet square, fitted with sink, drawers, &c., and will shift, so that light can be admitted at pleasure. There is no combustion inside the chamber, and abundant ventilation without draught. No dust can arise from curtains, as they are entirely superseded by india-rubber springs.

For convenience of carriage, it may be constructed in parts, and fitted with screws, carefully marked, so that with the printed directions, any intelligent youth may put it together. It may be painted or unpainted, so that it may be coloured the same as staircase or furniture.

It will be seen from the description, that the contrivance will frequently be useful to the amateur without a spare room at his command. We should prefer a little more space than the one exhibited possesses, but this and other matters of detail are easily modified.

Mr. J. Solomon (3158), has a very attractive case of apparatus, which is distinguished by the convenience and ingenuity of many of the contrivances for facilitating the labours of the photographer, as well as by the novelty and excellence of the articles. Some of these have been already noticed in our pages, amongst which we may mention a cutting table, and guides for trimming and shaping photographs, consisting of a plate of glass, on which to cut, fixed in a revolving frame, to enable the print to be trimmed on all sides without moving, the table revolving, instead of shifting the print. Developing holders, giving a firm hold of the plate in such a position as permits its progress to be examined during development, whilst there is no need whatever to soil the fingers with the solution. Chanter's collodion pourer affording more complete immunity from the possibility of any kind of floating matter or sediment in the collodion falling on the plate, than any other bottle we have seen. Chanter's syphon, another useful contrivance, consisting of a flexible tube of india-rubber, with an india-rubber ball attached, of sufficient capacity to exhaust the air entirely from the tube, and thus afford a simple efficient method of setting it in action, without the trouble which generally attends the use of a syphon. There is an excellent portable tent; some very efficient rolling presses; a very solid iron camera stand, admirable for the dark room, and, moreover, we understand, very cheap; a clever little microscopic camera, for producing minute photographs for subsequent enlargement in the microscope, or by means of a lens attached and mounted, as in M. Dagron's photo-bijouterie; a variety of other apparatus, and frames and albums for card portraits.

Mr. Spencer (3161), exhibits albumenized and other prepared photographic papers. The examples look well, but it is, of course, impossible to speak of quality, simply from appearance. From the catalogue we learn the interesting fact, that upwards of 200,000 eggs have been used in six months, to furnish albumen for the paper prepared in Mr. Spencer's establishment.

Dr. H. G. Wright (3187), exhibits a very cleverly contrived portable apparatus, consisting of a light and useful tent, with camera, bath, and equipment complete, each part belonging to a convenient whole. Some excellent pictures by Dr. Wright, who is an able amateur, illustrate what may be done in his tent.

We have now briefly noticed the whole of the apparatus in the British Photographic Department which as struck us as worthy of attention. We shall next have a few brief words on foreign apparatus.

## Critical Notices.

STEREOSCOPIC VIEWS OF THE INTERIOR OF THE INTERNATIONAL EXHIBITION. London: The STEREOSCOPIC AND PHOTOGRAPHIC COMPANY, Cheapside and Regent Street, London; and Broadway, New York.

ALL persons interested in the credit of photography, as well as the Commissioners of the International Exhibition, and the public at large, have reason to be well satisfied that the contract for photographing the interior of the building and the art treasures it contained fell into the hands of the London Stereoscopic Company. Without in any way depreciating the ability of other firms, we question whether one house in a thousand would have brought to bear so much enterprize, ability, and capital upon the work, or have executed it in a style at all comparable with that in which the photographs already issued have been produced. The firm to which we have referred took a large view of the project and made a bold offer; in addition to the fifteen hundred guineas paid down, and the prospective royalty on sales, a further sum of about £500 had to be paid for various advantages, in the shape of space for erections of various kinds, &c. A still further outlay was speedily made, when it was discovered that Dallmeyer's lenses executed the work better than the equipment of first-rate lenses already in use; these were all laid aside, and a complete outfit of new lenses ordered of Mr. Dallmeyer, costing, we believe, about £300 more. We have always pleasure in recognizing the debt which art owes to enterprize and capital, because it is a debt often ignored and by some utterly denied. We have known some short-sighted and feeble-minded operators in our own art, as in others, regard the interposition of capital—without which, in such a case, nothing could be done—with a grudging jealousy.* We are glad to believe that, bold as was the speculation, there is every reason to regard it as a successful one. The sales have been, we understand, enormous. Mr. England, who was entrusted with the production of the stereoscopic negatives and prints, has alone executed an average of little less than one hundred and fifty gross weekly. Of some of the most popular subjects the negatives have required continually repeating to secure facilities for rapid production. The number of stereoscopic subjects already photographed, is between two and three hundred, and the number of negatives between two and three thousand. Of the larger prints, of which there are several sizes, we have not any definite statistics, but we apprehend that the demand for these will have been in like proportion.

As to the quality of the photographs produced, the public verdict has been given in the demand for the prints. They comprise a treasury of the choicest gems which the world of art and science could produce, photographed with an amount of skill which could not, we believe, be surpassed. Some of the slides before us are choice gems of photography, as well as exquisite delineations of gems of art. Nothing can exceed the beauty of many of the general views of the nave, transept, and various courts. In the representations of ornamental glass and ceramic wares, the exquisitely delicate rendering of texture is something marvellous, the perfect detail and softness giving an effect of reality to these substances in the stereoscope, which we have hitherto regarded as only possible in stereoscopic transparencies on glass. The grouping of various art products, in some of the slides, has been managed with much judgment, taste, and skill.

The specimens of sculpture here presented, are truly magnificent, and present to the student such a collection as, it is probable it would be impossible to meet with elsewhere. We have rarely felt the stereoscope so valuable, as in its wondrous power of reproducing before our eyes, in the quiet retirement of the study, those exquisite embodiments of beauty. The glorious "Reading Girl" of Magni, which shows how a soul can be enthroned on a marble face; and features, which move not, be instinct with intellect and feeling. The exquisite grace and loveliness of Monti's Sleep of Sorrow, and Dream of Joy. The sensuous beauty of Marshall Wood's Daphné, the indescribable and mystic power of Story's Sybil

* It would be an interesting task to trace the ramifications of employment created by the spirited management of enterprizes of this kind. A staff of not less than fifty extra persons, not photographers at all, have been engaged in the commercial department of the business, as clerks, messengers, young ladies in charge of stalls, &c. To these, in addition to salaries, a commission has been paid on sales beyond an estimated amount. It would be easy to trace the matter further, and point out, how in all cases, the judicious interposition of capital, gives an immense impetus to art and commerce, and opens new fields for the employment of labour. Since the above remarks were in type, we have had a striking illustration of the need for diffusing sound and common sense views on such subjects, in the publication of an article in a contemporary, which is astounding in its singular ignorance of, or antagonism to, the first principles of political economy.—ED.

and Cleopatra, and the varying charms of scores more. We can wonder also on what was based the factitious reputation of the Tinted Venus, which excited so much expectation, and which turns out to be such a commonplace undressed young woman; and we can wonder as we examine the poor, meagre, hard figure which Hiram Power designates California, whether the sculptor has fallen off, or the Greek Slave was less beautiful than we, in common with the rest of the world, believed it to be eleven years ago. In short, we can revisit the Exhibition, and enjoy its beauties without fatigue, and with unalloyed delight. If in no other respect, the Exhibition of 1862 possesses an immense advantage in this respect, over that of 1851, and if every other department of the Exhibition has been characterised by mismanagement, this at least has been free from it. Almost all the subjects we have seen, have been pleasing as pictures, and perfect as photographs.

RAMBLES ABOUT CHESHIRE. By John H. Underwood.

This is a series of very charming stereoscopic slides, consisting of rustic scenery, farm yards, sylvan nooks, shady avenues, cool meadows, and quiet streams, of a most seductive character. The negatives are, we believe, by the collodio-albumen process, and fully maintain the reputation of that safe and excellent process. The pictures are rich and brilliant, without any hardness, being at the same time harmonious and full of tone.

"BRINGING HOME THE MAY." Photographed from Nature, and Printed from several Negatives. By H. P. Robinson, Leamington.

We have before us a production which we confidently aver to be the finest composition photograph which has ever been issued, and in reference to which, we should not feel much hesitation in stating our conviction, that it is the finest *picture* which has ever been obtained by the art of photography; and we speak very deliberately and advisedly when we express this conviction. Having said this much, we feel somewhat at a loss to proceed, because we feel it to be utterly impossible to convey, by criticism or description, anything like a perfect idea, either of the picture itself, or of the impression it produced upon us on seeing it. When sciolists in art have attacked the art qualities of photographs, and denied the power of photography, we have often, even with some secret misgiving that the attacks were not always unmerited, felt pleasure in doing battle for the art and its products. To all cavillers, in future, we should like to show this picture; and to their scornful enquiry, "Can any good thing come out of Nazareth?" we should gladly reply, "Come and see."

The picture before us is forty inches long by fifteen inches deep, having the general form of a panoramic picture, and is printed from nine negatives. We commence by these mechanical facts in our description, simply because such facts aid a photographer's preliminary estimate of a photograph; but these are the last thoughts that enter the mind on seeing this picture. There is, on the contrary, such a completeness and symmetry in the section of nature presented, and, moreover, such a sensation of vastness and space, that it scarcely enters the mind to consider whether the canvas containing it extend inches, feet, or yards; it is enough to feel that it constitutes one harmonious whole, neither a fragment, nor the various scattered portions of a picture. Here, at least, there is no "patchwork."

The subject consists of various groups of figures and landscape. These groups are connected in the composition so as to form one company, all girls, embracing young children and blooming maidenhood, all engaged in bringing home May blossoms, the fragrant wealth of English hedgerows in the advanced spring season. An admirable extract from Spencer, which is appended, will at once initiate the reader into the spirit of the picture:—

"When all is cladde
With pleasaunce; the ground with grasse, the woods
With greene leaves, the bushes with bloosming buds,
The younge folks, now flocken in every where,
To gather May-buskets and smelling brere;
And home they hasten, the postes to dight,
And all the kirk-pillours care daylight
With hawthorne buds"

Nearly in the centre of the picture is a group of four girls, each laden with hawthorne blossom, the central figure of the group bearing a large burden of the branches upon her head. This is the principal group in the picture, and upon it the eye instinctively rests first, in examining the composition; it is nearest and most prominent, most brilliantly lighted, and best made out. The figures are in full sunshine, and the breadth of light, free from chalkiness, and the broad masses of shadow perfectly transparent and free from blackness, have a charmingly sunny effect. The pose of all the figures is easy, natural, and perfectly harmonious with the general action; but the position of the central figure, to which we have referred, is perfect in its simplicity and gracefulness, and might be employed, without altering a line, as a Caryatis in a Grecian temple. To the left of this group is another of two girls, who are tardily bringing up the rear, one of them pausing whilst she shakes from her dress one of those long straggling parasitic plants which cling with such tenacity, and are familiarly known, in some parts of the country as "followers." To the right of the central group are other two figures, one of whom is stooping and gathering together a large heap of the newly cut hawthorne branches, the other waiting to assist in carrying them. Still further to the right is another group of two little children, who are toddling home in advance of the party.

The background and landscape generally, is, for the most part, thickly wooded; but, through the trees, the eye travels far away over meadows into a charming distance. In the middle distance, immediately behind the groups, a fine tract of open country shelves away, leading the eye into the forest path, divided by rustic railings and a stile from the open. The arrangement of the picture does not leave need for much foreground; but this consists chiefly of some well chosen and well made out wild plants.

It is a May morning and every figure is beautifully tipped with the sunlight, which pervades the picture. But it is early on a May morning, and the atmosphere is filled with the delicate misty vapour which clothes the distant foliage with that delicate and fairy robe of atmosphere, which gives a charm to English landscape scenery, rarely met with elsewhere. If the picture before us be filled with sunlight, it is not less filled with atmosphere. The thick, leafy, spring-like foliage of the background is thus thrown back from the sun-lit figures, which tell the story of the picture.

The first impression which strikes the mind on examining the picture is a conviction of the admirable composition and chiaroscura, which at once satisfy the eye as masses without distinct reference to forms. The arrangement of lines, and the general contour of the picture is especially pleasing, whilst the effect of light and shadow, the arrangement of light and dark objects, the perfection of gradation, and general breadth of effect is altogether satisfactory. The next impression produced is of the complete harmony and subordination; every thing takes its place admirably, and nothing obtrudes. It is harmonious in sentiment; the landscape is an unquestionable spring landscape; the children and damsels—there is too much of life about them to be perpetually called "figures"—are in the spring of life; the whole picture is pervaded by the feeling of spring-time. There is harmony in the action, purpose, occupation, and pose of each figure, which perfectly connects them as a whole, although divided into separate groups; and there is a feeling of gladness and freshness expressed in every part of the picture. It is harmonious as a composition, harmonious in gradation of tones; there is perfect gradation in the sun-lit and well pronounced foreground objects, and gradation in the distant hazy woods. There are no crude chalky lights, or black heavy shadows, no patch of white sky killing all the other lights in the picture. The masses of May blossom in the bright sunlight are soft and well made out, not mere masses of snow and the sky has a pleasant atmospheric tint which suggests the season.

There is that harmony which renders it difficult to remember that this is a "composition" picture, in the photographers' technical sense of the word. It is difficult to believe in it as the product of several negatives, each part so thoroughly belongs to the whole and so perfectly accords with the whole. Ruskin, speaking of the test of the true artist, says that his work, or the "imaginative work," as he calls it, "looks always as if it had been gathered straight from nature; whereas the unimaginative shows its joints and knots, and is visibly composition." The test is an admirable one and admirably put, and may, with augmented force, be applied to the "composition," or rather let us call it, as referring to the mechanism, the "combined" pictures of the photographer. It is when this test is applied that the picture before us claims its true position as an imaginative work. We do not see the "knots and joints," we do not mean the joints in printing, but in working out the conception and composition. Let us add, for the benefit of young photographers who may be tempted to tread in Mr. Robinson's steps, that a work of this kind cannot be produced from a crude conception. Months before this picture was commenced, we received from the artist a well-drawn sketch, in which the design and composition of the intended picture were fully indicated, these being specifically settled before a negative was taken.

The mechanical portion of the picture is, notwithstanding the difficulties, admirably managed. The printing of nine negatives on a sheet of paper, forty inches long, and requiring, from the commencement to the conclusion, about eight days, is not a light task. But it is admirably executed in all respects, and the general quality and tone of the print are admirable. Of Mr. Robinson's former compositions, especially the "Holiday," and "Lady of Shalott," we spoke freely, and whilst we admired their beauties, we pointed out what we thought to be their faults. We will not be so hardy as to say that this has no faults; but we are bound to say that, at present, we have not seen any. We are conscious that we have given but a very faint idea of our impression of the great beauty and excellence of this picture; but as it will be sent to the next exhibition of the Photographic Society, to be held in January, photographers will be able to supply for themselves what we have failed to convey.

## DOUBLE OR FANCY PRINTING.

BY H. COOPER, JUNR.

As I find that Mr. Harmer's communication, which appeared in the pages of the News a short time back, has excited considerable interest, and as a few specimens printed by some of the methods there mentioned have been much admired, I think I may be pardoned for going somewhat fuller into the subject than Mr. Harmer has done. I am afraid that several are in the same dilemma as your correspondent, G. G., with regard to it. I was myself, but having adopted some of the dodges beforehand, I was able, after some trouble in thinking over the subject, to make out the way to use the masks, &c., mentioned. I will, therefore, ask the reader to give me his careful attention, while I detail, as clearly and concisely as possible, the "ways and means." But I must first remind him that it is no easy task, as it is difficult to know how to say enough without becoming too prolix. But to the point.

A vignette generally softens off on to white paper, so that there is a mass of white all round, which in some instances seriously deteriorates the high lights of the pictures. Now, I dare say, it will occur to many, but why not make this mass of white of a middle tint, so that it will relieve and throw up, instead of detracting from the portrait or view, as the case may be. I will first explain how this effect can be gained. Many might think of a vignette glass, such as is used for vignetting positives on glass. But this would not do at all well, on account of the vignette being an oval. The following is the best. Print the vignette as usual. Let it be as "soft in the softening" as possible. When it is printed the required depth remove it from the pressure frame. Now procure a piece of very thin glass, free from air bubbles, specks, &c., and having made it perfectly clean, lay the print, face downwards, on it; then place a piece of black velvet over the back of the print, and over that another sheet of glass. The whole may be held together by American wooden clips. Then turn it over, and with a small brush filled with a solution of gum arabic, go over *carefully* that part of the front glass that covers the features, shirt-front, &c., supposing it to be a portrait. Lay on a lump of fine cotton wool, taking care that the centre part be opaque enough to prevent any light finding its way through. Now pull out the edges till it softens off just the same as the vignette. Expose it in the shade till all the uncovered part is exactly the tint of the shade behind the head. If the flat tint be required only of this depth, the operation is finished, but should it be wished to make it darker, collect all the wool up into a nob, so that it shall protect the parts sheltered by the gum, and no other. Now moving it about, to prevent a halo being formed, print to the required depth. I have explained this "dodge," first, as the effect is more simple, although more difficult, to produce than some I shall touch upon presently. If properly managed, the effect of the above is very fine, the photograph, particularly if it be large, giving the idea of a drawing on India paper, having the high lights put in with white. I would advise that all fancy prints be mounted neatly on a mount, having the centre of an India tint, so that when the photograph is placed upon it, there is a tinted margin between it and the white. For all the following "dodges," masks are required.

Procure some good black or deep yellow paper, which will bear inspection when held up to the light, being free from pinholes or other defects. Take a sheet of it the required size, and with a shape and a sharp pen-knife, cut an oval, round, square, or any other form, from the centre. So you will have a shape of paper, and a sheet with an aperture in it. These masks, as I shall call them, must be very evenly cut, the edges being perfectly free from jags. The next style to the one explained above, is a picture, vignetted on an Indian tint, with a white margin. The production of this is very similar to the preceding. Place one of the masks with an aperture in it, between the print and the sheet of thin glass, taking care that the vignette is in the centre. Proceed as before.

The third style is a vignette, softened on to white paper, with a tinted margin. After the vignette is printed, remove it and the negative from the printing frame, or better still, a separate frame may be used. Take one of the masks, or shapes, and place it on the print, carefully centring the picture. Put the print and mask in the frame, and expose to light till the required tint is gained. These three methods I call the single ones, all others are compounded of them. A very pretty picture may be produced in the following manner:

Having proceeded as in the last instance, using an oval mask, so as to allow the paper to be white for half an inch or so round the vignette, take the frame into the dark room, and remove the print and mask from it, then place in front of the print, an oblong mask, with the corners rounded off, of such a shape that the oval first printed may be equidistant from its four sides, and having replaced it in the pressure frame, expose to light, for half as long as it was exposed to gain the first tint. I do not think it necessary to describe any other styles, as, by the judicious use of different shaped masks, hundreds may be produced, and after the operator has become conversant with the ones detailed, numbers are sure to occur to him. To cut the masks, the mats used in mounting photographs on glass may be employed. By printing the different tints at different times, allowing an hour or two to elapse between each, several tones on the same picture will be produced, which may be often used with advantage. In conclusion, I would remind the reader that the end of all fancy printing is to improve the print so that any designs used, must be kept quiet and subservient. The flat tints should never be made very dark, as it would give a heavy effect to the whole.

## PHOTOGRAPHIC PRINTING ON WHITE SILK.

BY HENRY COOPER, JUN.

Since the publication of my last communication, I have printed some photographs on *silk*, by the aid of the resins used for preparing the paper for the new method of printing; and as the results have been much admired, and have excited considerable interest, I do not think a short account of the method used would be uninteresting to your readers; and I should be obliged if you could find space for these remarks in your valuable journal. I have tried several formulæ, and although Iceland moss gave very nice results, I prefer to use a small quantity of a resin to give a surface to the silk, to prevent the image sinking too much into its substance. A great deal depends upon the silk, so that the first point is to procure a suitable kind. It must be rather stout and opaque, and very perfect in the thread. The best French glacé answers very well, if it be of really first-rate quality; but I should think *gros de Naples* would do better.

Ascertain which is the right side, and mark it. As the silk will require to be ironed once or twice during the preparation, some fine flannel must be obtained, and three or four thicknesses laid on a board; this is to form the material to iron upon. If there are any creases in the silk, lay it face downwards, and over the back place a sheet of fine filtering paper, and then iron it until they disappear. Then prepare the following solution:—

| | |
|---|---|
| Pure frankincense ... ... ... | 4 grs. |
| Mastic ... ... ... ... | 2 grs. or 3 grs. |
| Chloride calcium ... ... ... | 15 grs. |
| Spirit... ... ... ... ... | 1 oz. |

Filter before use. Immerse the silk in the same manner as I directed for paper; but pin it up by two corners. To sensitize it, *immerse* in the silver bath, which should be 60 grains to the ounce, and faintly acid. Several pieces of silk may be immersed at the same time, so long as they are put in separately. This will save time, as they must remain in the bath at least a quarter of an hour. Turn the batch over, and remove the pieces singly, and again pin up by two corners. When the silk is quite dry, it is to be ironed, before exposure in the printing frame, in the same manner as I have described above. If this be neglected, the silk is very apt to cockle, rendering the prints misty in parts. The covering the back with clean filtering paper, both in the ironing and in the pressure frame, must on no account be omitted.

Print deeply; wash quickly; and tone in a bath of acetate of soda and chloride of gold, rather strong. Tone to the required depth; *wash well;* and fix in new hypo; this should be also rather strong. Wash very carefully and thoroughly; taking care that no impurities come near the prints, as the silk is easily soiled whilst wet. If the prints be small and are intended for book-markers, or things of that description, they may be simply dried and ironed; but should they be large, for screens, &c., they must be stretched, whilst wet, over a frame, and left to dry in a state of tension. Although the manipulations are rather tiresome, the photographer will be amply repaid by the results. The fruits are brilliant in the extreme; the shadows are particularly deep and transparent, and every detail in the negative is perfectly rendered on the silk. The uses to which this style of printing may be put, are almost numberless, and I would recommend it to the attention of all photographers; hoping that all who try it may succeed.

Note on Resinized Paper.—I have recently made some improvements in the formula for resinized paper. By the new method, the paper will keep after sensitizing as long as albumenized paper; the prints possess greater transparency in the shadows; and are free from the granular appearance to which I called attention in my last remarks. Immerse thin *Rive* (I used a negative paper) in a sufficient quantity of the following solution, which may be filtered through paper:

| | |
|---|---|
| Pure Frankincense ... ... ... | 10 grs. |
| Mastic ... ... ... ... ... | 8 grs. |
| Chloride of Calcium ... ... ... | 15 grs. |
| Spirit ... ... ... ... ... | 1 oz. |

The proofs are easily toned, and any tint may be obtained. The fact that the tone becomes bluer when the print is dry, must not be lost sight of. A slight application of Clausel's encaustic paste is a wonderful improvement in some cases. By a judicious use of it, some parts of the picture may be brought out more prominently than others. But I would not advise its use except as a last resource. H. C.

## THEORY OF ALKALINE GOLD TONING.

BY FRANCIS G. ELIOT.

Dear Sir,—Perceiving that you have been for some time endeavouring to work out the faults of the alkaline toning bath, and that a correspondent under the title of "Photographer's Assistant," has been writing some able articles on this subject, and has lastly advanced a theory on its supposed nature, I beg to inform you, that having for some time been working in the same direction, I have at length hit upon what I believe will be found to be the correct solution of the difficulty, and if so, will greatly improve our knowledge of this hitherto troublesome part of our manipulation.

Your correspondent has very nearly got upon the right track, when he says he believes a decomposition of the gold takes place, but I think he has a little missed the mark in his explanation; to go at once to the point then, I believe the gold solutions to exist in four states, and taking the chloride of gold as a simple terchloride, according to the English school of hydrogen being 1, not the Berzelius scale of 0·5, as your correspondent has it, we have, first, $Au\ Cl_3$, plus free acid, the state in which the gold is usually sent out, and the state in which it was used by Le Gray and others, for toning. Secondly, $Au\ Cl_3$, minus free acid, the state in which it exists in a bath in which any quantity, no matter how much, carbonate of soda is thrown in, and in this state a first batch of prints being *immediately* immersed: its action is as follows: the prints are very much reduced, a false colouring is given, which dissolves off in the hypo. If the prints are kept long in, to get full toned, a nasty slaty colour is produced, and general mealiness is the result; it is not until the gold is nearly exhausted, that the prints begin to tone properly.

Thirdly, $Au\ Cl_2$, this is the state in which No. 2 becomes after a number of prints have been toned in it: it also comes by keeping the bath for some time, and also by heating, but it is best produced by adding one equivalent of soda carb. only, to No. 2, and allowing decomposition to proceed as far as it will go. Here we are met with a difficulty, the varying amount of free acid in different samples of chloride of gold. The atomic weight of chloride of gold is 303, and of crystallized carbonate of soda, 144, and the dry, as sold for effervescing draughts, containing 40 per cent. of alkali, about one-third less, so that if my theory is correct, one-third grain to every grain of gold would be enough. That the quantity generally used is more than necessary, is proved by the fact, that Mr. Thomas, the celebrated collodion maker, exhibited at at a meeting of the society, some separate toned prints, with only three-fourths of a grain of carbonate of soda to each grain of gold; probably with any other gold but his own that would completely fail. I believe, however, that the chief failures are to be attributed to a *perfect decomposition*, as far as the soda will allow, not having taken place. I shall presently indicate a method of doing this quickly, and with certainty.

Fourthly, and lastly, there is Au Cl. This is the state in which Nos. 2 and 3 will become if a larger quantity of soda is added than is enough to destroy the free acid, and one equivalent more. It also is produced under the same circumstances when the prints are *boiled* in the bath, to try and make them tone quicker. Many operators are surprised to find the bath suddenly stop, when they know there ought to be plenty of gold in it, the solution when in this state; becomes quite colourless, and is so inert that it may almost be said to be devoid of toning properties altogether.

Now for some practical conclusions from the above: the first thing would be to find the amount of free acid in the gold; but the only method I know of to do this, is a very uncertain one in the hands of inexperienced persons: it is to add soda carb. to the gold, until test-paper is no longer strongly reddened, but the difficulty of seeing the difference between the acid of the hydrochloric, and the reddening of the free carbonic, will lead some to add a much larger amount than will be correct. I can therefore only recommend the following: lay in a stock of gold so as to save trying often, keep it in solution, say 8 or 10 grains to the ounce, for use; then take four or five beaker glasses—clean jam pots will do as well—put into each, say ½ ounce of gold solution, and into the first ½ grain of soda per grain of gold; second, 1 grain; third, 2 grains; fourth, 4 grains; fifth, 6 grains; pour on each 4 or 5 ounces *of boiling water*, which will, in ten minutes or so, bring on a perfect decomposition of the gold. Then dilute to the proper extent with water, and immerse a few prints in each, the results will probably be as follows: No. 1, prints reduced, bad colour, horridly mealy; No. 2, little better; No. 3, intense black and white, rather increased than reduced in strength, toned rapidly, and do not change in the hypo. This solution will tone from two to three sheets to the grain of gold before it is exhausted, and will not require to be heated to tone quick enough in any state of weather up to this date, end of October.

No. 4, the solution has become first, colourless, then slightly opaque, a greenish deposit on the side of the glass, and when prints are immersed, hardly any toned action at all. I do not say that these preparations will act exactly with all gold in the order indicated, but they can be produced most certainly with every sample of gold that may be obtained.* I can only say in conclusion, let every one work it out for himself, and if I have advanced anything that may aid the thoughtful printer in his endeavours, I shall be only too gratified, and would wish him every success.

## Photographic Tourist.

### A PHOTOGRAPHIC TRIP TO THE PITCH LAKE, TRINIDAD.†

BY W. TUCKER.

Next morning we returned by the same road, and found everything as we had left them the day before, safe and dry, although it had rained considerably during the night. Hills close up this side of the lake, and on the one over which we passed a very pretty view of the lake and its islands is obtained through a vista of trees. The depth of the pitch is probably less on this than on the northern or La Brea side. Patches of high grass, and islands covered with trees, occur frequently, and considerably relieves the monotonous appearance. After a refreshing bath in one of the larger fissures, we made our way to the centre of the lake, where the greatest uninterrupted mass of pitch is collected. The natives call it pitch-pot on account of its round form, resembling a giant iron cooking-pot, and from the bubbling noise in the soft pitch in several parts. To me it resembled an immense black pie-crust. The Pitch Lake is highest on this spot, and the rain water finds its level in the crevices of the lower sides. All attempts to ascertain the depth of the lake have been unsuccessful; a hole that had been cut out by Mr. Stollmeyer, large enough to allow of twelve men working inside, closed up in a couple of days, and before all the material cut out with wooden axes, could be carted away. The surrounding layers or waves of pitch press towards any disturbance of its equilibrium, and no practical purposes could be served by digging lower under increasing difficulties. The experiment, however, is sufficient to prove that millions of tons of asphalt are here attainable. Near the pitch-pot is found in several places the soft or semi-liquid pitch of the consistence of stiff dough, oozing up from beneath—the actual oozing is not observable, but in several places near the edge there is a bubbling of muddy water and gas—giving forth a disagreeable odour. The negroes said that several cattle had disappeared in the soft pitch, and some time after again reappeared floating in the gulf. The water oozing up is strongly impregnated with salt, and mixed with grey mud; and certainly from its taste, and the colour of the mud, strongly leads to the belief of its connection with the sea. The semi-fluid pitch, when cut, resembles fermented dough; and water can easily be squeezed from it by pressure from the hand. It is not at all adhesive, and will bear passing over it at a quick pace in the wet season. In no part is it deeper than the fissures, which, too, sufficiently proves the absurdity of the idea of any large animal disappearing in it. In fissures formed near the pitch-pot, the soft pitch generally replaces the rain water, which it forces out from the bottom, and retains the base of hard pitch. This soft pitch requires a long exposure to the sun, in order to evaporate the large portion of water with which it is mixed, before it will solidify and combine with the hard pitch of the lake; until then it lies on the surface as a flake, in the form of the fissure, and may be removed near the edges, curled up and rolled without much soiling the fingers. Near were several of the filled fissures, in which the pitch was quite hard. In several parts of the lake, but particularly near this spot, several parts of logs and branches of trees were above the surface. I examined several, and found them in different stages of transformation; some were merely saturated with petroleum, others were of the same bituminous consistency as the pitch, but more brittle, and retaining all the fibrous appearance of wood. Others were traceable on the surface of the lake only from the fibrous appearance of the log, having, as it were, become fused into the main body of the lake.

As the morning was showery I did not attempt to photograph. At mid-day, however, the sun shone out with a true tropical glow, and soon dispelled the icy appearance given to the surface by the rain, and resumed its usual dull black. Having taken off my boots a little time before, I was glad enough now to seek their protection from the heated surface, which rendered the manipulation of the next two views a matter of great difficulty, from the intense heat in the tent, combined with what I cannot better describe than as hot bricks under my feet. I was glad to lean on the edge of my tent and relieve the burning sensation by lifting both my feet at times during the process, which caused the tent so to sink on this side as to require a fresh removal and re-levelling (for this reason, that I made use of the top in place of a tripod stand). By perseverance, however, I obtained three views. In the meantime, the surface of the lake had become so hot, that standing in one position for twenty seconds caused a burning, blistering sensation in the soles of the feet. We now, and to my relief, moved over to the southern side, which is, perhaps, the most interesting portion of the lake, being bounded by beautiful Moriche palms, which are reflected in the rain-water between the pitch deposits in as clear and sharply defined a manner as in a mirror. Nowhere in Trinidad is the Moriche palm found in such numbers, and in such perfection as in this particular place, where they grow wild. No visitor to the Pitch Lake should omit seeing this jewel of Nature; but

* I would also add, that the gold in the state of Au Cl is much more permanent than is usually imagined. I have kept it undiluted for a week, and no doubt it would keep much longer; it is excess of alkali that causes it to go on decomposing, and then to precipitate the gold.

† Continued from p. 513.

from the difficulty of reaching this spot it is seldom seen. I had some trouble in obtaining a sharp negative of these trees, owing to the constant movement of the long pendulous leaves. In the woods behind these Mr. Stollmeyer had the fortune, a few years ago, to discover an independent nugget of exceedingly fine glacé pitch, which when shipped to England, realized a good price; unfortunately, it was only a few tons. None of the same kind has since been found. The southern half of the lake is dotted with small islands, composed of small trees, amongst which grows the Moriche. It is supposed that these islands are formed on the apex of the earth's uudulations, which run under the pitch, and at these spots approach the surface. Clouds, which had been gathering eastward, now covered the lake, greatly increasing its gloomy appearance; a cool wind blew in puffs; birds in hundreds flew over the lake westward; Nature seemed suddenly hushed; noise, like the falling of small pebbles over the forest, was now heard, and the burst of a regular tropical storm, which, in less than sixty seconds completely saturated every part of our clothing, and continued falling over a quarter of an hour, defying umbrellas and cloaks, and gave to the surface an appearance of a lake of rough ice, caused by the strong reflecting power of the water when covering the pitch. I obtained a view of the appearance just before the storm, and one immediately after. As I had seen everything interesting, and taken, in all, fourteen views, we now left the lake for the last time, and returned to Point Rouge. On the Saturday following we returned to La Brea, and at 4 p.m. embarked on board the return steamer for the capital, where we arrived at 10 o'clock. Observation has proved that the whole material of the lake is in a slow, but constant movement. During my conversation with Mr. Stollmeyer, I was led to inquire from him the probable origin of this wonderful work of Nature. It has not yet been clearly determined whether this asphaltum is a mineral or vegetable substance, Mr. S. takes it to be a link between the two; it appears to him to be the result of a distillation of vegetable fibre mixed with earthy matter under high pressure; but a circumstance which brought together such an enormous quantity of woody fibre to this particular spot, which, in its decomposition, produced millions of tons of asphalt must ever remain a secret. It is, however, not improbable that before the separation of Trinidad from the mainland of South America, viz., before the Brocas' and Serpent's Mouth were formed by the waters of the Atlantic, the Gulf of Paria was a lake receiving the waters of the Orinoco and the Gurapiche rivers, quantities of timber, brought down by them, may have drifted to that spot, until successive layers reached above the level of the water, which must have been then much higher than the present level of the Gulf, if, as it is supposed, the fertile valley of the Naparimas, which abounds in fresh-water shells, formed the bed of the river that delivered the water of the lake iuto the Atlantic Ocean. Whether the above hypothesis be correct or not, the existence of the Pitch Lake is a reality, and it is fairly to be supposed that at some future time it will become an important element in the prosperity of Trinidad. Upwards of 3000 tons were exported in the years 1860-61. Whenever enterprise and science take a firm footing in Trinidad, La Brea will become the Newcastle and Birmingham of the West Indies; and this black diamond of Trinidad will furnish the means of giving employment to thousands of industrious people, and wealth to many enterprising men.

The whole of the land circumjacent to the Lake, with Point La Brea, is the property of the Earl of Dundonald, who also leases from the Colonial Government twenty acres of the lake. Various specimens of raw asphalt, and a few of the purposes for which it may be used, have been forwarded to the International Exhibition.

## Proceedings of Societies.

### London Photographic Society.

The first meeting of the Photographic Society for the session was held on Tuesday evening, at King's College. Mr. Francis Bedford in the Chair.

The meeting was a full and interesting one, and the table was liberally bestrewn with many excellent specimens for exhibition and for presentation to the society. Amongst these were some fine large pictures by M. Debedts, and a series by Mr. Clifford, illustrating a work entitled "Scrambles in Spain;" both sets being forwarded by Mr. T. Ross. Mr. Martin exhibited a print and some negatives, intended to illustrate the excellent qualities of the bromo-iodized collodion—Messrs. Horne and Thornthwaite's—with which they were taken; and he also called attention to Mr. Harmer's two albums, containing specimens of double printing and chromo-photographs, to which we have before called attention. Mr. Hughes exhibited some charming *cartes de visite*. Mr. Dallmeyer exhibited some very beautiful examples of the work of his card lenses. The Stereoscopic Company sent a number of choice specimens of their photographs of the interior of the International Exhibition, by Mr. England and others. Mr. Warner exhibited a handsome album, made to hold a dozen card portraits on one page; the album was filled with specimens of views, &c., the introduction of which, in card size, Mr. Warner claimed. Mr. H. Cooper, jun., exhibited a fine collection of prints on resinized paper, and some very fine photographic prints on white silk. The whole of these specimens, with some others, were examined with much pleasure and interest.

The minutes having been read, the following gentlemen were elected members of the society: Messrs. J. W. Osborne; Hale, of Eastbourne; Reeves, of Falmouth; Mayland, of Cambridge; Heisch, of Piccadilly; and Clark, of Nuneaton.

Mr. J. W. Osborne then read a paper on "Some of the Difficulties of Photolithography." Presuming that members were familiar with his paper read at Cambridge, he called attention to points not before treated, and gave a brief description of the processes of other inventors. We shall give his paper in our next. At the conclusion of his paper he exhibited a series of interesting specimens, illustrating his own process, and also specimens of photolithographs, photo-engravings, carbon prints, &c, by Poitevin, Talbot, Cutting and Bradford, Pouncy, Pretsch, Ramage, and others, and by the process of photozincography, which he stated, though not identical with his own, was very similar.

After a few words from the Chairman,

Mr. Pouncy said he had listened with much interest to Mr. Osborne's paper, but had hoped to have heard some detailed account of the experiments by which he had arrived at his invention. If either Mr. Osborne or Col. James were the real inventors of the processes they claimed, they must have made many progressive experiments, the results of which would have been very interesting to see. However, Mr. Osborne had stated that he could not produce half tone, and that he did not know any one who could. Now he (Mr. Pouncy), could produce half tone, and was prepared to produce half tone on the face of a fine-grained stone, equal to that of a silver print. As he did not wish to challenge an opinion on his products by surprise, he was willing to attend the meeting that day month, and bring with him the stones, on which he would place the image from any negative with which any gentleman would supply him, and he would produce impressions in printers' ink of the same, equal in half tone to silver prints of the same negative. He was there to assert that the prints he now produced were *bona fide* impressions direct from the negative, in *bona fide* printers' ink, and he would produce impressions by the ink supplied by any printer in London with half tone equal to that of silver prints. Other prints he now produced were from the stone. Referring to the letter of Col. James in the *Times*, announcing the discovery of half tone, Mr. Pouncy said he doubted the truth of that statement. He did not believe that any one could produce half tone by the method described. Various persons had boasted of having invented the carbon process, and among others his own apprentice. If they had, they could produce results, and this he challenged them to do. His object now was to have the matter settled, and was prepared to have his claims tested. He wished it to be proved he was wrong, or admitted that he was right. If his offer were accepted, and a decision given, the matter would be settled; if not, the question might be re-opened twelve months hence. He wished first for the decision as to whether he had or had not obtained half tone; the method and its details would be a question for after consideration. If it were denied that he had obtained half tone then there would need no communication; but if it were admitted that he had obtained it, it would then be time to communicate how.

Mr. Jabez Hughes rose to a point of order. Were they now discussing Mr. Osborne's paper, or a distinct communication from Mr. Pouncy, of a character somewhat unusual to the Society? It was, he believed, not the custom to discuss any process, the details of which were not explained.

Mr. Pouncy said, he simply came forward, because Mr. Osborne said that half tone could not be produced, in order to show that it could.

Mr. Vernon Heath asked if the specimens handed round, were intended as illustrations of half tone. If they were, he had not another word to say, except that he did not see any.

Mr. Portbury said that he had been Mr. Pouncy's apprentice, and since he had alluded to him, he (Mr Portbury) distinctly said, that the carbon process, claimed by Mr Pouncy, was not invented by him, but by himself (Mr. Portbury), and that produced the very specimens Mr. Pouncy brought to a former meeting, some years ago, to illustrate his inventions. He produced the first carbon print, and Mr. Pouncy happened to come in whilst he was engaged upon it.

The Chairman deprecated further entering into personalities.

Mr. Pouncy said this person was not worthy of his notice.

Mr. Heath protested against such language.

Mr. Sebastian Davis, having had some experience in connection with lithographic printing, confessed that he had not much hope of securing half tones in photolithographs. There was no true half tone in lithographs at all; the only approximation consisted in the gradation formed by having greater or less space between the lines and spots of which the tint was formed, thus giving a certain granulation. The half tone in a photograph consisted of gradation of tint, and nothing approximating to that could be obtained from printing ink, which was one uniform colour.

Mr. Malone thought that this view seemed philosophical and true, but it was not absolutely so. He had reasoned in a similar manner to Mr. Davis, and, at one time, held the same view. He argued that the gradation in a silver print arose from variation in the depth of deposit of a more or less transparent substance, and that this was a condition, which could not be imitated in carbon, which was a uniformly black material. The carbon prints exhibited on a former occasion had not the half tone he claimed for them. These to-night had more, but, still, not so much as silver prints. There was still blackness in the shadows. As, however, they had neither the negative nor a silver print for comparison, much could not be said about the matter. Still, he thought it dangerous to state that half-tone could not be produced. He had recently seen some of Fargier's specimens in the International Exhibition. There were also some silver prints from the same negative. When he saw them apart, the carbon prints were so good that he thought them equal to the silver prints, and it was only when they were placed together that he saw that the silver prints really were superior in transparency and gradation. Carbon had, however, already accomplished more than had been anticipated, although not so much as silver prints.

Mr. Osborne was sorry that the discussion had not been confined to his paper, as its peculiarities might then have been considered. Regarding Mr. Pouncy, he had taken a somewhat incongruous position, in asking Colonel James and himself to detail their experiments, and thus tell him everything, whilst he told them nothing. He had made another error in saying, that he (Mr. Osborne) confessed he could not get half tones. He could get it, and did get it often when he did not want it. He got it whenever he had a dirty map to copy. The question was, as to getting perfect half tone, and as to the number of impressions which could be taken, and still preserving it as half tone. He was quite willing to admit, however, that he had not got any so good as that exhibited by Mr. Pouncy, as, indeed, in the work in which he had been chiefly engaged, they required just the contrary effect. Regarding Mr. Pouncy's claims, he did not quite see what he complained of. He surely did not claim the origin of the carbon process, or photolithography. These were due to M. Poitevin, who discovered them as early as 1855, long before Mr. Pouncy did anything. Photolithography by another process was executed as early as 1853, by M. Lemercier. Col. James or himself did not claim the invention of photozincography or photolithography, but of a certain simple method in which a transfer was used. Regarding the remarks of Mr. Davis, they were, in many respects, true, but it was dangerous to speak of such a thing as impossible, especially when they looked at the progress of photography. He believed that half tone would be obtained. Not, perhaps, as good as that in silver prints, but as good as that usually obtained in lithographs. It was possible that it might never be quite applicable to negatives from nature; but he thought that it might be obtained so as to admit of perfect reproductions of an artist's drawing, which, as a commercial question, might be of still greater importance.

After the usual votes of thanks the proceedings terminated.

## Correspondence.

### PRINTING DIFFICULTIES.

Sir,—Passing over the numerous arguments which tend to support the theory of toning, advanced in my last letter; we shall now briefly consider the nature of carbonic acid as a toning adjunct, so far as toning or surface clearing is concerned, the presence of this agent is unnecessary, for the binary compound NaO (plain soda,) will effect all this but the retarding influence carbonic acid exercises, on the process of decomposition produced by the chloride of gold in contact with soda, renders it a valuable agent, whose duty is to economize the consumption of $Au_2 Cl_3$ for its combination with soda must be destroyed before a connection can be formed with the chlorine, hence the greater the volume of the acid present with the soda, the more slowly will decomposition be effected. Again, its presence as an acid tends to neutralize, to a considerable extent, the causticity of the soda with which it is connected, and as it unites in various proportions with that substance, the printer has at his command a selection to meet the requirements of his paper; but for general purposes, the carbonate, in my opinion, is decidedly the best, the toning powers of the bath become exhausted sooner than when bi-carbonate is employed, but if toning is commenced soon after the bath is mixed, the gold will go as far with the former as with the latter substance, although a bath made slightly alkaline with the bi-carbonate, will retain its powers many hours after mixing, whilst the simple carbonate solution decomposes in an hour or two. The acetate of soda bath, owes its, not altogether deserved popularity, to the retarding influence exercised by its four equivalents of carbon, but although the process of decomposition is somewhat more complicated, its direct toning action is precisely the same as with the soda carb.; so also with Le Grey's chloride of lime bath, which is but a round-about way of bringing about the same action and results. The chloride of sodium takes the place of carbonic acid to stay the rapidity of decomposition, in fact, any base of a caustic nature, possessing an affinity for chlorine, would answer the purpose of a clearing agent, the important object is to introduce a substance, which, whilst it retards, does not altogether arrest the progress of decomposition, these properties we have to a remarkable degree, combined in the carbonate of soda bath, which is at once the cheapest, the most simple, and excuse me for saying, the most scientific toning compound in use; for I repeat, the numerous agents which have been brought forward to supersede the soda carb. are but complicated methods for producing the same process of decomposition, and so far as my experience goes, I have never found that they effect a greater saving of time or gold. A volume would be required to enter fully into details, but any one who will take the trouble to study the subject, will, I am sure, come to the conclusion that carbonate of soda is all we require in our present system of toning, and if Mr. This and Mr. That One, produce exquisitely toned prints, with this or that toning solution, it is because the negatives employed are as exquisite as the prints produced, and if fine tones are given by the acetate of soda bath, tones equally as good may be secured by adopting the carbonate solution; depend upon it the secret of fine tones is not in the toning bath, but in the negative! and to my mind there is nothing more absurdly unjust, than for a photographer to expect brilliantly toned prints produced from negatives without an unveiled shadow; by comparing, a veiled with a perfect negative, the contrast is as striking as a comparison of the prints produced from the same two negatives. In my next and last letter on printing difficulties, I shall endeavour to show that the process of toning may be reduced to a system.—Yours, &c., A Photo's Assistant.

## AMMONIA AS A DEVELOPING AGENT.

Sir,—In some experiments in the tannin and honey process, in which I tried fuming with ammonia as an accelerator, I remarked that, when the plate was washed after the fuming, the image came out very distinctly; it struck me that the ammoniacal vapour might have become, in some measure, fixed on the plate, and that, on the application of the washing water, it dissolved and acted as a developer. Following up this idea, I gave a plate a very short exposure in the camera, and *immersed* it in a very weak solution of ammonia; almost immediately the picture began to appear, and continued to come out until nearly all the details were visible. I then washed it well and applied the pyrogallic acid and silver, which rapidly completed the development of the picture, without the least sign of fogging or stain of any kind.

This development of the latent image could not have resulted from any free nitrate being left in the film, as I not only wash it thoroughly after sensitizing, but also pour a 3-grain solution of chloride of sodium two or three times over it, when I again wash and pour on the tannin and honey solution. The use of the ammonia in the liquid form, I think, has one great advantage over the fuming, it acts equally, and the picture being washed before applying the pyrogallic acid and silver, no deposit (such as sometimes occurs when the *fuming* is carried to any extent) can take place.—Your obedient servant, T. M. Leahy.

*Dublin, 23rd October*, 1862.

## Talk in the Studio.

Col. James's New Work on Photozincography.—We have received the new work on photozincography by Col. James and Capt. Scott. It contains some interesting historical matter, as well as a description of the process; and is illustrated with several fine specimens of the process. We shall shortly review it at length.

Medal for Card Portraits.—In our article last week on "Photography and the Contemporary Press," we remarked that Mr. Robinson received the only medal for card portraits. Mr. Mullins, of Jersey, has just called our attention to the fact that we are here guilty of an inadvertent error; as he exhibited little other than card portraits, and still received a medal. In making the remark, we were thinking of the British Department, and thus those of Mr. Mullins escaped our memory. We have pleasure, however, in correcting the error, and expressing our admiration of the very charming specimens for which Mr. Mullins obtained a medal.

Photographic Piracies of Engravings.—Mr. Gambart has recently commenced the prosecution of some photographers who have pirated his copyright engravings. Details of the cases, and some remarks on the subject stand over for want of space until our next.

Photography and Forgery.—Our article on this subject has been quoted into various commercial and scientific journals, foreign and English. We are informed that some of the Bank authorities have recently had their attention called to the subject, and that the question has received grave consideration. Hitherto, the system of check between number and date, together with Bank private marks, have been a safeguard to prevent payment of forged notes by the Bank. Now the question arises, although there is not much danger of the Bank authorities paying the representative of the same note twice, whether they might not possibly pay the counterfeit first. Moreover, however safe the Bank may be, it is important that the public should be made safe also.

*** Agents or subscribers having copies of the following numbers of the present volume, which they can spare, will confer a favour by forwarding them to the office, where they will be exchanged or bought at full price: Nos. 174 187, and 196 to 203.

Col. Sir H. James's Photozincographs with Half Tone.—We have been favoured by Col. Sir Henry James, with a couple of examples of his method of obtaining half tone by means of photozincography, and some further information on the process. So far as we can judge, by a hasty examination of the specimens by gas-light—they arrived at the moment of our going to press—there is every reason to hope, that a very wide step is at once made, and that photozincography, instead of being confined to reproduction, may be used for printing the images obtained by photography from nature.

## To Correspondents.

Amateur.—Negatives produced by the method of intensifying by means of bichloride of mercury, and iodide of potassium, as practised by the late Mr. Lacy, and described in our columns, are not likely to fade; but there is one drawback to their usefulness which has recently been brought under our attention, which becomes serious in pictures intended for publication, and where many prints are required. They become more intense with printing. The deposit seems to become more nonactinic by contined exposure to sunlight; and negatives originally soft, will sometimes become quite chalky by the time a few hundred prints have been produced.

W. May.—The recent Fine Art Copyright Act only refers to pictures not sold before the 29th of July last, as you will perceive on reading the first clause of the Act, giving copyright to all paintings, drawings or photographs "which shall not have been sold or diposed of before the commencement of this Act." 2. The answer depends entirely on the circumstances. If A be the owner of the copyright of the picture painted for B, you cannot copy it for B without the permission of A. If, however, no agreement exist, A will not possess any copyright, as, according to our reading of this obscurely worded clause in the Act, an agreement in writing is necessary to secure the copyright to either vendor or vendee in all cases where the work is a commission. If neither A nor B possess a copyright, there can be no impropriety in your making a copy for B.

Charles.—Your communication was duly received, and merely waits a convenient season for insertion. There has been a great pressure on our columns recently.

A Subscriber.—Glass is the best substance upon which to cut out photographs; it allows a clean cut free from ragged edges, and does not turn the edge of the knife as might be expected. 2. A good plan in cutting out stereo views is to go through them first and mark on each one a point to which a certain part of the guide must be placed. 3. The right hand view should possess a little (not more than the eighth of an inch) more of the right side of the picture; and the left hand view a little more of the left side; that is, the inside of each view should have a trifle more cut off than the outside.

B. K.—You will find instructions for erecting a glass-room in No. 59, p. 73 of our third volume. You may have six feet opaque over head, and the same space opaque at the side at the background end. For the remainder of the north side it will be better to have all glass down to the ground if you can manage it.

H. Steed.—The pink or ruby tint in your prints arises from a peculiar action of the gold bath, probably induced by the action of light on tho solution. In certain conditions, not always easy to define, the gold becomes reduced to a ruby condition, and is in such fine subdivision that it remains in a state of suspension resembling solution, and in this state it has a tendency to stain the paper. If prints are toned in the light this staining action is sometimes brought about.

F. G.—The development of bromo-iodized collodion proceeds more slowly than that of simply iodized collodion, and may be carried further without fogging. If you have been accustomed to simply iodized collodion, you may be easily deceived, and be in danger of under-development.

Argus.—Thank you for the clipping. We saw the paragraph to which you refer from the *Cornhill* chopped and twisted a little, and then inserted without acknowledgment. The journal in question has a strong *penchant* for this kind of appropriation, and hence its readiness to suspect others. As we have stated before, however, it is not a matter worth notice.

Francis S. Beatty, referring to the recent correspondence on photolithography, &c., in our columns, states that the claims made are for processes similar to those patented by himself, and states his intention to support his claims by legal proceedings. He rightly conjectures that the columns of the News will always be open in support of justice; but it must have escaped his attention that the discussion in our columns has reference to processes discovered and published in 1859, whilst the dato of his patent is 1860.

L. F. C.—The chief fault in your card picture arises from placing the camera too high. It is thus difficult to get the feet in focus; and an unnatural slope is given to the floor, which looks as if it were an inclined plane, upon which it would be impossible to stand. The accessories are also too obtrusive. The tone and printing, generally, are pretty good; but the printing might have been a little deeper. The mounting is, also, a little slovenly.

M.—You had better clean the plates with your old, decomposed collodion. An old red collodion which, instead of giving intensity, is slow, but gives a thin grey image, is useless, either for taking negatives alone or mixed with other samples. 2. With a freely-bromized collodion, sufficient exposure is necessary to obtain density. With a simply-iodized collodion, short exposure will often give intensity, but, lack of half-tone; this is not the case with a bromo-iodized collodion. 3. Tho method of intensifying with pyro and silver, after the iron, and before fixing, is generally safe and satisfactory. 4. Fix with hypo, in preference to cyanide of potassium, but be careful to wash very thoroughly.

Young Man from the Country.—The usual exhibition of the Photographic Society will be held this winter. The exact time and place are not yet fixed we believe.

Several articles, letters, and answers to correspondents are compelled to stand over until our next.

# THE PHOTOGRAPHIC NEWS.

VOL. VI. No. 219.—*November* 14, 1862.

## COPYRIGHT IN ENGRAVINGS.

In another page we give in detail the proceedings recently taken by Mr. Gambart, the well-known publisher of engravings, against certain dealers in photographic prints, who were selling photographic piracies of his copyright engravings. In the recent Fine-art Copyright Act, although engravings were not generally included under its provisions, being already protected by more than one Act, there is a clause inserted with the evident purpose of simplifying the mode of securing redress in case of piracy. The remedy given to owners of copyright by former Acts, was to be obtained through the operation of the superior courts of law; always a tedious, and generally an expensive mode of securing redress. By the eighth section of the recent Act it is enacted that the penalties incurred by an infringement of copyright granted by former Acts, shall now be recoverable by summary proceedings before two justices of the peace. Mr. Gambart, having been a considerable sufferer from piracy, sought a remedy from the sitting magistrates at Bow-street. It is not necessary here to recapitulate the details of the case, which appear in another page; suffice it to say, that on some technical grounds, Mr. Corrie dismissed the summons, stating, however, that a wrong had undoubtedly been done; but that the remedy must be sought in a civil court.

We cannot presume, of course, to measure legal opinions with Mr. Corrie, in such a matter; we must confess, moreover, we do not clearly understand the nature of his objection to exercise jurisdiction in the case, his judgment as reported in the *Times*, not being altogether so clear or intelligible as might be desired. From our own reading of the Acts passed in the 8th of George II, and the 17th of George III, with the 8th section of the Act passed last session, we should have had no hesitation in saying, that in the case tried, the Act had been contravened, penalties incurred, and that the penalties were recoverable by summary process before two justices of the peace. We should think it very improbable that Mr. Gambart will let the matter rest on such a decision, which makes the recent enactment practically inoperative.

Apart, however, from all considerations as to the legal boundaries set to this wrong, and the difficulty or ease with which a legal remedy may be obtained, it is clear a monstrous wrong is perpetrated. It is not a question of casuistry upon which conscientious men may honestly hold different views. Here is the broad fact that Mr. Gambart gave upwards of two thousand four hundred pounds for a painting, chiefly with a view to the profit to be obtained by multiplying and selling copies of it. Those who copy his engravings simply rob him. They seek to make a profit out of the investment of his capital. We know that some plead the uncertainty of the law, as an excuse. They say, let the law be clearly defined and we will obey it. But if the law of England, even, were somewhat inexplicit on this subject, there can surely be no uncertainty as to the morality of the matter. Every shilling made by these piracies is profit on another man's capital, who suffers loss, probably in geometrical ratio to the gain of the pirate. We earnestly call upon all photographers having interest in the respectability and legitimate use of the art, to discountenance, by every means in their power, this dishonest application of it.

On the other hand, publishers of engravings have, we regret to say, largely opened facilities for these piracies, and tended to complicate the popular view of the question by neglect of certain precautions. The original Copyright Act for engravings states it as a condition by which protection is to be secured, that each print must have upon it the date of publication and the name of the proprietor of the copyright. In many instances artist's proofs have been issued, we believe, without any such precaution having been taken. A photographic piracy of such a copy may be made with impunity. The fact becoming known that some copyright engravings may be copied without coming within the pale of the law, the ignorant or unscrupulous readily jump to the conclusion that it is a complicated question, and that there is no certain illegality in any case, and readily regard piracy as vulgar minds regard poaching or smuggling, as at least venial, if not praiseworthy.

The suppression of piracy does not in any way lessen the legitimate value of photography for reproduction. A wide field is open for the skilful and enterprising, in the reproduction of old, rare, and valuable engravings, which are not copyright, and the skilful multiplication of which, on moderate terms, would be a decided boon to all lovers of art. Let those who practise reproduction devote themselves to these legitimate fields, and avoid degrading the art by practices which are injurious to individuals, repressive of enterprize, and antagonistic to the sister arts.

## PHOTOZINCOGRAPHY, PHOTOLITHOGRAPHY, AND PHOTO-ENGRAVING—WHO ARE THE DISCOVERERS?

What is a discovery? What is an invention? The perpetual recurrence of claims for discovery or invention, in connection with photography, and the amount of discussion which such claims often involve, render it very desirable that the application of these terms should be strictly defined. Yet, in no art are the boundaries which divide modification or recombination from invention so slight, or the distinctions so subtle as in photography. As a broad definition, we may state, according to lexicographers and common understanding, that discovery is the first perception of bringing to light of any fact, either as to any substance or any property of any substance not previously known, but which, nevertheless, did exist; but that invention is the production of something which did not previously exist. The substances may exist, and their properties may be known; but a new combination, or new application, producing new results, is, nevertheless, an invention.

The various methods of producing impressions of photographs in printers' ink, such as photozincography, photolithography, and photo-engraving, have occupied an unusual share of public attention recently, and in all instances involve, more or less, of the question of invention. Papers have been read at scientific societies, discussions have appeared in the daily papers, books have been published, letters have appeared in photographic journals, &c., giving these subjects a prominence altogether unprecedented, although, by no means exceeding their importance. In attempting to decide where invention begins, and modification ends, here we are struck with the fact, that in no photographic process have the steps been so gradual as those by which photolithography and the kindred process have been brought to their present state.

The principle upon which all photolithographic or carbon-printing processes of any importance are based, was discovered by Mr. Morgo Ponton, in 1838, or 1839—we see both dates quoted, and we have not the original communication in the *Edinburgh New Philosophical Journal* at hand to verify. Mr. Ponton then pointed out the peculiar action of light on bichromate of potash, fixing it in the paper, and rendering it insoluble. The next step is that of Mr. Fox Talbot, who discovers that it is the combination of organic matter and bichromate which becomes soluble under the action of light, and he takes advantage of this property to invent a method of engraving photographic images upon steel, which was coated with bichromate of potash and gelatine, which, being rendered insoluble by the action of light, protected the required parts of the plate from an etching fluid. Mr. Ponton discovered the fact of insolubility being produced, but speaks of the chromic salt as being insoluble; whilst Mr. Talbot advances a step and finds that it is the organic matter with which that salt is in combination, which becomes insoluble. The next step is an important one, and is taken by M. Poitevin, who applies this principle to the production of carbon prints, and to obtaining a photographic image on a lithographic stone, capable of being worked at a lithographic press. The great disadvantage of his process, and which appeared to prevent its coming into commercial use, was the fact that the image on the stone, consisting of a film of organic matter rendered insoluble, was liable to wear off and deteriorate before many impressions were taken. To render a process of photolithography of any practical value as a branch of economics, it was important that the image should be, as in the usual lithographic process, formed in greasy ink on the stone, without any intervening layer of organic matter. This it was sought to effect in various ways, but with only partial success. Messrs. Cutting and Bradford effected it in America by a troublesome process, which they patented; but it was never, so far as we know, turned to much account. Mr. Pouncy produced the effect by a method not described, and with what success we have no evidence upon which to form an opinion. The principle upon which photolithography has been made a practicable working process, now rapidly coming into valuable commercial use, is based on the use of a *transfer*. Instead of coating the stone with bichromate and organic matter in any form, the process is performed upon paper, and a photographic image in lithographic transfer ink is produced upon it. This is easily transferred to the stone, which is then in the same condition as a lithographic stone produced in the usual way, without reference to photography. The substitution of a plate of prepared zinc, and a slight modification in manipulation, produces zincography, the principle being the same. The simplicity of the process, and the excellence of the results, at once bring this method into practical operation, and it is adopted by the Government in Melbourne, by Mr. Osborne's plan, and in this country by that of Colonel James.

There are other photolithographic processes, but we are now referring to a specific class, which is likely to possess the greatest economic importance.

In reference to the claims of Mr. Osborne to the invention of the process worked in the Government office, at Melbourne, and regarding which some correspondence has recently appeared in our columns, we think very few words are necessary. Mr. Osborne claims the production of an image on a lithographic stone, by means of a transfer from a photographic impression, in greasy ink, on paper. Some novel points of detail and manipulation are included in his claim, but the production and use of a transfer constitute the *differentia* in his process. But it is said that the idea of the transfer existed prior to Mr. Osborne's patent, and the attempt to work it had been made. Neither the existence of the idea or the attempt to carry it out, constitute an invention, unless the result be produced. We conceive this to be an important point. Credit is doubtless due to him who conceives a worthy idea; but the credit of invention is due only to him, who works an idea from its crude form into practical results. It is stated that the original idea of the use of a transfer was due to M. Asser, of Amsterdam. Probably it might be, but we cannot say. The first notice of M. Asser's process occurred in the Photographic News, of May 20th, 1859, in a letter from our Paris Correspondent, describing the French Photographic Exhibition. The passage is as follows:—

"We must mention, *en passant*, some lithographic stones exhibited by M. Asser, of Amsterdam. They are engraved photographically, and M. Asser calls them 'positifs à l'encre d'imprimerie (positives in printing ink),' and 'transfere autographique sur pierre pur sur cliché positif sur papier à l'encre lithographique,' or the transportation of a positive proof in lithographic ink on to stone. We are not acquainted with M. Asser's process. The specimens exhibited are far from perfect."

This was published on the 20th of May, in this country. Mr. Osborne's first use of the transfer, was on the 19th of the succeeding August. Admitting a good passage for the Australian Mail, and Mr. Osborne's eager examination of the News immediately on its arrival, he might possibly have seen this notice by the 19th of August; but we can scarcely conceive it probable that a process thus meagrely described, and disparagingly noticed, could have instructed him and enabled him to invent a process so perfect in its details, and bring it into use in the Government office on the 3rd of September in the same year. The next notice of M. Asser's process, appears in the Photographic News of December 10th, 1859, when more detailed particulars are published; and we then find that the two processes are widely dissimilar, and that so far as we can judge, Mr. Osborne's is vastly superior. We have Mr. Osborne's word, which there is no reason whatever to doubt, that he saw no notice whatever of M. Asser's process until the February of 1860, when his own had been months in active operation. M. Asser patented his process in this country, in the year 1860, but we have not heard that it has ever been brought into extensive practical use. Granting, however, for a moment, that Mr. Osborne saw the meagre notice which we have quoted, of M. Asser's process, his own is so materially different in details, and so superior, as to give it, in our estimation, an unchallengeable originality. The circumstance that Colonel James in this country, Mr. Osborne in Melbourne, and M. Asser in Amsterdam, should each, at the same time, have been working in parallel directions, is one of those odd coincidences of which the history of photography presents several striking examples. We may mention that the idea of a transfer as a means of getting an image on the lithographic stone was suggested by Mr. Sutton in 1858, but without any practical suggestion as to the means of effecting it. Our correspondent "Melbourne," invited our attention to a report of the evidence given before the committee appointed to examine Mr. Osborne's claims, and at whose instance his process was adopted and rewarded. We have gone through the dreary task, as in duty bound, and regret to state that we never met with more ignorance, self contradiction, recklessness, and manifest *malus animus*, than we find in the evidence of the witnesses opposing these claims. We have also seen another report, that of a meeting of the Melbourne Photographic Society, at which the committee appointed by the opponents of Mr. Osborne's claims, rendered their verdict. These gentlemen, notwithstanding the purpose with which they set out, report, after examination, that Mr. Osborne's invention was prior to, and superior to, the process it was said to imitate.

Mr. Pouncy has furnished us with a copy of a letter addressed to the *Times*, but not inserted by that journal, in which he claims priority in the use of a transfer. The following extract from his letter, embraces his claims:

1. That in January, 1859, ere either of the gentlemen mentioned above had come before the public with the promulgation of a process, I exhibited stones with transferred pictures upon them, at a meeting of the Photographic Society of London.

2. That in December of the same year a print, taken from one of these stones, was published in the *Photographic Notes*, not because I considered it a fair specimen of what I hoped

to be able to effect, but from circumstances having arisen which led the Editor to call on me for some available result of my process as it then was.

But (3) as I have recently attained the object of protracted labours, and reached a point which neither Sir H. James nor Mr. Osborne will claim to have been yet touched, namely, *the production on stone of photographs taken direct from nature*, while my previous process (identical in principle with that of both disputants) referred only to copies.

On reference to Mr. Pouncy's description of the stones exhibited in January, 1859, we do not find any mention of the word transfer, nor any allusion which indicates that they were so produced; and on reference to the *Photographic Notes*, we find the prints referred to described as carbon prints. It is quite possible that the stones were produced by means of a transfer, but they were not so described: and it is quite possible the prints issued in the *Notes*, were from stones produced by the aid of a transfer; but the term "carbon print," as technically understood by photographers, does not convey the idea of a print from a stone at all. In reference to the question of half tone, we shall have a few words in another article.

Colonel Sir Henry James in stating his own independent discovery, in no way challenges those of other people, but willingly recognizes their labours. We shall refer to his history of photozincography shortly, in reviewing his work on that subject. A letter from Mr. Ryder in the present number, by implication, claims a share in the invention, but is scarcely sufficiently definite.

Mr. Paul Pretsch writes to the *Times*, to protest against the injustice of awarding him a prize medal in the International Exhibition, for improved methods of photographic printing, whilst his real claim is for methods of photographic engraving, or producing, by the combined aid of photography and the electrotype plates, either in intaglio or relief, for printing at the copper-plate or typographic presses. We give his letter in another page. Mr. Lovell Reeve writes to the same journal, denying that Mr. Pretsch's processes are yet in a state for useful application. He says:

> On looking at some stereoscopic pictures prepared by his process, I found it to be an utter failure as regards its application to stereography. The pictures showed that the plate had been so much etched by hand, to mend the shortcomings of the etching by the action of light, that they would not combine in the stereoscope, to say nothing of a coarseness quite intolerable when viewed through the stereoscopic lenses. Compared with a photo-print from a negative, the picture was as the printed etching of a bee's wing seen through the microscope, when compared with the wing itself.

We may suggest, that to examine a picture in the stereoscope, is of all tests, that the least favourable to Mr. Pretsch's process, and that its unfitness for stereoscopic pictures, does not, necessarily, militate against its value for other purposes.

We feel it necessary to apologize to our readers for the amount of our space taken up by these subjects, in this and other numbers, at the present moment. But the great importance which attaches to every method of rapid production, and of securing permanent prints, renders a perfect record of progress of the utmost importance, both to photographers and their art.

## THE LONDON PHOTOGRAPHIC SOCIETY.

We have pleasure in recording a circumstance, which indicates the warm interest, which Her Majesty the Queen takes in photography, and in the Photographic Society of London as the recognized and representative guild of photographers. The Council of the Society, have recently deliberated on the subject, of presenting to each member a copy of a photograph, which, besides possessing excellence as a specimen of the art, should have an especial value, from the fact, that, it would be issued exclusively to members of the Society. At a recent meeting of the Council, it was suggested that the very fine portrait of His Royal Highness the late Prince Consort, taken by Mr. Vernon Heath, and never published, would be a most suitable picture for presentation to the members of a society, of which the late Prince had been the patron. Mr. Heath at once consented to place the negative at the disposal of the Society, subject to the sanction of Her Majesty. Accordingly, Dr. Diamond, the secretary, wrote to ask the permission of the Queen for such a use of the negative, which has been graciously accorded without hesitation. The following is the letter received from Buckingham Palace by Dr. Diamond:—

*Buckingham Palace, November*, 1862.

Sir,—I have had the honour to submit your letter, of the 5th inst., to the Queen.

I am commanded to inform you that Her Majesty willingly sanctions the presentation, to each member of the Photographic Society, of a photograph, from the negative of Mr. Vernon Heath, of the Prince Consort, who was the patron of your Society.—I have the honour to be, sir, your most obedient servant, C. B. Phipps.

Dr. Diamond.

Our readers will be glad to notice, that in according this permission, it is not only done graciously, but that direct recognition is made of the relation subsisting between the late Prince and the Society. His deep interest in, and active patronage of, all that concerned the art, will give an especial value to the portrait, and her Majesty's willing sanction to the gift, from her own negative, confers an interest which could not have attached to any other presentation print. As a photograph, and as a portrait, nothing better could be desired. We may mention that we believe, although without absolute certainty, that members now joining the Society will be permitted to share in the privilege of the presentation.

We may mention another circumstance in connection with the Society. We are glad to state that the Council have just decided on giving prize medals at the next Exhibition of the Society. Just at a moment when considerable discussion has arisen on the propriety of such awards, we are glad that the Council have had the wisdom to discriminate between the real value of such distinctions as incentives to progress, and the evils which attend their mismanagement, especially as there is a tendency to condemn the use of medals, because of their abuse. The exact details have not, at the time we write, been decided, but we believe there will be three or four silver medals, for which a very fine design from an antique medallion has been chosen. There will probably be one for the best portrait, one for the best landscape, and one for the best picture, and possibly, one for discovery, or for excellence of manipulation. We believe we violate no confidence in stating that the carrying out of the project of medals, is largely due to a liberal offer on the part of Lieut.-Col. Stuart Wortley. The Exhibition will be held in Suffolk Street, the Pall Mall Gallery being unattainable on this occasion. We trust that photographers will make an especial effort to secure a good Exhibition, and erase from the public mind as early as possible some of the impressions left by the half stripped and fading effect recently presented by the display in the attic at South Kensington.

## Scientific Gossip.

### The Proposed Change in the Grain Weight.—Examination of Glass in the Spectroscope.

No one knows, or ought to know, better than a photographer, the lamentable state of confusion our national weights and measures are in. It has been estimated that there are no less than ten different systems in use in this country, most of which are established by law. Thus there is:—1, The grain, computed decimally, for scientific purposes; 2, Troy weight; 3, Troy ounce, with decimal multiples and divisions, called bullion weight; 4, Bankers' weights for sovereigns; 5, Apothecaries' weight; 6, Diamond and pearl weights, including the carat; 7, Avoirdupois weight; 8, Weights for hay and straw; 9, Wool weight, using, as factors, 2, 3, 7, 13, and their multiples; 10, Coal weights, decimal numbers, 1, ·5, ·2, ·1, ·05, ·025. Besides these may be added the weights of the French metrical system, the gramme, &c., which is constantly used in this country by scientific men. Weights of the same denomination, moreover, vary in different localities. Thus there are about ten different stones: a stone of wool at Darlington is 18 lb.; a stone of flax at Downpatrick is 24 lb.; whilst a stone of flax at Belfast is both $16\frac{3}{4}$ lb. and $24\frac{1}{2}$ lb., having in one place two values. The hundredweight may mean 100 lb., 112 lb., or 120 lb.; and if we buy a pound of anything, we must enquire how many ounces go to the pound, and if it belongs to Dutch, Troy, or Avoirdupois weight.

All these discrepancies, and numerous others which are of only local importance, might be borne; indeed, the very annoyance to which they gave rise amongst persons engaged in scientific pursuits, analytical chemists, photographers, and others, was gradually introducing a system of recording weights and calculating proportions in grains only, according to the first system noticed in our above list. Thus the chemist has his set of weights from 1000 grains down to the smallest fraction decimally divided, and never dreams of stating quantities in ounces and drachms, but gives the number of grains only, when the gramme system is not employed. The grain being always the same in every system, and invariably constant in the midst of such confusion, has been a sort of harbour of refuge to fly to, when drachms and scruples, pennyweights and ounces, became too complicated; and it has always been our endeavour, seeing the numerous evils arising from the employment of two drachms (one the sixteenth part of $437\frac{1}{2}$ grains, and the other the eighth part of 480 grains) and two ounces in the ordinary requirements of every day life, to induce photographers to write, calculate, and give formulæ in grains only. Our readers will, therefore, be as gratified as we ourselves are, to hear that the fierce onslaught which the General Medical Council has recently made upon the existing grain has been withdrawn, owing, in great measure, to the opposition which the proposed innovation excited amongst scientific men. Our readers are, no doubt, aware of the nature of the attack just made upon the old established grain weight. A New Pharmacopœia for the entire Kingdom is at present under preparation by the General Medical Council; and this body, in order to suit some views which they had of simplifying the mental labours of apothecaries' assistants, proposed to upset the last trace of order and safety in our weights and measures, and introduce a most inconsiderate, inconvenient, and even dangerous change. Their proposition was to substitute the Avoirdupois for the Troy pound, to retain the Avoirdupois ounce, and to divide this ounce into 480 parts, each to be called a grain, in order to preserve the numerical values of the subdivisions of the ounce into drachms and scruples. Now, the Avoirdupois ounce containing only 437·5 *standard grains*, its division into 480 new grains would make that weight just about $\frac{1}{11}$th less than the standard grain, and the same, of course, with the scruple and drachm. The attention of the College of Physicians having been formally called to this proposed innovation, that learned and influential body immediately passed a resolution, to the effect that, however desirable it might be to substitute the Avoirdupois pound for the Troy pound, it was *not* desirable to introduce a new grain differing from the standard grain which has been so long in use, and is established by Act of Parliament. We feel sure that all our readers will gladly endorse this resolution. The advantages to be derived from the change are comparatively small and doubtful; about the confusion and the danger which would ensue from it there can be no doubt. Some advocates, more as apology than defence, have urged that, after all, the subtraction of $\frac{1}{11}$th from the weight of the grain is a matter of small importance in pharmacy; that supposing a medical man of the present generation to take the change into consideration when writing a prescription—a rather extravagant supposition—and the dispenser afterwards to compound the medicine by the old weights, the addition to the dose, even if one ingredient were strychnine, would be attended with no risk to the patient; and with stronger reason it might be considered, that a difference of $\frac{1}{11}$th in the various formulæ used in photography could cause no serious harm. We do not admit this; but if it were true, it would by no means justify the alteration. If the old weights could be at once discarded all over the country, the case might be different; but, as a matter of course, all recipes written or printed before the introduction of the proposed innovation would have to be made according to the old weights, and for that reason, the manipulator must retain these weights in use along with the old ones, when endless confusion would be sure to ensue; or he would have to constantly occupy his mind with arithmetical problems which would never lead to a perfectly accurate result. But it would not be merely in reading or writing recipes that confusion would be created. The unfortunate photographer would be beset with perplexities on every side. At present, when a scruple of anything is named, he is in doubt as to whether 20 grains or 18·229166 grains is meant; but hitherto, when expressed in grains, he has felt safe. Were there, however, to be two grains in the field, he would never know which was meant. A formula for any solution would vary in strength according to the grain the writer meant, or the druggist used to compound it; and in reading any physiological work, he would always be in doubt which grain was meant. These and other objections have been urged so forcibly upon the Medical Council, and the absurdity of introducing three grave difficulties for the purpose of removing one trifling inconvenience, have been so strongly laid before them, that at the last moment they have succumbed to common sense, and resolved not to interfere with the grain weight. They have determined, however, to retain the Avoirdupois pound, as proposed, against which no objection can be made, and also the Avoirdupois ounce, but discontinue the use of the drachm and scruple. As the values of these latter weights are not affected, they will, of course, be used as heretofore, but now as merely denominational weights. This is, perhaps, the most sensible resolution the Council could come to; and with this arrangement, no practical difficulties need occur.

A specimen of glass has been forwarded to us from Farringdon Lane, for examination in the spectroscope. To an ordinary observer, this seems of very excellent quality, being of a full deep brown; and when compared side by side with a piece of good adiactinic orange glass, it still seems as if it might be trusted. It is darker than the orange glass, and of a browner tone. In the spectroscope, however, it is seen to be inferior. Rays, which the silver coloured orange glass would stop back, are freely transmitted by it; and it is apparent that a photographic laboratory lighted through glass of this quality would be inapplicable for delicate photographic purposes.

## ON DEVELOPING ROOMS.

BY SAMUEL FRY.

Why developing rooms should be called dark rooms seems difficult to decide, if we examine carefully into the characteristics desirable for the convenient and facile development of pictures. That in nine cases out of ten they *are* dark rooms, none can deny, being generally miserable dark cells, in which the unaccustomed eye can perceive nothing but a faint dismal glimmer of yellow, until some minutes have elapsed. The primary cause of this wretchedness has been the iterated and reiterated counsel of certain photographic pundits. For example, Mr. Thomas says:—"Use as little light as possible in the dark room;" and in going through the back numbers of the Photographic News, the same advice is to be found in different words. Why use as little light as possible? Is it the quantity or the quality of the light admitted that affects the issue? Surely, the quality. Given, then, a certain thoroughly non-actinic light, you may admit any quantity, and the more you have, the better you can see to do your work. I write thus confidently, because, about twelve months since, having to build a glass room and developing chamber adjoining, I determined to step out of the beaten track, and have a large window immediately facing the developing sink. This window, of 4 feet each way, is filled with yellow flashed glass, of the lightest lemon colour; so that the room is sufficiently illuminated by this window, and another rather smaller at the other end, to read the smallest print.

During summer, the sun has frequently shone through this window on to the plate during developing, without the slightest appearance of injury, although the chemicals I use are invariably in a state of the highest possible sensibility.

Before this glass was put into the window, it was carefully examined in Mr. Crookes's spectroscope, and was found to cut off the whole of the blue, and to leave the smallest possible trace of green.

During last summer, I performed the following experiment, at least six times, in order to discover the presence of white, or actinic, light in the room. On leaving off work on Saturday night, a dry plate, prepared by the Fothergill process, was placed in a slide under a negative, having one half covered over, and by the side was placed another dry plate, both these were placed opposite the full glare of light, until Monday, when a developer of great strength was applied, but every means known to photographers failed to show that the slightest amount of actinic light had reached these plates. I, therefore, urge upon photographers the desirability of emerging from their wretched holes and corners, and putting into their *dark* rooms three or four 12-inch squares of yellow glass. The "Answers to Correspondents" of this journal almost every week will show, that, by sending samples of the glass to be used to the Editor the fullest information may be obtained as to its suitability for the purpose. These remarks apply in at least as great an extent, to the rooms for sensitizing paper, as to the developing room. What a wretched thing for people to be carrying on delicate artistic operations in a room so dark that the very furniture in the place can scarcely be perceived for some minutes after entering. How much more comfortable, and agreeable to the feelings, to work in a well-lighted room? and I do sincerely trust that this paper may have its effect in leading photographers to work with more yellow glass in their rooms, and by all means avoid the use of yellow calico, or paper; any such material must, of necessity, soon fade, unperceived, on the outside, and thus fog may gradually set in, unsuspected, and cause unheard of trouble.

In conclusion, I may just add, that I used at the sea-side, recently, a box for development, having a square of lemon-yellow glass to admit light, this box offered great advantages from the full stream of light admitted of perfect non-actinic quality; this glass resisted successfully the noontide rays of midsummer, in France, and also at a number of seaside places in the south of England. I do, therefore, beg of photographers to inquire for themselves into the question, as regards their own developing rooms, believing that their comforts will be materially enhanced. No deductions could possibly be more erroneous than those that have been drawn as to the effect of true yellow light on the sensitized plate.

## NEW PHOTOLITHOGRAPHIC PROCESS.

The German correspondent of the *Daily Telegraph* gives the following account of a "new" lithographic process recently "discovered." It is exceedingly amusing to observe how all former steps in this direction are ignored: and not a little singular, that an engineer on the central staff of the Prussian Army, should have been two years experimenting in this direction, and then making the discovery, when it is a fact, that about two years ago Mr. Osborne's pamphlet, describing his whole process, was sent to the Prussian Government. So far as the description goes, it does not appear that anything additional had been discovered.—

Immediately after the invention of photography the problem was started, instead of multiplying the negative plate by chemical processes and the effect of light, to procure copies from the same in a purely mechanical way, as in lithography and the kindred arts. Numerous experiments were eagerly made, and all possible materials, such as copper, steel, zinc, stone, wood, and the like, employed for the solution of attendant difficulties. After many abortive attempts, a gentleman at Southampton succeeded in producing multiplied copies on zinc; but the print was so defective in all the niceties of light and shade, as to confine the application of the process to autographs. One step farther in advance, as regards execution at least, of this creditable yet rudimentary beginning, was subsequently made in the Imperial printing office at Vienna, which, however, did not get beyond the sphere upon which it improved. A method has at length been discovered, which is likely to cause an entire revolution in this particular branch—a revolution hardly less sweeping, and perhaps even more important in its effects, than the starting of lithography by Sennefelder, or the rise of the photographic art under the hands of Mr. Talbot. For this progress we are indebted to Herr Burchard, a working engineer on the central staff of the Prussian army, and who, from the multiplication of geographical photographs, was led to extend his researches to the more difficult field of drawings and pictorial designs. After two years of incessant trial, his endeavours have been crowned with success. There is being exhibited a collection of maps and artistic plates, multiplied by his process, and which would seem to deserve unqualified commendation for the beauty as well as the cheapness of the article. The process, so far as it regards the transference of the photographic negative to the stone, and the preparation of the latter for print, is the secret of the inventor. Herr Burchard calls his new method photolithography. Once prepared for print, the stone, which is taken from the well known Solenhofen quarries, looks exactly like the common lithographs, but in so far differs from the inferior products of the simple art, that it admits of an almost unlimited number of copies being taken, 3,000 at least being struck off, before any diminution in their distinctness and general appearance becomes apparent. All these copies are perfect fac-similes of the original negatives, and, what adds considerably to their value, being produced by lithography, they are not subject to the changes of tone and sharpness of outline which go so far to deteriorate the artistic worth of photographs after a short lapse of time.

As yet Herr Burchard has devoted his chief attention to Albrecht Durer and Schinkel, two German masters separated by many generations, but linked together by an equal loftiness of artistic spirit. Of Albrecht Durer, he has produced in the size of the originals, the Lesser Passion, in 37 sheets; two woodcuts—the Trinity, and the Holy Virgin with Child; and the so-called iron engraving of the Germans, representing Christ on the Mount of Olives: all these copies being such successful repetitions of the original, as to have deceived the critical acumen of even the most distinguished connoisseurs. The works of Schinkel, the architect of the Berlin museum, comprehend a number of landscapes and architectural designs. Of the landscapes, that representing the waterfall of Gastein, 27½ inches by 20½, is the most prominent, by rendering the most delicate shades with a perfection not to be excelled. The perspective of the cascade, too, has been greatly admired, and is an effect not to be outrivalled in any kind of mechanical printing. All these works are taken from line engravings, or from drawings in the same style of art—a limitation of the powers of the new process, not yet entirely overcome by the inventor. It is, however, only fair to Herr Burchard to mention that his latest experiments, and the considerable progress he has already achieved in the multiplication of oil paintings, make it a matter of the highest probability that the new process will be shortly extended with equal excellence to the reproduction of every variety of existing photographs.

It may be expected with certainty, that the new invention will have an incalculable influence upon all branches of human activity, as well in the ideal realm of art, as in the business avocations of ordinary life. One instance will suffice to give an idea of this latest progress towards the subjection of matter to mind. On a variety of drawings being lately exhibited for a new town hall in one of the German capitals, a certain design of Herren Schmidt and Stauch attracted considerable attention among the art-loving public of the Fatherland, but as it happened to become a subject of jobbery, and was not to be accepted in consequence, would have been hardly accessible to larger circles of connoisseurs, without the invention of the new art. Availing themselves of Herr Burchard's process, the architects have now issued an edition of their designs for £3 10s., which they would not otherwise have been able to offer under ten times the price. It may be mentioned as another striking advantage, that they were enabled to get the copies struck off in a few days; while by the old process of lithography, and the necessary reduction of the original drawings to a smaller standard, a year would have been consumed, if not more.

Mr. Osborne has addressed a letter to the same journal, in which, after referring to the fact that his process has been in successful operation by the Victoria Government for upwards of three years, adds the following significant facts:—"A description of my process was communicated, with my permission, by Dr. Hochstetter, of the Novara expedition, who left Melbourne in November, 1859, to the Imperial Printing-office in Vienna; and in the early part of the year, 1861, nearly two years ago, I forwarded to the central staff of the Prussian army a reprint, in pamphlet form, of an elaborate paper read by me before the Royal Society of Victoria on 30th November, 1859, together with some specimens of photolithography, which I have never seen excelled. This paper and these specimens are still in the possession of the military authorities connected with the topographical bureau of Prussia."

## PHOTOGRAPHIC PIRACY OF ENGRAVINGS.

Sidney Powell, a dealer in photographic prints, of Chandos-street, Covent-garden, appeared at Bow-street, on Saturday week, to answer a summons at the instance of Mr. Ernest Gambart, charging him, first, with having copied, or caused to be copied, an engraving of the "Horse Fair," without his consent; and, secondly, with exposing the same for sale.

The defendant pleaded "Not Guilty."

Mr. Prentice, instructed by Mr. Bowen May, appeared for the prosecution; Mr. Marshall, instructed by Mr. Redpath, for the defendant.

In opening the case, Mr. Prentice said,—In this case I appear for Mr. Ernest Gambart, who is well known as a printseller and publisher in London and Paris. He has invested many thousands of pounds in the purchase of some of the most celebrated pictures of the day. It is of very considerable importance to him, to know, whether such persons as Mr. Powell are to be allowed to make photographs from the engravings which Mr. Gambart had published at so great an expense. The first Act of Parliament to which I would call attention, is the 8th of George II., cap. 13, known as the Act for the Encouragement of the Arts of Designing, Engraving, Etching, &c., giving to the designer and engraver a copyright, for 14 years from the date of publication, which must be engraved on each copy, and imposing penalties for the infringement of such copyright. Now, this Act gave protection to the engraver who engraved and published his own design, but not to the publisher or proprietor for whom an engraving was made. The 7th of George III., cap. 38, extended the protection to "any person who shall cause to be engraved," &c., with all the same penalties for infringement, as in the former Act. By the Act of last Session, the 25th and 26th of Victoria, chap. 38, it was provided, that all penalties incurred under the two former Acts, could be recovered by proceedings before justices. Hitherto, they could only be recovered by action at law. After explaining in further detail the provisions of the several Acts, Mr. Prentice concluded by observing that, although he was instructed for Mr. Gambart by Mr. Bowen May, the solicitor to the Association of Publishers, Mr. Gambart wished it to be understood, that these proceedings were taken by him, and not by the Association. He would prosecute every case of infringement of his copyright, on his own account, and at his own charges, without any aid from any other members of the trade.

Mr. Ernest Gambart deposed,—I am a publisher of engravings, in Pall-mall. At present I carry on business in London only—formerly, both in London and Paris. I purchased the original painting of the "Horse Fair," from Mademoiselle Rosa Bonheur, in 1854 or 1855; I do not know the exact date. I engaged Mr. Landseer to engrave it, which he did, and the engraving was published on the 20th of April, 1857. I now produce a copy of that picture. The defendant keeps a shop in Chandos-street, for the sale of what I should call piracies. His shop is full of them. From the moment the photographs come out my sale is destroyed. I have no objection to state what I gave for the painting and copyright. I got it at a very moderate price. I gave £1600 for the picture and the copyright, and I paid 800 guineas for the engraving. I am the owner of the picture of the "Derby Day," by Mr. Frith, of which I am about to publish an engraving, and it is chiefly with a view to prevent the pirating of that work, that I have taken this proceeding. I have also purchased the picture which Mr. Frith is now engaged in painting.

Cross-examined by Mr. Marshall.—There is a duplicate of the "Horse Fair," also painted by Rosa Bonheur. I had both. I have parted with one. I have sold both, but one remains in my custody. I purchased the picture from Mademoiselle Bonheur, without reservation, which always includes the copyright. In selling them, I reserved the copyright. An artist's proof, or proof before letters, is one before the title is engraved on the plate. It is usual to issue a certain number, with as little writing as possible. A certain number of these are given to the engraver, as part of his remuneration. It was so in this case. Many publishers, not knowing the risk they run, publish artist's proofs, without any writing whatever. They do not understand their business; but I, who know my business well, have from the very first, taken care that every copy issued has the publication line, except in one or two cases when I did not care. In the present case, I put the publication line on the plate, long before the engraving was finished. The duplicate was presented to me by Mademoiselle Bonheur. It was thrown in. I parted with the first about two years afterwards—in 1859—to Mr. Wright, a private gentleman in New York. It has not been engraved. It is a common thing to photograph engravings, of any popularity, and to sell the photographs, but not openly.

Mr. Marshall.—They are sold in every shop.

Witness.—Pockets are picked in every street. I have been suing the photographers for years. I have not always succeeded in getting my costs, but I always got a verdict when we went to trial. I did not always go to trial. They usually apologize, and say they won't do so again. I mean to prosecute in every case where my engravings are photographed. I must do so, or give up my business. It is of no use for me to go on publishing engravings, if the moment I publish I am to be knocked out of the field by piracies.

Herbert Everett, formerly clerk to Mr. Gambart, produced the photograph referred to by Mr. Gambart in his evidence. Witness bought it on the 31st of July, at defendant's shop, for 5s. 6d. The price of the engraving was £10 10s.

Mr. Marshall had to submit to the magistrates, several points of a purely legal nature, and he contended that these Acts of Parliament, being penal statutes, and conferring a monopoly, must be interpreted very strictly. The Act of Victoria only bore on this case to the extent, that it enabled the prosecutor to recover penalties by proceedings before justices. We must go back, then, for the nature of the offence, to the Act of George III. That Act only prohibited any person from engraving copies of the copyright print. It did not prohibit any other mode of copying. The first Act, that of George II., prohibited any person from engraving or copying in any other kind of manner, and when these words were omitted in the second Act, it was clear they were not intended to apply. He contended, that the two Acts could not be read together as if incorporated. The first Act did not apply, as it only enabled the engraver to prosecute. But even under the first Act, he contended, that "any other manner" only meant such other manner as was contemplated by the Act, and of a similar nature to the processes specified,—viz., engraving, mezzotint, and chiaroscuro. He also contended, that it was necessary to show that defendant knew the picture to be copyright.

Mr. Prentice said, if Mr. Powell was not the person who made the photograph, let him give up the really guilty person, and the proceedings would drop.

Mr. Corrie said, that if the prosecution failed on the last point, it would be easy in future to give notice to all photographers, not to sell these copies, and then the proof of knowledge would be easy. But, probably, if the defence were driven to that point, the other two being decided in favour of the prosecution, Mr. Powell would be willing to promise not to sell any more, and that would satisfy Mr. Gambart.

Mr. Marshall.—Certainly. Let the law be settled, and we will obey it.

Mr. Prentice contended, that the two Acts were to be read as one, and quoted passages to show that the penalties in one applied to the other. He also contended, that the words "any other manner," covered any possible process, though not invented at the time.

Mr. Corrie reserved his decision.

Frederic Pipère appeared, by his solicitor, Mr. Lewis, to answer similar charges, which were withdrawn on his undertaking to sell no more copies of these engravings.

On Saturday, Mr. Corrie delivered his judgment on the points of law which he had reserved for consideration.

Mr. Corrie said there were, in this case, two summonses; one for copying, or causing to be copied, and the other for exposing copies for sale without the consent of the owner of the copyright. The evidence was, that a person, called as a witness, purchased a photograph copy of the engraving of the "Horse Fair" at the defendant's shop. The complainant was also called, and proved that he was the owner of the copyright, and had complied with all the technicalities of the Act, so as to bring him within its protection. Now, these proceedings were brought under the provisions of the 25th and 26th of Victoria, cap. 38, which, by its eighth section, provides that all penalties imposed, by certain former Acts, might be recovered before two justices. This was one of the Acts passed in consequence of the 23rd Victoria, cap. 43, which enabled magistrates to deal with several matters not formerly within their jurisdiction, and if they committed any mistake, there was an appeal to the judges; thus securing two advantages which had hitherto been believed to be incompatible—good law and cheap law. Now, as this Act provided a new mode of enforcing penalties, it was necessary to see what those penalties were. The Act of the 8th George II., cap. 13 sect. 1, in substance, gave to the original engraver of any design a copyright for 14 years, with penalties for infringement against any person who, without the consent of the owner, should engrave, etch, or in any other manner copy, or who should print, reprint, or import for sale, or, knowing the same to be so printed, should sell, or expose for sale, any copies of such copyright design. A few years afterwards, in the 17th year of the reign of George III., was passed the Act on which this case must be decided. After re-enacting, almost in the same words, the provisions of the former Act, it provided, that if any person should engrave, etch, or work, or cause to be engraved, etched, or worked, a design taken from any ancient or modern picture, or sculpture, he should be protected in the same manner as for an original design; and the copyright both of the original engraver, and of the person causing an engraving to be made, was extended to 28 years, instead of 14; and if any person should engrave, print, or publish copies from the copyright work, they were liable to the same penalties as under the former Act. But in setting forth what persons should be liable to the penalties, it omits to mention any person who should sell, or expose for sale. It was contended for the plaintiff, ingeniously enough, that he was entitled to recover under the words of the Act, "That any person that shall engrave, or cause to be engraved, any print, &c., shall have the benefit and protection of the same Act, in like manner as if any such print had been graved or drawn from the original design of such graver." But under this Act proceedings could be taken by a common informer; and though, in the present instance, the proceedings were taken by the person who was entitled to the protection and benefit of the Act, that might not be so in all cases. Supposing, then, that the proceedings should be taken by a common informer, it would be rather a strained interpretation to say that he was to recover the penalties under those words. But it went further, for after the clause about the benefit and protection, to show that it was not considered that the penalties had been enacted, section 5 proceeds to impose the same penalties as in the former Act, but omitting the third provision with reference to selling, or exposing for sale. It might be said that the words must have been intended to be repeated, and that it never could have been designed to let the seller go unpunished; but even so, he did not feel justified in importing into the Act words which were not there. He certainly could not insert them after a lapse of nearly 100 years. It was, probably, on account of these difficulties that the Act of the 17th of George III. was passed, which cited, that the intention of the Legislature had not been carried out. Under that Act, it was not even necessary that the vendor should be shown to have known that the copy was sold without the owner's consent. There was no doubt that Mr. Powell had committed a wrong, and that there was a remedy against him, but it was not under the penalties imposed by this Act. He had, therefore, come to the conclusion, though somewhat reluctantly, that the summons must be dismissed.

Mr. Bowen May, for the prosecutor, said that the Act, giving power to proceed before justices, would be rendered practically inoperative by this decision.

Mr. Corrie said they had a cheap and summary remedy in the County Court. The remedy, under the 17th George III., was by action on the case, and all such actions could now be taken in the county.

Mr. Bowen May said, that five of his clients, who had thousands of pounds invested in valuable prints, had actions pending in the superior courts at present.

Mr. Corrie.—You must succeed in the action. But in the proceeding here you will have to show, even if I had settled the main point in your favour, that defendant knew the work to be copyright. Of that there was no evidence whatever. So, in any case, I must have decided against you. But in the superior courts you do not require to show knowledge.

Mr. Corrie then dismissed the summons.—*Times*.

## Proceedings of Societies.

A COUNCIL Meeting of the Amateur Photographic Association was held November 7th, at 26, Haymarket, JAMES GLAISHER, Esq., F.R.S. in the chair.

The minutes of the last meeting having been read and confirmed—

The SECRETARY read a letter from Matthew Marshall, Esq., Chief Cashier of the Bank of England, expressing his regret that he was prevented by indisposition from attending the meeting.

The following members and subscribers were proposed and elected.

| | |
|---|---|
| Lady M. J. Matheson. | Lady K. Hutchinson. |
| Lady Pine. | The Hon. L. Wingfield. |
| J. D. Harding, Esq. | Lieut.-Col. J. McGregor. |
| A. W. Eskine, Esq. | Professor Emerson. |
| J. S. R. Moss, Esq. | W. W. Charley, Esq. |
| Rev. Jno. Williams. | Mrs. J. Bullar. |
| D. Laurie, Esq. | Rev. H. Read, M.A. |
| M. G. Delisle. | S. Barton, Esq. |
| Captain C. J. Cox. | J. Toynbee, Esq. |
| W. Carte, Esq. | Captain Davies. |
| G. R. Playfair, Esq. M.D. | G. H. Frothingham, Esq. |
| J. L. Smith, Esq. | Henry Coxwell, Esq. |
| J. F. R. Atherstone, Esq. | R. H. Smith, Esq. |
| P. Barker, Esq. | J. Campbell. Esq. |
| Miss McGillivray. | Mrs. Ponsonby. |
| S. C. Allsop Esq. | Major P. Innes. |
| W. R. Anstice, Esq. | F. Orpen, Esq. |

The SECRETARY then read a letter from Lieut.-Col. C. Holder, Member A.P.A., containing suggestions relative to the holding of an exhibition of photographs by the Association, the subject was adjourned for further consideration at the next meeting.

The CHAIRMAN, having asked the Secretary when he purposed returning the Association negatives now in hand, and calling in the ones for next year?

The SECRETARY replied, that he proposed to apply for next year's negatives about the beginning of January; and that, although members could always have their negatives returned to them on demand, yet, that, owing to the continued and rapid increase of members and subscribers, it would be greatly to the interests of the Association, that the negatives for one year should not be returned, until those for the year following were ready for publication.

The SECRETARY also mentioned, that the number of negatives now in hand were about three thousand. The proceedings of the meeting then terminated.

A. MELHUISH, *Hon. Sec.*

## AMERICAN PHOTOGRAPHICAL SOCIETY.

A regular meeting of this society, was held in the New York University, Monday evening, October 13th, with President Draper in the chair.

The minutes of the last meeting having been read, Messrs. D. T. Lawrence, of Newburg, and Geo. Bartlett, of New York, were elected to membership.

On account of the irregular appearance of the Treasurer, Messrs Pike and Thomspon were appointed Finance Committee, and Secretary Thompson was vested with authority to receive and disburse funds for the society.

Professor Seeley read a letter from Mr. Waldack, who is now abroad. The letter, among several items, spoke of the use of bromides in collodion, as being of no advantage.

Secretary Thompson asserted, that without bromides in the collodion, the negatives were hard. This is especially the case in dry plates, where without bromide, it is almost impossible to get detail in foliage, &c.

Professor Seeley had a couple of items to show the society. First, some prints on ordinary paper, from photozincographic plates; and second, several surgical photographs of membranes, &c., magnified about ten diameters. The samples of Photozincography, were by Mr. Hall, and the microscopic specimens by Dr. John Dean, of Boston.

President Draper, had photographed through the microscope, and found the great difficulty to be inaccuracy of focussing. This, he entirely overcame, by throwing the sunlight through a blue solution of sulphate of copper and ammonia. The focus obtained through this blue light is chemically and visually coincident.

Secretary Thompson showed several prints on albumenized paper. He called attention to the colour and tone, especially. Herein he claimed a new practice and discovery, inasmuch as he used nitrate of copper and zinc, in combination with his gold bath. He simply added to the usual solution of bi-carb. sodæ, some brass filings previously dissolved in nitric acid. The soda, which should be in great excess, neutralizes the nitric acid, leaving the copper and zinc in the solution. With a given amount of toning bath, containing this copper and zinc, he could tone 33 per cent. more surface than with the ordinary alkaline gold bath. He always added a pinch of salt to the toning bath, and fixed his prints in a fresh solution of hypos. sodæ 20 per cent. strong, to which has been added 5 per cent. of alcohol. The alcohol must be at least 95 per cent. Some of the prints shown, were from negatives taken with Mr. Sellers, at High Bridge, in the great trial of Wet versus Dry. Plenty of bromide was used in the collodion, and the detail in the shadows was consequently very great. He had brought for inspection also, the camera and changing-box used by him on that occasion.

This elicited much admiration, on account of its compact size, and the fine work it shows This camera was invented by one of the workmen in the factory of C. Jabez Hughes, of London. It was brought to this country by Mr. Werge, to whose kindness the Secretary was indebted for its possession.

The lenses were of Ross's make, and the pictures proved their superiority. The angle included, was far greater than any portrait combination, and all things from five feet from the camera to the horizon, were in sharp focus.

Mr. Pike said he found bromides of the greatest benefit in all dry plates. He had taken a negative of the Fireman's Monument, in Greenwood Cemetery, in bright sunshine. He had preserved every vein of the marble, and had not lost a leaf of the green foliage surrounding its base. This would be impossible to do without an excess of bromide in the collodion.

President Draper stated, the bromides were more sensitive to green colours than iodides. He found the iodide of silver is most affected by blue; the chloride of silver, by violet and indigo; and the bromide of silver by blue, green, and slightly by orange.

Secretary Thompson showed copies of the celebrated picture by Jacopo Chimenti, supposed by some, to be the discoverer of the stereoscopic vision. The members present, after much squinting, concluded, they "*couldn't see it*," and if "*any other man*" could see stereoscopic relief in the two samples before them, it must be "*all in his eye*."

Mr. Pike had worked the milk and sugar process with success. He admired it very much for transparencies.

Mr. Burgess said, that although he had not worked this new process himself, yet, should any of his friends begin in photography under the auspices of a *dry* nurse, he should certainly recommend, as becoming their infant practice, the milk and sugar process. Its results had been seen, and spoke for themselves.

Victor Piard presented to the society several very fine stereographs of green-house plants, and such like difficult subjects, for which he received the vote of thanks of the society.

Mr. Burgess moved, that when we do adjourn, it be to meet on the second Monday of November, at ***half-past seven*** o'clock in the evening, instead of eight o'clock as at present.—Carried, and upon motion :

Adjourned as above.

F. F. Thompson, Secretary.

## PHOTOGRAPHIC SOCIETY OF MARSEILLES.

The opening meeting of this society for 1862, was held on Oct. 8th, M. Gabriel, President of the society in the chair.

The President opened the meeting by expressing the satisfaction he felt, at seeing the work of the society resume its habitual course. Already the Photographic Society of Marseilles, by its zeal, its activity, and its initiative efforts, had acquired a place in the foremost rank of those societies devoted to the art of Niepce and Daguerre. The first successes promised much for the future of the society. It would always give him pleasure to assist at its progress.

M. Leon Vidal having thanked the President for the kind terms in which he had spoken of the society, continued as follows :—The year which has passed away, gentlemen and dear companions, has been for us a year of creation. We have had everything to commence, and, thanks to your intelligent efforts, we have succeeded. The Photographic Society of Marseilles has proved that it knew how to rise to the altitude of the mission it had imposed upon itself. It has never withheld its influence where it was likely to be of use. I will not speak to you of the numerous difficulties we have had to overcome. We struggled together. I do not consider it necessary to remind you of the various flattering testimonies which have appeared to reward your activity: you know them. The past, in one word, was ours; it is, therefore, with the future we have now to deal. Much has already been done; how much still remains to be done? our art is scarcely out of its cradle, it has all its career to accomplish—a career which will undoubtedly prove rich in marvellous discoveries, and in results and applications of increasing usefulness. I do not doubt but that you will have part in this progress of the future. Everything makes me hope—your aptitude, your initiative force, as well as the fortunate position of the society— gives the means of action. These means of action you will find in the "Union of Arts," recently inaugurated, and which progresses rapidly. You know the part therein assigned to photography. You will find there not only an exclusive centre, where you may meet on days other than those on which meetings take place, and where you may consult the especial publications, but there will also be a permanent exhibition of the products of our art, and a laboratory conveniently prepared, and all the applications of heliography. In the rooms, practical courses of study may be organised under our care. Here, my dear colleagues, are the conditions of success, which cannot fail to impart to our proceedings a new impulse. More than a year ago, we recapitulated the chief points of interest in the progress of our art. The direction indicated was as follows :—

*Dry Collodion*, rapid and instantaneous.

*Enlargement*, as perfect as possible.

*Positive Image*, obtained by a permanent process.

In these three lines is all the future of photography. I would urge upon my dear colleagues that they should receive with especial interest the labours directed towards the realisation of these improvements. Great progress has been made ; and you know that the efforts of our experimentalists are incessantly directed towards accomplishing still greater results. Permit me before the society resumes its proceedings, in your name to renew our invitation to the sympathy of the photographic world. The numerous communications which have been sent to us up to this time, are a manifest proof of the influence which is inspired by our zeal and our impartiality. The good traditions of our society will be perpetuated ; and it will be our honour to have contributed to the progress of an art we love, and which holds a distinguished place in the rank of useful inventions.

The Secretary then proposed a modification in the rule referring to the election of the committee, so that the members might be eligible for re-election.

After some routine proceedings, letters from the following gentlemen were read:—M. van Monckhoven, referring to a new process of preparing iodide of cadmium; M. Marion, accompanied by some of his collodionised paper and a bottle of the collodion; M. Ed. Potonie, Director of the International Photographic Exchange, presenting to the society some very fine German photographs by Messrs. Gustave Schauer, of Berlin, and Jos. Albert, of Munich, after the cartoons of Kaulbach's Shakspeare Album. M. Potonie, in another letter, called the attention of the society to the Permanent Exhibition of Photographs which he had organised in Paris. Copies of the rules were distributed among the members. A letter from M. De Courcival, officer in the 3rd French Chasseurs, presenting to the society some interesting African photographs. The thanks of the society were presented to these gentlemen for their gifts and communications.

The President, in referring to Mr. Hudelot's successful report, on the contents of different publications, stated, that a committee of verification to test new formulæ would be established.

M. Meynier introduced a new developer, consisting of a double salt of iron and ammonia, which he said possessed the advantages of iron and pyrogallic developers. A committee was appointed to experiment with this developer.

M. Tissot showed an instantaneous shutter, which differed essentially from most of those hitherto introduced; it opened from the centre towards the circumference.

M. Leon Vidal exhibited a new actinometer for measuring the varying intensity in light. M. Vidal showed also a cardboard box for holding ten sensitized plates.

M. Tessier showed several beautiful specimens. General Pellisier sent his card portrait for the collection of the society. Thanks were given to all these gentlemen for their gifts and communications.

M. Hudelot, secretary to a committee appointed to report on M. Vidal's autopolygraph, read the report, which was highly satisfactory, and stated the instrument to be a great success. It would enable the photographer to work in the field without a tent, double backs, &c. and carry sensitive plates in the least possible space. Instantaneous dry plates were now only required to make the equipment perfect.

After some further proceedings, attention was called to the rules of the Exhibition to be held in the rooms of the "Union des Arts" in 1863.

After further votes of thanks, the proceedings terminated.

## Correspondence.

### FOREIGN SCIENCE.

[From our Special Correspondent.]

*Paris*, 29, *October* 1862.

M. Audry, whose colossal plastic productions in electro-metallurgy in the International Exhibition, have doubtless excited your admiration, has made a discovery as important as it is unexpected, and which has already received sufficient application to justify the belief that a great progress, if not a complete revolution in painting, has been realized. He ascertained some time ago that galvanic or electrolytic copper is susceptible of being pulverized, reduced to an impalpable powder, so as to become the basis of a new kind of painting, subsequently he had the idea of grinding this impalpable copper in a vehicle having benzine for a basis, which he has since always spread over the surface of iron before covering it with copper by the electro process. He thus became possessed of a paint of galvanic copper, easily applied to wood, plaster, cement, iron, the hulls of ships, &c., which perfectly covers the surface to which it is applied, dries very quickly, gives out no smell after four and twenty hours, and assumes a very agreeable lustre when dried, and what is truly remarkable, is capable of receiving, by means of chemical agents, every light or deep tint of bronze, verd antique, Florentine, &c., which hitherto could only be communicated to pure copper. Cast iron ornaments, statues in plaster, when covered with this new paint, lose none of their most delicate details, and completely assume the appearance of objects in bronze. These plaster statues, as well as those of stone, seem to become completely insensible to the changes of weather; we have seen them, after being exposed to rain for several months, without any sign of deterioration.

Proud of his first success, M. Audry has attempted to grind in his benzine vehicle, to which a small quantity of copper has been added, pigments having for a base, lead, zinc, &c., of which house painters generally make use, and he at once proved that the vehicle advantageously replaced turpentine, and all the oils, or sizings which, hitherto, have served for ordinary pigments. This metallic paint, so called because it contains a small quantity of pulverized copper, covers a surface much better than the old kind, it dries much quicker, gives out no smell after the second day, presents a very fine grain, such as hitherto has only been obtainable by the aid of pumice-stone, and shines with a very vivid, but also very soft gloss. M. Audry prepares two kinds, one very fine for interiors, another less fine for external surfaces. At the present price of benzine, the new paints, much preferable to the old, cost the same price as the latter for second qualities, and a third more for superior qualities, or for printing in copper. As benzine is now almost all converted into aniline and other dyes, it has become comparatively scarce, and as it will become dearer and dearer, it was important to learn if the volatile oil obtained from American rock oil and petroleum could be substituted for them, M. Audry found that the latter could be substituted for benzine, at least, for first coating, and if the lightest volatile oils are employed, for interior painting also.

The revolution will then be complete, the turpentines and drying oils replaced by volatile hydro-carbides, will be applicable to other purposes, and be materially reduced in price. It must also be added, that by mixing the pulverulent copper with certain fat-oils, without adding any chemical agent, M. Audry obtained very fine green pigments, varied in tone, and of agreeable hues; his new paint has been applied to several important public works, such as balconies, gates, railings, &c.

M. Mailand has suggested an improved kind of varnish for glass negatives. The varnish generally employed for this purpose, has the serious objection of softening by the action of heat, and in summer it frequently occurs that the paper positive adheres to the negative, injuring it, or receiving injury itself. Amber varnish melted in the fire, then dissolved in benzoin, and varnish composed of 10 parts of benzoin, dissolved in 100 parts of benzine, do not present the objections indicated, but the first is generally too dark, and the second, too brittle. M. Mailand gives the following formula for a very resistant varnish, which will sustain the softening action of a very hot sun.

| | |
|---|---|
| Alcohol at 40° . . . . | 100 parts |
| Lac Resin, in grains . . | 10 „ |
| Elemi . . . . . . . . | 3 „ |

After solution, which takes place in twenty-four hours, if care be taken to shake it from time to time, it is filtered through paper, and left several days to settle, it is then filtered again, and employed as a varnish. The glass plate must be moderately warmed before the varnish is applied, and after draining off the excess, dry the plate before a gentle fire. Care must be taken with this, as with every other kind of varnish, to wipe the edge of the plate, where it drains, with a piece of blotting paper, to prevent the varnish returning over the dried surface.

The encaustics employed to give the final lustre to paper positives, are generally formed of equal parts of white wax and spirits of turpentine, or essence of lavender. This encaustic, rather stiff to use, is not always so hard upon proof to resist accidental friction. M. Mailand adds mastic in tears, dissolved in 10 times its weight of essence or spirit. This addition permits of the employment of a smaller quantity of wax for the same quantity of spirit, to obtain this, a very unctuous pomade, very easy to spread without greasing the paper, which upon the evaporation of the spirit, gives a very fine gloss, which resists every cause of deterioration.

## PRINTING DIFFICULTIES.

Sir.—It has ever been the lot of every new science to be beset with theories, which, like the "humpty dumpty" of our childhood, have suffered a great and speedy fall. The first glance at Mr. Eliot's paper caused me to imagine that my bantling, like the Hypanian insect described by Aristotle, was doomed to pass through its stages of life and death in one short day, but a more searching scrutiny speedily convinced me that Mr. Eliot has unconciously provided stronger proofs to support the theory advanced, and explained in my last two letters, and I am sure, that gentlemen will forgive the liberty I now take, in analysing the contents of his, (in many respects,) very excellent paper. Without arguing the propriety of using the Berzelius or any other scale of chemical notation: I have first to notice the remarks on Au Cl3 rendered minus free acid by the addition of soda carb.; by comparing this portion of his paper with the statements that follow, a strange incongruity is so plainly visible that I need not enter into details. Mr. Eliot very correctly states that a batch of prints being immediately immersed after mixing the solution, a false colour is given which dissolves in the hypo bath; the cause of this may be easily explained. In a former letter I endeavoured to show that by the action of light a portion of free nitrate was converted into what I named, a bastard albuminate of silver, which is removed by the action of soda during the process of toning. Now, I am satisfied, that the decomposition described in the letters before alluded to, does not commence for some five or more minutes after the solution is mixed, that is to say, if artificial heat is not applied, but if a batch of prints is immersed before natural action commences, a disturbing element is introduced, which for some considerable time will govern and prejudicially alter results, for except each print has been thoroughly sponged, and passed rapidly through several waters, and finally soaked in pure tepid rain water, it bears a portion of free nitrate in an unreduced state, which unites with the chlorine liberated; a white chloride of silver is formed, and the gold deposits itself over the entire surface of the paper, thus preventing the soda from performing its work, which it left for the hypo to accomplish: but whilst the unstable bastard albuminate is dissolved out with its coating of gold, the white chloride, by some unknown means, is rendered impervious to the action of the hypo, hence, not only one form of mealiness, but also, in all probability; the reason why silver cannot be entirely removed from the whites of prints, for albumenized paper, unlike plain samples, cannot be saturated with the fixing solution, its highly varnished surface being proof against the attacks of cold liquids. Now it is evident, if no prints are immersed for some little time after the bath is mixed, a natural decomposing action will spontaneously commence, the chlorine uniting with sodium as I have before explained. That such is the case Mr. Eliots arguments go far to prove; in case No. 3, he states that chloride of gold, having lost a portion of its chlorine, stands thus, Au Cl 2; one equivalent of chlorine being gone; where? not to the surface of the paper, for by his showing, the less of chlorine the more perfect the toning. Proceed again, if the surface of the paper received the liberated chlorine, why should an excess of soda exercise an influence upon this agent, and from whence is produced the carbonic acid, which it requires an experienced eye to detect from the hydrochloric acid. If from the soda, decomposition must have caused its liberation, to make room for a new comer; this more favoured one cannot be gold, for the surface of the paper claimed that, then most assuredly it must be the liberated chlorine, except it can be proved that this substance is ejected from the bath and mixes with the atmosphere. If such is the case, why employ soda at all? Heat is sufficient to liberate chlorine; and the acetate bath is a speaking proof, that an alkaline agent is not indespensable for the production of toning action; but the specific gravity of chlorine, 2·5, decides the question; being heavier than common air, the law of gravitation is a sufficient proof that it cannot ascend except rarified by the molecular repelling action of heat. Again, if toning proceeds best when decomposition has proceeded so far as soda will allow, why is it that a bath so soon becomes useless, even when no prints have been exposed to its action? If Mr. Eliot be correct in his statement, surely no necessity exists for the acetate bath being employed because of its keeping qualities: certainly there is no necessity for putting into practice Professor Hyme's suggestion, for we have a bath which is perfection itself. And now for point No. 4, Mr. Eliot states that one equivalent in excess, reduces the terchloride of gold to a binary compound, Au Cl, and this condition is sometimes produced by boiling the prints in a bath, (certainly a queer mode of toning,) why, the well known decomposing power exercised by heat, would, under these circumstances, produce a decomposition so complete, that Au minus Cl would speedily be seen floating on the agitated surface of the bath! A moderate heat, I will admit, quicken toning by hastening decomposition, but this plan is dangerous in practice, for chlorine is liberated two quickly for soda to imbibe it, and mealiness will be the result if the paper is at all given to that disease. True there are some papers that will not give evidence of the evil under any treatment; on examination you will find a very slight coating of albumen on its surface. I must postpone an examination of the beakers until next week.—I remain, yours, respectfully,

A Photo's Assistant.

P.S.—Having made a free use of Mr. Eliot's name in this letter, I enclose my own, which is at your disposal.

## DOES THE TONE OR COLOUR OF THE PHOTOGRAPHIC PROOF DEPEND SOLELY ON THE DEPOSIT OF GOLD IN GOLD TONING?

Sir,—In your No. 216, for October 24, you inserted a communication of mine, on the subject of gold toning. Will you permit me to raise the question on the above subject, as it does not appear to have occured to your correspondents, that the tone is due, to a very partial extent, to the deposit of gold.

To enable you to understand my doubt, as to the agency of gold in toning, I must refer to the case of the Daguerreotype, where the gilding was affected by means of a solution containing gold, the same as used in the Sel d'or process; now the chief difference in the gilding a Daguerreotype and of a photographic proof on paper, seems to be in the agency effecting the decomposition of the solution; in the case of the Daguerreotype every other element but the gold was driven *away* by heat, and, owing to the nature of the surface, we could perceive, with comparative ease, the amount of change effected by the attenuated film of gold in the tone of the picture; that it did produce very beautiful tones of color I do not intend to deny, but that the tones, and especially the *depth* of tone, so produced bore an exact affinity to the tone produced in a paper proof, I very much doubt, although the deposit of gold in each case is probably similar in amount, and in each case deposited during a process of decomposition.

Now, the great difference that seems to exist in the two cases is this, that in the Daguerreotype, as I have remarked, the elements present, in the first instance, with the gold, were driven off the surface, which, being non-absorbent, could be effected very perfectly; but in the present case the paper proof is not only saturated with the solution, but remains in it, during the decomposition of the bath, exposed to every change in the formation of its elementary components, and it is only after a certain amount of decomposition has taken place that gold is set free from its solution to deposit on the image exposed to its influence.

It is scarcely necessary to call to mind, that toning can be effected in many ways without the aid of gold, as in the sulphuric acid bath, phosphorus printing, development printing &c., this of course would be no proof that gold also does not effect the same purpose, but when we consider the amount of tone yielded in the case of the Daguerreotype, where the deposit is probably even heavier than in the paper proof, when we consider how little the image is in any way changed, except in the slight change of colour on the surface, we can scarcely believe that the gold is the sole agent in changing a bright red paper proof, to a deep purpley black: *for as red is one of the components of purple, the tone*, in such case, should be effected by *an agent possessing greater depth of colour* than appears on the surface of the proof.

All experiments that have yet been made on the colours produced by minute subdivision of particles of gold tend to the belief that the normal colour in such cases is a purple or violet. This, therefore, could scarcely give the great variety of tones produced in the many methods of toning, even where the original tint of the proof is very similar. How, then, shall we account for the colouring of the paper proof if it be not entirely due to the deposit of gold? Let it be observed, that I do not assert the gold to be entirely unaiding in producing the tone, but that it does not possess the power of effecting those extreme changes of colour often observed in Photographic processes.

In my former communication I expressed my belief that the decomposition of the gold solution was effected by electrical agency; but whatever be the cause there seems no reason to doubt that a certain small amount of solution undergoes this process setting free its component elements. Amongst the elements so freed from combination, there would be a certain amount of oxygen from the acids and water so decomposed, and it is to the presence of the oxygen that I believe we shall be able to trace the change of tone, taking place simultaneously almost with the deposit of gold, which I take to act rather as it was supposed to do in the case of the daguerreotype than as a positive agent in effecting change of colour; that is, as a preservative from atmospheric influences.

Lest this view should be considered too heterodox, let me remind those who may doubt it, that we really possess no knowledge of any element save oxygen—the presence of which effects change of colour, whether the means of producing it be as direct chemical or mechanical agency. In this point of view it would not be difficult to trace the true effects of an addition of acid in renewing the energy of a gold bath, and also why, after a certain time, alkalies render such baths of no avail in toning proofs; in fact, it is only so long as decomposition lasts that the bath can be of service, and when this shall have been perfectly effected, no matter by what agency, the bath is no longer available for its purpose.—Yours respectfully, E. E. L.

## THE MEDAL FOR CARD PORTRAITS.

DEAR SIR,—In last week's "Talk in the Studio" you observe that you made an inadvertent error in your previous number in remarking that I received the *only* medal for card portraits, and admit Mr. Mullins' claim to having received a similar award for the same class of pictures. If you will refer to the official book of awards, you will find that Mr. Mullins received a medal "for general photographic excellence," and that I am the only photographer of any nation who is mentioned in that book as having received a medal especially for *cartes de visite*. It is probably Mr. Mullins' misfortune and not the fault of his pictures that his award was confined to "photographic excellence." I have very much admired, and have received great profit from an examination of his pictures, and quite think that "card portraits" should have been made a speciality in his award, at the same time, as that was not done, I cannot give up my claim to having received the *only* medal for *cartes de visite*.

H. P. ROBINSON.

*Leamington, November* 1, 1862.

P. S.—In writing on the International medals, has it not struck you, as it has me, that we all ought to be ashamed of receiving our medals, when the greatest name in our art, I mean that of Rejlander, has only "honourable mention" tacked to it.—H. P. R.

[We have already expressed a conviction more than once, that it is a subject for unmitigated regret that Mr. Rejlander did not receive the highest honours the jury could award. As regards the medal for card portraits Mr. Robinson is right. The official list mentions card portraits with his medal only.—ED.]

## Photographic Notes and Queries.

### NEGATIVE VARNISH—CROWN GLASS—HOT DEVELOPMENT.

SIR,—I see, week after week, in the NEWS, that there are great complaints of negative varnish. If your readers would only try the varnish recommended by Mr. Fitch, I think they would be, as I am, perfectly satisfied with the same. Always taking care to obtain the best white hard carriage varnish, I dilute it with methylated spirits of wine in nearly equal quantities. When first added it causes a milkiness, but after standing a day or so it quite clears itself, and is ready for use: if it is too thick, I then add more spirit. I have used it ever since Mr. Fitch first recommended it, on plates *carte de visite* size up to 9×7. I frequently use the plate directly. After varnishing I have placed in the full sunlight, and not in one single instance have I had cause to complain of tackiness. I beg to thank Mr. Fitch through the pages of your valuable journal for the same.

I see in a recent NEWS, a correspondent recommends cutting the corners off the plates, as a cure for negatives breaking in the printing frames. I always use the crown glass for large and small plates, as they are much cheaper, and I find I can get pictures equally as good as I can on the patent plate. The simple plan I adopt for protecting the plates whilst printing, is to place a piece of velvet or cloth over the plate, (after the paper is out) and then a square piece of cotton wool over that, thus protecting the glass from any irregular pressure. Since using this means, I have never broken a single negative.

I thought perhaps the following might be worth recording, seeming to show that hot water has developing powers over tannin plates. I took a plate 9×7 with me (that had been prepared about 3 weeks) to take a view, but before I could give it sufficient exposure, the weather changed, and the rain came down in torrents, causing me quickly to make a stir for shelter. When I reached home, knowing the plate was not near exposed enough, I thought I would try the hot water process. After heating the water, I placed the plate in, when the view began to appear, and steadily continued till the detail was fully out, but on pouring the developer over, a great many stains appeared, thus spoiling the plate. This, I find is the great drawback to the hot water, the plate drying in patches as soon as it is out of the water. The water used was spring water boiled in an iron tea kettle.

If you think this worth insertion in the NEWS, you will please to insert the same.—I am, sir, yours obediently, J. DRAKE.

### CARBONATE OF SODA IN THE TONING BATH.

DEAR SIR,—In this week's NEWS I see a correspondent makes enquiries about carbonate of soda in the toning bath, and alludes to Mr. Leake's remarks thereon.

I believe I have tried most formulæ, but must certainly give the preference to carbonate. As I before stated, if care be employed in the manipulation, exquisite results will follow.

The bath is prepared immediately before use, and thrown away when the gold is exhausted.

I enclose a stereograph which was printed more than three years ago, and toned according to my formula given in the NEWS, May 30th, and I leave you to judge whether there be anything objectionable in the colour of the print.—I remain, yours respectfully, JOHN H. UNDERWOOD.

*Beech Cottage, Sale Green. November 1st*, 1862.

[The tone of the print received is a rich, deep, warm sepia which is very pleasing; but we may mention here that those who object to carbonate of soda in the toning bath, are generally portraitists, and it is a fact that the mode of treatment which gives good results with prints from intense landscape negatives, does not always do so with those from thin portrait negatives.—Ed.]

## Talk in the Studio.

Photographic Piracy.—We regret to learn that a system of wholesale piracy has just been discovered, in which the exquisite photographs of the International Exhibition and its art treasures have been copied to a large extent. The vendors have, we understand, given up their stock, and agreed to pay costs and damages, to avoid prosecution. The producer's name has also been given up, and it is the intention of the Stereoscopic Company to proceed with the utmost rigour of the law, so as to deter others from these disgraceful piracies.

Photographic Reproductions of Sculpture.—A series of fifty photographs of Italian sculptures of the Middle Ages, and the time of the revival of art, selected and arranged from the collection in the South Kensington Museum, by Mr. J. C. Robinson, will be published in a folio volume next month. The photographs have been executed by Mr. C. Thurston Thompson.

Photographic Profits.—The *Times* says :—"We are glad to say that Mr. Story, the American Artist, has now given his consent to photographs being taken of his two noble figures 'the Cleopatra' and 'the Sybil.' Without these, the photographic record of the sculpture of the exhibition would have been sadly incomplete. One may judge of the popularity of these photographs of statues from the fact that the copies of the 'Reading Girl' have had, and still have, such an enormous sale that the profits realized on this picture alone would more than repay the £2,000 paid to the Commissioners by the Stereoscopic Company for the right of photographing. Yet the orders for copies of 'the Cleopatra' and 'the Sybil' are larger than this again." We fear that large as the sales have been, that these are somewhat random figures. We apprehend that Mr. Nottage would be glad if the writer could, to use a popular phrase, prove his words.

"Clearing up" Negatives.—Mr. Osborne's plan of "clearing up" negatives of engravings, &c., has excited some interest, and has been tried with much success and satisfaction by several photographers largely engaged in reproduction. It is perhaps desirable, in order to prevent the misconception into which a contemporary has fallen, misleading others, to repeat our information derived from Mr. Osborne, that after the negative has been treated with a dilute iodine solution to convert any slight foggy deposit into an iodide of silver, it should then be well washed, and submitted to the action of a dilute cyanide solution, to remove the deposit on the shadows, which has been converted into iodide. This is necessary before proceeding to intensify, where the utmost density and the utmost transparency are required, as in maps, engravings, &c. The process referred to by our contemporary, of using a solution of iodine before applying pyro and silver, is very old, having been published as early as 1854, and very useful for ordinary negatives we have regularly practised it for many years. But the process of Mr. Osborne is novel, both in purpose and practice, and has reference chiefly to reproduction negatives requiring pure blacks and whites; and it is necessary to remove all trace of deposit from the transparent parts of the negatives before intensifying, in order to secure sufficient contrast.

## To Correspondents.

A. R. P.—The extent to which a bath of hyposulphite of soda may be used for fixing positives on paper with impunity, is somewhat difficult to decide, and the skilful photographer must be guided largely by observation and experience, as the result is affected by a variety of circumstances. The quantity of chloride of silver dissolved by hyposulphite of soda may be roughly stated at a third of its weight, but to make this knowledge available it is necessary to know the quantity of unreduced chloride of silver in your prints, which is very difficult to get at Read the papers of Mr. G. Price in recent numbers. Mr. Hardwich says, that one ounce of hypo dissolved in six ounces of water, will fix forty stereo prints, or about two sheets of paper; but for safety he recommends that it should only be used for half that quantity, as hyposulphite is cheap, and it is well to keep on the safe side. 2. We do not know of any one resident in Manchester who prints backgrounds. 3. A negative bath may be neutralized either by freshly precipitated oxide of silver, or by means of bi-carbonate of soda.

Homo.—The best mode of preparing an ammonia-nitrate bath for albumenized paper with which we are familiar, is, first make a 60 or 80 grain bath, add ammonia until the precipitate first formed is re-dissolved, then add nitric acid drop by drop, testing in the mean time until it will only just restore the colour of reddened litmus paper. It is, in this state, just on the alkaline side of neutrality. The paper must be floated rapidly: less than a minute will be sufficient.

Jedburgh.—Our remarks in the criticism on photographs of the Exhibition had no reference whatever to an article in another journal to which you refer. As stated in a foot note our remarks had been written and waiting for insertion long before the other article was published. The coincidence was singular, but still only a coincidence. Had we been writing a reply to any article we should have mentioued it, and not have referred to it by indefinite inuendo.

T. R.—We must consider your proposal before giving it publicity. Personally we could not attend to the matter, but will ascertain if any one connected with our publishing office could undertake the duty. To make the plan of any value a register ought to be kept at the office for subsequent reference, and we fear that would involve trouble that might not be properly carried out. We certainly do not see that the registrar can possibly refuse forms sent by post, although he may have the power of refusing stamps as payment. We will make some enquiry on the subject.

T. P. E.—We think it possible that the plan suggested in diagram No. 2, which allows a little light to fall upon the background from the roof behind the sitter, might be tried with advantage; but as we have not seen it done, we can only speak conjecturally. The plan suggested in the fourth diagram, we should think, would answer well, as it is good in principle. The only front light it gives you is quite above the sitter. No. 2 might be tried first: if any objection were found, we think that No. 4 would certainly do.

Jackson Brothers.—The parcel of fine photographs received. We shall examine and notice them shortly.

W. Downey.—We shall have pleasure in seeing you.

Cassan.—Albumenized paper prepared on an ammonia-nitrate bath does not keep long without discolouration. The less alkaline the solution the longer the paper will keep. If you add a few more drops of nitric acid, taking care to keep the bath very slightly alkaline. Some samples of paper, however, discolour in a few hours, even when excited on the ordinary bath.

Dathus.—We are not aware that there is any especial agent in London for Jamin's lenses; they are sold by all dealers. There is not, that we know of, any printed instructions for their use. A little examination will give you the best idea of the purposes of the different parts if you bear in mind these hints: when complete, with the central lens in its place, it has its shortest focus, and most rapid action, and covers the smallest plate. When the central lens is removed, an ordinary portrait lens remains, working slower and covering a larger plate. The next combination is more complicated. You must unscrew the entire combination from the flange, removing the hood from the front lens, withdrawing the tube and front lens from the outer mounting, and screwing on the extra lens to the end of the tube; the front lens is then reversed in position and screwed into the flange, so that it becomes the back combination, and the extra lens the front one. The hood is then screwed on to the part of the mounting that originally screwed into the flange, and in a reversed position. This gives a lens of still longer focus; and finally, the first lens only may be used as a single view lens. There is a multiplicity of purposes, but we cannot assure you that they are all equally well effected. A *multum in parvo* lens generally sacrifices efficiency to comprehensiveness.

Astor.—Many of your prints are very fine, the copy of a Daguerreotype is especially good. The double printing is very effective. You must guard against a little hardness, arising probably from a little over-intensifying. We should think a frame of your best might be sent to the Exhibition.

Dry Colours.—A correspondent, whose letter is at the moment mislaid, asked, if card portraits might be tinted with dry powder colours? A very pleasing effect may be obtained by skilfully tinting albumenized prints with dry colours; but with this drawback, that the pictures must be covered with glass, as the colours would otherwise rub off. The usual method of tinting card portraits is with water colours.

Mr. Warner, of Ross, desires to call attention to an advertisement announcing a slight advance in his charges for enlarging negatives, which he finds imperative, to make the undertaking remunerative. He asks for our opinion on the reasonableness of the charges. So far as we can judge, the prices are only fair and reasonable remuneration for good work.

Melbourne.—We regret that we cannot, with justice to our readers, insert further correspondence on a question so purely personal as Mr. Osborne's claim to priority in his process of photolithography. After due examination of these claims by a committee appointed by Government, and by another committee appointed by Mr. Osborne's opponents, his claims were decided as substantially valid. After our own examination, we come to the same conclusion. You appear to be imperfectly acquainted with some facts, with which we are familiar. But, in any case, the question is not of sufficient public interest to justify us in further filling our columns with its discussion. You will find some remarks on the subject in an article in the present number. There is one remark in your letter, on which we offer a word of comment. You deplore a common tendency in Englishmen to worship success. It is not an uncommon thing to condemn this tendency, as you do. We do not join in that condemnation. To honour success, is merely another form of honouring merit. Men do not honour success if they know it to be gained by unfair means; but success is, generally, more or less, the result of some kind of merit, and whilst merit is not always honoured, because it is not always a self-evident thing, success is honoured as the general voucher for merit.

J. S. H.—The slides received. We are much interested, and shall be glad to hear more on the subject.

Mr Osborne's paper, continuation of Mr. Price's article on "Albumenate of Silver," and several other articles and letters in type, and answers to correspondents, in our next.

*** Agents or subscribers having copies of the following numbers of the present volume, which they can spare, will confer a favour by forwarding them to the office, where they will be exchanged or bought at full price: Nos. 171 187, and 196 to 203.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 220.—*November* 21, 1862.

## RETARDING ACTION OF A CHLORIDE ON BROMO-IODIZED COLLODION.

We have recently received from Mr. Keene, of Leamington, a note on the use of a collodion containing equivalent proportions of a bromide and of an iodide, for dry plates, as proposed by Mr. Sutton, and he calls our attention to the fact that he has, for some months past, prepared and advertised a collodion containing such proportions. Having referred to this fact, Mr. Keene proceeds to another, which is at once curious and important, as it may possibly furnish the key to many varying experiences in reference to the sensibility of dry collodion plates. We give this suggestion as Mr. Keene writes it —

Have you ever noticed the *retarding* influence *a chloride* salt exercises in combination with a bromide, when the latter is in as large as equivalent proportions with the iodide? During a series of experiments with the above highly bromized collodion, in connection with the dry process, undertaken during the early part of September, I added, to a portion of it, one grain per ounce of chloride of magnesium with the hope of combining the *intensity* given by chlorides with the extreme *sensitiveness* of the bromides. *The intensity* I certainly obtained, but at the expense of sensitiveness, which was very materially *reduced*; and, upon reference to my journal, I find the result was the same if the prepared albumen contained the chloride (in this instance ammonium) instead of the collodion.

I was not prepared for such a result as I had never noticed the slightest diminution in sensitiveness when the ordinary (bromo) iodized collodion was used in connection with a preservative solution containing a chloride; and the very sensitive plates obtained by the Messrs. Walter, an account of the method of preparing which, appeared a short time since in the News, were prepared with a bromo collodion and preservative solution of prepared albumen containing chloride of ammonium.

This is a circumstance of much moment at the present time, when bromides are likely to be used in large quantities for all quick dry processes, and a *thorough* washing *previous* to the application of the preservative solution—should any such be a necessity—for, if chlorides exercise the same retarding influence under all other circumstances, when a large quantity of bromide is used, as they do when albumen is used as a preservative—my experience does not go further—*all* waters containing chlorides will have to be discarded for washing the sensitized plates, and pure rain or distilled water only employed.

I hope shortly to be able to send you something of interest, relating to rapid dry process photography.—I remain, dear sir, very truly yours, Alfred Keene.

That the use of chloride is inimical to sensitiveness in dry plates has often been held, but the grounds upon which the idea has been based have not always been very clearly stated. One reason which has been alleged has been that free nitrate was necessary to extreme sensitiveness, which could not, of course, exist in the presence of a chloride. That the presence of free nitrate is not necessary to sensitiveness has been, however, repeatedly proved. The cause of the often-noticed retarding action of a chloride is not due, therefore, simply to the fact that it removes free nitrate. M. Mc. A. Gaudin expresses a conviction that chloride of sodium will not fail to destroy the sensibility of iodide of silver, in the same way that excess of iodide of potassium, and all solvents of iodide of silver destroy it. The retarding influence of chloride of silver, formed in the film, and especially the especial action in the presence of large proportions of a bromide, are new to us, and we think it worth while to call especial attention to M. Keene's observations. We shall be glad to learn the experience of other operators in the same direction, and the farther results of Mr, Keene's experiments. If the presence of a chloride in a dry plale really be antagonistic to sensitiveness, it will be very easy to wash in successive baths of distilled water.

## THE COMMERCE OF PHOTOGRAPHY.

In a recent article, we referred to the immense impetus given to the art, and its great commercial development, which resulted from the spirited management of an enterprise like the International Exhibition photographic contract.

We have just been favoured, in further illustration of this subject, with some very interesting facts, by Mr. England, to whose ability and fine taste, the public are indebted for the entire series of exquisite stereographs, and some other pictures, of the Exhibition interior and its contents. The number of these stereoscopic pictures alone, produced during the summer, by Mr. England, has been upwards of two thousand gross, or considerably more than a quarter of a million slides. The card portraits from the same negatives, have not been quite so numerous, but they amount to very many thousands. The materials used in the production of these, are stated as follows:—

| | |
|---|---|
| Albumen . . . . . | 200 gallons |
| Paper . . . . . . | 70 reams |
| Nitrate of silver . . . | 2,400 ounces |
| Pure metallic Gold . | 35 „ |
| Making of— Terchloride more than of Gold . . . . | 20,000 grains |
| Hyphosulphite of soda, 25 cwt., or . . . . | $1\frac{1}{4}$ tons |

The number of persons employed in Mr. England's establishment, in albumenizing, exciting, printing, toning, fixing, washing, mounting, &c., may easily be conceived; and this is only one portion of the Exhibition work, and does not include any of the large pictures.

## THE PHILOSOPHY OF POSITIVE PRINTING UPON ALBUMENIZED PAPER, IN CONTINUATION OF "ALBUMINATE OF SILVER AND THE ABBE PUJO."

BY GEORGE PRICE.

The Table No. 2, given in my last communication,* shows a very great diversity in the proportions which the albuminate, chloride, and free nitrate of silver bear to each other, in the various formulæ I have analyzed; as we may safely assume that each person has given that which he himself considers will produce good, if not the best results, this extraordinary diversity goes far to prove how little is really known respecting "the philosophy of positive printing upon albumenized paper."

Of the three compounds of silver, we find the *free nitrate* is, in every formula, considerably in excess of either the albuminate or the chloride; and in many cases, *is more than double their united amounts.* Comparing it with the chloride, we find it ranges between the two extremes, of *less than twice the quantity*, as in No. 7, Mr. Aleo's, to *more than thirteen times the amount*, as in No. 12, Mr. T. R. Williams's.

* Page 523.

If we compare the *albuminate* with the chloride, we find that it is always in excess, excepting No. 10, Mr. Hardwich's, where it is *little more than half the quantity* ; and that it ranges from this up to *very nearly four times the amount*, as in No. 12, Mr. T. R. Williams's. It seems, therefore, to be the general opinion, that the albuminate should be in excess of the chloride—Mr. Hardwich, in his last edition of "Photographic Chemistry," having given the same formula as No. 8, Mr. G. W. Simpson's.

An inspection of the tables I have calculated, suggests several interesting questions, well worthy of discussion. Firstly, *which* of the three compounds of silver—the albuminate, the chloride, or the free nitrate—plays the most important part in positive printing upon albumenized paper? Table No. 2 seems to infer that the free nitrate does, so as it is largely in excess of the others; but I ask, whether such an enormous excess is really *necessary*? It must be borne in mind, that the quantity there given is produced by sensitizing upon only a *seventy*-grain bath; and if we use from "one hundred to one hundred and thirty," which we are recommended to do "from experience," we, of course, materially augment the excess there given; for we cannot make any addition to the quantity of albuminate or chloride by increasing the strength of the nitrate solution.

Secondly.—What part does the free nitrate play?—is it a *principal*, acting in co-operation with the albumiuate and chloride in the intricate process of the formation of the image? or is it but an *accessory*, though, perhaps, a necessary one, to its formation? We are told that the action of light upon chloride of silver decomposes it, by liberating the chlorine, and that silver, having a greater affinity for chlorine than it has for nitric acid, the nitrate of silver is in turn decomposed by the silver leaving the nitric acid to combine with the liberated chlorine; this decomposition and re-composition going on during the whole time of printing.

According to this theory, which is generally, if not universally received, the nitrate of silver, *as such*, has nothing whatever to do with the formation of the image, but only furnishes a larger amount of chloride of silver for its production than the paper originally contained, so as to give it more vigour and intensity.

This re-composition of chloride of silver during printing, must have its limits with respect to the quantity *necesary* to be supplied for the formation of a vigorous image; and therefore, the free nitrate beyond what is requisite to furnish this amount, must be useless,—if it plays no other part than this. If it *really* has no other duty to perform, we have only to give at once, the required amount of chloride of silver, by increasing the quantity of salting chloride in the albumen, to enable us to do without any free nitrate whatever; but we know, that however large the quantity of chloride of silver, even in conjunction with the albuminate, it will not yield as good an image without the free nitrate, as it will do when it is present. Methinks, this may fairly be considered as affording presumptive proof, that the free nitrate of silver *as such*, does in some unknown way, tend to the formation of the image, in co-operation with the albuminate and chloride.

Because chemical science is not sufficiently advanced for any one to be able to state *how* the free nitrate acts, it surely is an unwarranted assumption to assert, that *its mere presence is necessary to enable the chloride to give good results.* But whether it acts only as a necessary *accessory*, or, as a *principal* in co-partnership with the albuminate and chloride; what is the use of, or rather, the necessity for the greater portion of it; viz. that which is washed out after printing, and previous to toning? This *un*-used free nitrate, if I may so term it, is, in many cases, fully *four-fifths* of what the paper took up from the sensitising bath, and nearly the whole amount of free nitrate which the sheet contained.

Assuming, according to the Abbé Pujo's statement, 135 to be the maximum number of minims of undiluted chlorided albumen, that a sheet of paper ordinarily takes up; and also, according to Stockhardt, that only one-eighth of the albumen is left upon evaporation; 16⅞ grains of dry albumen is the greatest quantity which a sheet of paper will be surfaced with. If we consider the atomic weight of pure albumen to be 8206 as I have calculated it, this comparatively large amount requires only a *fractional part of a grain of nitrate of silver* to convert the whole into albuminate of silver.

These 16⅞ grains of dry albumen will *never* require more than a fractional part of a grain of nitrate of silver, to convert them into the albuminate, *unless the atomic weight of pure albumen be estimated much lower than we should be warranted in assuming that of such a complex organic compound to be.* I have had the curiosity to calculate this; and find, that for 16⅞ grains of dried albumen to require *one grain* of nitrate of silver to convert it into the albuminate, the atomic weight of pure albumen must be 2868·75. Thus, whatever may be the atomic weight, the greater or lesser portion of albumen in the albumenizing mixture, creates no necessity for a stronger or weaker sensitising bath; it is the quantity of salting chloride which it contains that must regulate its strength; I do not think sufficient attention is paid to this fact.

The greater the amount of salting chloride in the albumen, the more sensitive the paper becomes; but the quantity of chloride of silver which is *absolutely necessary* to produce good effects, is extremely small,—as evidenced by the results produced by using Marion's and T. R. Williams's low salting formulæ. Upon referring to Table No. 1,* we shall find the proportion of dried albumen to the salting chloride, is, in Marion's 9 to 1, the fraction being too small to be worth consideration; in T. R. Williams' it is 10¼ to 1. That the albuminate and chloride of silver will not bear the same proportion, I have shown in my first communication, proving the fallacy of the Abbé Pujo's assertion that they will do so;† nevertheless, in these low salting formulæ, the albuminate is much in excess of the chloride; in Marion's it is nearly 3½ times the quantity, and in T. R. Williams's *very* nearly 4 times.

Judging by the *quantity* of each compound of silver present in the sheet of paper, the albuminate ranks *next* in importance to the free nitrate, *and last of all, the Chloride*; and yet it is to this latter compound that the chief honour is given for the production of the picture. That the chloride is not of the paramount importance which has been attributed to it, may fairly be questioned, when we consider the beautiful effect produced by low salting formulæ.

I know not how it has arisen, but a strange misconception exists, respecting the amount of chloride of silver usually formed in a sheet of paper; I read of *thirty grains.* This quantity must be produced from what may be deemed an *exceptional* formulæ; as the sheet of paper must contain 11¼ grains of chloride of ammonium, or their equivalent; and taking 135 minims to be what it takes up of the albumenizing mixture, there must be *forty grains to each ounce of solution*, to produce such an amount.

I believe, photographers, as a body, are not much conversant with chemistry, and thus are led to believe a thing to be a fact, because the knowledge of chemistry is not sufficiently advanced for those who *are* chemists to explain *how* the contrary can be the truth. Thus, it has been confidently asserted, and as confidently believed, that the base of the salting chloride has no influence whatever on the colour of the picture. That this is *another* of "the fallacies of the scientific," any one may convince himself, who will take the trouble to observe *attentively* the different colours produced by the action of light upon papers salted with barium and ammonium; I do not mention sodium, as I have never printed on paper so salted. Much twaddle, under the guise of science, has been published in the journals respecting the use of chloride of barium, and I have even been

* Page 523. † Page 494.

told that it *cannot* be, and never *is* used in albumenizing paper; however, the opinion that the nitrates *do*, in some way or other, affect the colour, appears to be daily gaining ground; if it were not so, why the use of *two* chlorides?

Those who use barium in conjunction with ammonium, do so because they say it renders the tone blacker; and, as far as my own observation goes, they say so with truth; but what possible effect does a *modicum* of chloride of sodium have, when added to that of ammonium? I fear, that if those who thus employ it, were asked their reason for so doing, their only answer would be, because they *thought* it had some effect; but they could not tell you what had induced the belief.

In Mr. Hart's Formulæ (Bourquin's Albumenizer)* we find *one grain* in every eight is chloride of sodium; this substitution of one grain, cannot be because it is an easier way of reducing the quantity of chloride of silver, than by taking its equivalent of ammonium; as the reduction, by using one grain of chloride of sodium instead of ammonium is only 4-15th of a grain, which is but 1-80th of the quantity that would be produced by eight of ammonium. If the chloride of sodium be employed with the idea that the nitrates affect the colour, the nitrate of soda must be believed to have a very *powerful* colouring property. Taking the atomic weight of chloride of ammonium at 54, nitrate of ammonia at 80, chloride of sodium at 60, and nitrate of soda at 86, I find the nitrate of soda is but the $\frac{357}{3187}$th part of the conjoint nitrates.

The chloride of sodium, is said to give a cold tone, and that of ammonium a warmer one; we can, therefore, easily imagine how, if any preference be given to sodium for any cause whatever, that an equal quantity of chloride of ammonium added to it, may render the tone perceptibly warmer, and yet not destroy the particular colour it may give, as in Marion's formula;† but I must candidly confess my *own* inability to conceive the good of *one* of sodium to *seven* of ammonium, and strongly believe that the addition is more a *fancied* improvement than a real one. When the chloride of barium is used in conjunction with that of ammonium, it has, in every case coming under my cognizance, been in *equal* proportions, as in Maxwell Lyte's formula.‡

The theory which attempts to explain the formation of the image, by the decomposition of the chloride of silver, and the recomposition of additional chloride by the liberated chlorine seizing upon the silver in the free nitrate, is based upon the manner in which chloride of silver acts when placed in totally different circumstances to what it is in positive printing. It is well known that altered conditions in many cases produce totally different combinations; are we then, warranted in holding this theory, when in printing the circumstances are that a mere film is formed and dried on a sheet of paper, which film is said to consist of chloride of silver *in conjunction* with the albuminate, and with the *addition* of free nitrate; the said chloride is, therefore, placed under peculiar conditions. Has it ever been *proved* that the chloride and albuminate of silver produced by sensitizing a chlorided albumenized sheet of paper, are in reality two *separate* compounds, and not a *double salt*, which for distinction's sake I will term the *chlor-albuminate*.

In taking leave of the subject for the present, I can only say that should I even be proved to be wrong in *every* particular respecting the tables I have given, and it should but lead to a profitable discussion, by which a single fact is added to our imperfect knowledge, I shall console myself in the words of Burke, who tells us, that "a man who works beyond the surface of things, though he may be wrong himself, yet clears the way for others, and may chance to make even his errors subservient to truth."

Allow me, in conclusion, to recapitulate the subjects which I think worthy of discussion, and on which I invite your various talented readers to give an opinion.

1st.—Which of the three compounds of silver plays the most important part in positive printing upon albumenized paper; the chloride, albuminate, or free nitrate.

2nd.—Is the free nitrate of silver *a principal*, or only an *accessory* in the formation of the image?

3rd.—Is the enormous excess of free nitrate of silver, as indicated in Table No. 2, *necessary?* and if so, why?

4th.—Is the albumenizing solution a mere *mixture* of albumen and chloride, or does the chloride enter into a *chemical combination* with the albumen?

5th.—Are there two *separate* compounds of silver formed by sensitizing a chlorided albumenized paper, viz., the chloride and the albuminate, and do they act *independently* of of each other; or, is one *joint compound* formed? if I may use such an expression.

It is, perhaps, scarcely necessary to say, that *reasons* should be given for the holding of an opinion upon these subjects, and not mere assertion, even though it be backed by the authority of names well known to fame. I have lived long enough to have learned that it is unwise and unsafe to accept as facts the assertions of any man, *however high may be his rank in the particular art or science which he has made his study*; and very many of your readers can no doubt supply, from their own reading, numerous instances where a thing has been declared upon high scientific authority, to be either an impossibility, or not the truth, which almost every little, ragged, uneducated urchin now knows to be a fact.

## PHOTOGRAPHIC PORTRAITURE.

BY M. MC. A. GAUDIN.

Photographic portraiture has become an important branch of industry, which improves daily, amid a host of difficulties which still prevent its attainment to perfection.

These difficulties are of many kinds; the greatest are those resulting from duration of the sitting, which does not yet permit of our rendering that instantaneous expression, without which *life* cannot be manifested. From this impossibility of rendering instantaneous expression, it happens that the most satisfactory portraits are those taken in profile, where the eyes are fixed on an object, a portrait with a natural expression is obtained, which photography, in its present state, renders in perfection.

But the public desires something more than this, it requires a "full face" portrait, without shadows, which accumulates all the difficulties of the artist operator.

For the present I shall say a few words about a fact which is not usually taken into account, but which acts with more or less intensity everywhere; it results, from this general principle, that photography operates under the influence of the invisible chemical rays rather than under the influence of the rays most luminous in appearance. Thus it is that light loses a great part of its photographic power by simply passing through a sheet of very thin glass. By an analagous reason, *reflected* light never produces a photographic effect in proportion to the light it sends to the eye. For example, if an operating room be entirely hung with yellow, red, or green drapery, the greater luminousness resulting from the employment of yellow drapery, in proportion to that resulting from green, would lead us to believe that much greater rapidity of exposure in the camera might be obtained from the yellow than from the green. Experience, however, does not confirm this hope; with the employment of draperies of these three colours, the chemical rays of light will be almost wholly absorbed; only the direct light will be efficient, consequently the model will be wholly deficient in chiaroscuro.

Unless then, the operating room be hung with white, or, better still, with light blue drapery, to diminish the daylight, I say that the photographic picture will never represent the model as it appears to the eye, in consequence of the transformation of the reflected light, which greatly increases the intensity of the shadows, and this is partly the reason why the public does not like contrasts, because they instinctively feel that they are too strong, while the photographer, who believes that he has rendered nature to perfection, believes they are not strong enough.

To remedy this radical imperfection in a general way, certain photographers provide permanent reflections by the arrangement of lights, or rather, what is to them much easier reflect upon the sitter, by means of a white screen, a supplementary light, which acts only during the sitting, without considering that the reflection from the screen upon the corner extinguishes the light of the eye, and invariably falsifies the model, since the result is a lighting greatly at variance with nature.

This remark has been suggested to me by a portrait which presents a *bizarre* aspect, with an unnatural expression and false shadows. Upon enquiry, I ascertained that the photographer had employed a screen to lighten the shadows, and he succeeded so well that his portrait was—nowhere.

Consequently, an indispensable condition consists in covering the walls of the operating room with white or blue surfaces, for any other coloured reflection gives not only a loss of sensibility but of harmony in the shadows. The background, when uniform, must be white, and never of a non-photogenic colour; no inconvenience arises from this, as the eye of the sitter cannot be affected by its brilliancy, while a non-actinic colour is always injurious as part of the picture by contrast with the model. By closing the shutter of the skylight, we can always diminish the quantity of light to any desired point.

In a word, the pose and the lighting are the bases of fine portraits, and to succeed with them, we must, as much as possible, employ only actinic light in the reflections.—*La Lumiere.*

## PHOTOGRAPHIC CHEMICALS:

### Their Manufacture, Adulteration and Analysis.

*Lime Salts* (continued).—Amongst the plans suggested for preventing the incrustation of boilers by the precipitation of the carbonate, or sulphate, of lime contained in the feed water, perhaps the best is due to the ingenuity of Mr. Spiller. He adds caustic soda, which is now prepared at a cheap rate, to the water in the boiler. This decomposes the lime salts forming carbonate and sulphate of soda, and, liberating caustic lime, rendering the accumulation of hard scale in the boiler an impossibility. Not only is this plan perfectly effectual in preventing incrustation, but it is equally valuable in removing the deposit when already formed. If a little caustic soda be added to the water with which a boiler is fed, it will gradually disintegrate the hard cake of carbonate and sulphate of lime lining it, and reduce it to a fine sand, which may easily be blown out at the lower taps, when the boiler is emptied. The plan has stood the test of many years' experience in some Government, as well as private, works.

We have already explained that carbonate of lime, a perfectly insoluble body, becomes soluble in water in the presence of an extra quantity of carbonic acid. If any substance be added to this solution of carbonate of lime in carbonic acid, which will remove the excess of carbonic acid, will be at once precipitated, and it is by an application of this principle, that Dr. Clark has succeeded in softening hard waters by his liming process. A solution of caustic lime in water is prepared, and this is added to the solution of bicarbonate of lime in such proportion that the caustic lime shall just unite with the extra quantity of carbonic acid present. It thus becomes converted into carbonate of lime, which is precipitated in the soluble form, and, at the same time, by removing the solvent for the original carbonate of lime, causes it also to be precipitated. The following equation expresses the action :—

$$\underset{\text{Solution.}}{CaO} + \underset{\text{Solution.}}{CaO2CO_2} = \underset{\text{Precipitate.}}{2CaOCO_2}.$$

The process is equally successful on a large, as on a small scale, and is, or was very recently, practically carried out at the works of one of the metropolitan water companies. It affords a curious instance of a chemical paradox—the removal of lime from water by the addition of a fresh quantity of lime. The same chemist (Dr. Clark) has also devised a very useful test for the hardness of water, by means of a standard solution of soap. This determination is one of the utmost importance in an economical point of view, and the indications which it affords are of such great value to all who have to use quantities of water, photographers especially, that we shall give a brief account of the process, as at present practised. The test consists in ascertaining the quantity of a standard solution of soap, or spirit, required to produce a permanent lather, with a given quantity of the water under examination, the result being expressed in degrees of hardness, each of which corresponds to one grain of carbonate of lime in a gallon (70,000 grains) of water. The soap test is made by dissolving curd soap in proof spirit, in the proportion of about 120 grains to a pint. This is graduated by comparing its action upon a carefully prepared solution of chloride of calcium of such a strength that it shall represent a water of 16 degrees of hardness. This, as well as the soap test, can be purchased ready prepared at the operative chemist's. To apply the test, the water to be examined is introduced into a stoppered bottle, which should be half filled with it, and violently agitated, in order to disengage any free carbonic acid, which would increase the quantity of soap required to form a lather; the air in the bottle is then sucked out through a glass tube, and these operations repeated two or three times, until it is judged that the free carbonic acid is entirely removed. A hundred measures of this water are then introduced into a stoppered bottle of twice that capacity, and the soap test very gradually added from a bourette (the stopper being replaced, and the solution violently agitated from time to time) until a lather is formed, which remains for five minutes over the whole surface of the liquid when the bottle is laid down on the table. The carbonic acid should be sucked out at intervals from the upper part of the bottle. The number of measures of soap solution used is then noticed, and the hardness of the water is then inferred directly from them by reference to a table. Thus 3·2 measures of soap test indicate 1° of hardness, 7·6 soap test show 3° hardness, 11·6 soap test show 5° hardness, &c.

The indications given by the soap test are very valuable, not so much for their chemical accuracy, for they only give rough approximations to the analytical results; but on account of their showing in a perfect manner the fitness, or unfitness, of a water for domestic purposes. For this reason, no analysis of a water is considered complete, unless it contains the degrees of hardness according to Clark's soap test.

*Sulphate of Lime*, known more commonly as plaster of Paris, is a compound of universal application. It is found in the natural state in combination with two equivalents of water, as gypsum, alabaster, &c. When this native variety is heated to a little above the boiling point it loses the combined water, and becomes then converted into the compound known as plaster of Paris. When moderately burned gypsum is mixed with water, it forms a paste at first; but this quickly hardens, heat being evolved, and the water passing into the solid condition of water of crystallization. Sulphate of lime is slightly soluble in water, 460 parts of liquid being required for one part of sulphate of lime. Heat does not increase the solvent power of the water, but rather seems to diminish it. It is to the presence of this salt in some mineral waters that their excessive hardness is owing. Many, in fact, being saturated solutions of gypsum, from the water having trickled through a stratum of this earth.

*Chloride of Lime.*—This, although strictly speaking an incorrect form of expression, has now become the recognized term for the mixture of chloride of calcium with hypochlorite of lime in equivalent proportions prepared by the action of chlorine upon lime. This is prepared on an enormous scale for bleaching and disinfecting purposes. Well-slaked lime is placed on sieves, and chlorine gas is passed over it until it ceased to be absorbed. When the operation is perfectly carried out, the gas is absorbed nearly in atomic proportions,

$$2CaO+2Cl=CaCl+CaOClO.$$

Chloride of lime is a white powder, usually moist, and smelling strongly of hypochlorous acid; it must be preserved in well-closed vessels, kept cool, and away from the light. When exposed to the air, bleaching powder soon attracts moisture, and finally deliquesces slowly, evolving oxygen gas, and forming a liquid which no longer bleaches. When treated with water, bleaching powder yields its active ingredients; when filtered from the insoluble residue, it forms a transparent and colourless liquid, having a slight odour of hypochlorous acid, and an astringent taste. When boiled its loses its bleaching power, and evolves oxygen; the same change likewise goes on gradually at ordinary temperatures, especially if exposed to the light. All acids, even carbonic, convert chloride of lime into a lime salt and free chloride, according to the following equation:—

$$CaCl+CaO,ClO+2CO_2=2(CaO,CO_2)+2Cl.$$

When exposed to the atmosphere, the same change is effected, but more slowly. A crust of carbonate of lime is formed over the surface of the liquid, and if this film be broken up from time to time, the conversion into carbonate of lime and chlorine is completely accomplished in a short time. If, however, the crust is allowed to remain, the liquid beneath is resolved into oxygen gas (free from chlorine), and chloride of calcium. It is important to recollect this circumstance when employing solution of chloride of lime for disinfecting purposes; it must also be remembered that chloride of lime only bleaches or disinfects in presence of an acid to set the chloride free. When it is employed *per se*, it is the atmospheric carbonic acid which does the work, and if a more rapid action is desired, another acid, such as sulphuric, or hydrochloric, must be added.

## PRINTING ON RESINIZED PAPER AND SILK.

BY H. COOPER, JUN.*

WITH your permission, I should like to make one or two remarks upon printing on resinized paper and silk. Mr. Shadbolt, in an article in the British Journal, says that the comparison does not lie between albumenized and resinized paper, but between resinized and plain paper. I do not think this is quite correct, and I will give my reasons. In the first place, we wish to dispense with albumenized paper, for two reasons, the highly glazed appearance of the prints, and the great probability of their fading, caused by the silver retained in the albumen. If we dispense with it we must have a substitute. Now, hitherto, plain paper, the surface either prepared with arrowroot, gelatine, or iceland moss, has been the only one known. Resinized paper is, I think you will admit, capable of giving better prints than either of these, and is, therefore, the best known substitute for albumenized paper. From this, it follows that the comparison is between resinized paper and albumenized, as well as between resinized and plain paper.

In a paper read at the last meeting of the North London, I called attention to several disadvantages in the resinized papers. Some of these I have since removed, and I do not doubt that, if gentlemen engaged in the art of photography will give a little attention to the subject, they may *all* soon be remedied, and the prints produced upon resinized paper be equal, if not superior, to those upon albumenized. The decomposition of the paper, after sensitising, was the first. Determined to find from which of the resins it proceeded, I prepared several pieces of paper in the following ways (all the solutions of resin containing 13 grains of chl. calcium to the ounce) mastic alone, frankincense alone, chio turpentine alone, and various combinations of these three resins. I then sensitised a sheet of each, and also one of albumenized paper, and hung them all up to dry, and carefully watched every day for a fortnight the progress of decomposition. The results showed that the mastic alone kept the longest, the frankincense and mastic next, frankincense alone and albumenised paper next, while all those pieces containing chio turpentine turned yellow very rapidly. The formula I now recommend is: mastic 8 grains, frankincense 10 grains, chl. calc. 10 to 15 grains, and 1 ounce of spirit. This solution is easily filtered through paper, so that it can be used directly the ingredients are dissolved.

Another sore point in the process was the granular appearance of the proofs. Subsequent experiments confirm the idea I then held that it was due to the paper itself; but I find that it is increased by using too large a proportion of resin. With the formula just mentioned it does not appear to so great an extent, in the same paper, as with the old formula, but with a suitable paper I have entirely got rid of it. Thin negative *Rive* has given the best results, yet it has one objectiou; it is very liable to tear in washing. I think that the use of a little stouter paper might prevent this.

The prints also possess greater transparency and brilliancy in the shadows, and the lights are much finer if printed on a suitable paper immersed in the resin solution just recommended.

It has been said that all resins become yellow by exposure to the air. This they certainly do, but some to so slight an extent as to be of very little consequence in the paper prints. I am of opiuion that paper prepared with a small quantity of frankincense and mastic will become yellow much slower than albumenized paper, and I even doubt if it would become more yellow than plain paper, for this reason: it is a well known fact that ordinary paper becomes very much discoloured by keeping, whether exposed to the light or not; now if each particle of the paper be encased or "locked up" in a resin, I contend that it will be so far protected from atmospheric influence as to remain a pure white much longer than if it were left unprepared, and I do not think that the discolouration of the resin will make it so yellow as the unprepared paper.

I see that Mr. Sutton, in the *Notes*, recommends a solution of lac for preparing the paper. My own experience tends to show that this resin is totally unfit for the above purpose. When an alcoholic solution of lac is evaporated, cold, the resin is left in a semi-transparent, if not entirely transparent state. If paper be immersed in a solution of it and dried, the thinner portions of the paper will be rendered more or less transparent; which will cause the prints to be very mottled and granular. I may be wrong, but this is the result of my own experiments. I tried to use lac 3 or 4 months ago, and met with no success.

I find that my meaning in the following sentence has been much misunderstood, and perhaps it may not be out of place to explain it here a little more fully. The chloride being, moreover, *locked up* in a resin, does not, in my opinion, form as much chloride of silver, as it would do if it were employed in albumenized paper. What I meant to infer was this: that the particles of chloride are so thoroughly encased, that it is with great difficulty that the nitrate of silver can get at them, to form chloride of silver, even after a long floating. I do not mean to say but that after very prolonged contact with the nitrate bath, it might all be decomposed, but by a floating of five to ten minutes some of it will remain unchanged. But then the question arises, if it is so encased as to remain unchanged under the influence of nitrate of silver, how can it be removed by water; as a chloride would be very objectionable in the finished proof? But it seems to me that the long immersion in water, consequent upon a thorough washing, is quite effectual in removing it.

And if the most infinitesimal portion remain, how can it injure, by atmospheric influence, when it is proof against the attack of silver and water? Should my meaning in the "locking up theory" be still obscure, I shall be most happy to answer any questions that may occur to any of you.

* Read at the South London Photographic Society, November 13, 1862.

I have been making some very interesting experiments on resinate of silver.

I have here a print produced by the direct action of light upon resinate of silver. The compounds formed from the different resins and nitrate of silver vary considerably in their character, as regards their sensitiveness to light, and their colour after exposure. Those formed from common rosin and Chio turpentine are the most sensitive. The specimen print was prepared with Chio turpentine frankincense and mastic. The resinate also receives the latest impression very rapidly, which may afterwards be very satisfactorily developed. It is from this fact that I attribute the very short time required to print by development in resinized paper. I may mention that I have produced good prints by development on resinized paper, of a nice tone, and entirely from motleyness and measles, by soaking in distilled water before developing.

I had hoped to have printed some pictures on iron instead of silver on resinized paper, but have utterly failed to produce anything worth showing. I hope others may be more successful, for I think it is a very good line to follow up, the dispensing with silver and hypo in photographic prints.

It is worthy of mention, that since I have used Sutton's neutral chloride of gold, I have had much less difficulty and vexations in toning all kinds of paper prints, than hitherto.

I will now say a few words on the formula for printing on white silk, which I sent to the Photographic News of last week. I think I cannot do better than read those remarks.

(Mr, Cooper then read the communication which appears in the Photographic News p. 536 which see).

I have brought a print with me to show why the silk must not be floated on the nitrate bath. You will notice that the threads of the silk show very plainly, totally destroying all the beauty of the photograph.

I will endeavour to explain the reason of this. Silk is a fabric composed of threads, of greater or less size, according to the kind. The glacè silk on which the specimens were printed, is rather large in the thread, which, curious as it may seem, appears to give greater brilliancy to the prints. Now when the prepared silk is laid upon the surface of the nitrate of silver, the solution filters through and runs over the edge of the threads, but in its progress it is bereft of its silver, so that a solution containing very little, if any, silver remains on the other side of the silk, and dissolves out, to a certain extent, the unchanged chloride, and when the silk is removed and hung up to dry, it finds its way back again to the surface that is to be printed upon, and uniting with the free nitrate, deposits chloride of silver, irregularly, which renders the image blotchy and weak. You will therefore see that the *immersion* in the silver bath, can on no account be dispensed with.

The photographs on silk may be washed without injury to them, in soap and water, when they become soiled or dirty; this is best done by laying the silk on a sheet of glass and scrubbing it back and front with a brush or sponge; it may then be ironed in the usual way or stretched as I mentioned before. I have tried printing on silk by development but with no very good results. Also printing on cambric and muslin, with what success you may judge from the specimens before you.

In concluding this paper, I must ask you to excuse any faults in it as it was very harshly prepared.

## THE HELIOSTAT.

Messrs. Foucalt and Duboscq have greatly improved their heliostat. The new model is specially intended for photographic purposes in the enlarging of pictures. It causes a mirror, 16 inches by 32 to move, the larger dimensions of which always continue in the place of reflection, so that the rays, reflected in a fixed direction, generally present a useful diameter of 13 to 16 inches. A similar mirror, made to orient itself in its plane at the same time that it inclines under the wished-for incidence, turns upon the disc which supports it, without encountering much resistance. For the friction from sliding, which existed in the first model, there is now substituted a rolling of the back of the mirror upon three pinions, which determine the reflecting plane. With the intention of retaining the faculty of inclining the reflected ray, more or less, the column of the mirror in the first model, was connected with a central point by an articulated crank, for the purpose of maintaining the distance between the principal centre and the point of suspension of the mirror constant; it was, therefore necessary, that this column should be mounted on a slide upon the level that sustained it. But this was a complicated piece of mechanism without an object; because it is seldom that we do not give a nearly horizontal direction to the reflected rays. It was, therefore, to simplify the instrument, advantageously in suppressing those portions which are useless. Nevertheless, the new apparatus partakes with all the heliostats known up to the present time, the defect of opposing variable resistance to the moving gear, which in certain positions became insurmountable. These variations of resistance are explained by the constantly changing extent of the movements executed by the different portions under the action of the constaut motion of the motor axis. In those singular positions in which the column of the mirror must turn upon itself, with a comparatively prompt motion, the reaction upon the gear becomes excessive and insurmountable. But seeing that the difficulty was limited to this point, I had the idea of placing an auxiliary spring within the column, to solicit it, independently of the gear, to overcome the difficult position. This spring acts in some measure at the will of the operator, and its introduction changes in no respect, the working of the apparatus: its effect is only to secure the evolution of the mirror in all the positions through which the instrument can geometrically pass.

This magnificent heliostat has excited universal admiration. Nothing can be more surprising than to see a little pendulum of the metronome produce a continuous motion of the truly gigantic mirror, of which an idea can only be obtained upon viewing it. M. Duboscq claims the merit of being the first who, practically, enlarged photographic pictures by apparatus of his own contrivance, which contains the elements of all the apparatus constructed since.

## FORTHCOMING EXHIBITIONS.

### Photographic Society of London.

*Rules and Regulations of the Ninth Annual Exhibition.*

The Photographic Society of London will open their Ninth Annual Exhibition of Photographs early in January, in the Gallery of the Society of British Artists, Suffolk-street, Pall Mall.

The Society propose to award silver medals for—

1. The best portrait or group.
2. The best landscape.
3. The best photograph of any kind.
4. The Council will also award a medal for any special novelties or improvements, if they shall deem them of sufficient importance to merit such a distinction.

The Exhibition will not be restricted to members of the Society, but open to all, subject to the following regulations, viz.:—

1. Negative and Positive Photographs of every description, whether on paper, glass, or other material, including Daguerreotypes, will be admitted, and also Stereoscopic Pictures and Stereoscopes.

2. Coloured Photographs will also be admitted.

3. Positive Pictures, printed from touched or painted negatives, and also touched or painted positive proofs, must be described accordingly.

4. For the sake of economizing space, the margins of all Mounted Photographs must be kept within moderate limits, viz., not exceeding 3 inches for the largest pictures, or 2 inches in those under 8 inches by 6 inches.

5. Pictures sent for exhibition must be numbered consecutively, and accompanied by a schedule in the subjoined form. Every picture must be protected by glass, and bear on its front a duplicate of the entry on the schedule referring to such picture.

6. All Pictures with advertisements will be rigidly excluded.

7. Exhibitors desirous of selling their Pictures will be permitted to make arrangements for that purpose with the attendant in charge of the Exhibition; and a commission of 10 per cent. will be charged on all sales effected during the Exhibition.

8. Facilities will also be given to the Makers of Photographic Apparatus, &c., for the exhibition of such of their productions as may be considered of peculiar interest from excellence of construction or novelty of invention.

9. All works intended for Exhibition should be addressed to the Secretary of the Society, and delivered at the Gallery, 5, Pall Mall, with all expenses paid, on the 22nd of December.

Exhibitors and Members of the Society will have the privilege of free admission, and members also of introducing one friend without payment.—By order of the Council,

Hugh W. Diamond, M.D., Secretary.

Exhibition of the Photographic Society, 1863.

Regulations of the Second Exhibition of the Photographic Society of Marseilles.

The Photographic Society of Marseilles, in organising a public Exhibition of Photographic Productions and Apparatus, invites all French and foreign photographers to send contributions.

Manufacturers of photographic apparatus are also invited to this Exhibition, to which they can send all their special instruments, such as lenses, cameras, dark slides, camera-stands, dishes, &c.; in a word, all apparatus, or parts of apparatus, employed in photographic manipulations. The same invitation is addressed to all manufacturing chemists, authors, editors, &c., for specimens of chemicals, or works of theory or practice interesting to photographers.

The Society recommends the exihibition only of new proofs—that is to say, of those which have not been exhibited before. Special attention also will be directed to obtaining pictures illustrative of new processes, such as dry processes, enlargements, carbon or ink prints, photolithographs, photo-engravings, impressions on cloth, enamel, and other materials.

1. The Exhibition will open in the course of January, 1863, and will be held in a hall constructed with especial reference to its being used for this purpose, near the site of the *Union des Arts*. It will be open one month at least.

2. All parcels should be addressed, *carriage paid*, to the Secretary of the *Union des Arts*, before the 15th December, 1862, at the latest.

3. Each parcel must be accompanied by a detailed notice of the number of articles sent, and signed by the exhibitor. Manufacturers of apparatus are desired to attach to what they send, independent of their catalogue and prospectuses, full instructions and descriptions necessary to the exhibition of their instruments, which will be made at public meetings organised by the Society.

4. Except in special cases, to be decided beforehand by the Committee of Management of the Society, there will not be awarded to each exhibitor a space of more than from six to nine feet square.

5. All pictures exhibited, except those in albums, ought to be framed and glazed. To avoid expense, exhibitors may send their proofs, unmounted, to the Secretary of the *Union des Arts*, who will take care that those proofs which are to be placed under glass shall be done as economically as possible. In this case the packages should reach him by the 10th of December, at the latest.

6. All coloured or touched prints are disqualified for exhibition on this occasion.

7. All negatives on glass or paper, impressions on metallic plates, on stone, or on wood, which exhibitors may desire to send with their positive proofs, will also be received and deposited in suitable places in the Exhibition, with all the necessary precautions. The same applies to negatives which may be sent with the apparatus by the aid of which they have been obtained.

8. Exhibitors should write their names and addresses upon each print, or on the frames containing a number of prints; but they are desired, under pain of non-admission, not to attach any inscription the form or wording of which would possess the character of an advertisement.

9. It is necessary that each proof should be named, and a description of the negative process employed, such as wet or dry collodion, albumen, waxed-paper or not, attached thereto. The Committee will also be happy to receive any further information on the method of taking the picture.

10. The selling price must not be indicated, either on the proofs or frames, or apparatus.

11. The Committee of Arrangement propose to purchase a certain number of prints, to be drawn for by lottery at the close of the Exhibition. Those exhibitors who are desirous of selling their proofs are requested to state the price to the Secretary, who will furnish the information to the Committee of Recommendation, and to the public. The same is made to the exhibitors of photographic apparatus.

12. Nothing sent for exhibition can be withdrawn before the close of the Exhibition.

13. The Photographic Society of Marseilles will receive with gratitude, and place in their portfolio, all proofs interesting in point of art or process which any photographer may offer for that purpose. The proofs sent for exhibition will be examined previously by a Jury of Admission, named from among the active members of the Society.

14. All objects exhibited must be withdrawn, or will be returned, at the expense of the exhibitors, within fifteen days after the closing of the Exhibition.

15. Although the Photographic Society has resolved not to offer any prize or medal, it considers that it should, nevertheless, bring to the notice of exhibitors the fact, that the *Union des Arts* reserves to itself the right to recompense those objects exhibited in its rooms, which it shall consider worthy of special distinction. The proofs, apparatus, &c., which shall have been contributed to the Photographic Exhibition, will be admitted to compete for this advantage.

All letters and communications should be addressed to the Secretary of the Photographic Society, at the *Union des Arts*, Marseilles.

---

Comptoir International des Photographs.

An Exhibition will shortly open under the direction of M. Edmond Potonie, at 97, Rue Richelieu, and 36, Passage des Princes, Paris.

*Rules Relating to Consignments.*

*Article* 1.—Photographs intended for exhibition at the Comptoir International des Photographes must be forwarded for inspection and (execution and price permitting) acceptance, to our Office, 46, Rue de Bondy, Paris, if from France, or any other country lying without the Zollverein; and to our Office, 6, Adlerstrasse, Berlin, if from any country within the Zollverein.

Such photographs only are accepted as are of a saleable nature, and are accompanied by a note of the prices that are to be paid by the Comptoir to the consignor after the sale shall have been effected. Portraits of unknown persons are not admissible.

*Article* 2.—The photographs consigned will receive a letter and number indicating their consigner, which will be entered in our books, so as to enable the Comptoir to inform the consigner, as often as he may wish, about the sale of his goods. Accounts will be settled every three months.

*Article* 3.—No consignment will be received for less than three months. A catalogue, published by the Comptoir periodically, will contain the designation of the pictures of each consigner, followed by the name of the photographer, the name of the painter (in the case of reproduction), and the selling price fixed by the Comptoir. Each consigner will receive a copy of this catalogue, as well as of every other publication of a similar nature that may be issued by the Comptoir.

*Article* 4.—At the request of consigners, the Comptoir will gratuitously undertake the nesessary measures for securing the exhibitor's copyright in photographs, whether French or foreign. In this case, four *additional* copies of each photograph must be forwarded to the Comptoir gratis, three of which will be deposited at the Ministry of the Interior, according to law, and one will remain at the Comptoir as a reference copy.

*Article* 5.—The expenses of transport and duty will be defrayed by the Comptoir. Foreign photographers are requested to be very accurate in their declarations, according to the requirements of the French custom-house.

*Article* 6.—The Director will give a written receipt for all pictures con-

**signed. The consigner likewise must give a written receipt on withdrawing his pictures, or on receiving the money for them in the case of sale.**

***Article* 7.—The Comptoir will do all that lies in its power for the good preservation of the pictures; but it cannot take upon itself any responsibility in this matter further than promising to give the greatest care and attention to the goods which shall be entrusted to its keeping.**

***Article* 8.—The present rules adopted by the consigner, shall serve as a contract between him and the Comptoir.**

## ENGRAVING BY PHOTOGRAPHY.

The following letter by M. Paul Pretsch, was published in the *Times*:—

Sir,—The dissolution of the juries of the International Exhibition, before the publication of their reports, leaves no means of correcting their blunders but the courtesy of the press. To this, as a foreigner, I appeal. The jury for photography have awarded me a prize medal for "improvements in photographic printing." Now, I can lay no claims to any such improvement. I have paid no attention to the processes of photographic printing. What I have done is photographic engraving. I have made light its own engraver, not its own printer. This is an important distinction; and, after a sojourn of eight years in England, for the purpose of completing my processes and bringing them before the public, I find the aim of my labours misrepresented by the verdict of a scientific jury.

You have done me the honour twice to mention my processes in your admirable articles on the photographic department of the Exhibition. In both instances you have been led, no doubt by the jurors' verdict to misrepresent my methods. In your first article, you class my process among the various modes of carbon printing, and in the second you state that I employ the electrotype in addition to photography.

Now my method differs essentially from the carbon printing processes. In the carbon printing, light is the printing agent, and light must print every copy. By the action of light I at once produce an engraved surface. I cause light to engrave a soft substance. Having obtained this engraved surface, I use the electrotype to copy it. Thus by a variation of my methods I can procure an engraved printing-plate of copper for plate printing, which plate can be coated with steel, to prevent wear and tear, or a raised block (surface-copper, backed with type-metal, mounted on wood like the copy of an ordinary wood engraving) for surface printing by the ordinary typographical press. I use light for the purpose of producing the engraved surface, the electrotype process to transform this into copper. Therefore an unlimited number of unfading faithful copies of any photograph, picture, or drawing, can be produced in printers' ink.

Trusting to your kindness to afford me your powerful influence in correcting what is likely to give a false impression of the methods I have invented, after many years of unwearied application, I am, Sir, your obedient servant, Paul Pretsch.

3, *Guildford-place, Russell-square, W.C., Oct* 31*st*.

## PHOTOGRAPHIC REPRODUCTION AND PIRACY.

(From the *Daily Telegraph*.)

After teaching the wind to drive his ships, the water to bear them, the fire to subdue and mould his metals, the beasts of the earth to do him "homage and service," and the steam, which is but the cloud of the skies super-heated, to whirl himself and his machines about, man has trained the sun to be his portrait-painter and arch-artist. Like all good servants, too, light has been shamefully tasked. It has been set to reproduce lofty things, and things of low estate—themes of thrilling sylvan or rural beauty, and pot-house interiors—the divine Diana of the Greeks, and the shameless guiltinesses of Holywell Street. "Didst ever see Titan, pitiful-hearted Titan, kiss a dish of butter?" asks Prince Hal in the play. Titan, in our time, has had many such a vulgar employment; and the result is the infinite reduplication of endless types of physiognomy, grand and greasy, and grades of art, mean and majestic. The last appearance of "light" is in the character of defendant in a police court. The radiant offender has, it appears, been reproducing, with his usual perfect counterfeit of line and shape, some of the engravings of Mr. Gambart, the printseller; and that gentleman has cited Light, in the person of Messrs. Powel and Pipere, photographic artists, to answer for the misdemeanor. Mr. Gambart owns, among many other popular and beautiful pictures, "The Horse Fair," of Mdlle. Rosa Bonheur, and "The Light of the World," an equally well-known labour of a name as great in art. For the picture and copyright of "The Horse Fair," he had given the sum of £1,600, besides paying £800 for the engraving made after it by Mr. Landseer. This engraving—the admirable result of great talent and pains—was naturally a favourite, and its sale was in a fair way to repay the publisher's outlay, when photographic copies of the work made their appearance in the windows of the two photographers named. Mr. Gambart assured the magistrate that the sale of the print was checked at once; and, unless the prohibition against such rivalry, on the part of the indefatigable and unerring sun, were enforced, he intimated that his business, and that of others similarly engaged, must come to an end. The presiding magistrate has reserved his decision—rather, as Mr. Gambart pointed out in a recent letter to us, upon technical grounds, than upon the question whether such ingenious piracy is to be held legal or illegal. But as everybody knows the pictures in question, and most people of any taste or information in the way of art, are familiar with the engravings and their photographic *replicas*, the case really rises from the insignificance of an alleged misdemeanour to one whose decision must have a good deal to do, not only with the future of photography and its professors, but with art generally.

In the first place, it is not denied that these heliacal forgeries of Mr. Gambart's property and other such engraving are very beautiful and perfect. They lack the value of thesoriginal, principally because the scale is smaller, and in point of colour, too, the doubtful browns of photography cannot match the clear whites and blacks of a steel plate. But the first objection could easily be removed by a new process lately patented; and as to the last, the collodion in the hands of a skilful manipulator is capable of giving tints of uncommon depth and equality. Thus the photographs are real as well as pretended rivals of the engravings; and indeed that point is sufficiently settled by the desire of the public to possess them. The first inclination of that public naturally is to get good works of art at little cost. If it cannot afford the picture, it secures a proof engraving; if that be beyond its means, it contents itself with one "after letters;" and in default of the necessary guineas for such a purchase, the photographers copy is prized and paid for. Our honest art-loving public will probably therefore set its sympathies at the outset rather against the printseller. Why should it not have perfect duodecimal copies of great works of art for half-a-crown or a shilling? What dog-in-the-mangerism forbids it so cheap and charming a boon? It begins to feel almost a grudge against Mr. Gambart and his grievance, like that instinctive indignation which is excited in its bosom when it hears of him as summoning his subscribers to witness the utter demolition of some beautiful and costly steel plate, which has worked off these engravings. Such might, they think, even after its first crispness of line, have furnished many a lowly home with a work of art, passable in respect of completion always, and lovely in design and outline. And this destruction of it, when the cruel cold chisel ploughs up the cunning labour of the "burin," does indeed seem outrageous, and an act of Vandalism. But let us be just to others before we are generous to ourselves. It would be delightful, doubtless, to all, and welcomed by the printsellers themselves, were the art of Holywell-street and the Seven Dials driven out of the field by artistic works, engraved or photographed after the best masters. But art is jealous, and jealous also are its votaries, so that one of them will often be rendered miserable if, having a "gorgeous Titian" or "glowing Claude," anyone else shall possess even a *replica* of the illustrious canvas. This benevolent feeling equally applies to engravings; subscribers to a plate will not be enchanted, however much their better feelings may be appealed to, with the idea that their choice proof is to have ten thousand "dittos" in the country. Unless they get guarantees to the contrary in some such way as the demolition of the plate, they will simply decline to ally themselves with the artist's enterprise; and there would be no engraving to multiply. So, too, with regard to the much debated photographs. Setting aside the slight fact that Mr. Gambart, having given £2,400 for his property, has the right to do what he pleases with it, one thing is very evident; if photographers may seize upon the first proof engraving they can get of any popular picture, and stop the sale of engravings made after it by their "negatives," there is an end to that special art. The dealers in prints will no longer produce an article which does not pay; and as the photographers will have nothing to copy, we shall get neither picture, nor plate, nor photographic reduplication.

Copyright must, therefore, be respected, on economical as well as equitable grounds. The public, as well as the publisher, is served by a strict regard for the law upon this head. But, at the same time, it is so highly desirable that good art, at a low price, should irrigate—should deluge, if possible—the country, that we should despair to think that the interests of the photographer and the publisher could not be reconciled. We believe they might, and by some of the numerous suggestions made on the kindred subject of patents. A royalty on the right to make duplicates for sale of any work of art the subject of a copyright—with some reductions, let us suggest, in the present exaggerated price of good engravings—might meet the difficulty. At present, there are two things certain; first, that photography must not expect to thrive upon the profits of the enterprise which gives it subjects; and, secondly, that the public will not be contented to have a beautiful and fertile field of art shut out from photography like a hay-field in summer time.

## Proceedings of Societies.

### South London Photographic Society.

The usual monthly meeting of this society was held in the City of London College, Leadenhall Street, on the evening of Thursday, November 13th, Mr. G. Wharton Simpson in the chair.

The minutes of the previous meeting having been read and confirmed.

The Chairman called attention to a variety of specimens of photography, exhibited by various members. First was a series of fine delineations of rocky scenery, exhibited by Mr. Cole. In addition to these, were two albums, by Mr. Harmer, one containing specimens of chromo-photography, and the other of double printing; fancy vignetting, &c. Mr. Harmer also presented two of his chromo-photographs to the portfolio of the society. Mr. Wall exhibited a very fine solar camera picture produced on resinized paper. Mr. Warner exhibited his large album, containing eight card pictures of landscapes, or architectural subjects on one page. Mr. Harman, the secretary, exhibited a very fine copy of a lithographic head, and some groups executed at one of the open air meetings of the society. The Chairman exhibited a photolithographic print, by Col. Sir. Henry James, possessing a good many gradations of half tone, and presenting much promise of success in this important direction. The Chairman also showed some prints from instantaneous negatives produced by Mr. Hurst of Mirfield, Yorkshire, on tannin plates by a method, the details of which, he has promised to communicate shortly in the Photographic News. Mr. Martin mentioned the fact, that, Mr. Hurst used Horne and Thornthwaite's bromo-iodized collodion, in preparing his tannin plates.

The various contributions were examined and admired.

Mr. Wall called especial attention to the excellent delineations of rocks, showing the well marked distinctive character of each, in Mr. Cole's photographs, and referred to their value as drawing studies, to correct a common notion that all rocks were alike in general character. After a vote of thanks to the gentlemen who had exhibited or presented pictures, the Chairman remarked that a paper "On the Enlargement of Negatives," had been promised by Mr. Samuel Fry, but as he was not present, some unavoidable cause must be presumed to exist. He had pleasure in stating, however, that his friend Mr. Henry Cooper, jun., would read a brief paper "On the Production of Prints on Resinized Paper and on White Silk."

Mr. Cooper then read a paper containing additional hints on these subjects (see p. 557), and illustrated his paper by a number of admirable specimens of double printing on resinized paper, and on silk and muslin. These were examined with much attention and warmly admired. He explained the importance of immersing the silk in the solutions, as the results were otherwise imperfect.

Mr. Martin asked Mr. Cooper why he had abandoned chloride of cadmium and substituted chloride of calcium.

Mr. Cooper explained that the insolubility of chloride of cadmium caused a difficulty, which was obviated by the use of chloride of calcium, which was abundantly soluble.

Mr. Martin thought that the deliquescent nature of the latter salt would be an objection.

Mr. Cooper had not found any inconvenience from the cause.

After some further conversation on the subject,

The Secretary asked if Mr. Cooper recommended the use of the encaustic paste in all instances. If so, it would be a drawback to the commercial production of prints needing such an application.

Mr. Cooper said the application did not involve much trouble; but he only recommended its use where the prints seemed to require it. It conferred additional warmth and brilliancy.

Mr. Martin asked the nature of the encaustic paste.

Mr. Cooper had received it from Mr. Simpson.

The Chairman explained that Clausel's encaustic paste was a preparation made and sold by Mr. Bailey of Wolverhampton. He believed the recipe was communicated by the late Prince Consort to Mr. Rejlander, from whom it was received by Mr. Bailey. He (the Chairman) understood from Mr. Rejlander that it consisted of white wax and *oglio cotta* (an Italian baked oil), dissolved in an essential oil, such as that of lavender, the whole being made into a thick paste. Its peculiarity consisted in the fact that it gave depth, richness, and transparency to the shadows of the photograph, without communicating a vulgar glaze.

Mr. Wall remarked that the paste was valuable for applying to touched albumenized prints, as it removed the dullness from the touched spots.

Mr. Warner said that rubbing on a little albumen answered the same purpose.

The Secretary asked Mr. Cooper how long the resinized paper ought to remain in the silver bath.

Mr. Cooper said from five to ten minutes.

Mr. Howard suggested that the application of albumen after the completion of the print would give brilliancy and transparency to shadows; and as the objection to albumen consisted chiefly in the combination with silver, this would be avoided when it was used simply as a finishing varnish.

Mr. Wall said that Mr. Howard had overlooked the fact, that one great recommendation of Mr. Cooper's process consisted in the fact that the prints free from the vulgar glaze of albumen. The encaustic paste gave transparency without adding a glazed surface.

The Chairman remarked that albumen applied as Mr. Howard had suggested would not be coagulated, and would mark with damp fingers, &c.

Mr. Warner said he thought not if it were well rolled.

The Chairman said rolling might improve the print, but would not make the albumen insoluble or protect it from the effects of wet or moisture.

Mr. Price said that albumen contained sulphur, and would certainly be better kept from contact with the print.

After some further conversation on this subject, a desultory discussion, on the modes of intensifying, arose, in which the Chairman, Mr. Wall, Mr. Blanchard, the Secretary, Mr. Fitch, Mr. Warner, and others, took part. The Secretary and some others held that iodide of mercury, formed on negatives intensified with bichloride of mercury followed by iodide of potassium, was sensitive to light, and that the negatives became harder and denser by continued printing. It was held by Mr. Blanchard and others that this only occurred when pyrogallic acid and silver were used in addition to the iodide of mercury, and that the sensitiveness to light were due rather to a combination of the iodide with silver. Mr. Warner recommended the use of ammonia with the iodide of potassium after the bichloride.

The Chairman said the varying experiences at least tended to prove one point; namely, that there was some uncertainty about the negatives obtained by bichloride of mercury and iodide of potassium, and said that Mr. Hughes, who had been printing the royal negatives of the late Mr. Lacy, found that where large numbers were printed, negatives once soft gradually became hard and chalky.

Mr. Howard recalled the discussion to the subject before the meeting. He said that the process of Mr. Cooper seemed to promise a new era in photography, and was, he thought, a subject for congratulation amongst photographers. The public had of late, he feared, began to get very suspicious of photographs, and very chary of buying them, because of their doubtful permanency. A gentlemen whom he knew to be a very large buyer of photographs had regretted to him that many of his very fine specimens were gradually going: getting yellow, and showing less and less of the picture every time he looked at them. If this process of printing would give them prints which would not change, it would be a great boon, and they might even sacrifice a little brilliancy. The subject was clearly worth attention and experiment, and it would only be fair to Mr. Cooper that he should have some aid from other experimentalists in bringing the process to perfection, in return for his pains and liberality in giving the results to photographers. For copies of engravings it appeared very excellent, as some of the specimens well showed, their tone being as rich, soft, and mellow as though they came from the pencil of the artist.

Mr. Cooper said that he had observed that resinized paper registered all the half tone in a negative much better than albumenized paper, and gave, consequently, softer and rounder prints.

The Secretary referred to the fact that albumenized prints did not necessarily fade. Some remained permanent, and this proved that fading was the result of imperfect or careless manipulation.

After some further conversation on the subject, it was remarked that encaustic paste containing wax would gradually become yellow. To this it was replied that the quantity was so small as to be of slight importance in this respect, and Mr. Howard remarked that he had seen some of the exquisite turpentine wax-paper negatives of the Rev. Lawson Sisson, which were free from any tinge of yellowness.

A conversation followed on the discolouration of benzoin, in which Mr. Price observed that some paper prepared with it, sent to him by Mr. Cooper, had become more discoloured during the few weeks he had kept it. He intended to keep it twelve months as a test. Some further conversation on the importance of very deep printing on resinized paper, and on its suitability for colouring followed.

Mr. Wall asked if Mr. Cooper had tried printing on canvas for painting in oil.

Mr. Cooper had not tried prepared canvas, but the plain canvas would present no difficulty.

After some further conversation, and a vote of thanks to Mr. Cooper, the proceedings terminated.

## Correspondence.

### COAGULATION OF DRIED ALBUMEN: A FALLACY OF PHOTOGRAPHERS.

Dear Sir,—Taking the world in general, I think it must be concluded, that for every person who is able to detect a particular current fallacy, there are numbers who are unable to do so; and thus, error gets bandied about from one to another, till at last it comes to be considered as an accepted fact, even by those who should know better.

Amongst the "fallacies of photographers," there is none more prevalent than the belief in the possibility of *coagulating* dried albumen. I find Dr. Fowler disseminating this error, in his "Short Lessons on Photography" published in *Humphrey's Journal*, and given at p. 415 of your present volume. Speaking of albumenized paper, he says,—"It is certainly an advantage to coagulate the albumen on the dried surfaces, which prevents the solution of the albumen. This coagulation is best effected in the following manner:—The albumenized sheets are folded together in one roll, and then placed in a round tin box, much longer than the roll of paper; the box is now dipped into a kettle of boiling water, deep enough for the water to stand higher on the outside than the top of the rool on the inside. In this way the paper is submitted for some time to the heat of boiling water, which renders the albumen, in a measure, insoluble in the midia in which it has afterwards to be placed." I likewise have read, as the suggestion of various other photographers, that the albumenized paper, should be ironed with a hot iron, in order "to coagulate the albumen."

Now I unhesitatingly assert, that dried albumen, as existing on the surface of an albumenised sheet of paper, *is not, and cannot be*, coagulated by heat however applied; *nor* by sensitising it upon a nitrate of silver bath. The drier a substance be rendered, the longer the time required for its solution; and thus, the *drier* the state of the albumenized sheet of paper *at the time of sensitising*, the sooner the solution of nitrate of silver is enabled to render the albumen *insoluble* by its action upon it, and therefore, the less time has the water to ferment it sufficiently for solution: hence, the drier the paper, the less the discolouration of the bath. This insolubility, however, *is not coagulation;* to produce the latter, *fluidity* is necessary.

Albumen may be said to exist in three states: *fluid*, as in its normal state of white of egg; *coagulated*, as when the egg is boiled; and *dried*, as when the water it contains in its normal state, is evaporated at a lower temperature than that at which coagulation takes place. In each of these states, it has different properties. In both its normal and dried state, it is soluble in water, but not so, when it is coagulated; at least, such is generally said to be the case, although a *small* portion of it is still so; in its normal state it can be coagulated by boiling water, heat, strong mineral acids, and metallic salts, and thus is rendered insoluble, except in a very slight degree; but, *when once dried, it cannot in that state, be coagulated by any means;* it can, however, be still rendered nearly insoluble by strong mineral acids and metallic salts, *but not by heat, however applied;* and hence, from coagulation being accompanied by insolubility, insolubility has erroneously been considered to be accompanied by coagulation.

In short, strong mineral acids and metallic salts, cause insolubility *and* coagulation in its normal state, and insolubility *without* coagulation in its dried state. Fluidity being necessary for coagulation, dried albumen *as such*, cannot be coagulated by boiling water, heat, or any other means.

The dissemination of any error, however innocuous it may appear, retards the advancement of knowledge, much more than most people are apt to imagine, for the honour then of science and truth, do not let us hear any more of the possibility of coagulating dried albumen, *unless* indeed, what I state can be found to be false, and this I challenge any of your readers to do.—I remain, dear sir, yours truly,

George Price.

### PRINTING DIFFICULTIES.

Sir,—In the pursuit of hidden causes there is a fascinating influence exercised, that men care not to resist, for it is to this influence we are indebted for the many brilliant triumphs science has achieved. So long as visible results are the products of unseen causes our minds naturally remain unsatisfied, and the results are examined and re-examined with the most scrupulous care, and by a process of reasoning based on the information derived from our powers of observation, theories are propounded whose success depends on their stability whilst exposed to the fiery ordeal of scrutiny as they are being analysed by a thousand penetratingly powerful intellects, which perhaps have long been labouring and searching in the same direction. In dealing with Mr. Eliot's paper, we have results only to examine, for causes remain untouched; that gentleman is therefore in error when fancying that he has launched into the photographic world a new "theory," but in common justice I feel bound to acknowledge his researches to be in the right direction, and like the friendly finger post, give us confidence as we endeavour to to push forward over the dark, and hitherto little trodden track we have chosen. An examination of the "beakers" will perhaps bear me out in this last statement. beaker No. 1 contains ½ grain soda to the grain of gold, but though submitted to the decomposing influence of hot water, the prints when exposed to the action of the solution when diluted, generate a bad colour and general mealiness, whilst 3 grains of the alkaline agent with 1 grain of gold under similar conditions yields tones which are satisfactory. Although I have not experimented in this direction, I am quite satisfied that Mr. Eliot is correct in his statement concerning the results derived from the above described solutions, but at the same time he over estimates the decomposing power of his hot water. In beakers 1, 2, and 3, the quantity of gold is precisely the same, consequently the same amount of chlorine is driven off by the heat applied, and for some little time the atmosphere receives the whole, for water, when its temperature is raised much above 60°, cannot hold in solution the above-named gas, but when the several solutions are diluted, evaporation ceases, and a natural toning action begins. In beaker No. 1, the quantity of soda present is not proportionate to the amount of chlorine the gold still holds in combination, and for reasons given in my former letters, unsatisfactory toning is the result. In No. 3, the case is different, the soda and gold is nicely balanced, and an advantage is gained by the reduced quantity of chlorine, as in all probability a deeper deposit of gold is secured, and consequently a greater depth of colour is obtained. And now, bidding farewell to Mr. Elliot, who I hope will forgive the liberty I have taken, and accept my criticism on the contents of his paper in the same spirit in which they are offered, I propose, in conclusion, venturing a word or two on the able and well studied subject advanced in your last number by E. E. L.: he has started an interesting question respecting the agency employed in the production of the varied colours yielded under the influence of toning action. Now the first question which naturally suggests itself is the enquiry, what is colour? Considered in bodies, it is a sensation produced on our visual organs, by a decomposition of light produced by reflection and absorption, and the diversity of colours proceeds from the varying disposition of bodies to reflect light, so that any alteration in the molecular arrangements of a body, will modify, or completely change its colour, by absorbing or reflecting additional rays of light; in considering the various colours produced by the same toning bath, we must not overlook the fact, that, the surface on which the gold is deposited, is of an ever-changing nature. The subtle agent that reduces by its electric influence, the chloride of silver, is seldom long existing in the same mood, its changes are as frequent and directly, more plainly visible, than its effects on the surface of the paper, than the changes that are ever present in the operating department. To day vigorous prints are produced, giving, when toned, a fine dark and brilliant colour.* To morrow, under apparantly the same treatment and conditions, the prints are brown, giving depth of printing reduction, without a vigorous appearance, these prints, when exposed to toning action weaken, and if pressed for dark tones, give slatiness. I have noticed those changes in one day, and with one batch of prints—more especially at this season of the year—the early morning seldom yielding the same class of prints as at mid-day; the ever varying character of the negatives will also exercise an influence on the reduced silver surface; the light being strained through these, ere it reaches the paper, many modifications of its action must ensue, from the peculiarities of each negative, and as many changes must be effected in the molecular arrangements of the reduced silver; in one, the requisite conditions are present to aid in giving opacity to the coating of gold; in another, the conditions are such, that its surface is too transparent to admit of a deep colour, and an attempt to procure it by toning is altogether useless, for by another molecular arrangement, slatiness becomes visible, and the print spoiled. I fain would go fully into this subject, but fearing I have too long trespassed on your space, I will forego the temptation.—Yours, respectfully, A Photo's Assistant.

* I am here speaking of portraiture.

## Photographic Notes and Queries.

### The Invention of Photolithography.

Sir,—As the question of who first invented photolithography seems to be interesting the public at present, allow me, as the party entrusted with the working out of that known as Col. Sir H. James's photozincographic process, to say a few words on the subject.

Photozincography is a working out and application of the theory set forth by Asser and others. My first experiments were printing in carbon on paper prepared with carbonate of potash and gum, gelatine or albumen, for the purpose of transferring to the waxed surface of a copper plate, as a guide to the engraver. Finding that the carbon print, when transferred, gave too faint an impression, it was thought that printing-ink would be a suitable material, which was tried and found to succeed very well. It then occurred that these prints could transfer equally well to zinc or stone; this also proved successful, and was the way that the discovery of photozincography was made at the Ordnance Survey Office. The experiments were first made in the autumn of 1859, at about the same time as Mr. Osborne was at work in the same direction in Australia. Col. Sir H. James first published this process in his report to Parliament for 1859, and did not announce it in the Photographic News until March 1860, so you will perceive that England was not behind her colonies in bringing out this new art.—I am sir, your obedient servant, Archd. J. Rider.

P. S. As the application of photolithography commercially seems to be little known to the public, I shall be glad to send you shortly some specimens of valuable and rare reproductions, which I and my partner, Mr. Preston, are at present engaged with.

[This letter was omitted in our last through an oversight in "making up" the formes. We have since received the following satisfactory and explicit letter, to which we have pleasure in giving publicity. The mention of exact dates in such matters is always desirable. We are glad to record Mr. Rider's initiatory steps, and also Col. James's recognition of them. It so happens, that in the co-operative labours carried on in a large military establishment, honours as well as labours are divided, the chief honour culminating in the chief officer, as leading, guiding, permitting, or controlling the whole. We now append the second letter.—Ed.]

Sir,—In an article in last week's News, on "Photozincography, Photolithography, and Photo-engraving—Who are the Discoverers?" you refer to a letter from me, claiming a share in the invention of Col. Sir H. James's process; and, as you say it is scarcely sufficiently definite, perhaps you will allow me to state a little more fully in what way I am connected with it.

In the autumn of 1859 (I cannot give the date), being then engaged in the photographic department of the Ordnance Survey Office, I was ordered to prepare some carbon prints of reduced maps, with the view of transferring them to copper. The process used was that published by Mr. Pouncy, the paper being coated with a mixture of gum, bichromate of potash, and carbon; the results were not very satisfactory, as very little of the carbon could be made to adhere to the waxed surface of the copper. Seeing a description of a carbon printing process by M. Asser, in the News, of November 25th, 1859, I tried it, but did not get very good results, as I found it very difficult to make the ink adhere to the insoluble parts of the paper while in a moistened state. I next tried the application of the ink before fixing, and in this was successful. Gum and bichromate were first used, but in course of practice gelatine was found to answer better. After producing a transfer by this method, I showed it to Sir H. James, who then ordered me to copy a small etching and make a transfer, which was transferred to zinc and printed.

In the pamphlet just published, Sir H. James, in his introduction, gives a history of the process, but has omitted to mention my name in connection with it; but if you refer to his Parliamentary Report for 1859, you will find he names me as having introduced something new: also, in his letter to the News, of March 16th, 1860, speaking of the process, he says: "With the aid of Mr. Appel, who is so well-known for his skill in zincography, and with the assistance of Corporal Rider, R.E., who is one of our photographers, we have, I think, perfectly succeeded, our success being due to the fact, that we have in this establishment both first-rate photographers and first-rate zincographers, although I am myself neither the one nor the other." Again, speaking of the invention in the introduction to the *fac similes* of "Domesday Book," which were published before my leaving, he says to Captain

Scott, R.E., who has charge of this branch of the work, and to Corporal Rider, R.E., who is employed on it, we are chiefly indebted for this success.

In giving these quotations, I merely wish to show my claim to a rather large share of the invention, or application, of the process.—I am, sir, yours obediently, ARCH. J. RIDER.

P.S. I enclose a specimen of half-tone, which I have done on paper prepared with bichromate of potash and gelatine, and used on the same day of preparation. I may add, it is from stone, and is untouched.

[There is unquestionable lithographic half-tone in the specimen forwarded, although not so much as in that we received from Col. James. We shall be glad to see and hear more on the subject.—ED.]

### ACTION OF LIGHT ON WALNUT JUICE.

DEAR SIR,—I see in your number of the 31st ultimo, a letter from "J. H. W." herbalist, of Canterbury, claiming the discovery of the extract of walnut green shell having the same properties as nitrate of silver.

Having written to you of my discovery of the same two years ago, and which you then noticed in the NEWS "To Correspondents," may I beg of your insertion of this letter, claiming *priority* of discovery. I would further add that, after exposure to light, if the resulting picture be placed to soak for a few minutes in liq. am. fort. and aqua, in the proportion of 2 drams to 20 ounces, no further treatment will be necessary to ensure fixation. (Colour, rich brown.) The same properties belong to the juice of the elm, oak, sycamore, lettuce, and others, giving in each case, a different shade of colour.

Albumenized paper must on no account be used, as the stringent properties of the walnut and other juices completely dissolve the albumen.—I am, dear sir, yours truly,

W. H. WARNER, Photographer, Ross.

P. S.—If the juice *direct* from the walnut tree be taken, a colour similar to raw sienna is the result.

## Talk in the Studio.

INSTANTANEOUS TANNIN PLATES.—We have received from Mr. Hurst, of Mirfield, prints from some instantaneous negatives taken on tannin plates on the third of November. One consists of a sea view with portions of a partially submerged wreck, the other a coast view with moving figures. It would be too much to say that there was no trace of under-exposure, but it is very slight indeed. An instantaneous view, and one exposed for a minute and a quarter by another process are nearly alike in photographic qualities. Mr. Hurst wishes to verify his experiments before publishing the details. When he is perfectly satisfied, our readers are promised further information.

VARNISH.—A correspondent says:—"Many of your readers seem to lack a *good* varnish for negatives. I think they will be satisfied if they try Ponting's Bristol varnish. I always use it and never find it stick in the sun."

ERRATUM.—Messrs Helsby and Co., of Liverpool, inform us that the card portraits from their establishment, which we recently noticed, as produced by Ross's ordinary 5×4 portrait lens, were not so produced, but with Ross's card lens No. 3.

PHOTOGRAPHIC CONTRIBUTIONS TO THE LANCASHIRE FUND.—Lieut. Col. Stuart Wortley has addressed the following letter to the Lord Mayor. We shall be glad to see others follow his noble example.—"My Lord Mayor,—The Council of the Photographic Society, whose annual Exhibition of Photographs will open early in January, have allotted me space for a frame of pictures therein. They have kindly consented to allow me to place spare copies of these pictures on sale in their rooms, the produce of which sale I purpose devoting to the relief of the Lancashire operatives. As money is most urgently required at this time, I enclose herewith £25, feeling no doubt that pictures to this amount, at least will be sold, and hoping even to send you a further sum before the close of the Photographic Exhibition. I have published my intention of thus disposing of my pictures, in the hope that other of my brother amateurs may be induced to make some like arrangement for the benefit of our suffering fellow-countrymen.—I have the honour to be, My Lord Mayor, your obedient servant, Henry Stuart Wortley, Lieut. Colonel.

## To Correspondents.

NOTICE.—The Publisher will be happy to exchange, or pay full price, for the following numbers of the PHOTOGRAPHIC NEWS—6, 9, 41, 53, 66, 70, 75, 76, 79, 80, 81, 101, 102, 169, 198, 202, 203, 214.

*** We have to claim the indulgence of many of our advertising friends this week, whose announcements are omitted for want of space.

VIATOR.—If you wish your backgrounds to roll without cracking, you had better paint them in oil colours, using turpentine chiefly as a vehicle, so that the colour may dry flat. Distemper or soap flatting may be used with advantage by one accustomed to the work of scene painting; but unless you are familiar with the work, oil colour will answer your purpose best, as it does not dry quickly, and allows you to correct the drawing readily, if necessary. 2. A variety of methods have been recommended, and used with more or less of success for keeping the plate moist a few hours, such as nitrate of magnesia, honey or molasses, water and acetic acid, glycerine, &c. A very excellent preparation for the purpose is a mixture of honey and albumen. If card portraits are carefully rolled after colouring, a smooth surface is obtained; or the use of Clausel's encaustic paste will answer the same purpose.

A. B. C.—In copying, it will, of course, be necessary to have a camera which extends sufficiently to allow you to obtain an image of the desired size; but this will not affect the question of lighting. The best mode of lighting depends much upon the nature of the subject to be copied, and whether it has a polished surface or not. Many photographers prefer to copy in the open air, where the light falls on the picture to be copied from all quarters. If you copy in a room, let the light fall on the surface to be copied at right angles. If the subject have a polished or varnished surface, take care that nothing be in the way to cause reflections. Take care that the camera and picture to be copied are quite parallel. Cover up the front of your camera with black velvet, with a hole for the lens, otherwise the brass mounting of the lens, &c., will be reflected. Use your judgment and try a few positions, and you will doubtless succeed. 2. The amount of silver in the clippings of fixed prints is so infinitesimally small, that it would not pay for the trouble of recovery.

H. R.—The brass bindings for corners, focussing screw, and bellows bodies of cameras, are all made by different persons, who manufacture for camera makers. It is possible that one of the latter might be willing to supply you with them; but we cannot tell. We cannot tell you the price, but the screw is a very expensive article. We have heard about fifteen shillings mentioned as the price for a screw of a 10 × 8 camera.

SOCIUS.—The process by which Dr. Hill Norris's extra sensitive dry plates are prepared is not published. Our pages have contained descriptions of several rapid dry processes, but entire certainty in their use has not been obtained. 2. We have not experimented largely in the restoration of faded prints: but we have not much faith in any of the processes which have been proposed. 3. We have not tried the keeping of dry plates prepared with sugar, but it is probable that if any trace of free nitrate be left they will not keep long, as sugar has a reducing tendency. If they have been perfectly washed, we see no reason why they should not keep.

J. PAUL.—The solution of iodine we recommended as a preventative to the formation of a red deposit on the shadows during intensifying, should be applied to the plate after washing away the iron developing solution, and washed off before applying the intensifying solution of pyro and silver.

R. H.—We have not purchased Stockholm pitch, but should presume that it would be kept in large towns at oil shops, or perhaps at tool shops. Perhaps our correspondent, Mr. Nicholls, will state.

W. H. H.—The largest of the two lenses is infinitely best for the work, and should be chosen by those who can afford it, and have length of room sufficient to use it. Almost all the first rate artists whom we know use the larger one. 2. To keep up the ammonia nitrate bath keep adding from from time to time more strong solution, made as at first. It may be rendered colourless with kaolin.

W. M.—The maker you mark as No. 2 is first rate. Write to him, and he will tell you which is best suited to your room.

F. M. Y.—It is by no means uncommon, in working in the field, to develop with iron only, and defer intensifying or fixing until evening, at home. Some prefer to cover the plate with glycerine to preserve its moisture; others allow the plate to dry. In the latter case it is desirable to fix before intensifying, as, if the plate have been exposed to light before intensifying, whilst it still contains iodide of silver, it is apt to fog. By fixing and intensifying at home, the amount of water required is reduced to a minimum. A bath with water would be sufficient, leaving one plate in until another was ready. A bath holding a quart might wash a dozen or two stereo plates. We should not recommend delaying for more than a day or two, unless the plates were very perfectly washed. 2. You may add from half a grain to a grain of bromide of ammonium to Ponting's iodized collodion with advantage for many purposes.

JUSTITIA.—The best kind of negative for enlargement is one which is very full of detail and modelling, very sharp, very free from defects, and not very intense. The transparent positive should be very thoroughly exposed, and full of detail, and not very dense. It is in the kind of positive that mistakes are generally made. It should be more fully exposed, and much more full of detail than would be deemed sufficient to produce a good transparent positive for ordinary purposes. Both the original negative and the transparency should be very free from fog or abnormal reduction; with a few brilliant points quite transparent, but not more than *points*. The faults you describe are those which are most common in enlarged negatives, and which may be avoided, we think, by carefully following out these hints. Mr. Warner and Mr. Heath each use Dallmeyer's triple lens for enlarging. We believe it is the best lens for the purpose.

FRANCAIS.—There is not, we believe, a law of copyright which protects photographers in France, but the attention of the French Government has been directed to the subject. If such a law existed it would probably apply in this country, as the recent Photographic Copyright Act includes the provisions of the International Copyright Act. As the matter stands, French photographs have no protection, we believe, in this country.

H. C. S. G.—The card enclosed has many excellent qualities. If the background were little less heavy, the picture would be very good. The negative would have borne the least trifle more exposure.

Several correspondents in our next.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 221.—*November* 28, 1862.

## THE GLASGOW ART UNION AND PHOTOGRAPHY.

We have received from Mr. Annan, of Glasgow, three very exquisite reproductions from paintings, the circumstances in connection with which mark another very interesting and satisfactory step in the history of photography. These three photographs, each about 15 by 11, will be presented this year to the subscribers to the Glasgow Art Union, and will take the place of the engravings hitherto distributed. Many of our readers may be aware that in this, as in the London Art Union, each subscriber of one guinea has been in the habit of receiving a fine engraving from some original picture, and a chance in the distribution of certain prizes. The Glasgow Art Union has been distinguished by the extreme excellence of many of the engravings it has issued, and its general liberality and beneficial influence in the encouragement of art, and we hail with peculiar pleasure its recognition by this year's distribution, of photography as amongst the sisterhood of the arts. We believe, moreover, that the project will be found successful and satisfactory, and that excellent as have been the engravings issued, three such photographs as those before us will possess a greater interest and higher value in the estimation of the picture-loving public.

We have no wish whatever to array the art of photography against that of engraving. We do not see in the advance of one art the necessary declension of the other. The productions of each have beauties of their own. But with the reproductions in question before us, we are compelled to echo the opinion of the able art-critic of the *Times*, as to "the superiority of photography, with all its drawbacks, over engraving as a medium of translating the painter's work into monochrome." The same writer, who will scarcely be accused of undue leaning to photography, after dwelling on the "inexpressible inferiority" of the very best engravings, which are styled "poor and dead," in rendering the spirit of the master, adds, "were we certain that photographs would last, we are not sure that we should not be content to see engraving numbered amongst the extinct arts." As we have said, we do not see in the success of the one the necessary extinction of the other, but we cannot but recall with pleasure the dictum of an art-critic of such recognized authority as Mr. Tom Taylor, in support of the innovatory step taken by the directors of the Glasgow Art Union.

The paintings reproduced consist of three of the prizes intended for distribution, painted expressly for this Art Union, by G. J. Sant, A.R.A.; J. E. Millais, A.R.A.; and Noel Paton, R.S.A., respectively.

The subject of Sant's picture, which is to our taste by far the best, is "The Better Land," and is an illustration of Mrs. Hemans' charming lyric, known by almost every child who can read. Seated on a sofa is a young mother, as sweet and maternal-looking as a young mother should be; her eyes are bent upon a noble boy of about six summers, who kneels by her side. She is telling him of this better land; and he is intently looking with rapt face in the direction whither, with extended hand, she points. The words on her lips, which have taken possession of the whole soul of the boy, and filled his young being with hitherto unknown reverent wonder and awe, are manifestly those in the closing lines of the poem:

> "Eye hath not seen, my gentle boy,
> Ear hath not heard its deep sound joy,
> Dreams cannot picture a world so fair,
> Sorrow and death may not enter there;
> Time doth not breathe on its fadeless bloom,
> Far beyond the clouds, and beyond the tomb."

The pose and expression of the mother, and the pose and expression of the boy, are exquisitely beautiful, and tell the story of the picture most admirably. The general arrangement of accessories, the composition, and chiaroscura, all are harmonious with the spirit of the picture.

Mr. Paton's picture is an illustration of Tennyson's "Morte d'Arthur." The wounded king is laid in the "dusky barge," supported, and wept over, by the "three queens with crowns of gold;" the deck is "dense with stately forms, black stoled, black hooded, like a dream." A huge canvas, covered with strange forms and mystic devices, forming the sail, stretches dark against the sky. Much of the glamour of the Laureate's poem seems transferred to the picture, which possesses a strange interest. The shape of objects, and the devices of ornaments, the forms and expressions of men and women, all seem to belong to a far back traditional period.

Millais' "White Cockade" is, to our taste, by far the least interesting picture, but, then, we must confess to the heresy, as regards latter day art, of admiring the paintings of Mr. Millais, with a very qualified admiration. Much of his excellence is of a kind in which he seems to emulate the literal detail of the photographer, and in this respect the photographer can beat him hollow. We have no objection, it is true, to a rather good-looking young woman, in the costume of the last century, sitting against a background of storied tapestry, sewing on to a three-cornered hat a white cockade, the emblem of adherence to Prince Charlie; albeit, the said young woman may be in a somewhat awkward position. But the picture is, doubtless, well painted, and will have many admirers.

As regards Mr. Annan's work, we can speak with unqualified satisfaction; better reproduction, we believe, it is impossible to obtain. That of Sant's picture is, perhaps, the most perfect reproduction from a painting we have ever seen, and is so perfect, as to have elicited the remark from several clever photographers to whom we have shown it, that the painting must have been executed with a view to the reproduction. It is wonderfully brilliant, and yet soft and detailed; rich, deep, and transparent in the shadows, without the slightest loss of those delicate greys and demi-tints, upon which perfect modelling, and roundness, and finish, so much depend. It would be very easy to believe that the face of the boy was photographed from nature, so perfect is the gradation of half-tone. The breadth of light, and depth of shadow are very good, and are rendered harmonious by the perfect gradation of tones with which they are united. The other pictures are just as well photographed, although from the nature of the picture this is most effective. The printing is also admirably done. We think it a subject of much satisfaction, that the Glasgow Art Union, having determined on such a course, entrusted the work to a photographer who has done such justice and credit to their determination, and, by the excellence of the results, will have contributed, we doubt not, to give perpetuity to the practice they have initiated.

Mr. Annan has favoured us with a few particulars of his operations in reproduction, which may interest our readers. The lens was a Dallmeyer's triple achromatic, with an equivalent focus of about thirty inches. In this instance a very small stop could not be used, on account of the loss of light it involved, as the paintings were only about one-third larger than the photograph, and required an extension of the camera to about four feet. A good commercial collodion, bromo-iodized, we believe: a strong iron developer with as little acid as possible, and further intensification with pyrogallic acid and silver. Regarding printing and toning operations, Mr. Annan makes a remark which was also made to us, a few days ago, by the first portraitist in London, and is worth remembering; it is, that much more depends upon the quality of the negative, than upon the method of printing and toning, as regards the value of the print. Important as good printing unquestionably is, it is impossible to get a good print from a bad negative. Our readers may see the pictures in the forthcoming Exhibition of the Photographic Society.

## PHOTOGRAPHIC PIRACY.

A very notable illustration of the importance and need of a law of copyright for the protection of photographs has just occurred. As all our readers know, the London Stereoscopic and Photographic Company paid to the Commissioners of the International Exhibition an enormous sum for the sole right to photograph the contents of the building: they employed some of the very ablest men in the profession to execute the task: they procured the best equipment possible of appliances for doing the work, without regard to cost: they entered upon the undertaking, in short, with a spirit which ensured the very best results. Just as they have won golden opinions from all sorts of people for the beauty and perfectness of the memorials of the Exhibition they have issued, and have won, we hope, something still more substantially golden than opinions, they discover a wholesale system of piracy in operation, by which their profits and their reputation are endangered together. By the operation of the new Copyright Act they have, however, a swift remedy and a sure prevention.

The case presents some singular features, and we shall briefly state the facts, as we find them related in that ominous document, a "Bill of Complaint" in a Chancery suit.

Some time ago, the Stereoscopic Company had in their employment, as operator, a gentleman who stated his name to be Albert, Count Leiningen, cousin to Her Majesty the Queen of Great Britain. How far this assumed title and relationship may be based upon truth, we cannot tell; for purposes of convenience, however, he assumed the alias of Albert Ceileur. M. Ceileur, as we shall call him, is an old photographer, and a skilful one. If memory serves us correctly, he was engaged in London in Daguerreotype days, and has been subsequently in New York. Two or three years ago, he was engaged by the Stereoscopic Company, and received an unusually handsome salary; a few months ago he was summarily dismissed, as it was discovered that he was conducting a private photographic business of his own at his residence, at the time he was supposed to devote his whole energies to the service of his employers. Something like a month ago, the Company incidentally heard that their quondam operator was carrying on a wholesale system of piracy, and that he had sold for export nearly a quarter of a million copies of their Exhibition photographs.

Shortly afterwards, they ascertained that Mr. H. L. Oppenheimer was selling these pirated pictures. They had lacked legal evidence of the former fact; but this was easily substantiated. Legal application was at once made to Mr. Oppenheimer, who, after some correspondence, agreed to give up and destroy all copies in his possession, and refrain from further sale. He also stated that he had been acting under a misapprehension as to the copyright, and gave the name of M. Ceileur as the person who had supplied him, adding, that he had believed M. Ceileur to be a partner in the Stereoscopic Company.

In some further steps which followed, we find M. Ceileur offering the Exhibition pictures at five shillings a dozen less than the price at which they were vended by the Company, and stating that he had the largest photographic business in London, employing not less than sixty hands in his establishment.

We may here pause to remark, that the extreme excellence of the Exhibition photographs, issued by the Company, would afford the best possible facilities to the pirate for obtaining good copies. Sharp, soft, round, brilliant, and wonderfully full of detail: very perfect and free from blemish, these photographs well rolled, to get rid of the texture of the paper, would copy admirably. The subjects, moreover, are those which present the least difficulty, as we find in the list given of those pirated, that they consist chiefly of the gems of sculpture with which the Exhibition abounded.

Notwithstanding this, however, it is impossible to produce photographic copies which shall at all equal the originals, so that, besides the loss of profit, there is the loss of reputation, which must result from the imperfect copies being attributed to the Company, who produced the originals, and the plaintiffs very pertinently state in their Bill, that "The defendant by taking such spurious photographs, as aforesaid, is not only causing great loss to the plantiffs, and injuring their trade in the sale of photographs, by selling at a reduced rate, but also injuring their reputation in such trade, as it is universally known, that the plantiffs have the sole and exclusive right of producing such photographs as aforesaid, and that these spurious copies would be considered by the public and the trade, as the productions of the plaintiffs, and bring them into disrepute." We may add that a portrait of the Lord Mayor elect, which was purposely reserved, and publication delayed, is also amongst those included in this action; some copies, ostensibly for export, had been obtained from the Company, so that by this ruse the pirated copies might be issued in anticipation of the genuine portraits.

Without entering into details, we may state that prompt action was taken, and a Bill in Chancery filed on the 12th of this month, Sir Hugh Cairns and Mr. H. Stevens representing the plaintiffs, and Mr. Swanstone the defendant. In a few days the case came for hearing, and a perpetual injunction was obtained, which not only restrains the defendant from further sales from the pictures he has pirated, but is prospective as well, and forbids him to copy any other registered photograph by the plaintiff, which either has been or may be taken, and compels him to pay all costs arising out of the action.

As we are anxious that the record of such cases should serve as preventives to piracy, we will add one or two extracts from a letter addressed to Mr. Nottage, by the able solicitor for the plaintiffs, Mr. C. H. Collette, of Lincoln's Inn Fields, in reply to some questions we had asked as to why proceedings in Chancery were taken instead of the summary process before magistrates, which the recent Act permits, as a Chancery suit is usually regarded as a tedious and expensive remedy. After giving some reasons why he preferred the jurisdiction of the Court of Chancery in this case, he adds:—

"The remedy by injunction is most extensive and summary; our decree extends at one blow to the prohibition of copying not only the 15 photographs named in the Bill, but all others which you may *have taken and may hereafter take and register*, of which you have not sold the copyright.

"As to the alleged tedious process, I got the order and injunction of the Court within twenty-four hours after proof of defendant's guilt was in our possession.

"As to the expenses, here again you are indemnified. In a criminal proceeding, you would have had to pay all your own expenses, whereas a decree which has been made perpetual against M. Ceileur, saddles him with every penny of the costs of every description.

"You might, had you desired to press it, have required an account on oath of all sales and payments of all consequent profits, and damages in addition, with this further advantage, that if Ceileur makes any other copies of your registered photographs, he can be summarily attached and put in prison for contempt of court."

That heavy damages have not to be refunded, as well as piracy immediately stayed, is, it appears, simply due to the forbearance of the Company. We are glad to find a remedy so prompt and comprehensive in actual operation, so that if, at any time, the summary penal process miscarry, either from a magistrate's crotchetty construction of the Act, failure of the kind of evidence necessary in such an action, or other causes, the Court of Chancery, despite its repute for tardiness, presents a full, certain, and speedy check to photographic piracy.

## Scientific Gossip.

### New Method of Manufacturing Oxygen Gas on a Commercial Scale.

Oxygen gas is attracting considerable attention just at present. It has especial interest to the photographer; for if procurable in quantity, and at a low price, it would place him in possession of intense and economical sources of light, and would thus give a great impetus to those branches of photography which depend, in some measure, upon intense light for their convenient prosecution, such, for instance, as the copying of microscopic objects. An important improvement in the manufacture of oxygen gas has recently been brought out by Mr. Webster, and as it is now attracting great attention, from its easy manipulation, as well as the cheapness of the process, we propose to bring the subject before our readers in a brief account of the chemical principles involved in the plan. Oxygen gas, as is well known, forms about one-fifth by bulk of the atmosphere, the remaining four-fifths being nitrogen. Disregarding, for the present, the part which nitrogen plays in the atmosphere by reason of its bulk—such as its influence upon evaporation, wind, &c.—we may consider it to be mingled with the oxygen simply as a diluent, to moderate and tone down to a manageable point the excessive energy of oxygen. Were there no nitrogen present in the air, the inhabitants of the globe would all be dead in a few hours, the unwonted stimulus throwing them into a high fever; whilst the first spark of fire which was lit would cause every combustible substance within reach to blaze with almost solar splendour, the coals in the fire-place and the iron forming the grate vieing with each other in their rapidity of combustion.

But although pure undiluted oxygen would be so fatal in every-day life, cases constantly arise in the arts and manufactures in which we require a more powerful supporter of combustion than is supplied to us in the atmosphere. Thus, in the metallurgy of platinum, Deville's beautiful oxy-hydrogen process entirely depends on the production of oxygen on a large scale; and the lime and bude lights are other instances of like value. Pure oxygen is, however, very expensive. In the laboratory, or for a lecture experiment, the manufacture of one or two cubic feet may not seem to cost much; but when wanted by 50 or 100 cubic feet at a time, it is very expensive when prepared by the ordinary methods. Thus, Deville has calculated that one cubic mètre (equal to 35·3 cubic feet) costs, when prepared from chlorate of potash, 8s. 4d.; and when prepared from oxide of manganese, upwards of 4s. The plan of making it from sulphuric acid would doubtless be cheaper; but on the large scale, there are serious difficulties to be overcome before this plan is adopted. Probably, any process whereby absolutely pure oxygen was obtained would be expensive. Comparing this gas to alcohol, the atmosphere might be likened to weak brandy and water, whilst pure oxygen would be represented by absolute alcohol—a chemical curiosity, very difficult to prepare, and also very expensive. If we want a stronger stimulant than brandy and water, brandy itself is taken in preference to absolute alcohol; and so, in like manner, if a stronger supporter of combustion than air is required, it may be found cheaper in every respect to use an analogue to brandy than to absolute alcohol —to employ a slightly diluted oxygen, obtained at a trifling expense, rather than make use of an absolutely pure gas. This is what Mr. Webster does. He does not attempt to prepare oxygen in a state of perfect freedom from nitrogen, but contents himself with getting a mixture three or four times as rich as the ordinary atmosphere, and in which combustion proceeds very vividly, although with slightly less splendour than if it were undiluted. The plan of operation is as follows: a portable fire-brick-lined furnace of iron contains an inner strong cast-iron vessel, ten inches in diameter, furnished with a cover and iron tube; into this is placed a second cylindrical iron retort, of seven inches diameter, open at the top, and provided with an orifice at the base, temporarily stopped with a piece of sheet iron, so that when the materials used are exhausted, the inner pot can be removed, and the contents easily knocked out with an iron bar. As the product left after the disengagement of the gas is not allowed to fuse, and only becomes slightly coherent or pasty, this form of retort, placed in the outer vessel of iron, which can be properly closed by a luted cover, answers remarkably well, and may be used by any intelligent workman. In connection with the outer iron vessel is an inch-and-a-half iron pipe, luted into a stone-ware tube, forming part of, and leading to the bottom of a 30-gallon stone-ware vessel, containing half a gallon of water, and eight moveable stone-ware colander-like shelves. Upon these are placed 48 lbs. of the alkaline residue from a previous operation. The purifier, thus arranged, is furnished with a lid dropping into a water joint, and the whole is connected with a gasometer. The oxygen is evolved from a mixture of nitrate of soda (Chili saltpetre) and crude oxide of zinc, 10 lbs. of the former, and 20 lbs. of the latter. As the success of the process, so far as the maximum of the oxygen is concerned, depends greatly on the thorough dryness of the materials used, the top of the furnace is converted into a hot plate, upon which the materials are dried. They are then roughly mixed together in an iron tray, and dropped through an iron funnel into the inner red-hot retort, which can easily be lifted in or out of the exterior one by means of a chain and small crane attached to the furnace. The cover is provided with a hole at the top, and is immediately luted on with a mixture of Stourbridge clay and sand. As soon as the proper tests applied to the hole show that oxygen is commencing to be evolved, the top aperture is closed, and connection with the purifier and gasometer opened. The gas comes over very rapidly; in two-and-a-half hours, when the operation is considered terminated, 33 cubic feet are obtained, the loss of weight of material being 5·5 lbs.

The gas obtained, upon being analysed eudiometrically, is found to contain 60 volumes of oxygen and 40 volumes of nitrogen per cent. Thus it is seen to stand about mid-way between the ordinary atmosphere and pure oxygen, and is probably as strong a gas as can conveniently be employed in manufactures without danger. It conjunction with a jet of coal gas in the blow-pipe, it melts platinum quickly, and when passed up into a gas burner or oil lamp, it produces a pure and brilliant light, by which natural colours are seen as well as by daylight. When used for the oxy-hydrogen lime light, it is but slightly inferior to pure oxygen, and it is only by comparing the two lights side by side that the difference in their relative intensities is observable. The cost of oxygen prepared by this method is still further reduced by the fact that the oxide of zinc can be repeatedly used, by merely washing it free from the soluble salts; whilst the aqueous solution, upon evaporation to dryness, yields a highly alkaline residue, which it is proposed to sell direct to chemical manufacturers, who would find the different ingredients readily separable by crystallization, and of considerable value in various branches of their art. Supposing all the products are realized in this way, it is calculated that the price of this highly oxygenous mixture would not much exceed that of coal gas; whilst, even supposing all the products are rejected, it would only cost about one-fourth that of the gas prepared in the ordinary manner.

## SOME ADDITIONAL NOTES ON PLAIN WASHED COLLODION FOR DRY PLATES.

BY W. HISLOP, F.R.A.S.*

About twelve months since, I asked the attention of the members of this Society to the fact, that no preservative whatever was required for dry collodion plates, but that they would retain their sensitiveness in every way unimpaired, and would allow of the development of the impressed picture better without than with the imposition of the numerous substances, simple and compound, that had been advocated by various manipulators.

Some gentlemen were unwilling to believe this, and when the results were shown, attributed them to various causes. Others averred that they had tried, but could not succeed, and that it could be done by no one but myself. Some said it had been done before; but not a few have communicated to me their acknowledgments for having had their attention called to a simple and certain means of obtaining good pictures. Since that time, I have, as an amateur, continued to use the method then advocated, as the best means I know of obtaining pictures on dry plates, and with more than the success of which I then spoke. The details of the manipulation have remained the same.

It may be remembered that I found the film very loose, after being again wetted, if the plate was not previously coated with some adhesive substance. Being in the habit of using a very weak solution of albumen as a substratum for wet collodion, I employed that for the dry plates, and found it satisfactory. I have subsequently tried india-rubber and gelatine in solution, but found neither of them as perfect as very dilute albumen. I had observed, however, that the pictures were more full of detail and half-tone when the film was supported by the bare glass only; but until lately I have not been able to find a collodion which would adhere with sufficient firmness to render it safe.

The plates I have used have been principally of stereoscopic glass size, and also larger ones, to nine inches by seven. I have found the larger plates equally certain and satisfactory with the smaller ones. In this process, however, as in every other with a dry plate, it is absolutely necessary that the drying process should be quick and uniform, if we wish for evenness of sensibility and intensity. I have not been able yet to use any method of artificial drying; but a close observance of what takes place in plates which have dried slowly, leads me to conclude, that the longer the film remains wet, the more insensitive it becomes, leading, if the drying be unduly prolonged, to stains and patches towards the end which has remained wet for the longest time.

The exposure I have employed has, of course, varied with the subject. From one to five minutes for a landscape, with a 4½-inch focus lens, and ¼-inch stop, has been the usual time; while for an orthoscopic lens of 17 inches equivalent focus, I have used from five to fifteen minutes for the same subject.

With respect to the keeping qualities, I have not kept them beyond three months, but have found them unchanged at the end of that time. After exposure, I have kept them for a fortnight before development, without any alteration that I could observe; but I have not experimented in this direction, being generally desirous of seeing results in as short a time as possible. I may here notice, that I believe many dry plates are spoilt from the boxes they are kept in not being air-tight. If I am travelling, or likely to keep the plates any length of time, it is my practice to paste strips of gold-beaters' skin or varnished paper over the opening, to exclude, as far as possible, the external air, as we can never tell where the package may be placed, or what deleterious fumes may envelope it. I have found plates soon spoilt that are kept in a box on a shelf near a ceiling where gas is burnt.

In most of my successful plates I have used Ponting's negative collodion; but within the last two months I have succeeded in obtaining a collodion which is a very great improvement, and which brings plain washed collodion for dry plates very nearly to a par with collodion in its wet state, for sensitiveness, while they are superior for detail, and as simple in manipulation.

The collodion in question is Ponting's bromo-iodized collodion. With this I can obtain a landscape in thirty seconds with a moderate light, while the details of foliage in shadow are beautifully defined. This collodion needs no substratum, it dries rapidly, and gives a beautifully clear and intense picture with an old nitrate bath.

I believe that the best means of promoting photography, especially among amateurs, is to endeavour to indicate those materials which are in the market, and can readily be obtained, rather than to make experiments on a necessarily small scale, which are likely to give different results when repeated under different circumstances.

To those who would like to save their time and to obtain pictures, I can confidently recommend this method of manipulation; and in order to make it as plain as possible, I will briefly state precisely the course I have found the easiest.

The collodion is Ponting's bromo-iodized collodion.

The bath is the ordinary 30 or 35-grain negative bath, slightly acidified with acetic acid.

The developer is 6 grains of pyrogallic acid, with 4 grains of citric acid, to 4 ounces of water. One or two drops of the nitrate bath are added to the necessary quantity for each plate.

The plate is cleaned, coated with collodion, and immersed in the bath. When uniformly sensitized, it is placed in a large dish, filled with common water. I use New River water.

The next plate is then dealt with in the same way, and when the first dish is full, the water is well waved to and fro, and the plates taken out one by one, and placed in another dish, so as to wash each equally. This is done a third time, and a small quantity of salt is mixed with the water in the last dish. The plates are taken from this, one by one, and a stream of water from a jug or tap is allowed to fall with some force upon the film, to remove any particles of chloride which might adhere to it, otherwise the film may be covered with transparent pin-holes. They are then set up on one corner to dry, taking care to draw off any moisture by means of blotting paper.

If it is suspected that organic matter exists in the water, it is desirable to immerse the plate, after the final washing, for a time in distilled water, or the negative may be found to redden in colour towards the edge which has been the lowest in drying.

After exposure, the plates are placed in a dish of water for a few minutes, and then developed, taking care that the developer flows equally over to the edges of the plate. The resulting picture is nearly of the same colour and intensity as if exposed and developed while wet.

In certain conditions of the bath, especially if it is new, it may happen that there is a want of intensity. In this case, a very small quantity of common resin, considerably less than is used for the resin process, say about a quarter of a grain to the ounce, will be found to darken the picture. Almost any intensity may thus be obtained.

* Read before the North London Photographic Association, Nov. 19.

I have not tried the effects of other resins sufficiently to speak positively of them; but I am disposed to think that shellac will prove better than any.

I have only further to remark, that if I have not been sufficiently clear, I shall be happy to give any further information I may possess.

## EXPERIMENTS ON THE CHEMICAL ACTION OF SOLAR LIGHT.

BY M. BAUDRIMENT.

These experiments, commenced in June, 1857, and continued until November, 1861, were divided into two principal series. Those of the first series were made upon coloured materials, in a square frame, contrived to receive nine plates of glass of different colours. The experiments of the second series were made upon vegetables, with the same frames of coloured glass. The coloured substances were: 1st, Chemical substances, salts of mercury, and of iodine, and chromate of silver. 2nd, Of papers impregnated with organic colouring materials soluble in water or alcohol, turmole, curcuma, alkanet, &c. 3rd, Of silk ribbons of various colours. 4th, Of dissolved substances contained in tubes, sealed at the lamp.

We regret that we cannot give all the details of these two series of experiments, but are compelled to limit our account of them to the general results of this important investigation, of which the most unexpected result is, that the quantity of water evaporated varied with the colour of the light illuminating the liquid, when the differences of temperature were very slight and insignificant.

The facts comprised in this investigation divide themselves into several distinct groups; the one consisting in the destruction, and probably also in the combustion of organic substances; the others, relative to vegetation, connect themselves with the formation of vegetable products by a kind of reduction; the last comprehend the reactions which take place by the simple action of light, without the intervention of any foreign body. Such is, probably, the case of the protochloride and the bisulphide of mercury.

Although these facts appear opposed to each other, it is evident they are due to the same cause, and that they have their origin in the action of solar light.

This identity of solar action suggests the idea, that it is possible to unite them with each other by a theory which permits the including the whole within it. I will here endeavour to give a sketch of the first elements.

The results to be deduced from the action which light exercises upon vegetables, are intimately connected with those researches upon various materials described in the first portion of this inquiry.

It is evident that the chemical rays recognised as belonging to the most refrangible portion of the solar spectrum, are not those which cause the fundamental chemical reactions that give rise to the organic products of vegetables.

These rays are found towards the yellow light, which is inert relatively to heliography, while the violet light, which is much more refrangible, is entirely incapable of exercising this action: but it must be recognized that no elementary light is capable of provoking vegetation completely of itself, and that the entire white light of the sun is requisite to produce that marvellous metamorphosis of inert into living matter.

Such is the simple summary of the facts observed; but to how many questions it gives rise!

How does the light intervene?

Does it act in a temporary manner, or does it remain in the products it helps to form?

Is it an imponderable acting by its presence in bodies? or rather, performing the part of a special dynamism, must it be regarded as a mechanical agent?

It is generally admitted that the carbonic acid which penetrates vegetables is reduced, that its carbon is fixed in them, and its oxygen liberated. But to those who have deeply reflected it must be evident that the accomplishment of this act is not so simple, that ammonia intervenes in the reaction, that it is possibly the same with many mineral substances; and, lastly, that instead of a simple reduction, there is a series of reactions analogous to those which we admit for the accomplishment of the nutrition of animals, and that act merely in an inverse order. Whatever it be, if we regard only the final reaction as it presents itself to us, and as it is accepted by all the world, the products formed should retain a certain portion of light, and especially that which corresponds to the refrangibility of the yellow rays; while the other portion, and chiefly that which corresponds to the most refrangible rays, must unite itself wholly with the oxygen, and remain in a latent state.

The oxygen given off by plants does not differ from that which enters into the constitution of the atmosphere; we are led to admit that in either case free oxygen contains latent light. When we burn any kind of organic matter, such as wood, coal, or charcoal, light appears during the combustion, and we have a right to conclude that this light was contained in a latent state in the body in question, as I have endeavoured to demonstrate in a work I published under the title of *Dynamique des Etres Vivants*. But, at the date of this publication I did not think that the light contained in vegetables differed from that contained in oxygen, and that they could complete each other to produce ordinary light.

From these facts it seems to follow that the oxygen given off by vegetables, in consequence of the kind of light it carries with it, may find itself in one of the singular states described by M. Schœnbein. The two lights condensed, the one in the vegetable, the other in the oxygen, will not only be complementary in respect to their colour, but they may also differ either as two rays of the same origin, rectangularly polarized, and still more, perhaps, as rays possessing contrary and complementary votary powers, which entail either *henriedry* or *plagiedry*, if the carbon and oxygen can at once assume a crystalline form.

In general, bodies lose light upon combination, and this light must be restored when they are separated, in order to restore them to their primitive state. But the field of hypothesis widens its horizon the further we proceed, and the end cannot be seen yet.

Some cotyledons take a foliaceous development, and produce green matter, like the graminacea, the *Lapidium Sativum*, and some of the synanthereas; and as this takes place whatever be the light which illuminates the plants, and also even in the dark, we are induced to think that these seeds must contain latent light, which becomes free and efficacious in proportion as the embryonic evolution is accomplished, and ends by disappearing, when the germ has acquired sufficient strength to draw direct from the solar emanations, the light indispensably necessary to the formation of the vegetable.

If we inquire in what special product, inherent to the seed, the light is found so condensed, we shall be led to recognise that it must be in the most combustible portion, in the oily matter that always surrounds the embryo; oily matter which during a long series of ages has been the principal and almost the only product that man has employed as the basis of lighting.

By an action the reverse of that which has produced it, the principal function of this matter will be that of uniting with oxygen, and thus commencing the series of chemical reactions which must be accomplished to produce organic matter.

Seeds are not the only primary matter which contain oily substances; it is the same with the eggs of every animal, whatever degree of organization it possesses, from the sponge to the human being, and doubtless the function of the oily matter is the same.

Germination and primary evolution of animals are, so to speak, confounded together. Both grow under the protection of light, both require the aid of oxygen, both consume organic matter, and do not create it. Germination, as I have long ago asserted, is an act of animal nature.

However hazardous these opinions may appear, they must not be too hastily rejected, for they are in perfect harmony with the entire grand theory of vibratory motions, which is the only one which, at the present day, will explain all the facts observed in nature.

## ON SOME OF THE DIFFICULTIES CONNECTED WITH THE PRACTICE OF PHOTOLITHOGRAPHY.

BY J. W. OSBORNE.*

In a paper read by me at the meeting of the British Association of this year at Cambridge, I gave exact directions for the execution of my photolithographic process, in as concise a manner as was consistent with a proper elucidation of my subject. On the present occasion I respond to the flattering request of Dr. Diamond, to continue the topic in a short paper before the Photographic Society, and I request the members to consider the few observations I have to make as supplementary to the paper just referred to.

Foremost among the difficulties which beset the operator engaged in the reproduction of drawings and engravings, should be enumerated the circumstances affecting the production of a good negative. I have already referred to the importance of this first step in the process, and explained my method of "clearing up," and pushing the development, with a view to obtain contrast upon the glass; but more yet remains to be said upon this theme alone than I can possibly find space for within the limits of the present communication.

It must be obvious to all, that the quality of the negative depends, first of all, upon the original from which it is taken. A drawing from which a very tolerable silver print copy can be made will not unfrequently cause the photolithographer much difficulty, which he is conscious of when endeavouring to produce a negative suitable for his purposes. This depends to a certain extent upon the peculiarities of the process, but chiefly upon the fact that we apply quite a different criticism to artistic productions emanating from the press and to those from the pressure-frame. In the one case we expect perfect cleanliness, sharpness, and solidity; in the other we are satisfied if the general effect upon the mind is such that we are forcibly and irresistibly reminded of the original. To secure, then, a good negative, the design to be copied, if drawn by hand, must be executed in a certain style, which will not be invariably followed by draughtsmen, unless their attention is particularly directed towards it; and this is true of those who work mechanically with the drawing-pen and scale, as well as of persons engaged in the essentially artistic expression of their conceptions.

That the acquisition of a good method of drawing is no insurmountable difficulty, is established by the success which has attended the introduction of improved systems into the Ordnance Map Office at Southampton, and the Survey Office in Melbourne. In the last-named department, the improvement in the character of maps, and plans generally, has been very considerable, and is, quite independently of photolithography, a great boon to the office. I may add that some of the reproductions of pen-and-ink sketches which I exhibit are from originals which leave nothing to be desired.

The object which the photolithographer should have in view, is not only to reproduce existing originals of convenient and suitable size; but, abstractly to bring the quality of his work, whenever that is possible, up to that of the best lithographic productions drawn by hand. And while I admit that the copy of an indifferent sketch, etching, or ancient manuscript, may from circumstances connected with its history, or from other causes, be a legitimate and useful application of the art, I am still of opinion that, until the excellence of ordinary reproductions by this means is ensured by adopting the necessary precautions as regards the original, photolithography will not take the honourable place it is destined to fill among the graphic arts.

Up to the present time, the draughtsmen and artists have drawn with the knowledge that they were to be followed by the engraver, whom they not unfrequently regarded as a mechanical man, whose business it was to set all right, and give finish and uniformity of style to their productions, by his rendering of them. The draughtsman (and I refer more particularly to the compiler of maps, and to the producer of mechanical drawings and designs) has now to remember that the lines he draws, and the word he writes, will be printed as he renders it, and that the ultimate quality of the work depends in the first instance, on him.

If it leaves his pen as a ragged broken scratch, it is out of the question to transform it, by the application of any amount of care or cleverness, into what it ought to be. Photolithography has not yet passed into general use. As far as practical results are concerned, its adoption has been almost restricted to one or two Government Departments; but its extension is inevitable; and for publications by its means, a number of originals have yet to be drawn, greater, I would hope, than the vast store of time-honoured manuscripts and engravings which the past has so temptingly provided for us.

It is to point out the necessity for the maintenance of a correct style, and plain and firm work, that I have urged this subject upon your notice on the present occasion. The chief and leading error which ordinary draughtsmen commit is the use of pale grey ink for all fine, delicate, or distant work. Such ink flows more easily through the pen, and the work, when finished, has a softer effect, owing to the fact that a grey line looks finer than a black one, and the imperfections of such a line are not so readily seen. When the photographer endeavours to copy such a drawing in the camera, he experiences much difficulty in making from it a negative of the requisite quality, because a long exposure, desirable for the sake of getting intensity, which would easily be borne by the blacker and heavier part of the work, is sure to cloud over with a considerable deposit the paler and fainter lines. Unless this cloudiness can be totally cleared away, it prevents such lines going down on the stone with firmness and solidity.

Depending upon the converse of this state of things for its explanation is the fact that engravings are, as a rule, much easier to reproduce than drawings by hand, the fine and distant work upon such being produced, not by paler, but by finer lines and markings, with larger spaces between, than are let remain in the foreground and shadows.

Let us now consider how far it is possible for the photolithographer to equal the lithographer in the quality of his work. If, without reduction, we copy a well-executed map from stone or copper, using the best instruments, the purest chemicals, and the greatest care, all that it is within the bounds of possibility to obtain, is a fac-simile somewhat inferior to the original in quality. How much inferior, depends upon the process, and upon the operator; and the constant endeavour of the latter will be to reduce that quantity to a minimum: but however much he may exert himself, a difference will always exist.

If we now suppose that the engraving or drawing is fitted for reduction, and that the operator, taking advantage of this, diminishes the copy in size, we shall find that the result may be a finished work, quite equal to, or even superior to the original in excellence,—this result depending upon the fact that, when the minute imperfections of a drawing are reduced beyond a certain limit, they ceased to be observed by the unassisted eye, and for all practical purposes cease to exist. It is by availing ourselves of this beautiful power of the camera, that decided superiority may be obtained by the judicious employment of photolithography. At the same time it should be remembered that the camera

* Read at a meeting of the Photographic Society, on Tuesday evening, Nov. 4, 1862.

never changes the general character of a drawing, but only refines upon it, and that an original, the several parts of which are out of keeping with each other, and wanting in finish, will never, by any amount of reduction, be made to produce a pleasing effect.

A just appreciation of this subject is one of such paramount importance to the future of photolithography, that a short treatise on it, appropriately illustrated with originals, of various kinds and qualities, accompanied by their reproductions, both good and bad, on various scales, might be written with much benefit to the rising generation of draughtsmen and artists.

Leaving this topic, I wish to draw your attention to one cause, which I am convinced militates more frequently than is generally believed against the production of good negatives. The disturbing influence to which I refer is vibration. This may exist either in the camera, in the original to be copied, or in both; and its amount may be quite imperceptible to the senses, and yet be productive of much mischief. The tables upon which cameras are placed, the floors upon which they rest, the plan-boards to which originals are attached, and the methods employed to secure them, are rarely as firm and solid as they ought to be.

When we consider that the image of a fine line upon the sensitive collodion has only to oscillate to the extent of one-fourth its own width (equal to about $\frac{1}{700}$th of an inch), during a long exposure of three or four minutes, to take much from its sharpness and delicacy, the importance of adopting sufficient means to ensure stability will be manifest. On this account alone, if other reasons were wanting, I object to copying in the open air; for there are few days so still and free from wind, on which a slight tremor is not imparted to the instrument or plan-board; and I prefer to sacrifice a portion of the light, for the sake of securing perfect rigidity.

In concluding this paper, a few words on the nature of the difficulties affecting the production of photolithographic half-tone may not be out of place, as they will also serve to explain one of the chief uses of my "clearing up" process, the object of which, as I have already mentioned, is to obliterate half-tone, and to make the greatest amount of contrast to be obtained by subsequently pushing the development.

The gradation in tint observable in impressions from a lithographic stone are invariably found to possess a certain definite structure; that is, a shade is composed of a systematized arrangement of perfectly black markings of more or less determined form, separated from each other by clear white blanks and spaces. The distinctive characters of lithographic drawing depend chiefly upon the form of these markings, while the differences in depth of colour and tone depend upon their size and proximity.

Thus we have crayon drawing, stippling, cross-hatching and ruling, which are some of the methods employed to produce shadows of varying depth; and however even and soft the tints produced by these means may appear to the casual observer, they will each be found, upon close examination, to possess a certain characteristic form. Further, a little consideration will show that, while the printer works with an *opaque* ink, the colouring matter in which is carbon, and while it is only possible to prepare the stone in such a way as either to *take* or *reject* the ink on different parts of its surface, middle tints must continue to be constituted in a manner resembling that I have described. Now, in the negative picture from natural objects, we have no structure, as its shadows are simply the result of the action of varying amounts of light, and the particles of opaque solid matter deposited in the film are so minute as to defy detection and isolation, even with a high magnifying power. Here, then, is the difficulty. To give structure to these shadows, to express them on the stone in a manner more or less conventional, to print them by a mechanical process on paper, and still keep up that delicacy of character which the subtle luminous influence, by its chemical power, has imprinted on the plate, is the great problem to be solved.

Although, by modifying my process, *half*-tone can be and has been obtained, I cannot say the same of the infinite number of intermediate tints which constitute the charm of a photographic picture. I am confident that it admits of extension in this direction; but want of time has hitherto prevented me from devoting the necessary attention to it. I believe that my predecessors have too ambitiously aspired to the attainment of this most desirable, but most difficult object, and that had I followed them in this respect, and not circumscribed my field of operations to the production of simple black and white, my labours would not have terminated so successfully.

I do not doubt that we shall ultimately possess a good photolithographic process, capable of giving half-tone as good as any now obtained from the stone by the ordinary manipulations; but much remains to be done before this is accomplished. It should also be borne in mind, that it is not sufficient for the stone to furnish one or two good proofs; the quality of the work upon it must be such as to supply an indefinite number, if the method by which it was produced is to be of practical value. Looking at this subject from a business point of view, I think you will agree with me, that the quality of future results must closely approximate the perfections of a good silver print before they become commercially valuable.

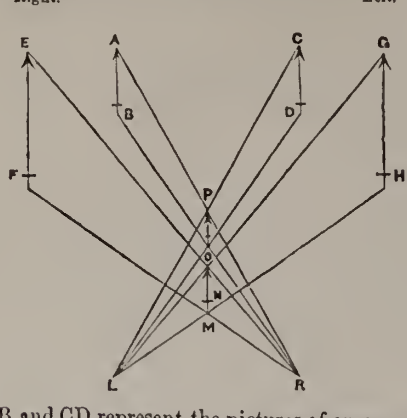
If, in the ordinary application of my process as I have described it, a portion of the work to be copied is washed in with a brush, or faintly drawn with pale ink or pencil, we obtain a negative which exhibits corresponding half-tone. Now the question may be asked, Why does not this print from the stone as a tint? The reason of its not doing so will be readily understood if we remember that the means by which the superfluous ink is removed from the transfer paper, after the blackened print has been sufficiently soaked, is a mechanical one, and deals roughly with the particles of matter (if I may be allowed so to express myself), compared with the delicate deposition and removal of atoms by chemical agency. If, then, the portion of the positive print sunned under half-tone in the negative has sufficient affinity to retain the ink, it retains a homogeneous and connected coating, which transfers to the stone as a solid patch of greasy matter, which will print black. If, on the other hand, the gelatine has not been sufficiently altered, the sponge removes the ink from such under-exposed places, clearing it right away, or at best leaving a broken line or shadow composed of inky patches which darken (if the transfers be effected to a smooth stone) with every impression taken in the press. Such results, save in as far as they can be made instructive by the investigator, are utterly worthless; and yet I take this opportunity to express my firm conviction that lithography, partly on account of its chemical character, and partly because of the excellent half-tone which the stone may be made to yield, is better fitted for union with the photographic art than are any of the other means of producing artistic works in the press, such as engraving, or surface-printing.

## THE STEREOGRAPH AND THE STEREOSCOPE.*

*The Stereoscopic Picture in front of the Photographs.*—In the first place it will be well to show, that when the stereoscopic effect is once produced with the strabonic stereograph, the axes of the eyes cross. Mark the left photograph with the letter R, and the right with the letter L; then, when three pictures appear (that is, the middle or stereoscopic one clear and distinct, and the two outside ones faint and indistinct), close the left eye; it will now be found that the axis of the right eye is exactly on the photograph R; reverse the experiment by closing the right eye; the axis of the left will now coincide with the centre of the photograph L. A peculiarity arising from the operation is, that when the eye is suddenly closed, the single unstereoscopic picture

* Continued from p. 442.

appears only of half its natural size, a phenomenon attributable to a short retention of the impression on the retina after its formation and its cessation; for, by suddenly rectifying the eyes to ordinary combined vision, the single image will at once be recognized of its natural size.



Let AB and CD represent the pictures of an arrow, as seen by each eye at a given distance, and EF and GH the pictures of the same object at a nearer distance. Let the photograph taken by the lens on the right side be mounted on the left side, and vice versa as in the adjoining figure. Let L and R represent respectively the left and the right eye. Draw lines from the right eye to the top and bottom of each arrow in the photograph marked "right," also from the left eye to the photograph marked "left." At the points of intersection draw the arrows MN and OP; these arrows will represent respectively the positions of the pictures of the original objects projected in space, with all the distances and sizes in true proportion; but these arrows might represent parts of one and the same solid object, so that the points of intersection would depict the corresponding points of a solid picture.

The arrows, of which AB and EF, etc., are supposed to be photographs, are supposed to be placed perpendicular to the plane of the observer, or to the surface of the paper, and to be twice as high as the elevation of the eyes above the horizon. The pictures are mounted so, or so deposited in the figure, that the distances BD and AC are respectively equal to the distance LR, or the distance between the centres of the eyes. For this reason BO will be equal to OR, as also DO to OL. In like manner AP and PR, and CP and CL, are equal to each other: and since the arrows are supposed to be perpendicular to the paper, and the eyes above the plane of the paper at a distance equal to half AB, the distances AP and CP will be equal to BO and GO; therefore, the superimposed pictures at PO will be equal to half AB or CD. The arrow, of which AB and CD are the pictures, is supposed to be placed at a great distance off, so great indeed that, in the strabonic stereograph, the distance from A to C will be equal to the distance between the eyes; but the distance between all nearer objects, as from E to G will be greater; therefore, the intersections of the two lines ER and GL, as also of FR and DL, will take place nearer to the eyes than P or O, and in such a manner that EN or GN is less than NR or NL, as also FM or HM is less than MR or ML.

From these circumstances we deduce the following conclusions: the superimposed pictures at MN are less than half the size of EF or GH inversely, as EN FM (which are supposed equal, since the arrow is intended to be perpendicular to the plane of the paper) is greater than NR or MR (likewise equal). Secondly, the picture MN will always be greater than PO, because the angle ERF will always be greater than the angle ARB, as long as EF is nearer to the eyes than AB

It is evident too, in the third place, from the similarity of triangles, that the same proportion exists between the two superimposed pictures MN and OP, as between either pair of photographs EF and AB on one side, or GH and CD on the other.

As I have already remarked, the two new pictures MN and OP thus formed by superimposition, will be *very brilliant;* in the first place, because they are condensed, on an average, to one half the size; and secondly, because the light of either photograph is superadded. In addition to the superimposed picture, we have other two pictures much less brilliant, and at the same time indistinct, one on the right and the other on the left; that is, EF and AB are seen independently by the left eye to the left of the brilliant picture, whilst GH and CD are seen by the right eye independently to the right of the new solid picture.

These secondary pictures I have not introduced in the diagram, because the lines would merely confuse the more important demonstration of the solid pictures. Their position is found between the lines drawn from R to C and D, and from R to G and H on the right side; and then from L to A and B, and from L to E and F, on the left side; and their size too, by some peculiar physical sympathy, is about half that of the originals, or in the same proportion as OP to NM, and probably respectively equal to them.

*Application of the Strabonic Property.* — Whenever the practical photographer, or amateur, has taken a favourite stereograph, he is desirous right away of seeing a proof-sheet of his workmanship in the stereoscope, or of having a print taken of his negative, in order to test his success. On a tour it is not always convenient to carry a stereoscope to gratify his ardent desire; but it is not at all difficult to practise the strabonic exploit; and when this is once attained, you can examine your negatives the moment they are fixed. It is not only a great pleasure to be able to do this, but it is a saving of time. Again, with this property made quite easy and familiar, your right and left printed stereographs may be promiscuously mixed together without any subsequent embarrassment; for picking up two photographs of the same view, and placing them on any flat surface, as on a book, in juxtaposition, you can easily and instantaneously say which belongs to the right side and which to the left, or whether they both belong to one and the same side. Besides this, I have no doubt that before long we shall have strabonic stereographs on sale as numerous as the ordinary ones; for each person's eyes will be his stereoscope.

I do not know a greater treat in photography than that of taking up two card pictures, taken in the open air with a natural background, and with the binocular camera and to be able to produce the stereoscopic superimposition. Each blade of glass, each flower, the old hollow tree, the irregular rocks, the log-house, and the lake, are all presented in miniature solidity with the beloved friend in the midst in living nature. What a difference between such card-pictures and those flat silly things that are daily presented to us, whose background is almost universally a broken pillar or a baptismal font! Strabonic card pictures once introduced, and their beauties once descried, would soon drive away all those stiff photographic contortions and snobbish grimaces depicted in front of columns and regal staircases to the land of Proserpine.

*Injury to the Eye-sight by the Strabonic Manœuvre.*—Hints are frequently expressed, both by the laity and the medical profession, that such attempts as recommended in the present article, will be likely to produce permanent injury to the eyes, by producing internal strabismus. Such medical men do not investigate the grounds from which they derive their opinion; they take it for granted, I suppose, that since to be able to see strabonically requires at the beginning an effort, therefore it is unnatural, and must of course produce an unnatural result. Before such a conclusion can be established, we must first ascertain whether those persons who have obtained the faculty of thus regarding the stereograph, have had their sight deteriorated, the axes of their eyes changed, or, in fact, have suffered any inconvenience whatever. For my own part I must and can with a good conscience (and I have made a hobby of this stndy), aver that, with daily practice in viewing strabonically, not the slightest result of an injurious nature has manifested itself, and no one has yet detected any ontward signs of the nnmistakeable squint in my optical apparatus.

Others, friends of mine and of science, have been in like manner wonderfully gratified with the strabonic experiments, and testify to the normal action of the eyes as soon as the stereograph is laid aside. In fact, there is no reason why the sight shonld be thns impaired: for the axes of the eyes are normally convergent, and this convergence is a variable angle with different persons, depending upon the occnpations of men, and with the same person in accordance with the transition from different objects. In viewing near objects this angle is greater; in viewing more distant objects it is less. The convergence changes involnntarily as we raise our eyes from the lines that we are penning to the distant shore on the other side of the lake; and I do not regard it as more injnrious to the sight to make this involuntary transition than it is to make a volnntary convergence when required. By what nerves and mnscles this voluntary effect is produced, I am not yet prepared to state. The study is worthy the attention of our most distinguished physiologists, and they will certainly not despise the undertaking.

In my next commnnication I shall demonstrate the mode of seeing this stereoscopic effect, produced by a less degree of convergence of the axes of the eyes, so that the solid pictnre is seen, as it were, behind the stereograph and magnified.—*Humphrey's Journal.*

## Critical Notices.

### PHOSPHORESCENCE, OR THE SPONTANEOUS EMISSION OF LIGHT BY MINERALS, PLANTS, AND ANIMALS. By DR. T. L. PHIPSON, F.C.S., &c. With numerons Woodcuts, fcap. 8vo. London: Lovel Reeve.

OF all physical phenomena, that pecnliar emission of light called *phosphorescence*, which manifests itself in certain circumstances in minerals, vegetables, and animals, has hitherto been less known than any other. The work before ns, by Dr. Phipson, brings the somewhat neglected question of phosphorescence np to the scientific level of the present day It is the resnlt of many years' labonr and numerous experiments, bnt the anthor has devoted his pages to the works of others as well as to his own researches, and has, moreover, given, in a copions appendix, a list of the works which have contribnted to our knowledge of phosphorescence from the fifteenth century to the present time.

It is true that Aristotle distinctly speaks of the light of glow-worms, and the phosphorescence of pntrescent substances; that Pliny was acquainted with lnminons properties of certain *medusæ*, and had seen dead *pholas* shine in the months of those who ate them. But it was not nntil Fabricius *ab* Aquapendente first called attention, in 1592, to the peculiar light emitted by the flesh of dead animals, and after Cascariolo, the cobbler of Bologna, had discovered the famous solar-phosphorns, or Bologna-stone, that inquiry into these phenomena was fairly set on foot; and the first thing that strikes ns on opening the interesting volume before ns, is the enormons nnmber of substances and beings which are capable, in certain circumstances, of emitting light, often powerful enough to allow us by its aid to read the smallest print.

The author's work is essentially divided into fonr parts, the first of which treats of the phosphorescence of minerals and chemical substances; it includes also a very interesting chapter (Chap. V.) upon meteorological phosphorescence, or the emission of light by rain, hail, snow, fogs, aërolites, &c., &c. The second part is devoted to vegetable phosphorescence; and the third to phosphorescence in the animal world. The fourth includes the historical notes connected with the subject, the theory of phosphorescence, and practical considerations concerning its nses to man.

As we have already stated, the number of well observed cases of phosphoric phenomena, which we possess at the present day, is very considerable. In the mineral world we find phosphorescence induced by insolation, or exposure to the light of the sun; by heat, by friction, by electricity, by cleavage and crystallization, and by chemical change. The author treats separately of all these circnmstances in the first part of his work, bringing forward a mass of curious information, showing ns not only what has been done, bnt what still remains to be done, in connection with this mysterions evolntion of light by bodies. In the chapter devoted to meteorology, onr attention is called to numerons cases of luminous rain, snow, and hail, and to certain dry fogs which emit so much phosphoric light, that a traveller sees his way through them withont the light of the moon; to lnminons waterspонts, and several other very interesting phenomena.* In the vegetable world we find phosphoric properties developed to a high degree in certain *fungi*, which are phosphorescent whilst living; for instance, the famons *agaricus olearius*, which grows at the foot of the olive trees in Italy, and of which the anthor gives a beantiful drawing, and certain *rhizomorpha*, which are also figured, growing in damp mines. But the phenomena of phosphorescence is observed also in phanerogamic plants, and Dr. Phipson calls attention to the *euphorbia phosphorea*, the jnice of which leaves a vivid phosphorence on paper over which the broken stem of the plant is passed, and several other light-emitting plants of high organization.

In the animal world, from *infusoria* and *rhizopods* to *insects*, and *myriapods*, there is scarcely a group of animals that does not possess numerons individuals endowed with phosphoric powers. Ehrenberg has described npwards of one hundred species of phosphorescent infusoria, and nnmerous medusæ, polypes, aurelids, mollusca, crustacea, &c., have been added to the list by other observers. The common earth-worm, *lumbricus*, is luminous in October during its period of coupling; and the *cgrosoma atlantica*, and *salpoe* among the *tunicata* illuminate the warmer seas for miles and miles with a pale phosphoric light. Many of these interesting creatures are figured by the author, who next proceeds to examine luminons insects, the *lampyridæ, elateridæ, fulgosa.* In Chap. VI. of the Third Part, Dr. Phipson alludes to certain problematical cases of phosphorescence in snperior animals, and phosphoric phenomena observed in man. Our limited space forbids us to follow the author as we would wish, through this interesting investigation, bnt we must draw attention to a set of phenomena which Dr. Phipson has called *subjectile phosphorescence.* These happen when the optic nerve is cnt or injured, no pain is then felt, bnt flashes of light are perceived. The light, like that of the glow-worm, and other phosphorescent animals, is of a greenish yellow tint. It occnrs, likewise, when an electric cnrrent is passed along the optic nerve, and in febrile diseases, and by the use of narcotic medicines. "A prodnction of light in the above circumstances," says the author, "is exceedingly interesting, and tends, perhaps, more than we are aware, to establish the fact that the phenomena of light are owing to a *vibratory* movement of matter."

The historical and theoretical portion of this work wonld require more space than we can afford to do jnstice to them, we must, therefore, abandon our readers to these interesting pages, assnring them that the subject is well worth their attention; and that it is not devoid of ntility, Dr. Phipson has shown, by proving in his own laboratory, that the most powerful light hitherto produced by man, *viz.*, that produced when oxygen and hydrogen burn in contact with lime, is a phosphorescent light.

* In this section of his work, Dr. Phipson devotes several pages to the mysterious phenomena known as the *Will-o'-the-Wisp*. He shows that several very distinct phenomena are huddled together under this peculiar denomination. The generally admitted theory of phosphuretted hydrogen is shown to apply, only problematically, to one of these, whilst the others are shown to be electrical mists, insects, and inflamed hydro-carbons. To the latter belongs our ordinary English *Will-o'-the-Wisp*, which is burning carburetted hydrogen, or marsh gas, the flame of which is invisible in the day time, but attracts attention at night.

## Proceedings of Societies.

### North London Photographic Association.

The usual monthly meeting of the Association was hold in Myddelton Hall, on the evening of Wednesday, November 19, Mr. G. Dawson in the chair.

The minutes having been read and confirmed, Mr. H. Hemans and Mr. Lonsdale wero elected members of the Society.

Mr. Hill (Treasurer) exhibited a series of very exquisite photographs 7×4½, taken with Dallmeyer's No. 3 triple lens. The pictures were similar in size, and also very similar in many of the qualities to those recently issued by Mr. Wilson of Aberdeen.

The Chairman exhibited a number of card portraits, taken with Mr. Ross's lenses, by Messrs. Abbott, Helsby, McNab, Deane, Ruff, and others. He also called especial attention to a series of theatrical portraits by Southwell Brothers, of most excellent quality, being delicate, soft, round, and brilliant in an unusual degree.

Some conversation followed, in which the question was asked as to which lens was used in the production of the last-named pictures. The Chairman being uncertain, Mr. Wharton Simpson said that Messrs. Southwell Brothers worked with Mr. Ross's card lens, No. 3, which had, he believed, an equivalent focus of about eight inches, and a back focus of six inches, or six inches and a half.

The Chairman then read the following letter forwarded by Mr. Wall:—

"To the Chairman of the North London Photographic Association.

"Sir,—Having just read a letter from the celebrated painter Mr. George Lance, published in the papers of to-day, and suggesting that his brethren of the brush should unite with him in aid of the Lancashire Operatives Relief Fund, by painting each a small picture to be sold for that special purpose at the ensuing exhibition of the British Institution, may I venture, through you and the Society over which you preside, to make a similar suggestion.

"It is urged, that, as the British Institution will open in February, the proposed aid would be raised at a time whon it will prove to be the most needed. Now photographers also have an exhibition, which will open at even an earlier date; and I think we have yet to learn that, as a body, we are more wanting in charity and patriotism than professors of the sister arts. I, therefore, venture to suggest, that a certain number of proofs from the negative of works exhibited should be set aside and announced in the catalogue as for sale, in aid of funds now being raised for the relief of our unfortunate and patiently-enduring countrymen in the North.

"Trusting that you will kindly see fit to proffer this suggestion in the course of the evening, and permit it to appear in the reports of the proceedings of the Association, I am, dear sir, yours obediently, A. H. Wall."

"*November* 19, 1862."

It will be seen, from a reference to our last, that a similar suggestion had already been made by Col. Stuart Wortley, who had initiated very handsomely the step he recommended.

The Chairman said, that the Secretary had received from Mr. St. George, photographic printer, a hundred copies of a very excellent card portrait of Mr. Hardwich; Mr. St. George wished to present to each member a copy of this portrait. The portrait excited much admiration as a brilliant photograph and a characteristic portrait.

Mr. W. Hislop then read "Some Additional Notes on Plain Washed Collodion Plates" (see p. 568). At the conclusion of his paper, Mr. Hislop exhibited some very fine transparencies and negatives taken by the method described.

Mr. Seely asked how long the negatives were in developing?

Mr. Hislop said about the same time as wet plates. As a general principle he preferred slow development, as it gave the manipulator more power over the result.

Mr. Seely asked if Mr. Hislop had tried development with iron with these plates?

Mr. Hislop was not in a position to speak with certainty as to the use of iron for the purpose.

The Chairman, referring to some of the negatives exhibited, said he never observed the deposit present such a piled-up appearance before. That in his hand might almost be used as matrix for an electrotype.

Mr. Seely asked Mr. Hislop if he found any uncertainty in the process?

Mr. Hislop said, no uncertainty but what he could trace to the neglect of proper precautions. If the manipulations and materials were right, the result was certain.

Mr. Seely said one great advantage of the tannin process was the great range of exposure it permitted without spoiling the results. Had Mr. Hislop found this to be the case with the simply washed plates?

Mr. Hislop could get pictures with much under-exposure, but not as good as with proper exposure.

Mr. Morley remarked that the negatives exhibited seemed to possess great intensity.

Mr. Hislop said the amount of intensity was quite under control.

Mr. Hill thought the prevailing error in dry plates was under-exposure and over-development. The negatives, from which the prints he had exhibited were printed, looked very thin, but they gave sufficiently brilliant results in printing, without being hard.

Mr. Seely asked if Mr. Hislop had used hot water?

Mr. Hislop had obtained a negative with five seconds exposure with the aid of hot water in developing, similar in character to one obtained in three minutes in the ordinary way. The chief difficulty with hot water was the tendency of the plate to dry in parts and cause stains.

Mr. Seely, referring to one of the negatives, said he thought it was solarized.

Mr. Hislop said it was a plate which had been long kept, and the defect was a slight amount of fogging at the edge of the plate due to long keeping. It was not solarization.

Several members confirmed this view of the case.

The Chairman said it was strange that this question so often mooted, had never been settled; and that plates simply washed and dried had never come into practical use. The very simplicity of the process ought to cause it to drive out all others, and now, since a suitable collodion had been found, he thought it would probably come into general use. The process had been recommended many years back, as early as 1854, when M. Gaudin in *La Lumière* praised it very highly. A month afterwards, however, he modified his opinion of its advantages, and suggested the use of honey, treacle, &c. A suitable collodion really appeared the thing required, and Mr. Hislop appeared to have met with one. A bromide appeared to be necessary, and that was consistent with general experience in dry plate photography. He saw no reason now why it should not supersede all other dry processes.

Mr. Hill referred to some analogous suggestions from Mr. Barnes, who was very early in the field of dry plate photography.

Mr. Wharton Simpson said he thought it was an important principle in awarding the honours of discovery to individuals, to recognize chiefly those who worked out ideas to practical results, rather than to those who merely made suggestions as to various possibilities, without working their suggestions into a practical form. Regarding the early date at which dry washed collodion was first proposed, it was even earlier than the Chairman had stated. As early as 1851 or 1852, Mr. Archer and Dr. Diamond had used excited collodion plates, simply washed and dried, and with some degree of success, but not sufficient to justify them in continuing it at that time. Probably, they felt what many since had felt, that some uncertainty attended the results. The right kind of collodion was not understood, and upon that much seemed to depend. The knowledge that a certain commercial collodion was suitable for the purpose, and the sight of such negatives as Mr. Hislop had produced, would doubtless, as the Chairman had suggested, give a new impetus to this simplest of all dry processes.

After some further conversation, the Chair was taken by Mr. Hislop, and

Mr. Dawson exhibited a number of instantaneous shutters, describing their mode of work and results. The principle upon which even those most recently brought out was old, almost every form having been used years ago. The first and most obvious mode of covering the lens was with a cap or cloth. Advancing a step, the flap shutter was introduced, which had the advantage of exposing the foreground first, and shading the sky. Next came a spring blind inside the camera. The next form was very ingenious; it was invented by Mr. Montefiore Levi, and described in the first volume of the *Photographic Journal*. The same shutter had recently been patented by another gentleman, who appeared not to have been aware that it was an old invention. By the kindness of Mr. Dallmeyer he was able to show one made under the new patent, which was very neat and well made. He, also, showed another neat form of the same principle, made by Mr. Ross. The distinctive feature in that described by Mr. Levi, and in those he now showed, was that the opening commenced at the centre of the lens, and gave the longest exposure with the best part of the lens. He was not quite certain that this was really an advantage, as in all double combinations there was already a tendency to excess of light in the centre. He also showed two shutters invented in 1854, by Mr. Wilkinson, of Pall Mall; one of which was a double-flap shutter, and the other based upon the spring-blind principle. He next showed Messrs. Horne and Thornthwaite's guillotine shutters, and Mr. Window's roller shutter; and finally, Mr. England's shutter on the guillotine principle, but working immediately in front of the exposed plate, inside the camera, instead of outside the lens. Its great advantage was, that every part of the plate in succession received the whole power of the lens; and that, moreover, as the aperture could be made larger, or less, it gave a certain amount of control over the duration of what might be termed an instaneous exposure.

Mr. Blanchard regarded the latter feature as a most important one. It was most valuable in instantaneous operations to have such a control, and secure as it were an intelligent agent in doing the work. The shutter he used for such exposure combined the principle of two of those exhibited, and worked inside the camera. It would give, if necessary, more exposure to the foreground than sky.

After some further conversatiou the subject dropped.

Mr. Simpson called attention to some prints from instantaneous negatives on tannin plates by Mr. Hurst. The mode of producing them was not yet published. He also called attention to an untoned and unfixed print on resinized silk, to show how much more deeply printing was required than was generally necessary on albumenized paper.

Mr. How, successor to the old established business of Knight and Son, Foster Lane, exhibited some fine apparatus intended for use in India, and some card portraits taken with Maddison's collodion.

The presentation print, consisting of a very pretty "Peep through the Trees," by Major Gresley, supplied by the Amateur Photographic Association, was distributed.

After the usual votes of thanks, the proceedings terminated.

## Correspondence.

### THEORY OF ALKALINE GOLD TONING.

Dear Sir.—I cannot but think that your correspondent must have greatly misunderstood me, as he has taken exception to the only part about which there is the least reason to object. I hardly intended to have brought forward any new theory, and should, perhaps, not have used the word, it should rather have been the practical results of the toning bath, as the theory has been so well explained by Mr. Hardwich, in his "Photographic Chemistry," as to leave very little more to be found out; if your correspondent has the fifth edition by him, and will turn to page 157, it will, I think, help him to understand the meaning of one or two points in my last, in which I think I differ from him, as to the causes of one or two difficulties, which require to be thoroughly understood to be able to overcome. And first, as to the cause of mealiness; your correspondent agrees with me, I believe, in saying, that when the alkali is first added to the gold, it only neutralises the free acid, and decomposition does not begin for some little time, heat accelerating the action; so that the gold is still in the state of terchloride; now what is the rationale of the process when a print is immediately introduced in this state,—"the chlorine, previously combined with the gold, passes to the reduced silver, it bleaches the lightest shades, converting them into white protochloride, and gives them a violet tint; at the same time metallic gold is deposited, the effect of which is not visible, *since the same violet tint is perceived when a solution of chlorine is substituted for the chloride of gold*." Now from this we have a very clear explanation of the causes of the false toning, and probable cause of mealiness. Chloride of silver contains only one equivalent of chlorine and tercloride of gold three, consequently there are two equivalents in excess, which produce the false violet tone which, as Mr. Hardwich observed, was entirely dissolved off in the hypo. Now as to the second point: what I wished most particularly to insist upon was, the mischief that arises by having any free carbonate of soda or other alkali in the bath; upon adding only one or *not quite* two equivalents of soda carb. to the gold previously deprived of free acid left in the manufacture; the same amount of chlorine passes from the gold to the alkali forming common salt, which plays no action whatever in toning, further than combining with the gold and forming a double salt which keeps it in solution; but when more than this of alkali is added, it reduces the gold to Au Cl, and then spontaneously precipitates it in the toning dish. I need hardly mention that Au Cl, or the protochloride of gold by itself is insoluble, but that in the state of a double salt Au Cl + Na Cl is soluble. I stated that this salt is useless for toning, on account of its almost insensible action. I will endeavour to explain the reason why the gold being obliged to be deposited in the state of metal, can only part with its chlorine to the metal silver, and to do this it requires a very little chlorine in excess over its one equivalent to commence the attack, when it is once started all will go right until the greater part of the gold is reduced on the print, so that those who use large quantities of alkali in reality do not use above a quarter of their gold, and probably throw the greater part down the sink.

I believe I shall shortly find some certain way of bringiug the gold to an uniform state, before adding the necessary quantity of alkali to bring on decomposition.—I am, Sir, yours sincerely, Francis G Eliot.

## Photographic Notes and Queries.

### Nomenclature of Stops, &c. &c.

Sir,—Would you allow me to offer a suggestion to opticians Few, if any, have any system of diaphragms for photographic lenses: now I would suggest one or two plans for their adoption.

1st. That the number on any stop should represent its diameter in tenths of an inch, or differ from this by a constant. This would apply to all the lenses in a shop.

2nd. That the time of exposure for the full aperture being taken as unity, all the stops should bear numbers proportional to their exposures, or inversely proportional to the square of the diameter of the stop. This would be most convenient for the individual photographer.

Another great advantage would be gaiued, if opticians would give the equivalent focal length of their lenses. By combining these two data, photographers would benefit by each other's experience, especially if the species of lens were defined by a fraction whose numerator was the working greatest aperture, and the denominator the focal length.

For instance, I have a Ross orthographic for plates 8½ and 6½. I should call this lens orthographic $\frac{0.90}{12.5}$ and the stops whose diameters are 0·85, 0·7, 0·6, 0·5, 0·4, 0·3, nearly.

| | | | | | | |
|---|---|---|---|---|---|---|
| On 1st system | 8½ | 7 | 6 | 5 | 4 | 3 |
| On 2nd system | 1 | 1½ | 2 | 3 | 4½ | 8 |

Either way would bring about a system by which the purchasers of lenses knew what they were buying, and we should be able to judge which lenses are quick in reality.

I know M. Claudet says that stereomonoscopic pictures are not attainable. I have one where the relief is marked (of course a good deal is out of focus) when properly looked at. I have not a print to send this mail, but hope the weather will let me make one, and try a plan for producing pictures without the waut of definition in the foreground, but having the same effect.

Allow me to remark that in your spectroscope experiments you are rather too particular. I, aud many others in India, are in the habit of using an unguarded candle for working in a perfectly dark room without any ill effects. If you take a stearine candle, and examine its spectrum, I don't think you will find blue rays wanting, at least I do not with what I use.

I have rarely fog since I took to strong iron and weak acid on a bromo-iodized collodion. Fog usually means *under exposure*, so do stains.

If you really want a photographie candle, could you not induce some candlemaker to use a highly salted stearine. It would be nearly perfect.—Yours faithfully, J. P. P.

*India, September 17th*, 1862.

[In our stereoscopic examinations of specimens of glass, we give their absolute actinic qualities, as considered in relation to the severest tests to which they can be put, and since really non-actinic glass can be procured, it should, both for safety and theoretical propriety, be used. Where it cannot be obtained, experiment must determine what amount of departure from it is permissible.—Ed.]

## Talk in the Studio.

Vignetting Glasses.—Mr. Charles Derby, a correspondent, sends us a method of making vignetting glasses, which he finds very efficient. After pointing out the disadvantages of the vignetting glasses usually sold, and the troubles of various other methods, he says: "I annex my process of producing real good vignetting glasses of any size, and of any shape. I first take a piece of sensitized paper, whole plate size, as for an ordinary print, and perfectly clean. I place it in the printing frame, with a clean glass before it. I now take a large piece of paste-board about four inches larger all the way round the printing-frame, and nicking it in the four corners, turn down the edges to make like a box lid of it to fit the printing-frame. I then black it inside, and cut a hole out in the centre, about $1\frac{1}{2}$ inch $\times$ $1\frac{1}{4}$, according to the shape of the vignette wished for. I now place this box lid as I call it, over the printing frame, and fix it about one and a half inch from the printing-frame glass, where it is fastened with four little tacks, so as not to shift. Now place it in the shade (not in the sun), expose the sensitized paper, as for a print, then tone the paper and fix it in the usual manner. It should be a little over printed, so as to get the centre perfectly black. When dry, paste this vignetting negative on a nice level card, and take from that, in the camera, negatives for photographic vignetting glasses, any size and any number, on a one-ninth, one-sixth, one-fourth, &c., &c., glasses. The sharper the better, and the finer I get the beautiful graduation of the vignette produced by the rays of light. The more intense you can bring the borders of the vignetting glass, the better. Avoid fogging the centre, which must be quite transparent. If any of my brother photographers will use my way of producing vignetting glasses, they will find it very cheap and very useful. To those who cannot spend a deal in useless experiments, I am desirous of contributing my hint, through the medium of the Photographic News, which, thanks to you, has been the first to bring those useful dodges, freely to the knowledge of photographers."

The Origin of Landscape Card Pictures.—Since Mr. Warner's claim to the originating of landscape card pictures, we have received several communications, making similar claims. We remember seeing the suggestion of the idea, as a novelty, in a contemporary journal, long after it was to us a familiar fact. Mr. Wm. Bosley, now of Ipswich, has sent us two very pretty examples of this kind, one of Wolsey's Gate, and another a view in Ipswich Arboretum. He states that he has long been taking them without having seen any others. We have seen some of the same size and style, taken by Dr. Diamond, as early as 1852, but the name by which they are now designated was then unknown. It is a matter which many persons might naturally originate, without knowing it was done by others.

## To Correspondents.

New Rapid Dry Process.—We have received, just before going to press, an interesting communication from Mr. Alfred Keene, on a "New Rapid Dry Process," which promises very successful results. The article will appear in our next.

Half Tone in Photozincographs.—We have just been favoured by Colonel Sir Henry James with some further specimens of half tone in photozincographs, which show decided advancement in the process. We shall shortly have more to say on this subject.

*** The Photographic News Almanac for 1862.—The Publisher has just received a few copies of this Almanac from an Agent.

An Amateur.—The print received is one of the worst samples of imperfect fixation we have met with. We have often explained the cause; it arises from weak hypo, old and exhausted hypo, too short immersion, or the prints sticking together in the hypo. Most likely one of the two first mentioned causes. There has been just sufficient action of the hypo to form insoluble hyposulphite of silver, but not to form the soluble salt, which would be at once redissolved in the solution. The insoluble hyposulphite of silver rapidly decomposes in the light, and produces the dirty yellow or brown which your print exhibits.

W. A. Y.—We have not much knowledge of Busch's lenses, they have not been much used in this country. The others we know more about. The No. 3 lens of maker No. 2 will probably be best for your purpose. It is only called a half plate lens, but we have seen excellent whole plate pictures taken with it. No. 1 is a good maker, but the lenses do not generally cover well for standing figures, having a very curved field. That you have by maker No. 3 will probably be much slower than either of the others. So far as we can judge, the lens by maker No. 2 will be quickest.

Liverpool.—We do not know the address of MM. Foucalt or Duboscq, but it is probable a letter addressed to Paris would find them, as they are both well-known scientific men. In any case a letter addressed to the care of the French Photographic Society, 11, Rue Drouet, Paris, would reach them, we think.

Subscriber.—We should think it very probable that a frame of transparent positives would be admitted at the next Exhibition, if some contrivance were arranged for showing them. But the usual hanging would be useless, and, if we remember rightly, the lighting is chiefly from the top of the room. Dr. Diamond can give you the correct information. We will take an opportunity to ask him.

X. L.—The notion that alcohol will coagulate dry albumen on albumenized paper is altogether a fallacy. It does nothing of the kind, we have an article on the subject in type, which stands over for want of space. It will probably appear in our next. The only modes of preventing the solution of the albumen by the ammonia in an ammonia-nitrate bath, are either to have very little of it, nitric acid being added until the solution is nearly neutral, or to have the bath very strong, so that the silver combines with albumen before the ammonia has acted. It is well also to have the paper thoroughly dry. We have not tried the fumes of ammonia with Fothergill plates, but see no reason why it should not be successful.

Jimby.—It is somewhat difficult to say with certainty the cause of imperfection in your prints. They are certainly not up to the mark. The sample of paper does not seem good, and the negatives are not quite sufficiently intense and brilliant to give brilliant prints. Try the acetate of soda in the toning bath. Make your toning bath neutral, and float a very short time. These suggestions may help you; but whilst the prints are far from satisfactory, the nature of the defect is not sufficiently marked to make it easy to decide the cause.

John Pearson.—With a half plate lens you will unquestionably require more than 14 feet for taking card portraits. It is probable the distance between the lens and the sitter will require to be about 20 feet. You may, of course, take the camera out of the folding doors, and if it be well shielded from diffused light, that will answer. But remember that the lens is a window through which diffused light can enter the camera as well as the rays of light from the sitter, and if the camera be placed in a bright light there is danger of the picture being flat and poor from the action of the diffused light. A cone of card-board lined with black velvet, fitting on to the hood of the lens, projecting a foot or eighteen inches forward, gradually widening its aperture, will be useful in such a case. Your half plate lens will probably give sufficient definition, but will be slower than a lens made for the purpose by either of the makers you name. We prefer the last.

Albumen.—Good collodion transparencies are quite as well fitted for the magic lantern as those on albumen. Some by Mr. England, on tannin plates, exhibited at the Polytechnic Institution, were as good as could be desired. You will find, however, the albumen process used by Messrs. Negretti and Zambra, described on p. 265 of the fifth volume of the Photographic News, being No. 144, June 7, 1861. It is, of course, too long for publication in this column.

C. F. W.—The size of the plate a lens will cover is determined by its focus, not by its diameter. We cannot tell you the prices of Jamin's lenses. They are applicable, for both views and portraits. 2. We like plenty of light in the dark room, provided it be quite non-actinic.

Robert Henry, Jun., Tasmania.—We are glad you find the News so useful, and shall always be glad to hear from you. You will find our forthcoming Almanac a valuable *resumé* of such processes as have been successfully practised by the best men.

Henry Regnier.—The defect to which you refer, where the films of collodion, "*se feudillait comme une dentelle*," is a familiar one to English photographers, who describe it as "craping," or "reticulation" of the film. It generally proceeds from the solvents containing too much water. Certain kinds of pyroxyline favour the tendency. The iodides do not usually affect the matter. The best plan with a sample of collodion with this tendency is to allow it to set well before immersion in the silver bath, as in that case the film becomes less permeated with the water from the bath. The Almanac shall be sent. The papers arrived, and will be placed to your credit.

P. G.—The resinized paper should be floated, not immersed: the word, *in*, to which you refer, in Mr. Cooper's answer to the Secretary of the South London meeting should have been *on*. The paper should be floated from five to ten minutes. The silk should be *immersed* from 15 to 30 minutes, and Mr. Cooper has used a 20-grain bath with results as good as when a 60-grain bath was used. Mr. Price, referring to the benzoinized paper he had received from Mr. Cooper, said, it had *not* changed since he received it. The word, *not*, was omitted by a careless printer.

E. A. R.—The triple achromatic is the best copying lens we know. It is quite free from distortion. We do not know any other lens in existence which is so.

Errata.—In Mr. Price's letter on the "Coagulation of Dried Albumen," which appeared in our last, p. 562, for "ferment," 2nd column, 7th line, read "permeate;" in last line but one, for "found," read "proved." Some other literal errors appear in the same letter, which will not, however, mislead the reader.

Several Correspondents in our next.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 222.—*December* 5, 1862.

## FALLACIES CONCERNING COAGULATED ALBUMEN.*

Fallacies generally have a very persistent vitality; but no photographic fallacy, that we remember, has had such undisturbed and tranquil longevity, as that which pertains to the coagulation of the film of dried albumen, used in different photographic processes. The origin of the notion we do not know, but it appears to have gained universal credit amongst trustworthy authorities, as well as mere sciolists. That the idea is utterly groundless, a few very simple experiments will prove, and a very little reflection will suggest that it is very foolish besides.

In regard to albumenized paper, the notion has universally prevailed, that, the coating of albumen on its surface could be coagulated by the same agents which would produce coagulation in white of egg in its normal condition. Heat is one of these agents, and it has been often recommended, that albumenized paper should be submitted to heat in various ways, in order to produce coagulation, and thus secure better keeping properties, less discolouration of the silver bath, &c. It has been recommended that the albumenized paper should be hot-pressed, passed through heated metallic rollers, ironed with the hot iron of the laundress, floated in trays of boiling water, rolled up and placed in water-tight tubes, and then placed in boiling water, and heated by a variety of other methods, all for the purpose of coagulating the albumen. It was known that white of egg in its normal condition was coagulated by submission to a temperature of from about 145° to 150° Fah., and it was *taken for granted* that dried albumen would be coagulated by similar means. Now it is a fact, that dried albumen is not coagulated by heat at all, that it may be submitted to a temperature of 212° Fah., without any alteration of its properties whatever, and that no degree of heat produces coagulation. This is a very simple fact, easily verified, and probably known to many interested in organic chemistry, but it has not been recognized by photographers generally, the contrary notion being constantly cited and acted upon without challenge or contradiction. Mr. George Price, whose letter on the subject we published recently, first called attention to the fallacies in a letter which appeared in our pages some time last year, but a reference to the writings of many authorities show that the notion still prevails.

Amongst the few who recognized the fact that dried albumen was not coagulated by heat, it has still generally been held that coagulation might be effected by the various other agents which produced that effect on white of egg, such as gallic acid, alcohol, ether, &c.

Gallic acid has been recommended for application to a film of dried albumen on dried plates, for the purpose of producing coagulation. Alcohol and ether have been constantly recommended for application to albumenized paper, to produce the same effect. Some short time ago the French photographic journals contained a recommendation to float or soak albumenized paper in alcohol for the purpose of coagulating the surface, the result, it was alleged, being that a much weaker silver bath might be used for exciting the paper with perfectly satisfactory effects. In England, and elsewhere, the same views have prevailed. It has been a very common recommendation to add a certain proportion of alcohol to the silver bath, in order, it was said, to produce rapid coagulation of the albumen, and thus secure the double purpose of keeping the image on the surface of the paper, and preventing the solution from becoming discoloured. In America, where the ammonia-nitrate of silver bath has been recently introduced for the purpose of exciting albumenized paper, it is generally recommended that a portion of sulphuric ether, about one part in sixteen, should be added to the bath to produce coagulation of the albumen the moment it came in contact with the bath, and so prevent it from being attacked and dissolved by the ammonia. Sometimes alcohol is added for the same purpose, some photographers using as much alcohol as from 25 to 30 per cent. In short, the idea that ether, alcohol, &c., would coagulate dry albumen, has been universally held. We recently received a letter from a very able photolithographer in Edinburgh, in which, whilst he has discovered that heat will not coagulate dried albumen, he, in common with others, believes that alcohol will. He says:—

"I have tried heat in every way to coagulate the albumen on paper, and cannot do it. I have boiled water in a tray, and *floated* the albumenized paper face up on it while boiling briskly—have boiled water in a vessel, and *dipped* the paper in—have applied sharp *steam* direct from the large boiler of a 30-horse engine to the back, and then to the face of the paper, all with the like result—that of *washing off* the albumen, not coagulating it. I have heated a steel plate and run the paper through the press on it, but no heat short of scorching the paper, would coagulate the albumen on its surface—of course it is easy enough to coagulate albumen on paper by alcohol, silver, &c., but I think it cannot be done by *heat*, unless you or some of your readers can tell *how*."

Having for some time had reason to believe that the idea that dried albumen could be coagulated by any of the agents referred to, was a fallacy, we recently undertook a series of experiments, for the purpose of testing very definitely the truth of these notions. We found in every instance that the ideas to which we have referred were altogether erroneous. We will now, without further remark, give the details, which were very simple.

No 1. *Heat.*—A plate of glass was coated with pure white of egg, and dried rapidly before a very hot fire, securing a temperature from 150° to 170° Fah.; the plate was subsequently baked in a hot oven. On examination no coagulation was found to have taken place, the film becoming quite soluble after masceration for a short time in water, as is the case with simply dried albumen. Another plate so prepared and dried in a similar manner was plunged into boiling water, with the sole result of dissolving and washing off the albumen. Various samples of albumenized paper were submitted to ironing, baking, and to boiling water with similar results. No coagulation took place in any instance.

No. 2. *Sulphuric Ether.*—Various samples of highly albumenized paper were brushed over with ether of ·725 specific gravity. On examination, no coagulation was found to have taken place. To make the experiment more satisfactory, a strip of the paper was immersed in the ether, and left for a quarter of an hour. It was then withdrawn, and placed in a dish of water at a temperature of about 60° Fah., which dissolved off the albumen in a few minutes. The experiment was again repeated, taking care this time to dry the paper well on withdrawing it from the ether. The results were the same; in no case was there any coagulation.

* The substance of this article we recently contributed to *Le Moniteur de la Photographie*, in the last number of which it appeared.

No. 3. *Alcohol.*—Experiments in this case were similar to the last. Various samples of albumenized paper were brushed, or soaked for a quarter of an hour with absolute alcohol. The albumen remained quite soluble, and easily washed off; there was no coagulation.

No. 4. *Gallic Acid.*—Various samples of highly albumenized paper were placed in a saturated solution of gallic acid, and left for a quarter of an hour. In each instance the albumen was found on withdrawal to have been dissolved, and washed off the paper by the immersion; no trace of coagulation whatever taking place.

On submitting dried albumen to the action of metallic salts, the result was, as we had anticipated, different. Albumenized paper immersed in a twenty-grain solution of bi-chloride of mercury, had its surface coagulated and rendered quite insoluble in water, without affecting its colour or appearance. Albumenized paper immersed in a thirty-grain solution of protosulphate of iron was coagulated, the compound produced, turning rapidly brown in sunlight. A two-grain solution of chloride of gold partially dissolved the albumen, and coagulated it in thick uneven ridges, turning it a permanent yellow colour.

We have used the word coagulation in reference to the change produced upon dry albumen by metallic salts in accordance with popular practice. But is it not incorrectly used to describe that change? To coagulate is to change a fluid body into a solid or congealed state, and the coagulation of normal white of egg by heat, &c., is an isomeric change; dry albumen cannot be congealed. What is meant by the term as generally used, is the state of insolubility, and the change which is effected by a metallic salt, which renders dry albumen insoluble, is really the formation of a new compound, which requires a new name, and which, when silver is used, we have called, for want of a better word, albuminate of silver.

To conclude this part of the subject, we recapitulate that dried albumen cannot be coagulated; that heat, sulphuric ether, alcohol, and gallic acid do not render it insoluble, that it is rendered insoluble by the action of nitrate of silver, bi-chloride of mercury, protosulphate of iron, chloride of gold, and other metallic salts; and that the change produced is not coagulation, but the formation of a new compound or combination with the metal. The perfect dessication of albumen is doubtless an advantage, as when the albumenized paper is thoroughly dry, the compound formed with silver is more completely kept on the surface, the bath is less discoloured, and the image is more brilliant.

In another page appears a further letter from Mr. Price on this subject, with especial reference to some remarks by Mr. Dawson. We prefer to discuss a subject of this kind in its general bearing, without reference to the views of individuals; but Mr. Price attacks a special error, promulgated by one who has recently laid himself open to special correction.

## A VALUABLE PRESERVATIVE PROCESS.

BY VALENTINE BLANCHARD.

The following preservative process, which has never been published, will be found very useful to those who desire a quick and simple method of preparing plates for use out of doors, in cases where long keeping properties are not essential.

I am indebted for the particulars to my friend Mr. Fysh, a gentleman who, through its instrumentality, has produced some charming photographs, and as it frequently has been of great service to me, making quite easy tasks that otherwise would have been attended by much trouble, I have obtained his permission to make it public.

In manipulation, this process will be found to be scarcely more troublesome than the preparation of an ordinary wet plate, as no washing or drying is necessary, and the picture may be developed by iron or pyrogallic at the will of the operator.

With iron development, when everything is in the most favourable condition, the exposure will be very little longer than is requisite for a wet plate.

The following solution will not be found very troublesome to prepare, and will be improved considerably by keeping.

Take of English honey, old and crystallized, 4 ounces, Price's glycerine 2 ounces, and nitrate of silver 30-grain bath, new and iodized, 6 ounces; shake well up together, and when thoroughly mixed, add kaolin about ½ ounce, and again shake well, repeat the operation occasionally for an hour, and then stand the mixture aside in a light place, but not in sunshine, for two days. When wanted for use, filter as much as is necessary into a clean bottle. Prepare a plate in the ordinary way with collodion, and immerse in a 30-grain bath, made faintly acid with *acetic acid*. It is important that the bath used in the solution, as well as that in which the plate is immersed, should contain no trace of nitric acid, as the glycerine is readily decomposed by it, and mortifying failures would be the result.

The plate, which by this time has been sufficiently long in the bath, may be now taken out and coated with the solution, which, if properly prepared, will be very bright and very clear, resembling glycerine in general appearance, but not quite so quick. Keep the preparation on the plate, moving it backwards and forwards until oiliness ceases. Return the solution to the funnel, and pour on a second quantity. Let it remain on a minute, return the surplus to the funnel, and stand the paper on blotting paper to drain. In a quarter of an hour, the plate will be ready for the holder, care being taken in putting it in that it be not reversed.

The plates thus prepared will be found to keep four hours in summer, and a day in winter. It is well, however, to use them as soon as possible, as sometimes in very hot weather reduction of silver commences round the edges of the plate two hours after preparation.

On returning to the dark room, the developer is poured on as on a wet plate, no wetting with water being necessary. The negatives will be found much more beautiful in appearance, than those produced by the ordinary wet process, for they have that peach-like bloom so frequently met with in negatives, produced by pyrogallic acid, but in a much more exalted degree, and faintly indicating, occasionally, two or three of the natural colours. The sky will frequently be seen of a pale azure blue on the surface.

For photographing interiors, this process will be found very useful indeed, in all cases where a plate is required for use at a spot distant from home, without all the washing and drying so imperative in the preparation of dry plates.

## A NEW RAPID DRY PROCESS.

BY ALFRED KEENE.

In my last I mentioned that I hoped soon to have something interesting on dry photography to send you. I have been very closely engaged upon it lately, and now forward particulars of a modification, which is diametrically opposed to the generally entertained opinion that, with the use of tannin or gum as a preservative, the previous removal of all free nitrate of silver is an essential, and which I find more sensitive and more nearly approaching wet collodion, both in in this respect and in its general character, than any previously published.

Before describing the process, a brief account of my previous proceedings may not prove uninteresting. Upon the appearance of Mr. Sutton's paper on gum as a preservative, in connection with a strongly bromo- (iodized) collodion, I tried it under the conditions indicated, and, though struck with the many good qualities it possessed, did not find it so sensitive as described, nor so full of half-tone as could be desired. The sensitiveness I increased fully twenty per cent. by washing off the preservative (gum) solution, instead of allowing it to remain on as directed; (increased sensitiveness, by the same means, I found to hold good with all the various preservatives subsequently tried). I then ascertained that sensitiveness was not further influenced either way by excess of (over a thorough) washing either before or after applying the preservative, a stream of water from a tap, falling upon one point only, producing no perceptible effect. Solutions of bromine, and also iodine, were next separately applied to the plates, and again washed off previous to the preservative, so as perfectly to remove all trace of free nitrate, and convert it into a bromide or iodide; the former reduced sensitiveness more or less, whatever preservative was used, but only very slightly with some, whereas iodine materially reduced, and, in one or two instances, all but entirely destroyed it. Finding no advantage either as regards sensitiveness, or freedom from tendency to stain, under a forced development from the above, I tried, first of all, less washing of the preservative without advantage, and finally of the sensitized film; the increase of sensitiveness, in the latter case, was very marked, and encouraged me to proceed further in the same direction. I then prepared a batch of plates, part of them on the same principle I introduced for the Fothergill process, commonly known as the four drachm washing, viz., the use of one drachm only of distilled water to every five superficial inches of sensitized surface, poured on and off till all greasiness is removed, and even dilution insured, when the preservative is to be applied and subsequently well washed off, and part by applying the preservative direct to the sensitized surface, without previous washing of any kind, and finally well washing it off.

I have just completed developing these, and find sensitiveness to have increased in proportion to decrease of dilution of bath (silver) solution on the surface, the maximum being obtained when the preservative is applied direct to the sensitized plate, the surplus being subsequently removed by a thorough washing, without, as far as I can perceive, the slightest increased tendency to fog or stain, but rather the reverse, the more concentrated solution plates being remarkably free in this respect.

The following is a list of the different preservatives tried:—Milk, milk and tannin, albumen (plain) and tannin, prepared albumen and tannin, gum, honey and tannin, glycerine and tannin, and gum and tannin; also collodion, containing jalap resin, as recommended by Mr. Maxwell Lyte, without any preservative. The most sensitive and best plates have, invariably, been with the tannin and gum, and in the experiments with the free nitrate of silver, I have confined myself to it—tannin and honey, and plain gum.

Collodions have been tried, prepared with different kinds of pyroxyline, and proportions of the bromide and iodide salts, varying from one of the former to four of the latter, to two to one. That containing equivalent proportions with my dry process normal collodion has answered best.

*Baths.*—35 grains of silver per ounce, neutral (nearly so, containing one drop of glacial acetic acid in twenty ounces), and acid, with nitric acid in the proportion of one and five drops to twenty ounces. The neutral bath preferred, decidedly.

Having given these preliminary particulars, I will now proceed to describe the process:—

*Collodion.*—Extra bromo-iodized dry process containing equivalents of the bromo-iodide salts.

*Bath.*—Neutral, containing 35 grains of nitrate of silver per ounce.

*Preservative Solution.*—Equal parts of a filtered 15-grain per ounce solution of tannin and mucilage, or gum water, (made with four ounces of picked gum-arabic, dissolved in sixteen ounces of filtered rain or distilled water), with ten minims of glacial acetic acid added to each ounce.

*Developer.*—The excellent one introduced by Major Russell, as follows:—

No. 1.—Pyrogallic acid (English make) 96 grains alcohol, with a little ether added, one ounce.

No. 2.—Nitrate of silver 10 grains, citric acid 10, 20, or 30 grains, distilled water 1 ounce; add to each drachm of distilled water 6 or 8 drops of No. 1, and 3 or 4 drops of 2, when required for use, or a 2-grain per ounce pyrogallic developer, with 1 grain of citric and 10 minims of glacial acetic acid, may be substituted, adding a few drops of a 15-grain solution of silver to each drachm, when used.

Sensitize the plate in the usual way, except allowing it to remain at least half as long again in the bath as with ordinary collodion (the conversion of the bromide salt into the silver compound being slower than that of the iodide) drain for a second or two, apply the preservative solution rather liberally, commencing at one corner and allowing it to proceed to the second, third, and off at the fourth, carrying with it the surplus bath; drain rather closely, apply a second or even third quantity in the same manner, passing it several times well round the plate; the last lot will do for the first of next plate, but should not be mixed with the stock; drain, pour on a little water, and work it about till mixed with the preservative on the surface, to facilitate even and complete removal with the subsequent washing (lukewarm water answers best with the present low temperature), then well wash with soft water under a tap, in dishes or any convenient manner, and place to drain and dry, face inwards, on blotting or filtering-paper, upon and leaning against glass; change the paper after about ten minutes for a fresh piece. Expose about the same time, or if anything, a trifle longer, than for wet collodion and pyro developer. Soak a few minutes in soft or distilled water, and develop in the ordinary way with the solution before described, changing it, should it become discoloured before sufficient intensity has been obtained, which will be the case when a short exposure is given and development have to be forced. Fix with hypo, or cyanide, the former by preference.

I have not tested the keeping property of plates thus prepared, but from the clean manner in which they develop, and the amount of forcing they will bear without any material deposit on the surface, argues, I think, very favourably for them in this respect; nor have I tried the ammonia and pyro development, lately recommended by Major Russell, and previously by another correspondent in one of the photographic publications, for tannin plates, which probably may have the same accelerating effect on these, and thus still further lessen the necessary exposure; though I should look for the ammonia in conjunction with pyro to have a great tendency in all cases to produce fog, from it possessing the power of decomposing both iodide and bromide of silver even in the dark.

The appearance of the negative, as far as my present experience goes, is very favourable indeed, the impressed image appearing well in the film and full of detail, more approaching an iron-developed one in this particular.

It is somewhat singular that tannin and gum combined should give more sensitiveness than either separately, but such has invariably proved the case, and may probably be attributable to the gum increasing the density of the solution, and thus causing the tannin to penetrate more completely the porous cells of the collodion.

It has hitherto been a maxim, that when gum or tannin are used as preservatives, all free nitrate of silver must be previously removed; but I think I very clearly show, by this modification, such an opinion to be fallacious, and that the free nitrate is not only not injurious, but may be advantageously retained; this at once occurred to me as probable when I saw the result of my first experiment in this direction, for, unlike albumen, they are not coagulated, but remain perfectly liquid, and to appearance unchanged, and all surplus is consequently easily removed by washing.

I find I have omitted stating that I give preference at present to a substratum of india-rubber dissolved in benzole, as recommended by Mr. Sutton, but shall be very glad to find an equally good substitute, as it is difficult to get quite clear, being as tedious to filter as collodion. I have tried plates coated a second time with preservative, and allowing it to remain, after previously washing the first applications off, but do not find any gain, but *loss*, of sensitiveness; though, for keeping, this plan might prove advantageous, by shutting up the sensitive compound from direct contact with the atmosphere.

All my spare and available time has been so completely occupied with this investigation, that I have not had any opportunity of further examining the influence of chlorides in connection with the use of highly bromo-iodized collodions. I purpose, however, following it up the first opportunity, and hope some of your numerous readers, who have time at command, will be induced, by your recent remarks upon my communication on this subject, to take the matter in hand, and ascertain its correctness, or expose its fallacy—it being of great and increasing importance, particularly as regards such modifications as the one now sent.

## PHOTOGRAPHIC CHEMICALS:

### Their Manufacture, Adulteration and Analysis.

*Magnesia Salts.*—As the basis of all magnesian compounds, we will commence with the metal magnesium itself, inasmuch as the vivid light which it produces when burnt in the air, must some day, when magnesium is produced at a cheaper rate, prove of value in the arts and sciences, and especially so in photography. This is, perhaps, the easiest obtained of any of the alkaline or earthy metals, and as no special apparatus or chemicals are required beyond those met with in most laboratories, we will give the most successful mode of preparing it, in the hope that some enterprising chemist will take up the subject, and supply scientific men with the metal at a reasonable price. The process is one adopted by MM. Deville and Caron; 600 parts of carefully prepared chloride of magnesium are mixed with 100 parts of a fused mixture of chloride of potassium and sodium and 100 parts of pure fluoride of calcium, the whole previously powdered. The mixture is put into a large wide-mouthed stoppered bottle and 100 parts of sodium cut up into small pieces are added: the whole is then well mixed by shaking together. A clay crucible is heated in a fire to dull redness, and the contents of the bottle are thrown, by means of an iron spoon, into the crucible, which is then closed with its cover. In a short time the reaction takes place with a considerable noise. When all noise has ceased, the crucible is removed, and the mixture stirred with an iron rod until all the fused parts are homogeneous, and the upper part of the bath is well exposed, when the globules of magnesium are distinctly seen. The crucible is then allowed to cool away from the fire, and when the saline mass is ready to solidify, it is again stirred with an iron rod, and all the little metallic masses collected together, so that they may form a single one; the whole is then poured on a plate of iron. By breaking up the scoria the globules of magnesium may be removed, and the scoria may be fused once, or even twice, affording a little more magnesium each time; 600 parts of chloride of magnesium with 100 parts of sodium yield 45 parts of magnesium. The crude metal is put into a charcoal tray, enclosed in a tube of charcoal, and heated nearly to whiteness, whilst a slow current of hydrogen is passed through the apparatus. The tube is strongly inclined in the furnace, and all the magnesium condenses in front of the tray, and is easily collected when the tube is cold. It is then fused in a mixture of chloride of magnesium, chloride of sodium, and fluoride of calcium. By gradually increasing the quantity of the latter, which is added by degrees to the fused bath, the scoria is rendered just less fusible than the magnesium, so that the latter may be poured off just as the scoria is about to solidify. Magnesium has a density only a little above that of water, namely, 1·75. It is malleable and ductile. It files easily, and burnishes wonderfully. When pure and polished it resists the air very well; it is very similar in this respect to zinc, which metal it also resembles in its fusibility and volatility; at a temperature a little higher than its fusing point it ignites, producing a brilliant flame, in the midst of which indigo blue tufts are seen, especially when a jet of oxygen is thrown upon the fused metal from an oxyhydrogen blowpipe. Magnesium is readily drawn into wire, and in this form may be set on fire in the flame of a candle, like a piece of paper, when it continues burning till it is all consumed. Bunsen and Roscole in some photo-chemical investigations, tested the illuminating capacity of a magnesium thread, when it was discovered that the splendour of the sun's disc was only 524 times as great as that of the metallic thread. Bunsen also compared the magnesium flame with ordinary lights, and found that a burning thread of 0·297 millimetres diameter, produced as much light as 74 stearine candles, of which five go to the pound. It is plain that it only needs a mechanical device to wind a magnesium wire into the flame of a spirit lamp, at such a rate that the loss, owing to its consumption, would be just supplied, when we should have a very efficient and portable magnesium lamp, more convenient and complete than the arrangements for the electric or bude light. A spool with its thread, clockwork movement to wind it off, with a spirit lamp would be easily transportable, and would become a rival to the strong lights now in use, could the metal be obtained cheaply. With a similar arrangement, moved however by hand, Mr. Crookes, some years ago, took photographs at night, and showed conclusively that the expense alone prevented this powerful light from being invaluable to photographers. It was found to be, not only a magnificent light, as far as its illuminating power was concerned, but was intensely rich in those highly refrangible rays which are of chief use in photography.

Magnesium forms only one oxide, magnesia. This is a well known fine white powder, of frequent use in the arts, on account of its property of perfectly neutralizing acids, without possessing a caustic action, like potash or lime. It is prepared by prolonged ignition of the carbonate of magnesia, and as it is the starting point in the preparation of many compounds of this earth, which are used occasionally in experimental and practical photography, we will give the best plan of testing it for the impurities which are most frequently present. *Carbonate of ma nes'a* can scarcely be called an impurity in a photographic sense, as there is no use to which the earth is put, which would be rendered ineffective by an admixture of carbonate. It may be detected by moistening the earth with water, and then adding hydrochloric acid; an effervescence shows the presence of carbonic acid. Even when the magnesia has been prepared free from carbonate, it gradually absorbs this acid upon exposure to the air. A more serious impurity is *lime;* this may be detected by moistening with water, and then dissolving the earth in dilute hydrochloric acid, employing an excess of acid. The solution, when clear, is rendered alkaline, with ammonia and a little oxalate of ammonia added. If lime be present, the addition of this latter re-agent will produce a white turbidity, or precipitate; whilst, if the magnesia be pure, no change will be apparent upon adding these various tests. Sometimes *oxides of heavy metals* are present. These can be detected by super-saturating the hydrochloric solution with sulphuretted hydrogen, and then adding ammonia. The characteristic precipitate is produced, and, from its colour, the kind of metal present may be inferred. *Silica* is not an uncommon impurity: it will be found insoluble, when the earth is boiled in slight excess of dilute hydrochloric acid. *Sulphate, or chloride of potassium or sodium,* is frequently present, arising from the carbonate of magnesia not having been sufficiently washed. Water boiled with the magnesia extracts these salts from it, and when filtered clear gives the reactions of sulphuric, or hydrochloric acid. After evaporating, also, a saline residue is left. The substance known in pharmacy and commerce as *magnesia alba* is a hydrated carbonate of magnesia, prepared by precipitating sulphate, or chloride of magnesium, by carbonate of soda, and well washing the carbonate which falls down. The most important salt of magnesia is the *sulphate,* known also as Epsom salts. It occurs in many springs, and in the bottom of sea water; it is prepared from various sources on an enormous scale, and, like most products of this class, is liable to contain many impurities. *Sulphate of soda* is detected by shaking up an aqueous solution with carbonate of baryta. Sulphate of baryta and carbonate of magnesia are formed, and if sulphate of soda is present, carbonate of soda is also produced. This latter is highly alkaline to test paper, and may be thus detected, and the presence of sulphate of soda in the original salt inferred. *Chloride of magnesium* gives a tendency to the salt to absorb moisture from the air. It may be detected by adding weak nitrate of silver to a dilute solution of the sulphate. Ordinary sulphate of magnesia of commerce contains seven atoms of water of crystallization; it forms transparent prisms and needles, which effloresce slightly in warm, dry air. When heated the crystals fuse, and at a higher temperature lose water and become anhydrous, forming a white spongy mass. After ignition, sulphate of magnesia dissolves very slowly in water: the crystals, on the contrary, dissolve rapidly, one part requiring only four parts of ice-cold water for solution, and less than its own weight at the ordinary temperature.

## PHOTOGRAPHY UPON GELATINE.

BY M. A. POITEVIN.*

Gelatine, which I have extolled since the year 1850, has always appeared to me the most advantageous material for obtaining photographic negatives upon; and every time I renew my experiments, I recognise new qualities in this substance, the employment of which, it appears to me, has been too much neglected until the present day. Quite recently, I have studied a new mode of preparing the film of iodide of silver; my aim was to solidify the gelatine, which enables me to obtain thin coatings, which do not shrivel up in the bath; moreover, I operate upon the surface, either moist or dry. I thus obtain very intense negatives, the lights of which are not veiled. My new method of operating is as follows; perhaps it may be adopted for this new kind of photography, and suggest new manipulations, applicable to other photographic processes.

In one hundred grammes of distilled or rain water, I dissolve, by a gentle heat, six grammes of gelatine; after filtering the liquid through fine linen, I add about fifty drops of a concentrated solution of bichromate of ammonia or of potassa. With this mixture I cover the well-cleaned surface of a glass plate, leaving on it a thin uniform film. I then place each plate as prepared in a horizontal position, until the gelatine film becomes solidified, which takes about ten minutes I afterwards expose the plates to light for nearly the same space of time; then the bichromate reacts upon the gelatine, and prevents it from creasing in the water during the subsequent operations. After this exposure, but before drying the gelatine film, I apply the glass plates, gelatine side downwards, upon a neutral bath of nitrate of silver, of the strength of about 8 per cent. Chromate of silver is formed immediately in the substance of the gelatine which covers the plate. I then wash it in plenty of water, to remove the excess of the nitrate of silver; then immerse the plate in a bath of iodide of potassium, of the strength of 6 per cent., previously saturated with iodide of silver. I never withdraw the plate from this bath until after the complete disappearance of the red hue of the chromate of silver. I next wash the iodized plate in plenty of water, and allow it to dry spontaneously, without protecting it from light. It is scarcely necessary to observe, that all these preparations can be made in full daylight, the iodide of silver produced in presence of an excess of iodide of potassium not being reduced by light. I can thus prepare a great number of plates before hand, and when I wish to make use of them, I sensitize the film of iodide of silver. This is done by immersing the plate in water for several minutes, till the gelatine is completely impregnated by it; then I pour upon its surface, several times, a solution of nitrate of silver, of the strength of two to three per cent. I then immerse the plate in distilled water, to remove the excess of nitrate, and I can immediately place it in the camera obscura; but I can defer this operation for an hour at least, because the gelatine film retains its humidity long enough; the exposure need not be much longer than with collodion.

If I wish to operate by the dry method, I wash the sensitized surface several times, leave it to dry in the dark, and develop it just as before described, that is to say, after the exposure; I immerse the plate in distilled water, in order to restore to the gelatine all the water it can absorb to replace the moisture it has lost. I next immerse the plate in a bath of gallic acid, to which some drops of solution of nitrate of silver have been added. but without acetic acid, which is unnecessary. I can also develop with sulphate of iron acidulated with tartaric acid, then intensify with gallic or pyrogallic acid. The sulphate of iron reduces the silver in a white state. If I consider the negative strong enough for this developer, I make it black by means of a weak solution of chloride of gold. I fix these negatives by means of cyanide of potassium, or hyposulphite of soda, but the employment of a weak cyanide is preferable, because it acts more promptly. and it is easier removed from the gelatine than hyposulphite is. The negative obtained and dried, can be employed for positives on paper without being varnished, but generally I varnish them like those on collodion as a measure of safety.

## INSTANTANEOUS PHOTOGRAPHY.

BY JOHN KIBBLE.*

After exhibiting some instantaneous specimens, and stating they were produced by Grubb's No. 3 aplanatic, and by his E stereoscopic arrangement, Mr. Kibble proceeded :—

To prepare the nitrate bath :—A saturated solution of metallic film in nitric acid, to be boiled, in contact with a surplus of the metal, for an hour or two, when part of the nitric acid forming the nitrate is decomposed, a portion of its oxygen combining with the silver, the salt becoming the hyponitrite of silver, a much more unstable body than the former. A sensitising bath composed of one part of this to three of the fused nitrate of silver is very active; and, if properly prepared, should show an immediate alkaline reaction with litmus paper. From the time it is once used it rapidly deteriorates for instantaneous action, but still may be considered quick for ordinary exposures.

The bath prepared with the following proportions is what I use: forty grains of the mixed salt to one ounce of water, saturated with freshly precipitated and thoroughly washed iodide of silver, which, after settling and then being decanted, is ready for use. The less you filter through paper the better. The above over an iodide silver surface is highly sensitive to the actinic rays, but, at the same time, I must confess, a little troublesome. The extreme of cleanliness is absolutely essential; also manipulating with the least quantity of light possible, otherwise fogging will be the result.

Another very important point in developing is not to allow the fingers to remain long in contact with any one portion of the plate, but to be continually shifting, as a very few degrees of additional heat communicated will cause a more rapid development at the points of contact. One quarter of an inch all round the plate is quite as much as any good protographer ought to allow, or less. The developer :—Ten grains photosulphate of iron, five drops of acetic acid, and five drops of alcohol to one fluid ounce of water: less of the two latter if the size of the plate will admit of being expeditiously and evenly developed without.

In very rapid exposures, as a rule, the image makes its appearance so slowly, that the silver necessary for the building of the image, is generally reduced from the nitrate by the chemical action of the protosulphate of iron, long before

* Read at a Meeting of the Marseilles Photographic Society.

* Read at the Glasgow Photographic Association, Oct. 2nd, 1862.

the very delicate tints so necessary to the beauty of the photograph have become apparent; hence a second, and, in many instances, five or six, additions of the developer are resorted to.

To prevent deposit, the exhausted developer is washed off the plate previously to adding more; but a much better arrangement is to have several vessels charged with the exact quantity of aceto-nitrate of silver in each, so that, should all the details not make their appearance, the protosulphate of iron can at once be added to one of the vessels, and the plate well flooded over in a manner so as to wash off all of the exhausted developer before it, and so on in rotation with the whole series if necessary.

Practice has already informed us that half a grain of chloride of sodium to the ounce of water will destroy the image of an ordinary exposed surface; so that we may argue from that, that a mere fraction of that strength will destroy the weakly-acted-on portions of an instantaneous exposure. No doubt distilled water could be resorted to after every addition of the protosulphate of iron, but that is not always at hand, and complicates the process.

In showing specimens of instantaneity, the question has been often put to me—"How do you ascertain what the twentieth part of a second is?" That, I think, can be simply and satisfactorily answered, viz., by using a spring attached to the disc for cutting off the image, then photographing a moving body the velocity of which is ascertained. For example, let me adduce the Loch Long steamer. Her length is 150 feet, her speed in the deep sea nearly fifteen miles per hour—that is, equal to twenty-two feet for every second of time; in other words, she moves through a space fully equal to one-seventh of her entire length in one second. It necessarily follows, that if her hull be photographed at full speed at a right angle to the axis of the lens, and the result divided into seven equal parts, if the time of exposure has been one second, one-seventh of the entire length will be blurred, for the fifth of a second one-fifth of that division, and so on; so that by using a finely-divided scale, and, if necessary, a magnifying power, you can arrive at a pretty exact estimate of the time of exposure with that particular spring. Its action may be pronounced constant. Of course, if any addition be added to the power of the spring it must be ascertained, as in the first instance, against a moving body the velocity and length of which is known.

I am also often asked—"What arrangement is considered best for rapid exposure?" That is not quite so easily answered; indeed it depends entirely on the subject to be photographed. For an extensive plain, on the foreground of which no very tall objects rise, the opening in front of the lens so as to expose the nearest objects first, the sky last and shortest, I have found in my own experience to give the best result; but should any tall object, such as a tree or spire, rising above the horizon intervene, you can easily perceive the higher portions will run the risk of being underexposed. My own arrangements are so constructed, by turning on an axis, that I can cut off the image horizontally or vertically. But one thing I would strongly urge, viz., that the shutter, disc, or whatever it may be, should be as small as possible—that is, as near to the size of the stop to be used as is consistent with safety. On a stormy day, with one shutter (as in the stereo. arrangement) to cover both lenses, the atmospheric resistance is much too great for extremely rapid action, and causes great risk on shaking the camera: the less friction of every kind in such mechanism the better. There should also be a check to keep it from opening the smallest portion beyond what is absolutely necessary.

I may mention that the collodion I used in obtaining the whole of the results submitted for your inspection this evening was kindly furnished to me by one of our members, Mr. John Stuart, photographer, Buchanan Street, who is at all times willing to aid a brother in distress. The paper of the positives before you I obtained from Mr. John Spencer, St. Enoch's Square, and is decidedly the best in every respect I have yet used; indeed, after the paper troubles I have come through lately, it is quite a treat to work with it—easily toned, and yields very little to the hypo in fixing. Any points I may have omitted, or not clearly expressed, I shall be most happy to answer.

N.B.—Time of exposure of glass positives of landscapes, $^{1}$th part of a second; of portraits, $\frac{1}{9}$th part of a second.

[We have before called the attention of our readers to Mr. Kibble's instantaneous pictures, which are amongst the finest and largest we have seen produced.—Ed.]

## BATH FOR TONING ALBUMENIZED PRINTS.

BY COL. PIKE.*

Take of

| | |
|---|---|
| Nitrate of silver | 2 ounces. |
| Distilled water | 16 ,, |

Dissolve the silver in the water by stirring with a glass rod; when all is dissolved, take two liquid ounces from the sixteen, and make it into ammonio-nitrate of silver, in the same manner as though you were to use it to silver your paper with. Take this two ounces of ammonio-nitrate and mix it with the fourteen remaining ounces. The solution becomes turbid, and is cleared by dropping drop by drop of nitric acid, stirring with a glass rod until it is clear. Test with litmus paper, as the solution should be perfectly neutral. Great care must be taken not to get too much acid in the solution; this is the floating bath. Albumenized paper may be floated on this bath about three minutes. Remove and hang up to dry in a perfectly dark room, as it is very sensitive to light. Paper thus prepared will print in much less time than that floated on plain silver solution twice the strength of this bath. The proofs must be printed a little deeper than usual, and thoroughly washed in running water for two hours. They should then be removed and placed in a bath made of one grain of common salt to each ounce of water; let them remain in this bath for one minute, then remove; and, lastly, wash them in clean water, and they are ready for the toning bath, which is made in the following manner:—

Take of

No. 1.

| | |
|---|---|
| Acetate of soda | 75 grains. |
| Phosphate of soda | 75 ,, |
| Distilled water | 32 ounces. |

No. 2.

| | |
|---|---|
| Pure chloride of gold | 15 grains. |
| Distilled water | 3 ounces. |

Neutralize with bi-carbonate of soda.

No. 3.

| | |
|---|---|
| Nitrate of uranium | 15 grains. |
| Distilled water | 3 ounces. |

Neutralize with bi-carbonate of soda.

When all is ready, mix by adding the gold solution first, and then the nitrate of uranium to the acetate and phosphate of soda solution. Shake so as to incorporate them well together, filter, and the bath is ready for use.

The prints, when placed in this bath, should be kept in motion all the time during the process, and carefully watched, as it is very active. After they are sufficiently toned they are fixed in a saturated solution of hyposulphite of soda and water; the hyposulphite should never be used a second time for this purpose, for it is certain to make the high lights of the prints yellow, and cause them to fade rapidly.

When this bath is carefully made according to directions, it will produce beautiful purple sepia tones, with all the middle tints preserved, as well as the pure whites which all amateurs and professional photographers desire.

* From *Humphrey's Journal.*

## A SHORT LESSON IN PHOTOGRAPHY.—No. 5.*

As in sun-printing, so also in the printing by development, we have two different sorts of results, exhibiting, respectively, *positives* and *negatives*. These different results are merely differences of intensity, coupled with the fact that one of them, the so-called positive or ambrotype, is viewed by reflected light, whilst the other, the so-called negative, is viewed by transmitted light. Both positives and negatives may be produced by the intervention of the same materials, although a preference is given in either case, for special purposes, to special materials. These will be enumerated by-and-by. Furthermore, both collodion positives and negatives are laterally inverted; hence the ambrotype and melianotype are inverted pictures, both exhibiting the sword, the pen, the whip, and the hammer in the left hand, which is unnatural or abnormal presentation. The positive print which is taken from the collodion negative is not inverted; that is, every part is presented in its natural position.

The absolute difference between a collodion positive and negative is a difference of amount in the intensity of the chemical reductions in the plate or in the collodion film. A less degree of intensity, or, in fact, a less amount of reduction of the salts of silver, produces the ambrotype or melainotype (the positive); a greater degree, within certain limits, produces the negative. The reduction just alluded to, and its intensity, are effectuated by a two-fold action: first, the physico-chemical action of light operates some change in the silver salts on and in the collodion film, which is quite invisible to the naked eye, even when aided by the most effectual microscope; secondly, the invisible change thus instituted in the film is promoted, exalted, and completed by the application of a chemical reducing agent. The salts of silver contained in the collodion, when placed in the plate-holder, are the iodide, the bromide, and the nitrate; other salts are also present, being the result of double decomposition, such as the nitrate of ammonia, of cadmium, potassium, etc., depending upon the iodides that were used in the collodion. By physical and chemical action the iodide and bromide of silver are reduced to *pure silver*, of greater or less intensity of deposition; and the intensity of this deposition depends upon the *light* and the *reducer*. Where the light, reflected from the object, whose picture we are photographing, is brilliant or intense, the chemical reduction will always be in proportion great; and the silver deposit will be thick, and, in proportion, impervious to light. The various gradations of reflected light upon the collodion film yield films of reduced silver of various degrees of thickness or intensity; some are quite opaque, others less so, whilst others again are so thin as to be almost transparent; and finally, those parts of the collodion surface which received no rays of light are quite transparent. Now, white objects reflect much light, whilst dark and black objects reflect very little or no light: the first of these reflections produce, induce, or command a reduction of silver, which is afterwards completed by the developer or reducing agent; the second give rise to very little reduction, or even sometimes to none at all. But reduced silver is white; the picture, therefore, has the white appearance of the light-coloured or white object photographed. The transparent parts of the collodion film, however, will reflect the colour of the background beneath it; so that, if the background be black, the reflection of light will be reduced to a minimum, and the transparent parts will appear also black. By this means we obtain the natural contrast of light and shade in the different thicknesses of the silver film.

In the preparation of positive collodion pictures, that is, of ambrotypes and melainotypes, it must be the aim of the photographer to obtain the silver deposit as pure, and, consequently, as white as possible; whilst the transparent and partially transparent parts must be as clean as possible. Whereas, in the production of negatives, the aim is to obtain the relative degrees of opacity in the reduced silver irrespective of whiteness of surface; in fact, the white reduction of the positive has, in the case of the negative, sometimes a yellow, sometimes a brown, reddish brown, black, or blue-black appearance, both by reflected as well as by transmitted light, that is, either by looking *upon* it or *through* it.

I will now show an experiment. These glasses are cleaned and prepared as recommended in the last lesson; I will now flow them with the iodized collodion and introduce them into the sensitizing bath. In two minutes or more, recording circumstances which I will afterwards explain, I take them out (this operation must always be performed in the dark-room). One of these glasses thus sensitized I expose for a single moment to the ordinary diffused light of day, whilst the other remains in the dark-room. You may now regard these two plates by means of a lighted candle or a fluid lamp, no difference is perceptible in the films, either by reflected or transmitted light; in fact, you cannot say which has been exposed to the light, and which has not. I will now make use of what is called a reducing agent, and pour a quantity of a solution of such an agent upon either plate. You observe that one of the plates undergoes no change, whilst the film of the other darkens and becomes opaque. The darkening effect must, therefore, be attributed to the action of light. How it has been produced I cannot explain. There are various surmises on the subject. Some philosophers suppose that light produces a different arrangement of the ultimate atoms of the silver salts from that where the light has not acted: others regard the phenomenon as attributable to the decomposition of the natural electricity residing in the film, produced by light, and either with or without any molecular change; others, again, suppose that light just starts an action which is continued and completed by the reducing agent. All such attempts at explanation are at present quite futile, because we are obliged to confess our utter ignorance of all about the ultimate cause of this most wonderful phenomenon. It is true we may adopt any of these hypotheses to assist in explanation of the result, without any respect to the prime cause. The phenomenon may be compared to a boy's hoop lying on a declivity. This hoop represents the sensitized collodion surface in the dark room before it has been exposed to the light. Now comes the boy with his stick; he raises the hoop, strikes it, guides it, and follows it to the bottom of the inclined plane. The raising of the hoop from the ground is comparable to the action of light on the film when exposed; this light raises places, arranges the molecules of the silver salts in such a way as to make them ready for action, to run, as soon as an agent is brought to give them a jerk and to guide them. The agent in question is the developer or reducer; but the reducer would act, or would cause the molecules to act, as the hoop would act if allowed to run its career alone down the precipice. The stick in the boy's hand checks the hoop, prevents it going too much either to the right or to the left, or of falling precipitously to the bottom of the declivity. The reducing salt contains an agent in itself homologous to the boy's stick, in the form of an acid, that moderates the all too energetic, precipitous action of the developer. To sum up: Light *commences* the action of reduction, the developer *continues* and *completes* it, the acid *moderates* it.

I will now complete this lesson, by giving you the formulæ for the preparation of the *sensitizing bath* for the wet collodion process, and of the *developer* or *reducer*.

SENSITIZING BATH.

2 ounces of crystallized nitrate of silver;
24 ounces of distilled or rain water.

Dissolve 10 grains of the nitrate of silver in one drachm of water; add one drop of ammonia to the solution: if a precipitate is produced, the nitrate of silver is good for the purpose; if no precipitate is produced, carry the silver back to the dealer of whom you purchased the article, for it contains free acid, or other materials which you do not want. We will suppose the nitrate is in a good condition. Now add to the 10-grain solution iodide of potassium, drop by

* From *Humphrey's Journal.*

drop, as long as a yellow precipitate is formed. Pour off the liquid and wash the sediment several times; this sediment is iodide of silver. Next dissolve the two ounces of silver in 12 ounces of the water, and add the iodide of silver, afterwards the remaining 12 ounces of water, and filter. Now add a few drops of nitric acid, if required, to prevent fogging. It is now ready for use.

DEVELOPER.

80 grains of the sulphate of protoxide of iron;
4 ounces of rain water;
2 drachms of acetic acid.
1 drachm of alcohol.

The sulphate of iron must contain no free acid; it is best for the purpose when crystallized in alcohol. The salt is first dissolved in the water, the other ingredients are then added and intimately shaken together.

## THE ACARI IN THE NITRATE OF SILVER BATH USED FOR PHOTOGRAPHIC PURPOSES.

BY COL. NICHOLAS PIKE.*

In the month of August last, I had occasion to make a series of examinations of the structure of the collodion films, with the microscope, and for this purpose a nitrate of silver bath was prepared in the usual manner, employing one ounce nitrate of silver and eight ounces distilled water. Twelve hours after it was made, one drachm of alcohol was added, the whole filtered and put into a clean glass bottle, and placed on a shelf in my operating room ready for use. Two days afterwards I took from this bottle one ounce by measure, which I placed in a small glass test tube, and tightly corked it, so that no dust or floating matter should enter it. This remained on my operating table for ten days before I had occasion to use it, as my samples of collodion were not ready until that time. I then prepared a small glass microscopic slide, which I coated with a single drop of collodion, and placed it in the nitrate of silver solution in the test tube. In two or three minutes the slide was removed and placed on the stage of a microscope, and to my surprise little animals were observed darting across the field in every direction. I at once concluded that they were species of acari, introduced into the room with some specimens of natural history, which had recently been placed on the table near this bath, and they being so minute had accidentally got into the liquid. Upon further examination, however, I found the surface of the bath covered with them. I immediately secured as many specimens on glass slides as I wanted, and then carefully filtered the solution, washing the test tube perfectly clean, placing the filtered solution in the test tube, and corking it tightly as before, using a new cork for the purpose, so as to be sure that nothing from the outside should enter the liquid. After this was completed, I examined the solution with a powerful eye-glass, and was satisfied that it was free from all foreign substance, being bright and clear as spring water. I then placed it on a shelf where it remained two weeks without being disturbed. At the expiration of that time, I carefully took it from the shelf, and removed the cork, and to my astonishment the surface was nearly covered with them. They appeared to huddle together in the centre and on the surface of the liquid, and on my attempting to remove specimens to a glass slide with a minute pointed instrument, they scattered in every direction, moving to the edge of the glass tube, and some of them going under the surface of the liquid. Their movements over the surface were very similar to the Natantes, or water spiders; very quick, darting from one place to another when disturbed. They are also very pugnacious. I observed that when confined together in a microscopic glass well, they were always fighting, often times killing each other.

A general description of these little animals, perhaps, would be interesting. The body is very minute, oval, depressed, tapering towards the head, with antennæ one-third as long as the body. Legs eight in number, the two front ones the longest, and all covered with long slender spines or hairs. Eyes two, rather prominent, situated on the side of the head. The sides and back of the body are also covered with numerous spines or hairs, two very long ones being prominent on the anterior part of the body. Legs appear to consist of several joints terminating in minute objects, antennæ also jointed; general colour reddish brown.

The genus to which this species belong, are diffused throughout all parts of the world, and in all probability there are many species remaining yet undescribed. Their minuteness is extraordinary, many being scarcely visible without close inspection, and easily escaping the notice of the common observer. It is a remarkable phenomenon that any living animals can sustain life in a solution of nitrate of silver, and still more remarkable that these minute animals should generate and live in it. It is a question for the naturalist to solve, and I hope some one who is interested in the subject will investigate it more fully than I have done. Specimens are still living in the original bath, which I should be most happy to show any gentleman who wishes to see them.

*Brooklyn, N. Y., November 10th,* 1862.

[Our readers will remember a similar discovery by Dr. Maddox, recorded in our pages a few months ago.—ED.]

* Read before the American Photographical Society, November 10, 1862.

## Proceedings of Societies.

### LONDON PHOTOGRAPHIC SOCIETY.

The usual monthly meeting of this society was held on the evening of Tuesday, December 2, at King's College, Mr. PETER LE NEVE FOSTER in the chair.

The minutes of a previous meeting having been read and confirmed, the following gentlemen were proposed and elected members of the society: Messrs. F. W. Hart, Henry Cooper, jun., Ernest Edwards, Warden, Boscher, W. Bishop, C. Newcombe, G. Hare, Callaghan, Lucas, and Baron Jasmond.

In calling attention to some fine pictures by Mr. Hughes, of Osborne and Whippingham Church, 7 by 6, and $7\frac{3}{4}$ by $4\frac{1}{2}$, by the No. 1 triple lens, the Chairman mentioned the importance of a communication being in all cases made to the Secretary of the particulars to be made known regarding such contributions, as otherwise the meeting was often left in ignorance.

The CHAIRMAN said, in accordance with Bye-Law VII., which he read, the Secretary would now mention the names of the retiring members of the Council, and also the gentlemen nominated by the Council to supply their places. Any member of the society who had other names to propose, must do so at the next meeting in January; and all the names proposed would be hung up for a month before the election at the annual meeting in February.

The retiring members were: Messrs. Major, Maskelyne, Fenton, De la Rue, and Kater. The gentlemen nominated as their successors were: Lieut.-Col. Stuart Wortley, and Messrs. Henry Pollock, Cole, Hennah, and Lord Henry Lennox. Mr. Forster retired from the Vice-Presidency to the Council, and Mr. Glaisher was proposed as Vice-President. The Lord Chief Baron was proposed for re-election as President.

Mr. MALONE, on being called for a paper on the

COMPOSITION OF THE PHOTOGRAPHIC IMAGE,

said that he was not prepared with any paper, as he had not contemplated filling the principal position, but rather supplementing any other subject, by a detail of some experiments he had during the last few months been engaged upon in connection with the subject. He thought the subject should be treated now experimentally; time enough had been spent in conjectural statements, which led to nothing. He would now, therefore, briefly describe his experiments and conclusions. He had, during the summer, had occasion to prepare some paper with ammonia-nitrate of silver, the washings of which, containing ammonia-nitrate with the soluble organic matter, which might be removed with water, he had placed in a large bottle. This bottle was allowed to stand in sun-light and frequently shaken, the first action of light was to produce a dark substance, similar to the positive image, diffused through the water in a light flocculent state, which gradually became black, like chloride of silver, in contact with organic matter. By long exposure it passed into an ash grey, and was no longer light and flocculent, but fell heavily through the liquid, to the bottom of the bottle; it had evidently changed its physical character as well as its aspect. Collected by filtration, it appears a dark mass, like charcoal, with nothing of a metallic appearance, as metals were ordinarily understood.

But by burnishing, a metallic lustre was obtained. This seemed to confirm Mr. Spiller's idea, whose analysis showed that chloride of silver was reduced into the metallic state by light. Still, they must go further to disprove the sub-chloride theory. Many persons took objection to experiments performed in water, they insisted that with paper, a different result followed, that a sub-oxide was formed, combined with the organic matter of the paper, and that this went to form the image. Those who hold that view must hold that he had produced this sub-oxide of silver. But chemists were not agreed as to the existence of the sub-oxide. Its existence had been first suggested, he believed, in 1822, by Farraday, but Berzelius had remarked that the subject required re-investigation. The difficulty presented itself, that if they said it was a sub-oxide, they really did not know that such a thing had an existence; if they said it was an oxide, they did not know its properties. Oxide of silver was dissolved by acids, but they could treat the photographic image with acids, without destroying the image. After some further remarks on the analogy to and difference from oxide of silver, he proceeded to substantiate the view which decided that the sole action of light upon photographic materials, whether in the production of negatives or prints, was simply the reduction of the silver to its metallic state, and that a difference in its physical condition, gave rise to different results. Pure silver beaten very thin, and examined by transmitted light, was of a dove colour, analogous to that of the silver reduced by the method of Liebig. He proceeded to refer to various samples of silver flashed glass, which by reflected light, presents a blue metallic appearance, and by transmission were yellow. Some persons had held that the colour was oxide of silver, but Farraday had shaken that idea by showing that the colour in ruby glass, was simply finely divided gold. The so-called natural colours which had been occasionally produced in negatives, was, he thought, analogous. After a careful examination of all the facts, he thought there was presumptive proof that the image consisted of finely divided metallic particles. Regarding the reproduction of natural colours, he was not sure that even M. Becquerel's results would stand a searching examination, and that, perhaps, Mr. Hunt was right when he said he feared it would be that it was not the true action of light, giving colour for colour, but was due to the iridescence arising from differences of thickness in the film. He proceeded to enforce the fact that the same substances, in different physical conditions, presented various colours without indicating any change of constitution, adducing allatropic phosphorus as a striking example. But having arrived at the conclusion that the image was reduced metal, they must not assume its imperishability. It was true it would resist acids; he had submitted a photograph to a mixture of one part of nitric acid to three of water without injury. Oxide of silver would not stand that, nor would sub-oxide. But although the print would stand this, and would, to some extent, stand caustic potash, they must not be misled by that. The image would not resist certain compounds of sulphur, especially certain compounds of sulphur and ammonia, which dissolved silver without difficulty, the same as did cyanide of potassium. This was especially the case in the presence of the air. Farraday had shown that the gold dissolved ten or twelve times less rapidly when immersed in the solution than when also exposed to the air. Hyposulphite of soda would doubtless much more readily dissolve the image in the presence of the air. Faraday had suggested that this was probably due to electric action, the air completing the voltaic circle. He then adverted to the importance of removing not only all fixing salts from the print, but also those of common water. Regarding the albumen it contained sulphur, so long as there was no decomposition the sulphur and silver might remain in contact without danger; but if any decomposition of the organic matter took place, amongst the products would be ammonia, and sulphuretted hydrogen, these forming sulphide of ammonium, and this, in contact with the finely-divided metallic silver, would cause it to disappear entirely. So long as a print was kept dry it might remain safe, but rapidly faded when subjected to the conditions of decay. Referring to the recent investigations of Mr. Graham, in dialysis, he remarked that white of egg was a colloid body, and that colloid bodies retained salts very tenaciously, and thence argued the importance of keeping the prints horizontally suspended in the washing water, and not allow them to lay in a heap at the bottom, where the salts dissolved out were accumulating. Dr. Diamond had shown him a print which had faded underneath the mat placed over it, whilst the part exposed to light had retained its vigour. This, he thought, agreed with his view that light and warmth would help to preserve the picture. He had some further experiments, but would reserve them for a future occasion.

Mr. Mayall was quite prepared to bear out Mr. Malone's views as to the constitution of the image. He believed it consisted of metallic silver, and that gradation and colour were produced by its state of subdivision. It appeared to him that in order to come to a satisfactory conclusion as to the nature of the image it was important to inquire into the manner of its production. There were two things went to the production of the photographic image; first the light, and next the haloid salt of silver, whether a compound of chlorine, iodine, or bromine with the metal. The purer the haloid salts of silver the purer the resulting image. But then there was another element, the light itself, or the blue part of the spectrum, with which it was well known the image was produced, and this ray was, magnetically speaking, in an electro-negative condition. This came into contact with the electro-negative portion of the haloid salt, and when two electro-negatives met one was pushed out of its feeble combination, a fretwork was left precisely equivalent to the quantity of light acting on the film on which the image was produced. In illustration of this, if an excited collodion plate were placed near a stationary magnet, and then developed, a distinct line would be produced. This showed that other forces besides light would produce an image. He then referred to the views of Mr. Johnson, of Birmingham, on this subject, who was a very old experimentalist and had given the subject much attention. Mr. Johnson believed the film to be in an electro-magnetic state of tension the moment light impinged upon it; and that if the plate were taken into the dark and submitted to the action of steam no image could be developed, as the steam had the power of restoring the equilibrium of tension, and that the moment the magnetic tension was destroyed you destroyed the image itself. The production of the latent image was thus an electrical action, and only became a chemical one when the developing solution was applied. He had tried to get Mr. Johnson to write his views, but failed, but he (Mr. Mayall) would promise to bring the subject more fully and clearly before the meeting on an early occasion.

Mr. Sebastian Davis thought, whilst agreeing with Mr. Malone that the final action of light upon a salt of silver, in connection with organic matter, was to reduce it to a metallic state, there was evidence to show that there was an intermediate state, before light had acted so long as the experiment of Mr. Malone. In the lengthened exposure of excited paper it was possible to obtain all the appearances of metallic silver, but there was an intermediate state in which no such reduction was observed. With a negative also the ruby effect was got by prolonged exposure, as in the case of an over-exposed sky; but when exposure was less prolonged they obtained an intermediate tint of violet.

Mr. John Williams mentioned that gold was soluble, not only in acids and in cyanides of potassium, as shown, but in ioduretted iodide of ammonium. In this it dissolved as freely as sugar in water, and crystallized in a beautiful manner.

Mr. Mayall expressed a wish for Mr. Malone to throw some more light upon the nature of the haloid salts.

Mr. Malone said chlorine was generally described as a greenish gas, indeed its name was derived from a Greek word meaning green. Now in the sealed tube he produced, containing chlorine in a liquid state, it would be seen that it was of a beautiful yellow colour by transmitted light. Silver might also be yellow. Both might be in the same physical condition, and that might have some relation to the mode in which they were acted on by the undulations of light, both being antagonistic to the higher end of the spectrum. Then with regard to the colour of bromine, it was variously described as a reddish brown, red, and black. Now on careful examination by reflected light, he had come to the conclusion that it was indigo blue, and red by transmitted light, in which it had an analogy to iodine, which was a kind of blue by reflected light, and a yellowish brown by transmitted light when in solution. It might be that, having a surface antagonistic to the blue rays, compounds containing them were decomposed. It had been said that pure iodide of silver was insensitive to light, but nothing was more difficult than to say what was pure iodide of silver, as it was capable of forming double salts with other bodies. With iodide of potassium it was capable of forming a second compound, but whether chemical or mechanical he would not say. The same difficulty occurred with nitrate of silver;

so that it was uncertain with excess of either. If it were formed by the direct union of silver and iodine, it might contain excess of free iodine. His own impression was, that in that way chemically pure iodide of silver was obtained. If so, what was the action of light on that body. Claudet had shown that it was to split it up into iodine and metallic silver, and that in the camera, without the long direct action of light to which Mr. Davis had referred. The same fact occurred with Becquerel's plates with chloride of silver, in which a bright metallic spot representing jewelry was reproduced by bright metallic silver. Regarding the magnetic theory held by Mr. Johnson, to which Mr. Mayall had referred, he thought it was purely a conjectural matter, and not based upon evidence. Mr. Grove had made some experiments with the galvanometer, but nothing conclusive had been effected. Besides, an eminent German held the opinion, that magnets emit light; and the action of the magnet, according to that theory, would still be that of light. Men might hold many fancies, but they proved nothing. M. Niepce held the fancy that he could bottle light. He (Mr. Malone) thought it more probable that it was bottled heat. Regarding the action of light upon chloride of silver, &c., the question arose what was a pure haloid salt? Dr. Percy had formed chloride of silver by means of chlorine gas and silver foil, and it no longer blackened in the light. There might be two explanations for this; it might be that it was in a different physical condition, like the horn silver, and light had not the same power over it; or it might be the presence of more chlorine. After some further observations, M. Malone concluded by placing ignited phosphorous in a jar of oxygen, and exhibiting some negatives with the sky yellow by transmitted light, a metallic blue by reflected light, analogous to certain samples of silver flashed glass.

Mr. MAYALL stated that he had taken a bottle of silver prepared by Dr. Percy's method, and covered it all up but a certain slit. After exposure to light, without apparent change, he applied gallic acid, when the exposed part blackened.

Mr. DAVIS asked if this sample was exposed in the presence of chlorine.

Mr. MAYALL: Yes.

The CHAIRMAN announced that Mr. Highley would read a paper on "Photography applied to Educational Purposes," at the January meeting. At the February meeting, Col. Stuart Wortley would read a paper on "Obtaining Instantaneous Pictures on Large Plates;" and at the March meeting they might hope for Mr. Mayall's promised paper.

### MARSEILLES PHOTOGRAPHIC SOCIETY.

AT a meeting of the 8th ult., the President, M. Gabriel, expressed the thanks of the society to the *Union des Arts*, for having graciously accorded to it a temporary hospitality, by which the existence of the society will be secured, and the elements of its prosperity increased.

M. Poitevin, the indefatigable experimentalist, communicated to the Society a remarkable notice of his new process with gelatine, which he employs as a vehicle for iodide of silver.*

A note was received from Dr. Mitchel, of Ile de la Reunion, testifying to the excellent results obtained by the addition of tannin to plates prepared by the Taupenot process, according to to the modification suggested by M. Vidal. He considered this mode of preparation invaluable in hot climates. M. Tissot's instantaneous diaphragm stop possesses so much merit that the committee decided to congratulate the inventor upon his solution of a very interesting problem. His invention is calculated to render great service to photography. The instantaneous stops in use, hitherto, although very ingenious, left much to be desired. Very little is required in order to render M. Tissot's apparatus perfect.

M. Megnier presented a specimen of a salt, which he calls *sulphocyanhydrate of ammonium*, which he has recently applied to photography, for fixing positives and negatives on paper and glass. This salt possesses the valuable property of dissolving all the haloid salts of silver (chlorides, bromides, iodides, &c.) without possessing poisonous qualities. It possesses another advantage in not weakening the half tones, or of altering the texture of the collodion. Lastly, it is preferable to hyposulphite of soda, because it does not, like that salt, precipitate sulphide of silver from the nitrate, nor sulphur by the action of any acid whatever, so that if the proofs to be fixed contain traces of nitrate of silver, or any acid remains in the substance of the paper, there is no risk of sulphurization. The fixed proofs are washed in the usual manner, as when the other fixing agents are employed, but there is no speciality in this particular.

The PRESIDENT, after thanking M. Megnier for his communication, observed, that if experience confirmed the results claimed for this new salt, he will have conferred a great boon upon photography, for he will have contributed to the preservation of works, the sole defect of which consists in the uncertainty of their duration.

A committee was appointed to examine the *sulphocyanhydrate of ammonium*.

M. VIDAL, the Secretary, then proceeded to the examination of the publications of the month. He specially directed attention to the excellent ideas emitted by M. Claudet on the subject of enlarging proofs, and on the theory of the action of light upon iodide of silver, announced by Mr. Thomas Sutton. A very interesting discussion ensued between the Secretary and M. Jaquemont, upon a phenomenon observed by the latter in the tannin collodion process.

* See p. 581.

## Correspondence.

### THE NON-COAGULATION OF DRIED ALBUMEN, AND MR. DAWSON.

DEAR SIR,—As being, I believe, the first person who drew attention to the erroneous opinion prevalent amongst photographers, respecting the coagulation of dried albumen, allow me to make a few remarks on a sentence in a paper entitled, "On Some of the Chief Causes of Fading of Photographs, by George Dawson, M.A., Lecturer on Photography, at King's College London," read at the North London Photographic Society, October 22nd, and published in the *British Journal*, Nov. 1st.

At p. 403, I find the following:—"According to my experiments, completed so far, albumen, coagulated by heat, before treatment with nitrate of silver (but not exposed to light), contains, after fixing and washing, more silver than when merely dried, and moist albumen less than either." Now, I am old-fashioned enough to think, that he who takes upon himself the office of "teacher" and "lecturer," should so write, that the reader should never be in doubt as to what he means; but the passage I have quoted is so obscurely worded, as to be wholly unintelligible to those who, like myself, do not know beforehand. what meaning Mr. Dawson intends to convey. What do the words, "not exposed to light," refer to? to the albumen, *whilst being coagulated?* or, to it, during and after sensitizing? Again, what is meant by "*albumen* coagulated by heat?" albumen in its normal state of white of egg, or, in its dried state, as existing on a sheet of albumenized paper; also, what is meant by "moist albumen?"

As experiments in a test tube upon coagulated albumen can afford no information respecting the "causes of fading of photographs," I cannot but suppose that Mr. Dawson's "experiments completed so far," refer to albumen as it is found on a sheet of albumenized paper, *viz.*, in its *dried* state. If this supposition be correct, we have him assuming a fallacy to be a fact, and promulgating it as such; this is, in fact, tantamount to his assertion, in broad terms, that there is no fallacy in his assumption; and thus, he is *mis*-teaching the rising generation of photographers.

Before proceeding further, I will quote a few words from Mr. Dawson's "Lesson for the Learned," as published in the *British Journal* for September 15th, p. 351:—"A photographic teacher would find too much to do, were he to fight with, and overcome all the dragons and chimeras, in the shape of false doctrines and misconceptions, which are continually besetting his path in this photographic world of ours. However, I need no apology for doing battle with, and, I trust, conquering one of these monsters, which put in an appearance lately in the pages of your contemporary." After quoting what he considers to be a "false doctrine," he proceeds thus :—"The matter quoted, I consider a good sample of those not uncommon *fallacies* in photographic chemistry, which, arising from imperfect knowledge, having been once announced, are passed from mouth to mouth, till they begin to be regarded as established facts."

Now, sir, I ask—Who that reads these words would expect to find that the writer of them, before many weeks had passed, would himself be promulgating one of the very strangest "fallacies in photographic chemistry?" Yet, such we see is the case; the possibility of coagulating dried albumen is such an extraordinary and unaccountable fallacy, that I am at a loss to conceive how it could ever have originated; since common sense, without any chemical knowledge, will teach us the contrary. I unhesitatingly say, that if Mr. Dawson's chemistry teaches him that he can coagulate dried albumen by heat, his chemistry, in this particular case, is at variance with fact, as it cannot, in that state, be *coagulated* by any means whatever. I believe Mr. Dawson draws a false inference respecting his so-called "coagulated," "merely dried," and "moist albumen," retaining different quantities of silver. Suppose we divide a sheet of albumenized paper into three equal portions; from No. 1 we will expel all the moisture, either by drying it before a fire, or, what is better still, by ironing it with a hot iron; No. 2 we will leave as it is; and No. 3 we will submit to the influence of a damp atmosphere; thus giving us what Mr. Dawson calls "albumen coagulated by heat," albumen "merely dried," and "moist albumen." According to his assertion, the *albumen* on each piece of paper will contain different quantities of silver, No. 1 containing the most, and No. 3 the least. Notwithstanding it is Mr. Dawson who states this, I venture to dispute its truth. The drier the albumen can be rendered at the time of sensitizing, the sooner does the nitrate bath render it insoluble, and the sooner it be rendered so, the less of it will be dissolved off the paper. As No. 1 *is completely desiccated*, very little albumen will be dissolved; No. 2, from not being so, will have *more* of it dissolved; and No. 3, from being in a damp state, will have *a considerable portion of it* dissolved off; thus, each piece of paper, after sensitizing, will contain *different quantities of albumen*, and must, therefore, necessarily retain different quantities of silver: Mr. Dawson infers that the difference in amount of the retained silver, is due *to the different state of the albumen*; whereas, I believe it is due *to the different quantity of it*, and that *equal* quantities of albumen, will, in each case, retain *equal* amounts of silver; by the by, his inference involves a rather startling theory, viz., that the atomic weight of albumen varies according to its more or less desiccation.

As Mr. Dawson's promulgation of the possibility of coagulating dried albumen by heat, can only have arisen from "imperfect knowledge," in consequence of not having investigated the subject—I trust that when he has done so, and is thus better informed, he will have the candour to acknowledge he has been in error in giving credence to such a fallacy; for I am sure he needs not to be told, that where "dragons and chimeras in the shape of false doctrines and misconceptions" are concerned, *the suppression of truth by "a photographic teacher," is equivalent to the dissemination of error.*

Those who are desirous of reading what has been already written on the subject, are referred to my letters signed G. P., and the answers they elicited from Mr. Sebastian Davis, which will be found in your 5th vol., pages 33, 47, 59, and 129.—I remain, dear sir, yours truly, George Price.

## MORPHINE DRY PROCESS.

Dear Sir,—Having read with interest Mr. Hislop's paper on his plan of preparation of dry plates, and as the present moment seems an opportune one for a few more remarks on the preparation of simply washed and dried plates (which is supposed impracticable by most photographers), I have sent you a few stereo prints from negatives taken in November of this year, on plates simply excited, washed, and dried, to endeavour to help to dispel the idea that a preservative is necessary. You will, doubtless, remember the disfavour my morphine process encountered in the commencement of this year, one said, "That I proposed to do what every sane photographer strived to avoid!" "The bath *must*, inevitably, be spoilt!" So I resolved to let time settle the question. I made my bath with the morphine in it last January, and have used it occasionally ever since; the plates (prints from which I have sent) were excited in it, and it is as good as ever for wet or dry plates. Hardwich lays down this theory (which is by this process proved to be strictly correct), that if a plate is to retain its sensitiveness and developing qualities after simple excitation, washing, and drying, "it must be in contact with organic matter during its sojourn in the bath," and this I accomplish by adding a fractional part of nitrate of morphine; nitrate of quinine, or strychnine, or any alkaloid, will, doubtless, have the same effect.

You can form your own opinion as to their sensitiveness, from the particulars at the backs of the prints, and, when I add, that my collodion was purchased by me nine months ago, and the plates exposed in cold, dull, and damp weather, I think you will say that it was a pretty severe test.

The advantages of this formula are, to me, so palpably evident, that I cannot adopt any other; it is more economical, easier of manipulation, requires no extra solutions, is always ready, can be used with any bromo-iodized collodion, is very sensitive, develops beautifully and quickly with iron, and keeps well: my opinion may seem extravagant to some, but, I think, in all essential requisites, it surpasses all other plans. I have not tried hot-water development, but they are eligible for it, and if their sensitiveness is increased in the same ratio as with tannin plates, they must be extra sensitive; in conclusion (with an apology for this "dry" letter), if your readers would like to have my plan of manipulation and development, I shall be happy to furnish it in your columns.—I am, dear sir, yours faithfully,

*Farnham, Surrey, Dec. 2, 1862.* Wm. Bartholomew.

[This letter was accompanied by several very pleasing stereographs, fully bearing out our correspondent's position. —Ed.]

## PRINTING DIFFICULTIES.

Sir,—From the tenor of Mr. Eliot's last, *more comprehensively composed letter*, I perceive his views on alkaline toning in every point, save one, go to support the theory I have advanced and explained in my letters on "Printing Difficulties." The point in which we differ, although admitting of many arguments *pro* and *con*, its importance is of too limited a character to occupy your valuable space by a lengthened discussion. I have recently entered on a series of experiments which promise results much to be desired, *viz.*, entire immunity from mealiness. When I have brought the matter into something like a manageable form, I shall not fail in placing the details at your disposal. Fearing that I have troubled you too frequently of late, the remarks I intended offering on practical toning must stand over for the present.—Yours respectfully, A Photo's Assistant.

P.S.—Having long, and I may add daily, practised the "strabonic manœuvre," described in your last number, I can bear testimony that the eyesight is not at all injured by the exercise. A very little practice will enable any one to produce the stereoscopic super-imposition instantaneously, without the slightest straining effort.

## CHEAP VIGNETTING GLASSES.

Dear Sir,—If the following is worth a place in the News, you may make a note of it.

Paint an oval or other figure, having the edges softened a little, in black or bright yellow on a white card. A negative taken from it, having the image very much out of focus, will make a capital vignetting glass, which might be made still better, by moving the lens backwards and forwards while taking the negative. Of course, it is evident that any *size* vignetting negative may be taken from the same card.—I am, dear sir, yours truly, J. W. Fall.

*Ironbrige, Salop.*

## Talk in the Studio.

The Collodion Processes, Wet and Dry.—Mr. Sutton's new work on the Collodion Processes, Wet and Dry, is just out, price three shillings. It is, as it could not fail to be, from Mr. Sutton's pen, a valuable and interesting book, and exceedingly well written. We shall endeavour to review it at length in our next.

Mr. Fenton's Photographic Effects.—At the recent sale by auction, of the photographic effects of Mr. Fenton, a singular discrepancy of appreciation was manifested in the valuation of the means and the end. The lenses, in most cases, realized their full value, and, in some instances, we believe, were sold for considerably beyond their original price. The negatives, on the other hand, in many instances, realized very small prices indeed. In some cases, three 10 × 8 negatives and a print of each sold for eight or ten shillings. The reason for this was, probably, the fact that many of the negatives were in bad condition with blistered and cracked varnish. The cameras and other appliances, had the neglected dirty appearance of having long been out of use, and did not produce high prices. The photographic carriage, of which much had been said, was a very convenient, but somewhat clumsy and omnibus-like vehicle. We did not hear the price it realized.

Photographic Proverbial Philosophy.—A celebrated photographer, who is not ambitious of literary fame, and modestly declines to allow us to publish his name, has been beguiling the time during November fogs, by preparing a volume of Photographic Proverbial Philosophy, which promises to out-Tupper Tupper. We submit one or two examples for the benefit of our readers, who will, doubtless, at once bespeak a large edition :—

"Hear, oh! disciples of the sun, the voice of your prophet, albeit he is not a Tupper; to be that man, entereth not into his desires.

"Let thy light so shine that it produceth relief, a flat picture is tame and unprofitable.

"Dash not thy buttons if thou failest, but try again.

"Lend not thyself to the infringement of copyright, piracy is but a black-art profession.

"It is the early birds that pick up the worms, but the skilful photographer is up to the time of day.

"Half-tint is a thing of beauty, be not too heavy with thy developer.

"Be not hasty over thy work, but keep thy head cool, and thy operating-room at 60°.

"Wouldst thou command a mastery over thy art, study deeply; a photograph is not always a picture.

"A negative image will come at the bidding of a fool, but wisdom is necessary to produce a positive impression on the imagination.

"Then study, oh! my son, to obtain wisdom.

"A negative should appear through the glass darkly, but not 'as black as your hat, sir!'

"Avoid the expression of thy wrath when thy tent blows over; evil passions will not pick up the fragments."

Mr. Hill's Pictures.—The photographs exhibited by Mr. Hill at the last North London, were by Dallmeyer's triple lens, No. 1, not No. 3, as stated in our Report. The No. 1 triple has an equivalent focus of between seven and eight inches.

## To Correspondents.

H. B. Y.—Transparencies for the magic lantern should not be dense, but somewhat thin and full of detail. The tannin process yields excellent pictures for the purpose; your difficulty of not being able to get them sufficiently intense is not a usual one with tannin plates, as it is generally easy to obtain a great deal of intensity. Another sample of collodion, somewhat older, may help you, or you may increase the strength of your tannin solution, and that will give you greater intensity

Johannes.—We have not tried the recipe, but gave it just as Mr. Dawson stated it. If you followed the instructions exactly, we see no reason why you should fail to clear the solution without adding much nitric acid. Try again.

A. G. Grant.—We believe Condy's fluid may be had of many chemists. Mr. Condy's establishment is at Battersea, but we do not remember the exact address.

An M.P.—Our forthcoming Photographic News Almanac and Year Book of Photography will contain an epitomized formulæ and manipulations of the principle of dry processes at the present time practised. There is a work by Major Russell, on the tannin process only, of which a new edition is promised shortly. Mr Sutton's book is just out, and contains some good information on the subject.

J. W.—Report on your glass in our next.

T. H. M. A.—Spots in the negative may proceed from many causes, such as a turbid bath, dust in the camera or operating room, super-saturation of the bath with iodide, or the condition of the collodion. An article on the latter subject is in type, and will appear in our next.

A Subscriber (Derby).—Negatives intensified with bichloride of mercury, and iodide of potassium, if properly managed, bear varnishing well enough. It is possible that you get an image which is too feeble to begin with; or, it is not improbable, that you continue the action of the mercury too long, so that when the iodide is applied the negative turns a canary colour, in which case it would, probably, be much reduced by varnishing. The final colour should be greenish drab, or greenish gray, or an olive tint; the mercury should be applied for a very short time only, and then a 1-grain solution of iodide potassium poured on and off until sufficient intensity is gained. The negatives we describe will bear varnishing.

Subscriber (Torquay).—We find, on enquiry, that there will be facilities for exhibiting transparencies at the forthcoming Exhibition, if they are properly fitted up for the purpose.

Matthew Anderson.—In Mr. Osborne's original manipulations, he used albumenized paper as a basis, coating it with gelatine and bichromate of potash. He has since found it desirable to apply the albumen at the same time as the gelatine and bichromate. An account of his original process appeared in our fourth volume.

I. H J.—The oxyhydrogen light is the best for exhibiting photographic transparencies with the magic lantern. If you have facilities, and it is probable you will have, for procuring a supply of carburetted hydrogen by attaching a flexible tube to an ordinary gas-pipe, it will answer nearly as well as pure hydrogen, and will involve much less trouble. The oxy-calcium light (using the flame of a spirit-lamp and lime in connexion with oxygen) gives a good light, but not so good as the other. You will find instructions for making the gases and managing the apparatus in some articles on the lime light in the early part of our fifth volume. Or you will be able to obtain the necessary apparatus and a pamphlet of instructions from most dealers in philosophical instruments. We may mention Bland and Co , Horne and Thornthwaite, and Negretti and Zambra, who each we believe, not only supply apparatus and material, but have some pamphlet or printed instructions.

De Jay.—Spectroscopic examination was meant, as the context showed.

Charles Scarfe.—If you can wait for about a week you will find in our Year Book of Photography for 1863, now in the press. more detailed information on glass-rooms and lighting than we can give here. In a glass-room 36 feet long you ought to have much more glass than you propose. If it be placed in the proper place to light the sitter from a proper angle, it would do for bright weather, but you would find a lack of light in dull weather. If your room stand east and west, let the sitter face the east. Do not use ground-glass, it obstructs more than half the light. If it be necessary to stop out direct sunlight the corrugated light will diffuse it, and obstruct much less than ground-glass.

M. Wynter.—We cannot tell you of any establishment where you will be quite certain of obtaining non-actinic yellow glass; but wherever you get it, ascertain that is silver flashed glass, which obstructs actinic rays better than any other.

Wm. Roberts.—The defect is a well known one, and may proceed from many causes. If you use 1 grain of citric acid to each grain of pyro in your intensifier it will probably disappear. You will find the causes fully considered, and remedies stated in the first article of the Photographic News, August 1st of this year.

An Old Subscriber.—You are right; the No. 1 triple was meant.

Justitia.—The white or grey precipitate obtained at the first solution of the gold is chloride of silver. Having thrown down your gold with protosulphate of iron, and redissolved it, you should have no further precipitate, unless decomposition from evaporating it at too high a temperature, which, by driving off chlorine, brings the terchloride to a protochloride, which is insoluble in water. This has probably been your error, the use of a temperature slightly too high. When you obtain crystals soluble in water it is not probable that anything is present which will interfere with toning. 24 grains of pure gold will yield about 37 of the terchloride. 2. We cannot, of course, say whether the yellow colour of your crystals of nitrate of silver may not be due to some accidental contamination which would not materially affect its action in the bath The foggy stains may proceed from that, but we cannot say they do. Add a little carbonate of soda to the bath, sun it, and then try it. A yellow tinge does sometimes indicate an impurity almost irradicable, namely, the presence of a trace of palladium. This would cause fog, &c., and infused nitrate of silver is made manifest by its yellow tint.

Carte de Visite.—A little observation will help you better than instructions given without examining the place. Build up the south wall sufficiently high to prevent direct sun-light troubling you, and place the back-ground next it. Have about six feet of canopy overhead. We don't know any material better than wood, or a wooden frame-work with slates or asphalte felt covered over it. A platform to raise the whole a few feet would be an advantage.

Tyro.—Your chloride of barium and ammonium, are very sparingly soluble in spirits of wine, and will, therefore, serve but little purpose by their presence. Iodides, also, are not reduced by direct sun-printing, and are of little use except in the presence of a developer The thin *Rive* sample is the best picture. We think the results will repay you for proceeding.

Zeno.—The silk prints must be carried much further in the printing frame than paper prints, or they will be too pale. They do not lose tone in the hypo like paper.

Wm. Bartholomew.—Your first letter and slides were received. The insertion was simply delayed for want of space. Your second now supersedes it. We are always glad to hear from you.

Exeter.—The custom of the profession vests the ownership of a negative in the photographer who takes it. Any deviation from this arrangement is the subject of special arrangement and extra payment.

Several Correspondents in our next

Advertisements and Communications for the Publisher for the current number, to be addressed to the Office, 32, Paternoster Row, not later than 3 o'clock every Thursday. Post-Office Orders are to be made payable to Mr. Thomas Piper, at the Money-Order Office, St. Martin's-le-Grand.

Vol. VI. No. 223.—*December* 12, 1862.

## CRYSTALLINE DEPOSIT ON THE NEGATIVE.

Most operators are familiar with a certain trouble, which usually occurs towards the close of a heavy day's work, when a large number of negatives have been taken in one bath. The plate, on removal from the bath, appears to be covered with a gritty, sandy deposit. Sometimes it is not observed until the developer is applied. In some cases the negative does not suffer much when finished, but in others, after fixation, it appears covered with pin-holes. This sandy-looking deposit, on examination, is found to consist of fine needle-like crystals. At times the negative is working perfectly well in other respects, but at other times the appearance of these crystals is accompanied by a tendency to the production of a thin fogged image.

The most usual explanation of this defect has been the supersaturation of the nitrate bath with iodide of silver. When this is the case, the gradual weakening of the bath, or a fall in the temperature, would cause the iodo-nitrate of silver to crystallize out of the solution, on to the plate, on to the dipper, and on to the sides of the bath. These crystals give a rough, sandy appearance to the film, and generally end by causing pin-holes where they have been. The remedy, in this case has always been found very simple.* It was simply to dilute the bath with distilled water, to precipitate the excess of iodide, filter out the precipitate, and add sufficient fresh silver to make the bath the proper strength.

But this explanation and this remedy do not always meet the case. We have occasionally met with the defect where excess of iodide would not account for its presence. And we have recently had several cases brought under our attention where the circumstances were altogether different from those present in supersaturation with iodide or iodo-nitrate. In these cases this sandy or crystalline deposit would appear, in a comparatively new bath, not at all exhausted. Instead of appearing when the temperature had fallen, they appeared in the middle of a summer afternoon, when the bath had been working well during the morning; and would, probably, next morning, after the bath had rested for a few hours. These cases were puzzling; but a history of two or three cases helped us to what we believe to be a solution of the difficulty.

If we are right in our information, the latter form of this defect generally occurs with collodion which has been made some time, and which has been made with pyroxyline produced at a high temperature. Not having had any of the silver bath in the condition to yield the results in question, we cannot speak with absolute certainty, but from the details mentioned in different accounts which reached us, we have come to the conclusion that these crystals consist of *oxalate of silver*, to the characteristics of which they answer. Old collodion, or moderately new if made from pyroxyline obtained at a high temperature, have frequently, on analysis, been found to contain oxalates, and have yielded oxalic acid in considerable quantities on being treated with the proper re-agents.

It may be within the recollection of some of our readers, that three or four years ago, Mr. J. Williams stated at a meeting of the Photographic Society, that from twenty Winchester quarts of old collodion residues, he obtained oxalic acid sufficient to form upwards of twenty ounces of oxalate of lime. M. De La Haye, had also stated previously, in a foreign journal, that various samples of collodion, when treated with potassa, yielded oxalate of potassa; and we believe it has since been confirmed, that one of the products of decomposition in collodion, especially where the pyroxyline was obtained at a high temperature, is oxalic acid.

The immersion of one or two plates coated with collodion, containing oxalic acid in infinitesimal proportions, might not produce any perceptible effect, but the result of continued exciting of such plates for a few hours, would be a gradual accumulation of the oxalate of silver, which would produce a tendency to fog, and to the deposit on the plate of needle-like crystals, giving the sandy effect described. If the solution were examined at this time, it would, probably, present a turbid appearance. On standing a few hours, the infinitesimal particles of oxalate of silver, which is insoluble, would gradually precipitate; and thus the bath be found, after a night's rest, to work well again.

As a hasty method of testing this view in the absence of the defective materials for examination, we essayed to produce the result intentionally. A single drop of a solution of oxalic acid was added to a bath in good condition. A general turbidity was the result, and a plate immersed at once showed a sandy deposit, like that described. On fixing a picture obtained on such a plate, the image showed a strong tendency to dissolve on the application of cyanide, the film having a somewhat green appearance where it was attacked by the cyanide, an effect we remember to have noticed before, when using old and decomposed collodion. On examining the bath shortly afterwards, a white precipitate of oxalate of silver was found thrown down, and then the solution worked well again.

If this view be correct, this defect is due to a certain condition of the collodion, and not the nitrate bath, as has been generally supposed. It will be found to occur when using some samples, and not with others, unless they be used at once in the same bath. The source of the defect thus traced it will be easily avoided.

* See p. 597.

## AMMONIA DEVELOPMENT.

The use of ammonia for developig dry plates is one of the few new things in photography, and may prove to be as valuable and important as it is novel. Until the conditions of its successful application are better understood, we fear that some disappointment may attend its use, as it appears capricious and uncertain. In the meantime, we may note the gradual steps by which even a decidedly new application is discovered. American photographers discover—we believe Mr. H. S. Anthony was the first to do so—that submitting tannin plates to the fumes of ammonia before exposure, considerably increased the sensitiveness. It was next found that the ammonia fumes need not be applied before exposure at all; if done just before development it answered the same purpose. At this point, for some time, the matter rested.

The first announcement of the use of ammonia as a developing agent is due to Mr. T. M. Leahy, of Dublin, who, in a letter dated October 23rd, published in the Photographic News of November 7th, describes his experiment. Having found the fuming successful in permittin; short exposure, it occurred to him that a solution of ammonia might answer the same end. On trying a very dilute solution prior to the application of pyrogallic acid, he found the image at once began to appear, and gradually became developed without any application of pyro whatever, and after washing well, it gradually acquired intensity on the application of pyro and silver in the usual manner.

Major Russell next communicated the results of some experiments in a contemporary, published on the 15th of November. He has used ammonia in combination with pyro with very satisfactory results, one drop of strong ammonia, added to three or four ounces of pyrogallic acid developer, without either silver or acid, yielding a good image with a short exposure, which readily intensifies with pyro and citro-nitrate. In a letter received from Major Russell a few weeks ago, there are some interesting particulars. He says:—

"I have been working in this way ever since some time in September; but cannot even yet say how much is gained in shortening the exposure, as there has been some discrepancy in different comparative trials, and I have not yet been able to discover the reason. There appears, however, always to be some gain; and a rather under-exposed picture is much less liable to loose deposit than when acid and silver are employed from the first. A different mode of treating the development by ammonia will produce the most brilliant negatives I have ever seen, apparently entirely free from *all* deposit on the transparent parts, and from all loose superficial deposit on the blacks, though a great amount of intensity is easily produced. Unless the exposure has been somewhat prolonged, the half-tones are lost; but for this very reason I have hoped that this method may be of use in copying prints. I do not yet publish it, as I have only tried a few plates in this way, and once failed entirely. The development by ammonia and pyrogallic, whatever may be its practical value, is interesting, as throwing light on the nature of the developing action. From the great similarity of the appearance of the image in both cases, I suspect that the nitrate of silver has no other concern in the early stage than that of decomposing the pyrogallic; and it must be accompanied by acid, which has a retarding effect; hence the gain by using ammonia. From the results of recent trials, I am not quite so sanguine as I was some time ago as to the amount of this gain."

So far as we glean from Major Russell's letter, he has not met with any of the failures of which we have heard from other correspondents. On this point he observes:—

"The great points to be observed are, not to use too much ammonia—one drop of the strongest in from one to four ounces of water; and to wash thoroughly afterwards before redeveloping with acid silver. The ammonia developer may be left on the plate for any length of time, even twenty-four hours, when it will be nearly black, without any deposit or other injurious action; but nothing appears to be gained, except a trifle more intensity, after a short time."

In some cases, however, very singular results have followed. Two or three accounts have reached us of utter failure; one or two of fog and irregular action. Mr. Hurst, of Mirfield, who is one of the most successful tannin manipulators we know, has recently favoured us with an inspection of some of his results. A stereoscopic negative, now before us, which received an instantaneous exposure in November, is on one half a good negative, clean and perfect, except perhaps a slight tendency to fog in the deep shadows; the other half is covered with granulated opaque spots, has the effect of being much under-exposed and fogged. Some other plates, treated the same way in all respects, having been prepared at the same time, exposed at the same time, and developed at the same time, turned out irregular transparent positives, apparently on a similar principle to that propounded by Dr. Sabatier. The quality of the successful negative is just what Major Russell describes, the image perfectly in the film; and in this respect very unlike the usual results of forced development, which gives generally a piled-up superficial image.

As to the mode in which the ammonia acts, we do not at present offer any suggestion. We are scarcely satisfied with Major Russell's idea, that development is due to the decomposition of the pyro whether by the presence of silver or ammonia. In Mr. Seahy's case no pyro was present; in other cases warm water alone has developed an image; in others, an image has been apparent after exposure before any treatment at all. In each of these cases, it is probable the tannin acts as a developer without any decomposition. We have, moreover, developed almost all kinds of dry plates with pyro alone without either ammonia or silver. We believe that wherever there are two salts of silver present, pyro alone is generally sufficient to develop an image. Mr. Hurst states a conviction that the ammonia simply helps to render the film readily permeable to the developing agent proper. More experiments will be required, however, before any satisfactory theory can be deduced.

Mr. Hurst's instantaneous views on tannin plates, to which we have alluded in former numbers, are also due to development, but in an entirely different direction. From the negatives we have seen the process appear attended with much fewer difficulties than the use of ammonia. We hope to have Mr. Hurst's permission to announce details shortly.

## SOLAR CAMERA PICTURES.

We have recently been favoured by Mr. Stuart, of Glasgow, with an opportunity of examining some enlarged prints produced by the solar camera, which have at once surprized and delighted us. We had not believed that it was possible to produce in this country, and by the means employed, amplified prints at all approaching these in delicacy, brilliancy, exquisite definition and modelling, and general perfectness. In examining the results of photography in the International Exhibition, we were compelled, however unwillingly, to award the palm for enlarged pictures to Continental artists. Half-a-dozen Continental photographers—Ghemar of Brussels, Disderi of Paris, Albert of Munich, Wothly of Aix-la-chapelle, and some others; all seemed to take precedence of those in our own department. M. Claudet, Smyth and Blanchard, and Owen Angel, all exhibited good enlarged pictures; but, grudgingly and unwillingly, we felt compelled to admit that their productions did not quite equal those of their foreign compeers; and we felt satisfied that it was the fault of our climate: the conditions of light, &c., were unfavourable in this country.

But the enlarged pictures by Mr. Stuart, we consider to be the best we have seen. Equal in all respects to the best of the Continental pictures, they are superior in some points; and had these been exhibited, we should unhesitatingly have claimed the palm for the British department. And yet it is probable that Glasgow is the smokiest town in the United Kingdom. Development printing has been regarded in this country as almost imperative in solar camera operations; but these are by direct sun-printing, and four pictures all equally good were obtained in the day's work which produced those before us. It has been affirmed—we believe we have ourselves endorsed the statement—that perfect definition with direct sun-printing would be impossible without a heliostat; but in this case the mirror was moved entirely by hand.

To what, then, it will naturally be asked, is the great superiority due? We must confess that we cannot fix upon any especial point as the source of this excellence. On another page we give Mr. Stuart's lucid account of his mode of operating. From this and some letters we have had from him on the subject, there does not appear to be anything very unusual in the process or mode of operating. An intelligent use of the solar camera, good formulæ, and careful manipulation appear to have been the sole appliances. The solar camera is placed vertically, instead of horizontally as is customary, and it is fixed in a small room erected for the purpose in a garden in such a position as to secure direct sun-light for as many consecutive hours as possible; and especial pains is taken to secure the camera from shaking. The enlarging lens here was a quarter plate Voightlander. Albumenized paper, excited on a 100-grain silver bath is used, the exposure being from two to three hours; the prints are toned in bath of acetate of soda and gold, and fixed and washed as usual.

The mirror is moved from time to time as soon as any indication of displacement of the image is perceived. To aid in observing, a number of drawing pins are placed at the outset, on the yellow ring forming part of the chromatic fringe of the disc of light, so that any change in the position of the disc is easily seen. By means of a heliostat the mirror might be made to follow the sun with rigid accuracy; but by careful watching, Mr. Stuart has obtained perfect results without this expensive instrument.

We believe that in the pictures before us very much is due to the quality of the negative, which appears to have been perfect for the purpose. Perfect lightning, perfect materials, and perfect manipulation, are imperatively necessary to perfect results, inasmuch as everything is practically examined under a microscope, and defects imperceptible in a small picture are here magnified into monstrous blemishes. Mr. Stuart makes his own collodion, and takes care that for this purpose it yields a perfect, textureless film. It is bromoiodized, and developed with iron; and for this purpose is not intensified in any way. A perfectly sharp small image with a lens of long focus is obtained so as to secure depth of definition; the lens used for the negatives of which we are speaking was a half plate Ross's portrait lens. The image to be enlarged was about 3¼ inches by 2¼ inches, full of detail, and perfectly sharp all over. The lighting appears to have been a combination of side and top light, front light being carefully avoided.

The two prints before us are both busts of gentlemen, one life size, the aperture of the mount being about 21 inches by 16 inches. The other is about two-thirds of life-size, the aperture of mount about 17 inches by 14 inches. Every part of each image is well defined, and wonderfully round well modelled; the texture of the skin is rendered without rigosity, every hair in the beard sharp without wiriness. The figure is well relieved from the background, which is clean, pure, and atmospheric. The tone of the prints is a rich deep neutral tint, or purple black, giving great brilliancy and boldness. The pictures are perfectly untouched, and quite spotless.

We have spoken in terms of unqualified admiration of these pictures, and it affords us much pleasure therefore to add that we have obtained Mr. Stuart's permission to send them to the forthcoming exhibition of the Photographic Society, where many of our readers will have an opportunity of seeing them. We feel certain that our praise will not be considered as undeserved or exaggerated.

Mr. Stuart has been engaged in the construction of an improved solar camera, by which he hopes to be enabled to produce double the number of good prints it is possible to do now in one day. Our readers are promised a description of it as soon as it has been satisfactorily tested.

## PATENT ALBUMENIZED PAPER.

Mr. Sutton has just patented a method of preparing albumenized paper which promises to give very successful results. If the patent had been for a method of dispensing with the use of albumen we should have liked it better; but, as for many purposes, such as stereoscopic and card pictures, requiring the finest possible surface, albumenized paper will continue to be used at present, it is important to be able to secure the hard, fine surface in the greatest perfection, and Mr. Sutton's process gives every hope of the highest success in this direction.

Complaints have been loud and frequent of late years as to the bad quality of much of the photographic paper in the market. Mr. Sutton's process will go far to render the results largely independent of the quality of the paper, inasmuch as he purposes to insulate it, or render it impervious to aqueous solutions, and thus prevent it from having much influence on the character of the print. The paper is to be saturated, previous to albumenizing, with a solution of india-rubber: so that, practically, the image will be formed from chloride of silver and albuminate of silver without the organic matter of the paper playing much part in the matter. We will now allow Mr. Sutton to speak for himself, and quote some extracts from an article in the *Notes*, on this subject:

Everyone who has printed upon albumenized paper, prepared in various ways, and obtained from different manufacturers, will have observed not only a great difference in the amount of glaze obtained with the same albumen upon different kinds of paper, but also a great difference in the vigour and brilliancy of the prints; for according as the albumen sinks more into the paper, so the prints lose in brilliancy and those other good qualities which albumen confers. If, for instance, you use albumen containing no water, you obtain an amount of glaze upon the paper, and vigour in the prints, which is greatest with the Papier Rive, and least with unsized paper. It appears, therefore, that according to the nature of the sizing employed, so the albumen either lies upon the surface of the paper and yields a high glaze and brilliant prints, or sinks into the paper and gives very little glaze and flat inferior prints.

Everyone is agreed as to the truth of these statements, and it is evident that if we wish to manufacture albumenized paper with the highest possible glaze, and to obtain upon it the most vigorous and brilliant prints, we must size the paper with some substance which will prevent the albumen from sinking into it. Our patent consists in employing for this purpose a solution of india-rubber in mineral naphtha; or any other similar waterproofing solution. The mineral naphtha is re-rectified in order to purify it, which renders it absolutely colourless; and the papers are dipped into this solution and hung up to dry. They dry in about five minutes and do not then show any visible trace of the operation to which they have been submitted, their purity of colour and smoothness of surface remaining the same as before, but they have a slight smell, resembling waterproof Mackintosh garments. This smell, however, goes off entirely in the subsequent operations of printing, and the finished print has no smell whatever. As soon as the papers are dry they can be albumenized in the usual way, and rolled; and are then ready for the printer. We have arranged with Messrs. Ordish and Lampray, of 21, Paternoster Row, to manufacture the patent albumenized papers for us, with pure undiluted albumen, and to roll them and send them out with the highest possible finish; and in this state they offer a highly satisfactory and superior appearance. We hope with the next number of this journal to enclose a small sample of our patent paper, in order that every reader may judge for himself, and print upon it if he chooses.

Mr. Sutton then proceeds to describe the method of printing on this paper, which does not materially differ from that generally employed and we need not reproduce it. We will quote one paragraph, however, for the purpose of making a passing comment:

On the morning of the day on which you wish to print, excite the papers by floating them for two minutes upon a 100-grain bath of nitrate of silver, having an acid reaction. Do not excite the papers until the day on which you use them; do not use a weaker bath than 100 grains to the ounce; do not leave the papers more than two minutes upon the bath; and do not use an alkaline bath, or an ammonia-nitrate bath. The reasons are these:—1st. A mixture of albumen and nitrate of silver undergoes gradual decomposition, even in the dark, and papers so prepared and kept long in a sensitive state never yield such fresh, clean prints as those which are used at once, but are liable to discoloured lights and a brown deposit within the fibre of the paper. 2nd. A weak bath is certain to yield inferior prints, because it does not properly coagulate the albumen and fix the albuminate and chloride of silver upon the paper. 3rd. If you float the paper too long upon the bath the paper becomes softened and porous, and some of the chloride of silver is dissolved out. 4th. When the nitrate bath is alkaline, the papers become very quickly discoloured, and turn brown in hot weather, even before they are dry; besides which an alkaline nitrate bath does not coagulate the albumen so well as an acid bath, because alkalies dissolve albumen.

We pass over the use of the term *coagulate*, in reference to the film of dried albumen, in the sense in which it has been generally used by photographers, to describe the formation of the insoluble albuminate of silver; but we should like to know if Mr. Sutton has ascertained by definite experiment that a weak or alkaline bath do not properly form this compound. The fact that a strong bath gives better prints than a weak one is well known, but the reason why is not by any means satisfactorily ascertained. Free nitrate of silver is necessary to the production of good prints; but how much free nitrate, and what is its especial use, is not well understood. In the case of the paper in question the proportion of salt is not stated; but suppose for a moment that ten grains of chloride of sodium to each ounce of albumen be used—and that is a larger proportion than is employed in most commercial samples—speaking in round numbers, a 30-grain bath would be required to convert the chlorine into chloride of silver. The proportion required to combine with the albumen is so inconsiderable as to scarcely affect the calculations: so that we have a bath with an excess of nearly seventy grains per ounce. That a large portion of this is not used in the print will be rendered evident by the quantity which is obtained in washing the print. Then what is the part it plays? We have the conviction that its chief use has been to form the insoluble albuminate of silver rapidly, without soaking the paper much, and so keep the image on the surface and secure brilliancy. The more rapidly an insoluble pellicle of albuminate of silver enclosing or combined with chloride of silver could be formed, and the shorter the necessary time of floating on an aqueous solution the more completely the conditions of brilliancy would be secured. But with Mr. Sutton's patented paper, the image would be kept on the surface, we apprehend, independent of this; and we should have conceived, *à priori*, that one of its chief advantages would probably have been found in the fact that a much weaker silver bath might be used without the sacrifice of any of the advantages usually appertaining to a strong one. We commend this part of the subject to Mr. Sutton's further attention. We now add a few more words from the *Notes:*

We will now point out some of the important advantages which arise from the preliminary treatment of the paper with the india-rubber solution.

In the first place, this treatment renders you independent of of the eccentricities of the paper maker, as regards the mode of sizing which he employs. If the paper is well made and free from spots, it matters but little how it is sized. The sizing which you add yourself would be sufficient even for blotting-paper If for instance, you dip a piece of blotting-paper into the solution of rubber,you can afterwards write upon it exactly as upon common paper, and it takes the albumen beautifully. A great deal has been said about the manufacture of paper and the sizing which should be employed, and it is because the English paper makers do not use the proper sizing that photographers are forced to send to France for their paper, and pay four times as much for an article which is inferior in some other respects. But with the rubber solution, any clean, well-made paper, of close gain and fine surface, will do, provided it does not contain that abominable contamination, ANTI-CHLOR, which ruins everything. We have tried a large number of samples of English paper by different makers, and regret to say that the majority of them are rendered unfit for photographic purposes by the presence of anti-chlor. This shows its baneful effects at once, for the paper containing it turns yellow even before it goes into the pressure frame. Messrs. Hollingworth's paper is free from this contamination, and gives fine prints, but the surface is rather too rough. For the present we shall use the Rive paper made by M. M. Blanchet & Kleber, but hope before long to meet with a better sample of English paper at one-fourth the price.

Another important advantage of the new paper is that it gives finer tones and more vigorous prints than the common paper. Vigour and beauty of colour in an albumenized print depend upon the albuminate of silver and not upon the reduced chloride. If you were to spread the salted albumen upon a glass plate, and when dry excite and print upon it, the colour would at first be a fine rich ruby-red, and this would turn in the toning bath to a superb chesnut-black. So it is with our new paper. The print when taken from the pressure-frame is a rich ruby-red, and it turns to a rich chesnut-black when toned and dried.

## Scientific Gossip.

The Violet Flame of Chlorides—The Action of various Solutions on the Spectrum—Examination of Coloured Glass in the Spectroscope.

Experimentalists who have been in the habit of examining various compounds of metals in the spectroscope, have doubtless employed, when they wish to briug out the coloured bands with greater vividness, the very simple expedient of moistening with hydrochloric acid, the bead left on the platinum loop after ignition. In this manner the strontium and calcium spectra, which are somewhat difficult to obtain well, are brought out with remarkable vividness; and many other spectra are likewise obtained in this manner much more readily than by the ordinary method. It will be as well to warn those of our readers who may have been in the habit of employing this artifice, that the results are sometimes liable to be very anomalous; frequently, a series of other lines, having no connection whatever with the metal under examination, make their appearance. The cause of these is not thoroughly known, although it is certain that they depend in some way on the presence of chlorine. They have been lately investigated by Dr. Gladstone, who has published some very interesting, but at the same time, far from exhaustive notes upon this subject. The violet flame produced by many chlorides, when thrown into a fire, has long been noticed. Nothing, perhaps, in this branch of physical optics, is better known than the fact that common salt produces, under ordinary circumstances, a homogeneous yellow light showing as one, fine, double line in the spectroscope; yet, it is an oft-noticed fact that common salt thrown into the fire gives a blue flame; Dr. Gladstone says that the same thing may be beautifully seen when old ship-timber is burnt. When analysed in the spectroscope this violet light is found to consist of a series of well-defined green, blue, and violet liues arranged in three groups—the first being green, and extending to the fixed line *b;* the second, bluish green, and blue lying on either side of F; and the third, violet stretching from midway between F and G to a little beyond G. It is evident, from what is stated by Dr. Gladstone, that many of the blue lines ascribed to copper, when the chloride is introduced into a flame, are these lines, the origin of which is doubtful, but which are common to many chlorides. Thus the chlorides of copper, platinum, or of gold, if put into a spirit flame, give a violet light resolvable into these bands. Chloride of mercury in the gas flame from a Bunsen's burner, gives this light also. A hydrogen flame is capable of producing it from the chlorides of nickel and cobalt; but it requires the heat of a good fire to obtain it from chemically pure chloride of sodium, potassium, barium, zinc, or iron. Chloride of silver gives doubtful results, and the colour is not obtained from either chloride of calcium, lead, or manganese. The question naturally arises to what is this violet flame due? "Is it," asks Dr. Gladstone, "the chloride itself, in the gaseous form, that emits these rays when heated up to a certain temperature, which differs according to the metal with which the chlorine is combined? or is it the peculiar flame produced by chlorine, when the chloride is decomposed by heat? or does it depend on the combination of the chlorine with the carbon or hydrogen of the combustible?" The latter supposition is negatived by the fact that anhydrous chloride of copper emits these rays equally, whether it be placed in a flame of hydrogen or of pure bisulphide of carbon. It is difficult to accept the second supposition; for though chloride of copper or gold is certainly decomposed in the spirit-lamp flame, chloride of nickel or iron is so likewise, and chloride of mercury is reduced to the subchloride, and yet these last do not exhibit the coloured flame at that temperature. Besides, a stream of chlorine or of hydrochloric acid passed into a flame, never gives the violet light, nor do chlorinated liquids mixed with alcohol and burnt in a spirit lamp. It appears, therefore, most probable that the violet light is caused by the incandescent chloride itself, but there are difficulties in the way of such a supposition. The subject evidently requires further elucidation, which we have no doubt it will soon receive in the hands of the able experimentalist to whom these notes are due.

The action of various coloured bodies on the spectrum has been a subject of examination by many experimenters. In the last number of the *Philosophical Magazine*, Sir David Brewster has published a large number of observations on this subject, which have been noted by him from time to time during many years past. He likewise gives the nomenclature of the 354 lines observed by Fraunhofer, which, in many respects, will be found more useful than the spectrum itself. Glancing over the different liquids which Sir David has examined, several liquids are seen to be applicable to photographic purposes, serving as perfect screens when inclosed in a glass cell, and let into a window; thus an alcoholic solution of alkanet in some thickness, absorbs all the rays more refrangible than D; the same takes place with cochineal. Chromate of ammonia, when tolerably thick, commences to attach the spectrum at the violet end, and advances almost simultaneously over the blue, and gradually up to the yellow; this would, therefore, form an admirable screen. Bichromate of potash, although of an intense yellow colour, is not nearly so good an absorbing medium as chromate of ammonia, as it only attacks the spectrum up to *b*, a line in the green; it is, however, quite available for photographic purposes, as rays far higher than this line are without action on the photographic plate. One of the most remarkable salts is the oxalate of chromium and potash, this has a specific action upon a red ray between A and B, cutting out a sharp and narrow black band, forming a fixed line in all artificial lights, and of great practical value in many optical experiments.

Several pieces of glass have been forwarded to us by correspondents for examination in the spectroscope. J. G. L. forwards three specimens, Nos. 1 and 2, being technically known as dark amber *pot metal*, and No. 3, light ruby flashed glass. No. 1 cuts off from the centre of the blue upwards, and No. 2 obliterates very nearly the same extent of spectrum, but leaves the yellow and red end considerably darker than No. 1. Either of these glasses would answer for the window of a dark room. No. 3 is a beautiful glass in the spectroscope, being perfectly transparent to the rays below D, and cutting off the higher ones very sharply. Were this action perfect, nothing would be superior to this glass for the dark room. Unfortunately, however, it lets a little white light through, which is rendered evident by a very faint continuous spectrum extending right up into the violet. It is more than probable that with two thicknesses of this glass this imperfection would be obviated. A specimen of glass sent by J. W. is of no value whatever, the chemically acting rays passing through it, with only slightly diminished intensity.

## THE LUMINOUS IMPRESSION.

BY J. JACQUEMET, CO-SECRETARY OF THE MARSEILLES PHOTOGRAPHIC SOCIETY.

At the last meeting of the Marseilles Photographic Society, an incident occurred of a very interesting character, which is calculated to throw a new light upon the still mysterious origin of the luminous impression. The following are the circumstances of the case:—I presented to the meeting several negatives taken by the dry collodion process with tannin; some of these had been developed a short time (twenty-four hours) after exposure in the camera, the others after a lapse of about twenty days. The first presented a very remarkable intensity of tone, with very strong contrasts, perhaps somewhat exaggerated: the second, on the contrary, presented only an excessively weak and flat image, in which the portions that ought to have come black—the sky, for example—assumed, after every attempt to strengthen them, only a very pale gray hue, quite unavailable for taking positives from. All the plates having been prepared and exposed under identically similar conditions, there was reason to conclude that the faculty of development in the tannin process becomes weaker by time, and that, consequently, the development ought not to be delayed beyond three or four days; and that it is even more prudent to do it the same day. I remembered, however, that M. Vidal, in his first trials of Major Russell's process, had experienced an opposite result; and he himself, at one of our meetings, developed some tannin plates, which, three months after exposure in the camera, gave very vigorous negatives.

Immediately after my communication was made to the meeting, M. Vidal gave an explanation of this apparent anomaly, which, in the highest degree, excited the attention of the audience. It was as follows:—

"Everything leads to the belief, that the operation of the luminous impression belongs to the class of physical phenomena, and not to that of the chemical; and the experiments, the results of which I now proceed to detail, are a proof of this fact, for if there were a combination or a reduction, even rudimentary, of the iodide of silver, this state would persist, even if it did not increase with time. Now, we perceive that the contrary takes place, and must, therefore, seek another cause. We may, not without some justice, suppose that there is a certain molecular change produced in the parts acted upon by light: still, I rather incline to admit that a certain portion of the actinic rays is absorbed by the film of iodide of silver, which becomes their temporary receptacle.

"Either of these two hypothesis permit an explanation of the fact in question: in the first, the iodide of silver, obeying a general physical law, tends to return to its anterior molecular state, just as forged iron returns, after a time, from its fibrous texture to the granular, or lamelar texture it originally possessed. And in the second hypothesis, the luminous fluid imprisoned, *stored up* in the pores of the collodion, gradually escapes, just as a heated body, if left to itself, gradually loses its caloric.

"This change of condition, or loss, occurs with more or less rapidity, according as the collodion film is more or less protected. Thus a vitreous substance, a varnish more or less dense, guarantees it within certain limits. The plates which became weak after the lapse of twenty days, were preserved only by a feeble quantity of tannin (the ordinary solution of 3 per cent.); mine, on the contrary, which kept well for three months, were covered with a thicker (saturated) solution; such is the reason which explains the assumed contradiction between the two experiments."

It follows, then, from these explanations, that unless, by the aid of certain means, which we have neglected to study, the faculty of development can be retained for a longer or shorter period of time, it must some day disappear completely; and it will be one of the most curious experiments, to place anew in the camera a plate which has already been exposed. I am convinced, by intuition, that the sensibility will not be found altered, and that the second image will appear alone in a very clear and perfect manner. This fact will, therefore, corroborate the opinion now given in the origin of the luminous impression.

## PHOTOGRAPHIC STUDIES.

BY DR. SCHNAUSS.*

### *Examination of Various Formulæ.*

We now proceed to the examination of the processes employed for strengthening negatives. We shall confine ourselves to the study of two out of the numberless suggestions which have been made to effect this object; viz. strengthening negatives by the solution of *bichloride of mercury*, and the superficial change in the negative by

* Continued from p. 392.

*iodide* of silver, with re-development by pyrogallic acid and nitrate of silver.

These two processes of strengthening are not always successful; they sometimes even destroy the negative; but, to be just, we must not always attribute this accident to the process, as we shall see by what follows. The intensifying is not successful, if the negative be not sufficiently vigourous, on account of an unfavourable light, or of a deteriorated collodion, or of an exhausted nitrate of silver bath; but it will yield a good result, if the lack of vigour arises from the collodion, or the bath being too new, or contain too much bromide, or if the developer be too old, and does not possess sufficient strength to completely develop the negative.

The bichloride of mercury acts very differently upon the negative at two different periods. The negative must at least possess sufficient strength, so as not to become white immediately upon the action of the solution of bichloride; otherwise, it will be impossible to obtain sufficient power by the subsequent reaction of the ammonia.

The first reaction of the bichloride upon the negative is a blue-black colouration; if this colour appears to give sufficient vigour, the negative is well washed, and only requires to be dried and varnished. It will become more intense in drying. If there be a trace of hyposulphite of soda on or beneath the collodion film, it is decomposed by the bichloride, and forms an irregular deposit of brown sulphide of mercury, which destroys the picture. The iodide of silver contained in the film will be converted into orange or red iodide of mercury, but always, even after complete washing, the action of the solution of the sublimate is combined with a partial change of the chloride into sub-chloride, which is white and insoluble in water. It must be removed by careful washing. A certain quantity always penetrates the collodion, and injures the lights. By causing it to react a much longer time the black image entirely disappears, being converted partly into chloride of silver, and partly into sub-chloride of mercury. However, the negative is not lost, but it acquires very great strength if perfectly washed, and a dilute solution of hydrosulphate of ammonium be poured on. The black sulphide of mercury formed gives a very dense film, and yields very vigorous copies.

The superficial change of a negative weak in iodide of silver is made with a solution of iodine in the aqueous solution of iodide of potassium. Iodine is too little soluble in water, and its alcoholic solution reacts disadvantageously upon the collodion film. After fixing and *complete* washing, the solution of iodine is poured on and allowed to remain on the proof until the superficial change into iodide of silver is remarked. This operation may be performed in daylight, washing and exposing the negative to the light, so that the newly formed iodide of silver may be acted upon by it. After that we can further strengthen the negative by means of pyrogallic acid with nitrate of silver; this last operation is made in the dark room.

One of the most important questions of the day has been raised by the rage for *carte de visite* portraits; namely, a good gold toning bath for proofs on albumenized paper, which will keep several days at the least. The ordinary gold bath consisting of a solution of *sel d'or*, a combination of hyposulphite of soda with the double chloride of gold and sodium, answers perfectly for copies on ordinary paper, if it be employed before fixing and after the proofs are completely washed; but it is almost without action upon proofs upon albumenized paper, if they are not left in it a very long time. Now we must find a bath, which, beside active chloride of gold, contains another salt which will moderate its rapid action, and yield blue-black tones, for this tone is a happy medium; a bath acting too slowly yields *red-brown* tones; a bath which acts too rapidly, yields *grey* tones. The printing of the positives has also its influence upon these tones; a feeble print from a given negative will acquire a grey tone in the gold bath, while a strong impression will yield the finest blue-black tones.*

The salts usually added to the chloride of gold are the phosphate, citrate, carbonate, and acetate of soda. As to the chloride of gold, we may employ either the double chloride of gold and potassium, or of sodium, if they are *conscientiously* prepared. Some chlorides of gold met with in commerce contain a very large proportion of chloride of sodium; nothing can be done with these. The alkaline gold bath, which contains carbonate of soda, will not keep. The citrate of soda promises well; it is prepared, by adding a little citric acid to the preceding bath. It appears to me that the bath, prepared with *acetate of soda* is the best, as it will keep good from eight to ten days, while it gives constant results, and can be renewed by adding fresh chloride of gold. But it must be left to repose at least a day after it is prepared, else it will act too promptly. The best proportions are,

## ON PICTURES BY WOODWARD'S SOLAR CAMERA, AND HOW TO TAKE THEM.

BY J. STUART.*

I assure you that it gives me great pleasure to acquiesce in the request made on the last night of meeting. The solar camera pictures are now before you, and if you give me your indulgence for a short time I will endeavour to fulfil the other part of the request. The four pictures now before you are not shown as all that can be done or desired, but merely as one day's work with that instrument.

Having, in the course of this season, made a tour to London and the provinces for the special purpose of seeing what progress had been made in the production of enlarged pictures, the conclusion I came to was that pictures by development were, seemingly, the only satisfactory kind that could be produced (in this country at least); and I must say that, to my end, they were not quite agreeable, but if touched up with chalk, or some other medium, they are passable.

For a considerable time previous to this I had a solar camera, which was obtained from Mr. Atkinson, of Liverpool, and, as Mr. Mactear stated to you in his paper, had it placed in working trim, but with a focussing-board with as many joints as a "Blondin." In this state it lay for a considerable time, and from what I had seen on my tour I almost despaired of ever being able to produce prints by the direct action of light. Nevertheless, as it was, I thought that a trial on my part was the best way to proceed in the matter, and that by a little perseverance I might overcome some of the difficulties that lay in the way. The window at which I had the solar camera then placed had a south-west exposure—the best for the purpose I could obtain. In this situation I could only get the sun for five or six hours a day, and that on the longest days in summer. However, the experiments I made convinced me that direct prints could be produced with ease and certainty, but that I should be tied up to a few hours' use of the sun per day did not at all meet my ideas on the subject. Think how provoking it was to have him (the Sun) blazing away all morning and not able to make use of him; and about the time he should be round a cloud to cover him from your view the rest of the day, thus ending a whole morning's work of preparation.

Allowing you to be so fortunate as to have the sun, the most that could be done would be two prints, although by this method I never succeeded in getting more than one. I saw plainly that a window was not the place. Something else must be done: the camera must be placed so as to get the sun at all hours of the day (if he shone at all); and how this was to be done best and cheapest caused me no small

* It should be observed that in Germany, blue-black tones are generally preferred to the brown tones, even for portraits.

* Read before a meeting of the Glasgow Photographic Association, on the 6th ult.

amount of thought. For the mirror thus to catch the sun the camera must be placed on end like a "bear looking for buns." At last I succeeded in patching up a house for it in one corner of the garden, so that there was nothing to intercept the sun ray's from morning till night.

The accompanying photograph, from a window of my dwelling-house, will give the outward appearance; and a drawing of the inside, showing camera and arrangements for the focussing-screen, will give you an idea of the apparatus by which the four photographs now on the walls were taken.

I will give you as briefly as possible the *modus operandi*; and if any gentleman, when I have finished, does not quite understand it, I shall be most happy to answer any question on the subject. For the benefit of those who have not seen the solar camera I have brought it here with me to-night, so that any explanation regarding its construction will be unnecessary on my part. It is my opinion that thirty or forty shillings more night be well laid out upon it to render it more efficient.

To produce the negative, make up a new silver bath of pure nitrate of silver, 30 grains to the ounce. See that you have collodion giving you clear pictures without crapy lines, as defects in the collodion will show in the large pictures: spots not visible before will show like buttons, which might do very well in the right place, but not on the face. Everything in the dark room must be in the best order. Look to the camera and dark slide, and see that they are clean, as, if everything does not work well, you will be sure to raise dust. In short, do everything in your power to avoid raising dust; for, if you do, your faults will be magnified a hundred-fold.

The glass must be of the best colourless patent plate, and as thin as possible. Do not give the plates to a boy to clean, but do it yourself. As they are much softer than other glass, they should not be cleaned in the dark room; only wipe them with a wash-leather, coat, and sensitize in the usual manner. Do not blow on the plate before coating, and after coating do not hold the face up till it sets: blowing gives little transparent spots, and holding the collodion side up attracts dust, which transforms itself into comets.

The lens should be what is termed a full-plate (nine or ten inches focus), with as small a top as possible, without making the sitting too long. The lens used by me for this purpose was a Ross's half-plate. The model should be placed in a good light, so that he may stand out round and bold.

Having thus arranged your model, place your camera at such a distance as will take in all that you want, on a space of, say, $3\frac{1}{4}$ by $2\frac{1}{4}$ inches: have it sharp all over, and give it such an exposure as will bring out all the detail. Over-exposure tends to reduce the high-lights of nose and brow, which, in a life-size, should never be wanting. I cannot help thinking a common error with photographers is supposing that *over-exposure gives density*. The proper timing of the negative is a very nice matter.

The developing may now be done with sulphate of iron 15 grains, spirits of wine 15 drops, glacial acetic acid 15 drops. Pour over the plate in the usual manner till all the details are up, wash, fix, and wash, and the negative is complete. Dry at once, to prevent dust adhering to the plate. The negative must not be varnished.

Now dust out your solar camera, polish up the mirror, rub up the condenser and the enlarging lens, which should be the best $4\frac{1}{2}$-inch focal lens you can get: the one I use is a Voigtlander's. You are now ready to place the negative in the groove prepared for it in the camera. Before preparing the paper, we will arrange the focussing-screen, which must be placed in such a position as will give the image the size wanted. Having moved it up and down, and decided on the place, we will say that we have obtained the rough focus (till we get the paper ready there is no need of doing more). The mode of preparing the paper, and the paper itself, are just the same as used for all my prints.

Sensitising Bath.

| | |
|---|---|
| Nitrate of silver ... ... ... | 100 grains |
| Pump water ... ... ... ... | 1 ounce. |

Make the bath slightly alkaline with ammonia: keep it always so, as it makes the paper more sensitive, giving at the same time a richer tone to the prints. Some are quite astonished when I tell them that my bath always keeps as clear as spring water, and that too with every kind of paper.

Having floated the paper—say, if Saxe, three, and if Rive, five minutes—on the above silver bath, pit it up to dry above a hot-water pan, covered of course, allowing it afterwards to cool: it will then be ready for pinning down on the stretching board—drawing-pins will do for this purpose. Having stretched it (the paper), cover it over with a sheet of blotting-paper, and then with a board. I presume, here, that your solar camera and sensitizing house are two distinct places.

If the sun be now shining take it to the camera, place the board on the focussing-screen, in such a position that the enlarged image will fall in its right place. This being done, you will require to get the mirror in such a position as will bring its focus right on the centre of the enlarging lens. Having done so, you will see on the focussing screen a coloured disc formed by the condenser: stick, without loss of time, some drawing pins, here and there, all round the yellow ring, and in this way you will have a guide for the shifting of the mirror.

You must now have a piece of orange-coloured glass the size of the negative, which place over the negative in the camera. Having done so, lift off the board and blotting-paper, leaving the sensitized sheet exposed to the image.

Now, with the rack-work of the camera, focus the image very nicely on the paper. When you have obtained the best focus, fix up the negative and frame which holds it, so that it will not move in the least, as the wind on the mirror is very apt to make it do, and which it might do just when the picture is all but finished. Make up your mind, if you wish a good picture, to be now a prisoner for two or three hours.

Take the yellow glass off the negative, watch the yellow disc, to keep it right on the drawing pins, and, if all goes well, in two hours and a-half you will have a beautiful enlarged print, far exceeding those now on the wall before you. I may mention that the depth of printing is just about the same as if it were a print from a negative by contact. The print is now washed and toned in the usual manner with acetate of soda.

Toning Bath.

| | |
|---|---|
| Acetate of soda ... . ... | 7 ounces |
| Water (distilled)... ... ... | 80 ,, |
| Chloride of gold ... ... ... | 15 grains. |

One hour before using add 80 ounces more water and $7\frac{1}{2}$ grains more chloride of gold.

Fixing Bath.

| | |
|---|---|
| Hyposulphite of soda ... ... | 6 ounces |
| Water ... ... ... ... | 20 ,, |

With regard to the apparatus I feel satisfied with it, and I think that something cheaper and better may yet be obtained; in fact, for such an end I have been labouring for some time past, and, with your leave, at no far distant day will introduce to your notice "Stuart's solar camera," which is already a fact—not an idea.

## TONING WITHOUT GOLD.

BY H. SCHNATZ.*

The toning of albumen prints has been performed up to the present time by the alkaline gold bath alone. The great expense of gold induced me to commence a course of experiments with such salts of which the effects are similar to those of the gold salts. From among the numerous salts which I have consequently examined, a solution of chloride

* From the *Photographische Archiv.*

of platinum in connection with acetate of soda is the only one which has yielded results of a superior nature. The tones which have been produced by such a mixture, are scarcely to be distinguished from prints toned with gold. Chloride of platinum is two-thirds cheaper than chloride of gold; so that for those who have to tone a large quantity of albumen prints this circumstance will be worthy of some consideration. The composition of the bath is as follows:—2 parts of pure acetate of soda; 64 parts of distilled water; 1 part of a strong solution of chloride of platinum (such as is sold as a chemical reagent by the dealers in pure chemicals). The bath can be used as soon as the acetate of soda is dissolved.

The effect of toning is altogether similar to that produced by the gold bath.

The pictures have to be printed until the shadows begin to be bronzed. Before the prints are introduced into the platinum bath they must be thoroughly washed in water in order to remove the undecomposed nitrate of silver. They are left in the platinum until they have assumed a deep blue-black tone; and, before they are fixed, they are allowed to remain in pure water from half an hour to an hour. The fixing bath consists of

1 part of carbonate of soda,
8 parts of hyposulphite of soda, and
80 parts of rain water.

The prints are kept in this bath until they have become quite clear and transparent, a circumstance which will take place in about a quarter of an hour; they are then carefully washed in frequent changes of water. This bath must not be used many times in succession.

## A SHORT LESSON IN CHEMISTRY.—No. 5.*

THE property, which all bodies possess, of combining chemically in certain definite proportions or weights, being universal—without exception—it is denominated the *law of chemical equivalents*. In addition to this beautiful law we have another similar one, and equally beautiful in reference to the volume of those bodies, which either exist in the gaseous state, or may be converted into it. The relation that exists between the combining volumes of gases is of the simplest nature, being in the proportion of volume to volume, or of multiples of a volume of one substance, to a single volume of another. There is a connection, too, between the combining weight of a gas and its specific gravity, as also between the combining volume. Thus an atom, or one combining proportion of chlorine, is 35½ times heavier than an atom, etc., of hydrogen; in like manner, a volume of chlorine is found to be equal to a volume of hydrogen. Thus then, these two bodies combine in the ratio of pint to pint, quart to quart, etc., so as to form gaseous hydro-chloric acid. Again, an atom, or one combining proportion of oxygen, is sixteen times heavier than hydrogen, so that in the combination of atoms, two volumes of hydrogen combine with one volume of oxygen in the formation of the vapour of water. An atom of nitrogen is 14 times heavier than an atom of hydrogen, hence their combining volumes are equal; but since two volumes of hydrogen are found to combine with one volume of oxygen, it is inferred that both chlorine and nitrogen will combine with oxygen in the same ratio of double volumes.

Hypochlorous acid and protoxide of nitrogen, therefore, consist by weight respectively of equal atoms; but by volume of two volumes of chlorine to one of oxygen, to form the former, and of two volumes of nitrogen and one volume of oxygen to form the latter. And since this is so, that is, since the combining proportion of chlorine is in double volumes, and the combining proportion of hydrogen is also in double volumes, then hydrochloric acid will be formed of two volumes of chlorine and two volumes of hydrogen; the specific gravity, therefore, of the resulting compound, will indicate its combining volume; for in the latter case, if the specific gravity of the resulting gas be one-fourth of the sum of the four specific gravities combined, the combining proportion will be four volumes; if it be one-third, it will be three volumes; if one half, it will be two volumes. Since the specific gravity of the compound can never be greater than the sum of the components engaged, the combination by volume can never be greater than the sum of the volumes; it is, however, very frequently less.

*Chemical Notation.*—In order to facilitate the preparation of formulas, or the analyses of formulas, a system of notation has been adopted by chemists. The capital letters of the Roman type, representing the initials of the names of each elementary substance, are used for this purpose as far as they extend; after they become exhausted the first two letters are adopted. The symbols for compounds are the combination of the component symbols either by the sign +, by a comma, or simply by the apposition of the characteristics. The multiples of elements may be placed either before the symbol or after it, as - 3 O, or $O^3$, which signifies in either case three equivalents of oxygen. The latter form is preferable, and may be read in the formulas O sub 2, by which means the expression is quite distinguished from $O^2$, which is a mathematical form and read O to the second (power). Such compounds as nitrate of potassa may be written and expressed either $KO+NO^5$ or $KO, NO^5$. Acetic acid is written; $C^4 H^3 O^3$, and acetate of soda is therefore, $NaO, C^4H^3O^3$. The following table exhibits the combining proportions by weight and by volume, the specific gravity, and the symbols of the elementary bodies now in use, both in this country and in Europe.

## IODO-NITRATE OF SILVER.—PIN-HOLES CAUSED BY IT.

BY CHAS. WALDACK.*

Photographers all know that if a collodionized plate is put into a simple solution of nitrate of silver in water, the iodide of silver which is formed in the film will, in a few minutes, be all dissolved. It is for this reason that a bath has to be iodized before being used, and this is done by adding to it a few grains of iodide of potassium previously dissolved in a little water.

By dissolving iodide of silver in a solution of nitrate of silver, a new compound or double salt is formed which is called iodo-nitrate of silver. This salt is soluble in a solution of nitrate of silver, and its solubility is in proportion to the strength of the nitrate of silver solution and its temperature. It is insoluble in water by which when in solution it is decomposed in nitrate of silver and iodide of silver, which last compound is precipitated.

Iodo-nitrate of silver can be obtained in crystalline needles. For this, dissolve in a warm or boiling 160-grain nitrate of silver solution as much freshly precipitated iodide of silver as it will take up; let the excess of iodide settle for a few minutes, and pour the clear liquid into a porcelain dish. In cooling a small quantity of iodo-nitrate of silver will crystallize.

Another way to illustrate the crystallization of iodo-nitrate of silver is, to sensitize a collodion plate and allow it to dry. The nitrate of silver on the surface, concentrating by evaporation, will dissolve all the iodide of silver which is in the film. Iodo-nitrate of silver is thus formed, which will crystallize. These crystals will stand a washing with distilled water, and will only be decomposed on the surface, which will be covered with yellow iodide of silver.

Iodo-nitrate of silver may crystallize out of an ordinary silver solution which is saturated with it. This happens:

1. When, by continued use, the solution loses its strength and, consequently, its power, retaining the same amount of iodo-nitrate of silver in solution.

2. By a reduction in the temperature.

In both cases the salt crystallizes in needles on the sides of the bath and on the plate while it is being coated. When this happens the plate, after fixing, will be found full of holes. The remedy for such a bath is very simple:—Decompose a part of the iodo-nitrate by the addition of a few ounces of water; then filter, to separate the precipitated iodide of silver, and to the clear liquid add a quantity of nitrate of silver corresponding to the quantity of water added previously. For instance, if the bath be 40 grains to the ounce, and you have added 4 ounces of water to it, you will have to add 4 times 40 grains, or 160 grains of nitrate of silver to the filtered solution.

If you only perceive the condition of your bath during the business of the day, and you have no leisure to apply the remedy given above, you can avoid the pin-holes by keeping your plate in motion while it is being coated.

## HOW TO MAKE THE NITRATE BATH.

BY CHARLES A. SEELY, M.A.†

Nature teaches us in all her operations that the easiest way to do anything is always the best way. The more we study natural phenomena, the more we are impressed with the simplicity of the relations of causes and effects.

Also in the operations of the arts the easiest way is the best. Our progress in arts consists mainly in eliminating our first redundancies of false motions and other crudities. Witness the labour of the tyro artist who grasps his pencil, or his violin bow, as if it were a crowbar, and the grace of the adept, who without an effort enchants the eye or the ear. Witness the booby photographer in fearful struggle at the dirt on a glass plate, and our friend Kuhns who touches the plate so gently, and at once presents it clean to the most fastidious. Photographers, believe me, it is the living truth that you are wasting much of the precious vitality of soul and body in useless labour. The shortest road between two points is a straight line. If you have an object in view, the quickest, surest, safest, best way, is to go right straight towards it. Of course I know that to determine the straight road requires intelligence, but I also know that most men have enough of that for ordinary emergencies, if they will only use it—there's the rub.

Our art is full of illustrations of the above sentiments. I take only one, viz., the making of the nitrate bath.

There are two ways of making the nitrate bath; these I will designate as the process of Tippette, and the process of Grosskoff.

*Tippette's Process.*—Tippette is a neat, polite, precise little gent, whose ancestors lived in France. He does all things elegantly, with precision and a grand flourish. He measures water to the fraction of a drop, a grain of silver in variance from his formula (which he purchased by the way from the celebrated Reynard of Paris) would extinguish all hopes of success. This is the formula:—

| | |
|---|---|
| Distilled water ... ... ... | $10\frac{1}{4}$ ozs. |
| Nitrate of silver ... ... ... | 1 oz. 3 grs. |
| Alcohol ... ... ... | 2 drops |
| Iodide of silver ... ... ... | 3 grs. |

Where Tippette prides himself is in the preparation of the iodide of silver. I have often pumped him on the subject, and succeeded in eliciting the fact that he gets his iodide out of iodide of calcium, and uses a quart of water in washing every grain; but although thus much is very important, he still holds back his grand secret. I am persuaded, however, that it pertains to the manner and amount of exposure to light of his purified iodide of silver before he dissolves in the bath, and a certain manipulation by which there shall be finally no excess or deficiency of iodide in the bath. Also the quality of the alcohol is of the greatest moment; it is made expressly for him, and is always tested before use. The alcohol is distilled from the fermented juice of the Sorgho. But, I regret to say, he is unwilling to let its strength be known; he only asserts it is not 95. I am unable to give Tippette's process in all its details for lack of information, and I confess it if I understood it as perfectly as he does himself, I doubt if I could spare time and space enough to do it full justice. The public are, however, able from the hasty outline to form some notion of the nature and intent of the process. I only add that friend Tippette is not invariably successful. He has trouble in procuring the suitable materials, and he sometimes fails in their compounding. Thus he has told me he has been in a fog a whole day, suspecting his iodide of silver, before he discovered that his alcohol varied three per cent. from his standard. My friend is an enthusiast, and says he is content if he produces one *chef d'œuvre* in a year.

*Grosskoff's Process.*—The other process is that of Mr. Grosskoff. of philosophical German ancestry, the original German element under our bracing climate has assumed a practical cast. Grosskoff is not greatly esteemed among strangers, for to them he appears somewhat careless and lazy; he seems to do nothing with head or hand. Yet those who know him say he accomplishes a great deal by virtue of taking short roads to his destination, never wasting time in false motions, the grand flourish, &c. To make a two quart nitrate bath he proceeds thus:—He puts his two quart bottle under the tap and nearly fills it with the pure croton. He places the bottle of water on the table, and then chucks in three ounces of silver. Then he takes a little pinch of iodide of ammonium, or cadmium, or pulverized iodide of potassium, whichever is most convenient, and pops that in. He gets his filter paper, funnel and bottle, convenient on the table, now and then giving his silver solution a little tip or turn around (not a shake) so as to get the crystals dis-

* From *Humphrey's Journal*, p. 174.
† *American Journal of Photography.*

solved at the bottom of the water. When the filter apparatus is ready, he corks up the silver bottle, and gives it a good shake up and down, and then the contents go through the filter, and the bath is ready for use. All this he would do about as fast as I have been writing it. I have talked with Grosskoff about his harum scarum way of working, and I find he defends every movement he makes, giving reasons which he thinks are scientific. His reasons are ingenious to say the least; for example, he says that in the concentrated solution of silver quietly formed at the bottom of the water the iodide of silver at once dissolves, and on shaking, the silver solution is so diluted with the water above that the excess of iodide precipitates, *carrying with it all the impurity of the water and of the silver, &c.*; he believes he could make a good working bath out of dish water.

## A SHORT LESSON IN PHOTOGRAPHY.—No. 6.*

The fixing of a photographic picture on collodion, or on any other transparent medium suffused on glass, consists in removing the undecomposed iodide and bromide of silver together with the free nitrate of silver, the nitrate of cadmium, of potassium, of sodium, of ammonium, &c., from the film, before it is exposed to the light; for if these were not removed they would, when so exposed, be acted upon uniformly, and become gradually and uniformly decomposed and blackened.

Fortunately means have been discovered of dissolving the yellow of cream-coloured iodide and bromide of silver, whilst, at the same time, no injury is done to the picture, that is, to those iodized and bromized parts that have undergone the actinic influence and the consequent reductions on the actinized film. The remaining salts, in or on the film, can be removed afterwards with the dissolved iodide and bromide by a thorough washing. The solvents of the iodide and bromide of silver are *cyanide of potassium* and *hyposulphite of soda*. These are not the only solvents of the salts of silver; but they are those which photographers invariably employ. Both of them in a concentrated form act partially upon the actinized and reduced parts, and especially so whilst these parts are still fresh, moist, and just developed; and they would no doubt in a short time totally destroy the picture, if they were not in like manner removed by washing with the rest of the unnecessary salts. Hence you see the necessity of *fixing just enough*, that is, of removing all the yellow or cream-coloured substance from the collodion and no more, then of *washing the collodionized surface immediately and thoroughly*. As soon as this operation is performed, the picture can be examined by the diffused light of day, and will be designated either a negative or a positive according to the characteristics which it possesses. If, when placed on a piece of black velvet or black cloth, it exhibits a pleasing, bright, distinct—although inverted—picture of the original with a proper gradation from white to black, and hence, as we say, endowed with the natural middle tones as well as the high lights and shades, all in their places, the picture is then called a *positive*, an ambrotype if on glass, a melainotype if on prepared plates of iron. On the contrary, if, when so viewed through a film of mica or of semi-transparent glass, or of a hazy atmosphere; or, if viewed by looking through the glass, it exhibits deep blacks where the lights ought to be, transparent parts where the blacks ought to be, and grey or foggy parts for the intermediate tints; such a picture will be pronounced a *negative*.

*Positives on glass.*—Besides the positive just mentioned, viewed by reflected light, we have another form of positive, in which there is no lateral inversion of the objects, and which exhibits in every sense of the word a true picture of the reality. Such a positive is recognised in the transparent glass stereographs. These two kinds of positives I will now teach you how to take; and firstly, let us commence with the melainotype, which is the simplest and easiest picture in photography; and let our aim be to take a portrait, and furthermore to take a portrait that shall be an *agreeable picture*. Now all our senses are gratified with contrast; meat without salt, fish without sauce, coffee without sugar, are insipid—*disagreeable;* the gnawing of a mouse, the picking of the teeth with a quill, the croaking of a bull-frog, the waste stream-jets from a flour mill during the livelong night, and the smacking of the lips by lady gum-chewers—these are *disagreeable* operations, discordant sounds, offensive to the sensorum—because there is no contrast; brick houses built in contiguity, without the vine or the trellised rose, are the dull habitations of moles—a cloudless sky, a treeless farm, and a dreadfully plain quakeress, are not to my fancy—there is too much sameness about them—too little contrast. Feed a rabbit with cabbage, a horse with oats, brother Jonathan with pumpkin pie, or brother John with beef steak for three continuous weeks—they will all die for want of contrast. What has all this to do with a photograph? you ask; a great deal, I say. To be brief, a photographic portrait must be endowed with a proper and tempered degree of light and shade between the different parts of the subject itself and between the subject and its surroundings; and this difference between the lights and shades depends upon the material and colour of the dress and background and their artistic arrangement among themselves, as well as on the appropriate admission of light. Whilst, on the one hand, it is offensive to the sight to make too much uniformity in, or too little difference between the lights and shades, it is, on the other hand, equally shocking to a cultivated taste to make too great a contrast, and especially in photography, where we have only two colours, so to speak, that is, black and white, to deal with Here comes a soldier; let him be the subject of our lesson. His uniform is blue, his cap is blue, and he looks rather blue! In this case it will not look well in the photograph to have a blue background—the picture will be altogether too monotonous, too uniform, in fact, *too blue*. Take away, then, the background, and substitute in its place a white one. Besides this, our soldier is made up of uniform, mathematical lines—his legs are two parallel lines—his arms ditto—from hip to hip and from shoulder to shoulder, two lines intersecting the former at right angles—whilst the head and neck is a ninepin superposed on the latter line—there is no contrast here between these lines and the liny background—it is one flat uniform, liny surface. But, what's to be done? Why, make something crooked; put into the view the poker, tongs, fire-shovel, a skeleton, a panther, a dismantled cannon, the quartermaster's gridiron, or a lady's hoop, and twist up your subject into some contorted shape, by which nature may be better represented, and art and taste satisfied. But this is not all—your materials, the paraphernalia of attire, of accessories, of background, may all be arranged in accordance with a cultivated mind and the requirements of art, and yet you will fail to obtain a good photograph if your light is not admitted in conformity with optical principles and with a due regard to the position of light and shade; in addition to these observances, the light itself must not be too vivid, in order to avoid a too intense contrast of light and shade.

Thus, then, we have two important points to observe, to attain to, in reference to light: To introduce the light on the sitter in the right direction, and to introduce this light so softened or diminished in intensity as to render the transition from the illumined parts to the shaded parts almost imperceptible. If light be admitted perpendicular to any surface, as, for instance, on the moon, or on the face, the photograph of such an object will be flat, monotonous, and devoid of contrast—mount Tycho in one case and a respectably prominent nose in the other will be flattened down into a ring and radiating lines in the former, and a figure of eight suspended on a wire in the latter photograph.

Furthermore, when the light falls from above, perpendicular to the head, the shadows beneath the eyebrows, the nose, the chin, or any other protuberance, will become

* From *Humphrey's Journal.*

distinct and offensive; a similar phenomenon will occur if the light is entirely on one side; that side will be illumined, the other will be dark. It is very evident that a single light, that is, light in one direction will, if intense, always produce intense shadows; a single light, therefore, is not suitable for taking a good photograph. By a proper arrangement, however, of screens, reflections may be obtained, by which the deep shadows can be avoided.

I find this lesson is growing somewhat lengthy, and will consequently resume the subject in my next lesson.

## Correspondence.

### MR. ASSER'S PROCESS OF PHOTOGRAPHY.

Mr. Editor,—Having seen some of the recent numbers of your esteemed journal, I read therein with interest several articles respecting Photolithography or Photoziucography, and am much pleased to observe that the parties engaged in that discussion all agree in admitting the priority of my invention of the transfer-process therein alluded to; a fact which is incontestable, as not only the catalogues of the Paris Exhibition in the year 1859 (published in the middle of April of that year), containing the words quoted in your Journal; but it is also proved beyond doubt, by my having taken out patents, both in France and Belgium, in the month of January, 1859.

The priority of my invention being thus generally acknowledged, there would be no occasion for me to interfere in the controversy now going on, were it not that the following assertion occurs in your number 219 (14th Nov., 1862):

"Mr. Asser patented his process in this country, in the year 1860, but we have not heard that it has ever been brought into extensive practical use,"

—which induces me to appeal against the inaccuracy of this representation, for I can assure you most positively that I have never up to the present time, discontinued my experiments, which had been commenced long before I gave publicity to my invention; but I can also inform you that my said process has long since been successfully applied to every description of photographic objects, by the eminent lithographic printers Messrs. Simonau et Toovey, of Brussels, the present patentees under my Belgian privilege. In addition to which I may state that at the last "Exposition des arts industrielles," held at Brussels in the year 1861, the jury awarded a medal to my process *(vide Le Moniteur Belge*, 5 Jan., 1862, No. 5). Besides which medal, another *(medaille d'excellence)* was adjudged to the production of Messrs. Simonau and Toovey, both in chromo and photolithographies *(pour leurs impressions chromo et photolithographiques)*.

In consequence of the said Exhibition, the Directors of the Edinburgh Museum of Industry by a very flattering letter, requested to have copies of photolithographic productions for their establishment, which request was accordingly complied with. Consequently I have never, for a moment entertained the idea of renouncing my right to avail, at the proper season, of my British patent; and seems by the articles referred to, that the results of my said process are not generally known in the United Kingdom; it is my intention shortly to afford to those who take an interest in the matter, an opportunity of becoming acquainted with some of the results obtained by my said process.

By inserting the present letter in an early number of your esteemed journal, you will confer an obligation on your obedient servant, E. T. Asser.

*Amsterdam, 7th Dec.*, 1862.

[It affords us much pleasure to learn that Mr. Asser's process is successfully worked on the continent; our remarks had chief reference to this country. We believe his priority in applying the principal of the transfer has never been denied, but we fear that the date of his patent in this country would be too late to secure him any exclusive rights; as, if we remember rightly, both the processes of Col. James and Mr. Osborne were published in this country before the date of his patent. It will give us pleasure to see some of his results, and we take this opportunity of inviting him to send some to the forthcoming Photographic Exhibition in connection with the Photographic Society.—Ed.]

### CALCIO-CHLORIDE OF GOLD.

Sir,—Having heard a good account of the results from toning with calcio-chloride of gold, as manufactured by Messrs. Bailey and Son, of Wolverhampton, it would, no doubt, be interesting to many of your readers beside myself, who are not practical chemists, to know the effects that chloride of calcium and hypo-chloride of lime have on the ordinary solution of gold. If the solution of calcio-chloride really is permanent after having been used for toning paper prints, it will be a great boon to amateurs who only print a little now and then. I have for some time acted on the inventor's advice of making my own collodion, but cannot see any reason why I should not make my own gold toning solution also. Even granting that it can be bought as cheap, there is a charm about making it oneself—there is a secret satisfaction of knowing it is genuine; you take no other person's word for it, but know exactly how many grains of pure gold your solution contains. I have, for some time, been in the habit of dissolving standard gold in *aqua regia*, and just neutralizing a small quantity with carbonate of soda as required, of course using up each time as closely as possible; succeeding tolerably well beyond the inconvenience of being obliged to have as many prints as would take up the gold, or waste any that might spare; nor is it very evident to any amateur photographer that, if these promises can be realized, it will be both a great saving and convenience; and as there are doubtless many besides the writer who prefer to be independent and make their own, I have made free to ask you to explain the *rationale* of the process, and what precautions are to be used in preparing it. Of course a *very* acid solution of gold like mine must be, in a great measure, neutralised before adding the calcium and lime; which is the best method for so doing? Is the chloride of calcium alkaline, or the hypochlorite, or both? What would be the effect of adding too much or too little of either ingredient? Can you refer me to any full description of the properties of each substance? And lastly, can you recommend a photographer to a good "common-place book" for notes? Yours, &c. Carbon.

[The double salt of gold and calcium has received but little attention; but some curious and interesting facts, in reference to thiscombination as a toning agent, have transpired within this last year or two, the rationale of which are not well understood. The hypochlorite of lime has a decidedly alkaline reaction; but a solution of chloride of gold and hypochlorite of lime, quite neutral to test paper, retains its toning properties for months. In the process of Mr. Lacy, which we published a short time ago, it was necessary to keep, the solution some weeks to get the best results. We shall publish, in our next, a process of preparing a toning solution of this kind from metallic gold, which we have recently received from a photographer in France, from whom we learn that it is almost universally used by Parisian photographers. There is no need, however, for amateurs to waste their toning solutions. We keep ours in hand for months, as we recently explained, readily reviving its toning powers when they become inactive. For a common-place book, some of those issued by Letts will probably be most useful—Ed.]

## Photographic Notes and Queries.

### The Morphine Dry Process.

Dear Sir,—Since writing to you last week, I have carried out an experiment which I have had in view some little time, and as it appears to me to be worthy of note, I have sent you this.

I have noticed that I never got an over-exposed plate by the morphine dry process, and this led me to expose one half of a dry stereo plate 1¼ minutes, and the other half 30 minutes, same size stops, to the same view at the same time, viz 3 o'clock p.m., sunshine, I developed it without any fog or solarization into two good printing negatives, although they of course would not match to mount together, the one being denser than the other, but marked by *no* fog. I have to-day done the same with another dry plate with the *same* result. This is, I believe, a curious and most important feature in this process, and even at the extreme exposure I tried, the limitation of time was not reached.—I am, dear sir, yours faithfully,

W. Bartholomew.

## Talk in the Studio.

Diorama and Photography.—At the last meeting of the Glasgow Photographic Association, held on the 4th, a number of transparent photographs were exhibited in combination with the marvellous changes and beautiful natural effects obtained in exhibiting dioramic scenery. Dr. Taylor, to whom, in conjunction with Mr. McNab, this application of the art is due, read an interesting paper descriptive of the arrangements and of the principle upon which the effects were produced, which we hope shortly to place before our readers. In January a tea party and conversazione will be held in place of the usual monthly meeting for business.

"Spirit Photographs."—A correspondent sends us the following clipping from a provincial paper. We presume it is a *canard*, founded on the fact that the ghost of a former image has been developed in company with the portrait of a sitter. "Our American friends, who claim to be a-head of us in many things, have certainly distanced us completely in the practice of spiritualism and photography. The good people of Boston can not only call up the spirits of their departed friends, and hold conversation with them—through a suitable 'medium,' of course—but they can *take the portraits of the spirits!* The operation requires to be performed by a medium who combines a spiritual nature with a competent knowledge of photography, and Mr. William H. Mumler, of the city of Boston, seems to be the only person possessing those qualities in the necessary degree, who has yet become known to the fame. This lucky individual, who seems to be in a fair way to make a fortune out of the spirits, gives the following account of his discovery:—'A few Sundays since, he being alone in the photographic saloon of Mrs. Stuart, 251, Washington Street, trying some new chemicals, and amusing himself by taking a picture of himself, which, when produced, to his great astonishment and wonder, there was on the plate, not alone a picture of himself, as he supposed, but also a picture of a young woman sitting in a chair that stood by his side. He said that, while standing for his picture, he felt a peculiar sensation and a tremulous motion in his right arm, and afterwards felt very much exhausted. This was all he experienced that was unusual. While looking upon the strange phenomenon—the picture of two persons upon the plate instead of one—the thought and conviction flashed upon his mind, *this is the picture of a spirit!* and in it he recognised the likeness of his deceased cousin, which is also said to be correct by all those who knew her.' Since this discovery has been made, a great many bereaved relatives have been furnished with pictures of the dead, taken in groups with those of living sitters, 'the picture of the spirit being fainter and less distinct than that of the one who sits.' The Boston paper, from which we take the above extract, assures us that the most searching investigations have been made, with the view of finding out any deception, but without success! After this, the claims of the Boston folks to be considered an 'advanced people' will hardly be disputed."

Photography in America.—A letter recently received from Professor E. Emerson, who was suddenly recalled to the States by a severe domestic bereavement, puts us in possession of some items of American photographic intelligence. In the first place, we are desired to place on record that it is to Mr. Henry T. Anthony, of the well known firm of E. & H. T. Anthony, photographers are indebted for the discovery of the value of ammonia fumes in printing on albumenized paper. We willingly make this announcement in deference to the wish, and means of information, of Professor Emerson, who communicated the process to us in confidence. We believe, however, that there are other claimants in America for the originating of the idea. We learn also that much interest was felt by the American Photographic Society in various illustrations of British photography Professor Emerson took back with him. Amongst these were some fine panoramic prints by Sutton's panoramic lens; a small model of the lens, &c., which was presented by Mr. Ross to the Society and was an object of much interest and curiosity; several fine views by Mr. Mayland, of Cambridge, illustrating the working of Dallmeyer's triple achromatic lens; several of Rejlander's charming studies; and by Ross's Card lens, No. 3, were also exhibited and admired. We further learn with pleasure that steps are in progress for establishing a Photographic society in Philadelphia.

## To Correspondents.

Pip.—A knowledge of chemistry will aid you very considerably in your photographic operations. The only distinct work which treats of the chemistry of photography is "Hardwich's Manual." You will find a mass of chemical information bearing upon photography scattered through the pages of the Photographic News, from the commencement to the present time. An elementary work on chemistry generally will be useful to you. "Wilson's Chemistry," published in "Chamber's Educational Course," is a good book for beginners. But for general photographic chemistry, you cannot do better than get the volumes of the News, or, at least, such of them as are in print.

Old Subscriber.—We do not know of any mordant that will fix Indian ink, and make it washable. There are, however, many modes of obtaining a fast colour by using other materials. You will find full information on such subjects in "O'Neill's Dictionary of Dyeing and Calico Printing." We cannot tell you the prices of yellow glass; we believe it varies from about one shilling to two shillings a square foot.

S. C.—We see no advantage of any kind in the use of blue glass for the studio. White glass admits just as much actinic light as blue glass, without the disagreeable effect and sensation of gloominess present when blue glass is used. You will find an article on the "Glass Room" in our Year Book, now in the press.

J. H. W.—We have not much faith in any method of reviving faded photographs. We fear there is no method of efficiently getting rid of the colour on your slides tinted with sulphate of copper.

Gillard.—We believe most of the makers of first-class cameras, &c., such as Meagher, Hare, and many others, make table-camera stands. You will find something more about Mr. Bartholomew's process in the present number.

A Novice.—The best aspect for the sitter to face is the north, because it is the most steady light, having the least variability. In a well-arranged glass room you may vary the position somewhat to suit circumstances; a little inclination to north-east or north-west will not do any harm, but unless you happen to have an open space of light from one of those quarters, we don't see any advantage to be gained from either. See an article on the subject in our Year Book for 1863.

G. F. L.—Pure gutta-percha may be used for the silver bath without risk. The chief difficulty is to know when you have got pure gutta-percha. For that reason many photographers avoid its use for silver solutions; for washing-trays, hyposulphite solutions, &c., it may be used without any disadvantage.

S. M.—We believe there is no especial difficulty as to the admission of photographic apparatus into Holland. The quaint old architecture of many of the towns is effective in photographs; the months of January and February are not very propitious for photography, but this is of less consequence in reference to architectural photographs than to any other subject.

Perplexed.—We have not seen any of the very highly glazed portraits of the Princess Alexandra to which you refer, we cannot, therefore, tell you how they are done. Talc or mica can only be applied to the card when fitted into some case or frame, as it could not easily be attached to the card itself. It is possible they may be varnished, as there are several kinds of varnish occasionally used for such purposes. Possibly it is a kind of French polish sold for the purpose, consisting of two applicatiins; first, a solution of gelatine, as a sizing preparation, and then a solution of white lac in alcohol, applied after the usual method in French polishing.

A Constant Reader.—Chloride of gold may be kept in a strong solution with advantage. A toning solution of chloride of gold and acetate of soda will generally keep for months; with carbonate of soda, however, it often becomes useless in a few hours, especially if added in any excess.

W. Ball.—Temperature materially affects the operation of toning. Many operators warm the solution in winter. The paper may be a little in fault, but longer time in the toning solution, or a little more gold, or a little elevation of temperature, will probably help you. Your print is a little too brown, but the tone is not very bad.

F. Vincent.—One of the great difficulties of development printing on large sheets of paper, is the tendency to tear in washing, &c. If you wish to use very large sheets, you will probably have to use drawing paper, or good cartridge paper. Some of Whatman's drawing papers will probably answer the purpose best. 2. Large sheets of paper may be prepared with the resinizing solution, with a glass triangle, as you propose, taking care that the paper be well saturated.

Charles Derby.—We shall be glad to see a description of your photometer.

Coagulated Albumen.—We have received a letter on this subject, from Plymouth, without any signature. Will the writer kindly forward his signature.

F. M.—A much stronger iron developing solution may be used, with more advantage in winter than in summer; you may use 30 grains to the ounce with advantage. A 5-grain solution is too weak at any time for a bromo-iodized collodion, for which a somewhat stronger solution of iron is desirable than for a simply iodized collodion.

Resinized Paper.—In an advertisement in our last, announcing that this paper is prepared by Messrs. Francis and Co., of Islington, the price should have been 12s. per quire, not 2s., as appeared in consequence of a printer's error.

Several correspondents in our next.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 224.—December 19, 1862.

## JURORS' REPORT ON PHOTOGRAPHY AT THE EXHIBITION.

The Report of the Jurors, in Class XIV., has just been issued. It is a somewhat lengthy document, of about seventeen closely printed imperial octavo pages. It contains a brief history of photography from the period of its discovery to the Exhibition of 1851; from that period to the present time its progress is more definitely traced, both as regards its processes and applications. The contributions to the recent International Exhibition, both in apparatus and pictures, are then fully reviewed with much discrimination; the tone of the Report, in many instances, compensating for the injustice in the awards of prizes. As the subject is one of great interest to photographers generally—and it is important to preserve a record of such a Report—we shall, by permission, reprint the bulk of it in our pages. We must defer this, however, for another week, so as to commence it in our new volume.

## RESINIZED PAPER.

A recent number of the *American Journal of Photography* has some remarks on resinized paper, which are scarcely just, and display some misapprehensions on the subject. The editor says:—

"The English journals are full of the discussion of a new (?) process of preparing paper with resins, as a substitute for albumen. The resins (with a suitable quantity of chloride) are dissolved in alcohol, and into this bath the paper is immersed; after drying, the silvering and printing go on as usual. The editor of the News, with some others, were quite enthusiastic at first—albumen had had its day; but later, on trial and on sober reflection, it appears that there is nothing in it. The gum becomes dark, the surface does not preserve its integrity, the details of shadows are no better than on plain paper, and so on.

"We introduce the matter here chiefly in order to make a proper occasion to suggest to our neighbours, before they proclaim a discovery, that it would be well to find out if the discovery be of recent or ancient date. Such an inquiry conscientiously made concerning resinized paper might have saved our good neighbours from the awkward predicament in which we now find them.

"About two years ago, Mr. Snelling, our late esteemed brother editor, talked much about resinized paper, and showed prints on it, and imagined advantages; others did not see the advantages, and the subject was buried in oblivion till its resurrection by Mr. Cooper, of London. We do not charge Mr. Cooper with plagiarism; indeed we cannot, for his process is greatly less perfect than Mr. Snelling's. Mr. Snelling used gum dammar, which is less changed by light than any other gum, while Mr. Cooper seems to have used the gums which darken most promptly. Mr. Snelling used chloride of ammonium, while Mr. Cooper recommends the deliquescent chloride of cadmium."

We must correct our American *confrère* on one or two points. On trial and sober reflection we remain fully convinced of the value of resinized paper, and feel certain that for many purposes it is better than any other. We have seen some most charming prints upon it, which were, to our taste, decidedly more artistic in effect than albumenized prints, and richer and more delicate than most plain prints. We never believed that for small pictures, such as card portraits and stereoscopic slides, albumenized paper would be discarded; but, for larger pictures, we hope to see resinized paper largely take its place.

Regarding the originality of the process, we have no disposition whatever to deny to our American friends any credit which may be due to them, and always readily concede to them both ingenuity and manipulative skill. But we certainly do not remember the intimation of the use of resin referred to, and we feel perfectly assured that Mr. Cooper had not seen or heard of such a thing. Indeed Mr. Cooper is, in the paragraph quoted, acquitted of plagiarism, but for a reason to which we must demur. We must here insist also upon a principle we have often maintained—namely, that he is best entitled to the credit of invention who works out a process to a practical and successful issue. That Mr. Snelling failed in establishing the use of resinized paper we can well conceive, from the outline of the process given. He used, it is said, gum dammar as the resin, and chloride of ammonium as the salt. Now, gum dammar is very sparingly soluble in alcohol, although quite soluble in benzole or turpentine, which solvents, however, would not dissolve the chlorides. Then chloride of ammonium is still less soluble than dammar in alcohol, scarcely a trace being taken up. Mr. Snelling's paper would contain but little resin, and scarcely any chloride at all. It is not surprising, therefore, that he did not succeed in convincing others of the excellence of his prints, or in establishing his process.

## PHOTOGRAPHIC CHEMICALS:

### Their Manufacture, Adulteration and Analysis.

*Iodide of Magnesium.*—This salt is sometimes used as an iodizer for collodion; it is, however, not a very good one for that purpose. It may be prepared by neutralizing hydriodic acid with pure carbonate of magnesia, employing the latter in very slight excess. When all the acid reaction has disappeared, filter, from the undissolved carbonate, and evaporate over a water bath. The solution will dry up to a difficult crystallizable salt, very deliquescent and easily decomposing by exposure to the atmosphere, with separation of iodine. Upon exposure to heat hydriodic acid is given off, and pure magnesia remains behind. According to Gay Lussac, when magnesia and iodine are brought together under water, reddish brown plates are deposited, and a small quantity of iodate and hydriodate of magnesia are found in solution; these, on evaporating the water, are likewise changed into brownish insoluble flakes. This brown compound is resolved by heat into magnesia and vapour of iodine. Boiled with a large quantity of water, it is converted into iodate of magnesia and iodide of magnesium, which dissolve, and magnesia, which remains as a white precipitate. The anhydrous iodide of magnesium has not been much examined yet.

*Bromide of Magnesium* possesses some interest, as being the salt which exists in sea water, and from which most of the bromine of commerce is obtained. The hydrated salt is prepared in a similar way to the iodide just mentioned. The solution, upon evaporation to a syrup consistency, deposits the hydrated bromide of magnesium in crystals; they are very deliquescent in the air, and prone to decomposition. The last portions of water should be removed by being placed under a bell-jar, the air of which is artificially dried by sulphuric acid. The anhydrous bromide of magnesium is formed by passing vapour of bromine over a mixture of magnesia and charcoal, at a red heat, a white mass of crystalline aspect, not fusible below a red heat, and with difficulty volatile, is produced and carried forward by the carbonic acid gas away from the magnesia and charcoal. This is anhydrous bromide of magnesium; it dissolves in water, with evolution of considerable heat, hissing like a hot iron, and then forms a solution of bromide of magnesium similar to the one above described. The elements of water are retained by this salt, as part of its constitution, and, when once united with it, they cannot be driven off without causing the whole to decompose: the anhydrous salt is a compound of bromine and magnesium in equal equivalents, but when once it has come in contact with water it seems to be converted, by the assimilation of oxygen and hydrogen, into a compound of hydrobromic acid and magnesia, which, when dried and heated, splits up into these two bodies. When dry bromide of magnesium, or a very concentrated solution, is mixed with oil of vitriol, bromine is evolved. A dilute solution, on the contrary, upon addition of sulphuric acid, evolves the whole of the bromine in the form of hydrobromic acid. Bromine added to magnesia forms a hypobromite of magnesia analagous to bleaching powder, and containing hypobromous acid, the compound discovered by Mr. Spiller some years ago. Upon shaking bromine and magnesia together with water, and filtering, a yellowish liquid is produced, which first turns reddened litmus blue, and then bleaches it; bromine is evolved on the addition of even the weakest acids. Light, heat, excess of bromine, or even evaporation in vacuo, decompose this compound into bromate and hydrobromate of magnesia.

*Chloride of Magnesium* is used in the preparation of metallic magnesium. It is best prepared in the following manner:—Divide a certain quantity of hydrochloric acid into two equal parts, saturate one of these with magnesia and the other with ammonia, then mix the two solutions together and evaporate to dryness, a salt will be left behind consisting of the double chloride of magnesium and ammonium. This must be thoroughly dried and projected in small quantities at a time into a red-hot platinum crucible; continue the heat until all the chloride of ammonium is expelled, and the mass enters into tranquil fusion. Anhydrous chloride of magnesium, as prepared in this manner, forms a white translucent mass, consisting of large flexible crystalline plates with a pearly lustre. It fuses upon gentle ignition, forming a clear liquid; when perfectly dry it may be heated to redness without decomposition, but when water is present it undergoes a similar decomposition to the bromide, evolving the acid and leaving magnesia. Exposed to a moist atmosphere chloride of magnesium deliquesces, forming an aqueous solution, which may be supposed to contain hydrochlorate of magnesia. This compound may be much more readily prepared by dissolving magnesia, or its carbonate, in dilute hydrochloric acid, and, evaporating the solution, it crystallizes with difficulty in needles and prisms, and has a sharp bitter taste: it is very soluble in water, dissolving in about half its weight; it is, also, tolerably soluble in alcohol. When chlorine gas is passed through water in which magnesia is diffused a liquid is obtained which has powerful bleaching properties, not destroyed after a quarter of an hour's boiling. This is a mixture of hypochlorite with hydrochlorate of magnesia, similar in composition to chloride of lime: if the magnesia be in excess it is decomposed by evaporation, whilst, if the chlorine has been passed through to saturation, the solution is likewise gradually and spontaneously decomposed.

*Nitrate of Magnesia* was much used formerly for the preservation of sensitive photographic plates, and possesses some interest, as being the first practical suggestion which was made for that purpose: it is prepared by dissolving magnesia in nitric acid, and concentrating by evaporation. It crystallizes, on cooling, into rhombic prisms and needles, which have a sharp bitter taste, and deliquesce rapidly in the air, dissolving in half their weight of cold water, but being almost insoluble in absolute alcohol. The salt was utilized in photography, by coating the washed collodion plate with a solution of a certain strength of nitrate of magnesia containing a little nitrate of silver. The deliquescent character of the film of nitrate of magnesia, with which the plate was thus coated, retained the sensitive surface in a moist condition, admirably adapted for receiving the luminous impression. With carefully prepared nitrate of magnesia and suitable collodion nothing could exceed the beauty or certainty of the process, even after the plates had been kept for some weeks. The tendency of nitrate of magnesia to form basic compounds, and the difficulty which experimenters had, in consequence, in obtaining a salt of a uniform composition, has caused this process to be now but rarely employed.

## INSTANTANEOUS PHOTOGRAPHY.

BY VALENTINE BLANCHARD.*

I purpose this evening, with your kind permission, to describe the method I adopt in the production of the pictures before you, and to point out some of the many difficulties which perpetually cross the path of the operator who adopts the wet process for out-door operations, but the more especially when aiming for instantaneous effects; but, before proceeding to the details, I will, if you will permit me, glance, by way of preface, at the labours of the veteran photographers, who may be fairly considered the pioneers who have cleared the way, and who have, by their bold achievements, made safe the path to the timid who follow slowly in their footsteps.

The productions of Le Grey are familiar to most of you. All must remember the burst of admiration which greeted the appearance of his first cloud effects; and the opinion at that time was freely expressed, that a new era had commenced for photography. Tried by the present standard, these productions may not be considered remarkable; but to those who may be disposed to be hyper-critical, let it be said that he may justly be considered the first to indicate the direction in which to work; and when we take into account the size of the pictures, and consequent difficulties in procuring a lens of long focus capable of working quickly, and also of obtaining a film of sufficient sensitiveness, we must say that all honour is due to him for his labours.

Immediately following in his steps, but working in somewhat a different direction, came Wilson, whose pictures, tried by no matter what standard, have never yet been surpassed. I shall not readily forget my impressions on seeing, for the first time, his wonderful sunset and sunrise effects. The boldness of the idea which prompted him to turn the daring gaze of his lens at the sun—and coming suddenly, too, upon our old notions about the necessity of keeping the sun *out* of the lens—almost took my breath away.

On glancing at the immense number of pictures Wilson has produced, and the wide range of effects introduced into them—the life and vitality apparent in all of them—it must be admitted, by those most chary of praise, that photographers are all much indebted to him for having produced the greatest number of really beautiful pictures that have yet been secured by photography. The statement that Breese had really produced moonlight effects was, for a long time, considered quite mythical; and many will remember the amusing incredulity of some of the French journals; but after an inspection of his charming studies in the International Exhibition, I think the most sceptical must have been convinced of the reality of the fact.

I was much amused the other day, in taking up a journal containing an extract from the Birmingham paper, giving a glowing description of his instantaneous pictures of the opening of Aston Park. As that is now some five years gone, I think to Breese is due the honour of having first produced instantaneous street pictures. I am not, however, sure on this point. In our list of worthies, we must not omit that of England, whose American pictures, especially those

* Read before the South London Photographic Society, Dec 11th, 1862.

of Niagara, were considered so wonderful, but who has since obtained undoubtedly the best series of street views (of the finest city in the world) yet produced.

The question is repeatedly asked by the uninitiated, who see instantaneous pictures for the first time, to what wonderful discovery are these results due? and they stare with incredulity when informed that most of the wonderful effects of Wilson are produced by nothing more startling, in the shape of an instantaneous shutter, than a Scotch cap dexterously placed over the lens.

Now, in describing my plan of working, I need scarcely say that I have nothing new to announce; but I trust that something profitable will come of the discussion, to repay you for the tedium of listening to much that is commonplace. All the pictures before you are produced by iron development. I find in practice that, by using a bromo-iodized collodion, I can employ a bath much stronger than is ordinarily used, and can also use the iron solution in a very concentrated form.

The most instantaneous results I have yet obtained, have been secured by using fused nitrate of silver for the bath; but, unfortunately, it is so uncertain in action that I cannot recommend it. I will begin by describing the bath. It is made 40 grains to the ounce, and is saturated with iodide and bromide of silver. I find in practice that the immersing a plate is not sufficient; and that, when that method of saturation is employed, the plates sensitized in a bath so pre-prepared—especially if kept a short time before they are developed—will be covered with myriads of microscopic pinholes.

For instantaneous operations, the re-crystallized silver is necessary. The commercial article will frequently answer, but is not to be absolutely relied on. The best plan is to assume that it is acid, and drop in a few drops of moist oxide of silver; and then, after filtration, to add three or four drops of very weak nitric acid—say one part of acid to one hundred parts water. It will be found that a bath so prepared will be in its most sensitive condition.

The bath very rapidly deteriorates, and soon looses sensitiveness, and is, therefore, unfit for operations when very rapid effect are desired; but it will be found to be in splendid condition for ordinary work.

I always use bromo-iodized collodion; for though, under some conditions, iodized collodion will give very rapid results, still, as a rule, the negative, though denser than that produced by bromo-iodized collodion, will be found to be too strongly marked in the contrasts, and that the delicate shadows will be buried long before the high lights are well printed. In some cases, where the subject to be photographed presents strong contrasts, I have used equal parts of bromide and iodide with great advantage.

For development, the iron solution is generally 30 grains to the ounce, and frequently 50. I am particular to employ glacial acid that is really pure, for much of the acid sold is not fit for photographic purposes, as it causes the silver to be reduced irregularly upon the plate, with a coarse metallic reduction in the shadows.

The dark box I employ I consider very portable, for it does not take up more room than a portmanteau when packed. I prefer to work through sleeves, for I have a strong objection to tents. A photographer working for instantaneous results should be very cool and collected—a state not easily obtainable with the thermometer at 90° in the shade, and the unhappy operator not only boiling over with perspiration, and made game of by the boys, but *bagged* as well. But the greatest objection to tents is the difficulty of keeping dust under subjection. We know that malevolent spirits love to abide in inanimate objects, otherwise how is it that the handles of jugs will come off—that bottles will tumble off shelves, and glass measures butt at each other until one or both are smashed? I presume this supposition is the only way of accounting for the large amount of spite found to animate a small atom of dust. Most certainly dust is always present in large or small force, watching the operations of the photographer; and when his back is turned, darts down into the most conspicuous spot in the negative, which is regarded by these mischief-making spirits as the post of honour. This is no isolated experience. I appeal to all present, if, in portraits, the nose is not always selected for the final abode of these very small atoms of dust?

I have found great difficulty in procuring yellow glass that is really nonactinic. I have, too, thicknesses of glass pronounced by the shopman to be absolutely impervious to chemical light, having been tested by the spectroscope; but I am compelled, when the light is very bright, to hang a piece of yellow calico over the window.

Too much attention cannot be paid to this matter, for one of the chief sources of annoyance is caused by faith in the obstructive power of the glass. When a plate shows a tendency to fog, it is so easy to blame the bath, the developer, the collodion—in fact, anything but the real cause, which is above suspicion.

I like to finish the negatives on the spot, when possible; but when working for rapidly-changing cloud effects, a great loss of valuable time would result. I, therefore, after fixing, coat the plates with diluted glycerine, and put them aside in the plate box, to be finished at leisure.

If the negative be tolerably dense, to begin with, the plate may be dried; and after well wetting it again, a saturated solution of bi-chloride of mercury, in cold water, should be rapidly poured over; and as soon as the film is of a uniform grey, the plate should be washed, and a solution of iodide potassium (about one grain of iodide potassium to one ounce of water) may be applied. This should be poured on and off once or twice, until a greenish slate colour is seen. There should be no indication of the greenish colour on the wrong side of the plate, for it would be a proof that too much had been done to the negative.

The instantaneous apparatus on the table, is that employed by me in the production of my pictures during the past summer. You will see it is constructed to give a longer exposure to the foreground than to the sky. The shutter is placed immediately behind the back lens, and is closed by pressure on a rod that comes through the top of the camera. As the rod can be pressed down slowly or quickly, it will be seen that the exposure can be varied at will. The apparatus is manufactured for sale by Mr. C. E. Elliott, and is the invention of a workman in his employ. I consider it a most valuable contrivance; for while the most rapid exposure can be given, if necessary, yet, should the light suddenly fail, as is frequently the case, the rate of exposure can at once be moderated to suit the new requirements.

I have to thank you for your kind attention to a paper hastily prepared; and should I have omitted any detail of importance, I shall gladly answer any question on the subject.

## DIORAMIC EFFECTS PRODUCED ON PHOTOGRAPHIC PICTURES.

BY JOHN TAYLOR, M.D.*

In common pictures a certain definite arrangement of light, shade, and colour are chosen; and by these the *effect*, as it is called, is produced and rendered *permanent* under all varieties of light and position. No change takes place in the aspect of the picture, whether the light by which it is seen is strong or feeble.

The well known inventor of photography, M. Daguerre, many years ago devised a method of executing paintings which could change their effect according to the manner in which they were lighted. Thus, for instance, a landscape first seen as if in the full luxuriance of summer, with foliaged trees and browsing cattle, or groups of figures, would change by insensible degrees into the desolation of winter, with the same objects as previously seen now covered with snow, the

* Read at a meeting of the Glasgow Photographic Association, Dec. 4th, 1862.

figures entirely gone, and no sign of life visible but, perhaps, the glimmer of the fire-light from some cottage window. Those only who have seen such pictures, when well executed and properly managed, can conceive the surprise and gratification produced by these transitions of effect.

In common with every one who has seen these dioramic productions of Daguerre, I have frequently longed to possess some of them, and many years ago even tried my hand at their execution, with sufficient success to enable me to understand the methods of this art, and also to perceive the great labour as well as care necessary to produce the full effect.

These pictures required great skill in execution, with most accurate drawing; and were, consequently, so expensive as to be beyond the reach of ordinary purchase, except for public exhibition.

When the transparent photographs on glass came out, with all their truthfulness and precision, it occurred to me that here again was a chance for the diorama. New trials were set about, and the results are exhibited in the apparatus now before the Society. They are on a comparatively small scale, and their chief defect is, that they can be viewed by only a very limited number of spectators at a time.

If large pictures on glass could be executed with the force and detail of the new art, such an exhibition as never before was possible might be got up on a scale that would render it visible at once to a large assembly of spectators, each of whom, instead of looking through a cosmoramic glass, might be provided with a binocular opera-glass, for the purpose of bringing out the minute details of the pictures.

The apparatus, as at present constructed, consists of—first, the cosmoramic box in which the picture is contained; second, the colour cylinder, by which the picture is illuminated; third, the twisted string and viscid liquid, by which the motion of the colour cylinder is maintained and regulated.

The cosmoramic box is a rectangular box, three feet in length, by two feet deep and two feet broad. In the one side of this there is an opening of about the same size as the picture. A sliding frame, having two apertures capable of containing two pictures, is so arranged that it can bring either of the two pictures to be viewed through the opening in the box. The use of the frame is to allow one of the pictures to be changed while the other is being seen by the spectators. This is simply, however, a matter of convenience, and has nothing to do with the effects of the apparatus. In the side of the box, opposite the picture, four lenses, each about twenty-two inches in focal length, and about four and a half inches in diameter, are placed—a part of the frame in which they are fixed being made curved, to allow of those at the sides being presented more directly at the picture. The interior of the box is blackened, and in it are placed some small pieces of natural foliage, so as to come, to some extent, between the eye and the picture, to afford variety of form, and to increase the illusion as to distance.

The pictures should be as large as possible; in the present instance they are fourteen inches by twelve inches. They are prepared by carefully dimming the glass, on the opposite side from that of the photograph, with a small portion of fine white-lead paint, applied by means of a pad of satin over cotton wadding. Careful manipulation is necessary to apply this, so as to make it look like finely and very slightly ground glass. The sky and all the parts of the picture should be similarly dimmed; but over hills, buildings, and other opaque objects, the film of paint must be made thicker, so as to obstruct the distinct vision of objects through them. A little practice easily enables the operator to judge of the degree of opacity required. The picture might now be put into the apparatus; but a better effect is produced by applying thin films of appropriate colour, by means of the dabber, over the white lead. Delicate bluish tints over parts of the sky and distance, and of warmer colours on the near parts, increased in strength on prominent objects, such as figures, will add strength and contrast.

The colour cylinder consists of a light cross of wood, with a wire encircling its outer border, so as to form a hoop of about six feet in diameter. To this is fastened the upper edge of about eighteen feet of white cotton cloth, in such a manner as to form a cylinder about three feet deep. The lower edge is kept stretched by a hoop of wire without any cross-bars in it. The outside of the cylinder is painted with oblique bands and irregular cloud-shaped patches of colour and darkness alternating with light. The colour of the lights round the cylinder varies from white through yellow, then orange, and ultimately red and deep crimson, so as to represent the transitions from daylight, through the evening colours, to darkness. The inside of the cylinder is also painted, but each portion of a different hue from the corresponding part without. This cylinder, being made of collapsable material, can be flattened into a disc for packing or putting aside when out of use. When in use, it is suspended, at the centre of the cross, from the roof, by a string four or five feet in length, made of about twelve strong threads. This string, when twisted, communicates, in unwinding itself, a rotatory motion to the cylinder. To regulate this motion, a rod or thick wire passes down from the centre of the cross for a distance of about three feet, and has attached to its lower end four vanes of tinned iron, which dip into some viscid liquid, such as molasses, placed in a dish at the proper height. It is easy, by raising this dish, or by lowering the cylinder, to produce as slow and steady a motion as may be desired. When it is requisite, more twist can be given to the string by pulling a thread which has previously been wound round a bobbin, which runs on a small axis attached to the cross. This apparatus is exceedingly simple and efficient in its action, though, without a diagram, rather tedious to describe.

To afford the requisite light, a row of four or five gas-burners is placed along the front of the cosmoramic box, immediately above the pictures, but so arranged that no portion of direct light falls on the picture. The colour cylinder is placed at a distance of about ten inches from the gas jets, and a white surface, such as white-painted tinned iron, is put behind the gas jets, to throw forward the light to the cylinder, which would otherwise pass backward toward the eyes of the spectators. Another light, consisting of two or three gas jets, is placed inside the cylinder, at a distance of six or seven inches from the side next the picture. Both of these lights, the external and internal, are controlled by stopcocks, to enable the operator to vary the effect at pleasure, by lessening or increasing them alternately.

The only remaining portion of the apparatus consists of a means by which the appearance of a moon or sun can be introduced into a picture, or by which one picture can be made apparently to dissolve into another; or a summer effect may gradually seem to deaden down into winter, with a covering of snow, &c. The means by which this is accomplished—though it occurred to me without having seen anything of a previous invention—I now find has been in use in what is called the dissolving stereoscope. I have not seen this instrument, but am told that the method is the same. A plate of thin glass, nearly as large as the box will hold, is placed in its interior, at an angle of about 45 degrees with the horizon, the lowest edge being nearest the spectator, and the highest nearly close to the upper edge of the aperture in front for the pictures. In the roof of the box another aperture is made, and another picture is laid on it. The result is that, when a white reflector is put above this picture, the latter is seen by reflection in the glass plate, and appears to occupy a position in front similar to the ordinary picture. By shutting off the light from the painted cylinder, the first picture vanishes, and the second vividly takes its place, or by illuminating both they are seen overlapping each other. If a sky, covered with clouds, and having a transparent portion to represent the sun or moon left in it, is put on the upper opening, the ordinary picture in the front aperture may be made to appear as if the clouds were clearing away, and the moon bursting forth in the sky. So also a photograph of a summer landscape being placed in the front aperture, and the same scene taken in winter placed on the roof, the one can be made insensibly to change into the other.

A peculiarity of these pictures, exhibited in the manner described, is the apparent depth of their atmosphere. The clouds seem, as in nature, to lie far beyond the buildings, and behind each other.

These appearances are due to the actual difference of distances from the eye to the pictures of the buildings, &c., and to the colour cylinder on which the clouds are moving requiring a different focal adjustment of the eyes, and a corresponding perception of difference of distance. This effect is heightened by the presence of the lens through which the spectator is looking. The apparent motion among the clouds themselves, by which one set seems to move faster than the other, in close imitation of nature, is owing to a different cause, which may be shortly described as follows:—The colour cylinder, on which the clouds are depicted, is illuminated by two different lights—one shining on it in front, the other from within—and therefore casting transmitted light and colour on the picture. The clouds on the outside are seen through the sky of the picture, and move with the common velocity of the surface of the revolving cylinder. The clouds depicted on the outside are shown only as shadows cast on the picture from the internal light, and appear to move as much faster than the real cloud or portion of the surface of the cylinder on which it is depicted, as the picture on which it falls is further from the internal light than the surface of the cylinder. So by using at the same time an internal and an external light, and by placing the internal light more or less near the surface of the cylinder, we can have any required degree of apparent relative motion between the different masses of cloud.

A remark has sometimes been made by those who have not seen the effects produced by the dioramic apparatus of which we are now speaking, but have only heard a description of it, that as the bands of colour on the revolving cylinder pass successively behind all the solid objects represented in the picture, such as mountains, buildings, &c., as well as behind the sky portion, these objects must become tinted with the same hues as the sky, the water, &c., and thus a degree of monotony of colour will be produced, which would not be in keeping with the variety seen in nature. In reply to this, it is sufficient to observe that in the preparation of the photograph for use in the instrument, the different parts of the picture are themselves tinted on the glass with different colours—not strongly, yet sufficiently to distinguish them from each other, and to modify any hue which may afterwards be transmitted through them from the colour cylinder. For instance, the sky and distance may be tinted of a bluish or cool neutral grey; while near buildings, banks, roads, &c., have varying tints of red, yellow, or brown.

The effect of this is, that though a piece of flat colour were put behind them all, they would each retain partly its own shade, while partaking of the general hue of the background. Those who are familiar with ordinary pictures, the production of the artists's hand, know how rare it is to see a work well varied in colour, yet possessing a glow as of real light. They also know that this latter quality is got, not by the mere brightness or whiteness of the colour, but by the prevalence of a certain *unity* of hue through the whole picture, giving it what is called *tone*—a quality eagerly sought after by artists in the finishing up of their works. It is often given by a thin wash or glaze, as it is called, of one colour over the whole picture. The effect of this glaze, if properly managed, is, though dark in itself, to make the picture look brighter or more luminous than before.

In nature we constantly observe this tendency of light, when brilliant, to imbue all the objects seen by it with its own hue. In a sunset, for instance, if the light be dim, we see the light of the sky of a yellow or red tinge, while the objects seen against it, such as mountains, spires, &c., seem of a cold grey, or even of a blue colour. But let the light become intense, as in a vivid sunset, the whole of the intervening atmosphere partakes of its hue—the distant mountains, as well as the nearer masses of foliage and buildings, lose, in a great degree, their local colour, and take on the tint of the light. Hence the expressions—"a yellow radiance filling all the vale;" the whole landscape was "steeped" in sunshine. The term "bathed in light," and many others of a similar import, refer to the same "toning" effect of bright illumination. The philosophy of the origin of this effect of tone would be a subject for long discussion; but it may be briefly stated that the chief causes of it are—the illumination of the atmosphere, the effect of reflected lights, and a physiological action of light on the eye itself, producing what is called "irradiation."

This quality of tone, proceeding from one prevailing hue, is essential to every picture which is to represent brilliant illumination. It is a chief source of beauty in landscape, and it fortunately happens that it can be got in those transparent glass photographs when subjected to the dioramic apparatus more perfectly than in any other species of picture; hence their aptitude for representing the brilliancy of noonday sunshine, or the splendours of tone of dawn or sunset.

To judge of the capabilities of this dioramic apparatus, it is necessary to watch for a considerable time the succession of changes which appear, and also to witness them on several pictures and in favourable circumstances. On an occasion like the present, this, I fear, will not be easily accomplished; but I must only assure those who may not succeed in seeing any effect which comes up to their expectations, that it is, in some degree at least, the fault of the circumstances.

I have thus described the simplest form of the dioramic apparatus and the mode of exhibiting some of its effects, and have only time to allude to other modifications of construction by which greater efficiency can be produced. 1. By a sliding frame in the roof aperture of the cosmoramic box, various skies can be successively introduced, as moonlight or sunset effects, &c., the same picture all the while remaining stationary in the front aperture. 2. By a little skilfully-applied tinting with the brush on the side of the picture which is to be placed next the spectator, and by the introduction of a light on it from the interior of the cosmoramic box—while the illumination of the colour cylinder is kept low—it is easy to produce on the same picture many changes, such as the vanishing of figures, &c., as in Daguerre's dioramas—the figures, &c., re-appearing when the front light is lowered, and the back light from the colour cylinder again made to traverse the photograph.

## A SHORT LESSON IN PHOTOGRAPHY.—No. 7.*

### HOW TO TAKE A MELAINOTYPE.†

*Light.*—A single ray of light produces too great a contrast of light and shade.

A brilliant light, as the direct light from the sun, is very unmanageable, and under all circumstances with solid objects produces too great a contrast of light and shade.

Two equally brilliant lights produce on the eyes of the sitter two illuminated circles on either side which are not artistic; and the effect of two such lights fails to produce a proper degree of contrast.

The mild light from a cloud, or a clouded sky, is the easiest to be managed, and produces effects that are agreeable and soft in contrast.

A single light, from whatever direction it may proceed, can be converted by reflectors into any number of lights, and may be made to take any direction whatever.

Therefore it is in our power to arrange our lights according to circumstances.

To avoid the direct rays of the sun we choose a skylight facing the polar star; and, if possible, place our model in front of the inclination. The skylight is furnished exter-

* From *Humphrey's Journal.*

† A melainotype is the American name for a collodion positive on an enamelled iron plate.

nally—that is, on the roof—with vertical projections on the east, west, and south sides, in order to exclude the rays of the sun more effectually. The same end can be attained by making the panes all translucent by paint, or by interposing a curtain. The light that thus enters is the diffused light from the sky, or the reflected light from the clouds; which light may be made to fall perpendicularly or at any angle between 90 degrees and about 45 degrees. The side lights, which are intended to soften the shadows produced or left by the skylight, can be obtained either directly from side windows, or by white screens which admit of being arranged at any angle whatever in the neighbourhood of the sitter. The latter must not be placed immediately beneath the perpendicular light, otherwise the head will receive the most light, and will produce by contrast white reflections. It is very difficult to tell you how to arrange the moveable screens for every special occasion; although it would be an easy task to show you how if the case were present.

I will tell you a few general principles. Place your sitter not beneath the skylight, but about one foot farther back, and fronting the north pole as before observed. In this position the face is equally illuminated, and the shadows are equally dense and similarly placed; these shadows are offensive; you will find them beneath the eyes-brows, the cheek-bones, the nose, and the chin. All these can be softened down by placing a white screen in front of your sitter and inclined at an angle of 45 degrees or less with the floor of the room. But by this proceeding we have two inconveniences; the one is that, when the screen is so placed, you cannot see the model in front, unless you have a hole in the screen to allow the light to pass to the camera; the other is, that your picture will be quite flat, because the face is equally illuminated and free from shadow, and consequently devoid of contrast.

Both these inconveniences can be obviated at the same time by placing the screen either to the right or left of the camera facing the sitter, so that the whole figure can be seen. If you place the screen either exactly east or west of your model, one side will be in the shade, whilst the other is well illuminated. This must be avoided. Side lights can be used so as to produce the same relief of shadow on either side by means of curtains. Your success as a photographer depends very much on the happy arrangement of your lights. It is a very curious fact, that you may frequently experience, as a beginner, that of having the whole figure and face of your sitter suffused with much light, and yet you will have great difficulty in obtaining clear and bright definition on the ground glass; whereas, with much less light, the picture on the glass is clear and distinct. With the latter condition you will easily take a photographic impression; with the former you will not succeed. Therefore, let this always be your criterion: if your picture is not clear, not easy to see, not sufficiently contrasted with objects around on the ground glass, make no attempt at photography; on the contrary, arrange your lights otherwise; soften or contrast them by curtains; by means of screens contrast light and shade so that they may exist as required or desired, until your picture stands out as it were in perfect relief and definition; then proceed and sensitize your plate.

*Sensitizing Bath.*—Dissolve one ounce of nitrate of silver in twelve ounces of rain water; add to this a grain or two of well-washed iodide of silver; shake well; let it stand some time (for instance over night), then filter and use; for, if the nitrate of silver has been properly prepared, the bath is ready for use. Now try a picture. Brush off all dust from the surface of the plate with a broad camel-hair pencil, and float it with collodion in the manner already described in one of my previous lessons. As soon as it is covered, and the collodion has all run off from one corner, hold the plate horizontally, until the whole surface is perfectly free from ridges; otherwise your picture will exhibit these ridges when it is finished. Now introduce it into the bath, and let it remain for a couple of minutes until the collodionized surface has assumed a uniform cream colour; move it slightly up and down in the bath to remove the apparent streaks of oil, arising from the ether and alcohol in the collodion. Now place the plate in the plateholder, and expose it in the camera before your model. The time required will vary with the season of the year and the time of the day. Experience alone can guide you, as soon as you know the general principles connected with the subject. Try, on the present occasion, six seconds. We will now test two things: firstly, whether the time is right; and, secondly, whether the bath is in a right condition.

*Developer.*—The developing solution consists of two drachms of protosulphate of iron in four ounces of water, to which add from four to five drachms of acetic acid; that is, five drachms in summer, and four in winter, and two drachms of alcohol. Pulverize the iron, dissolve and filter. Float the plate in the dark-room with this solution. We will suppose the picture begins to appear immediately; but the dark dress, that is, the blue dress of the soldier, remains perfectly white; it does not change in the slightest degree; the time is too short; try, therefore, two seconds more, and even more than this if required, until the collodion-film of the dress begins to exhibit gradations of shade in the folds. When this is attained, you have got the right time of exposure. But now you have to get the right time of development. This is not a difficult task. Observe well the change of tone as soon as the development commences; it will proceed until the bright lights have all darkened; the darkening then stops all at once; the contrast already manifest between the lights and shades begins to be impaired; a retrograde action sets in, and the whole surface soon becomes fogged or covered with a veil. The line of demarcation between the two actions is quite visible to an experienced photographer; you have to learn to distinguish it. The moment the bright lights cease to darken, or the retrogade action of fogging commences, then stop all further action of development by washing the surface well with water; then fix with a solution of cyanide of potassium. For the present we will suppose you have made a successful melainotype. In the next lesson I will suppose the contrary, and expatiate on the subject.

## PHOTOGRAPHIC PIRACY OF ENGRAVINGS.

Mr. Gambart is proceeding against photographic piracy of his engravings in the superior courts, and under the old Engraving Copyright Act. We compile from several morning papers the following account of a recent action before Mr. Justice Willes, in the Court of Common Pleas:—

### GAMBART V. HALL.

Mr. Collier, Q.C., Mr. Prentice, Mr. Brandt, and Mr. John Thompson, were for the plaintiff; and Mr. Coleridge, Q.C., and Mr. Rew, for the defendant.

It appeared, from the opening statement of the plaintiff's counsel, that the plaintiff had carried on the business of a publisher of first-class engravings on a large scale for many years, but had lately confined himself to the production of a few, but valuable prints, engraved from paintings of great merit, purchased by him at high prices. In this action, he sought to recover damages for piracy of his copyright in two well-known engravings, taken from equally well-known pictures. The first is a costly engraving of Mademoiselle Rosa Bonheur's "Horse Fair;" and the other, of Mr. Holman Hunt's, "The Light of the World." Mr. Gambart paid Mademoiselle Rosa Bonheur £1,600 for the "Horse Fair," and he paid Mr. Thomas Landseer 800 guineas for engraving it. To Mr. Hunt he paid 200 guineas for the right of engraving his celebrated painting of the "Light of the World;" and to Mr. Simmonds 300 guineas for engraving it, and £130 to the owner of the picture for the loan of it for the purpose of making the engraving. The original picture of the "Horse Fair" has been sold to an American gentleman, and is now in New York. Formerly, spurious prints could only be made by the same means as those used in the engraving of the real plates, and were always very inferior productions; but, since the discovery of the art of photography, the copies of first-class engravings, taken by the newly-invented process, are, in some instances, actually superior to the engravings themselves; and inasmuch as a ten-guinea print may be imitated successfully, and copies sold at prices varying from 6d. to 5s., it became clear that a profitable traffic in photographic copies of valuable engravings might be carried on, and Mr. Gambart found that his best prints were pirated in this manner. The defendant carries on the business of a printseller in Middle Row, Holborn, and on being informed that he was selling photographic copies of the two engravings in question, the plaintiff sent and purchased one of each at his shop, and the purchaser then saw a number of similar copies for sale. The defendant declined to give any other account of how he became possessed of them, than that he bought them from hawkers who went about to printsellers with such things for sale, and refused to give the plaintiff any assistance towards discovering the photographer who had pirated the plaintiff's engravings. The plaintiff then commenced this action against him, founded on the statute 17 George III., cap. 57; and, although interrogatories were administered to the defendant, his answers were far from satisfactory. The plaintiff has also brought other actions against other printsellers, who are selling similar pirated copies of these engravings, which are now pending.

Mr. Gambart was then called and said: I am the plaintiff in this case. I purchased the copyright of "The Light of the World" of Mr. Holman Hunt, for the sum of £210. I paid Mr. Coombe £130 for the loan of the picture, and I also paid the sum of £300 to Mr. Symonds to engrave it. The plate is not destroyed. What is called "the publication line" is on the plate, and was so when it was originally engraved. [The publication line contains "the date of the first publishing, and the name of the proprietor of the plate," according to the statute 8 George II., cap. 13, which requires those particulars to be printed on every print in which copyright is claimed.] The publication line was on the plate before a single impression was struck off. The photographs produced [they were admitted to have been sold at the defendant's shop] was taken from my engraving. The photograph produced [a small photograph about four inches long and three wide] was purchased at the defendant's shop. It is a copy of my engraving, and must have been photographed from it. There is no other engraving but my own in existance. The painting is still in the possession of Mr. Coombe. A photograph could not have been taken from the original painting, because it is too dark. If this photograph had been taken from the original the colours would be different, because there are some dark colours in it which must have come out light if it were photographed from the painting. I never gave the defendant, or any other person, authority to copy that engraving. I purchased the picture of the "Horse Fair" of Mademoiselle Rosa Bonheur. I have sold that picture since to an American gentleman, reserving to myself the copyright. Mademoiselle Rosa Bonheur did not retain the right to engrave. She sold me the picture and the copyright. There are two pictures of the "Horse Fair." One I sold, and one is still in my custody. I purchased the picture for £1,600. Mr. Thomas Landseer engraved it for me. I paid him 800 guineas for doing so. The date of the publication line on that picture is February 20th, 1857. The photograph produced [the same size as the other] must have been taken from my engraving. It could not have been photographed from anything else. I never gave the defendant, or any other person, any right to copy any engraving. The "Horse Fair" and the "Light of the World" were very successful pictures. They are worth to me £1,000 a year as long as I live. I lose money by ninety pictures out of every hundred that I publish; and, therefore, when I get trumps like these two pictures I make them pay.

Mr. Collier:—So you lose by the plain cards and win by the trumps?—Yes. The sale of the pictures was very successful up to the time that the photographs were published.

At this stage, Mr. Coleridge objected to the plaintiff's going into evidence of the depreciation of his property, occasioned by the piracy.

This led to a discussion, when the damages against this defendant were agreed to be taken at £10, but

The Court said that the plaintiff was not to be bound down to this sum as against other parties, but might sue for more substantial damages if they continued the sale of similar copies during the pendency of the question of the plaintiff's copyright.

The plaintiff was then cross-examined.—There are three classes of proofs of prints—artists' proofs, proofs before letters, and proofs with letters. I have known a few cases in which impressions have been struck off before the publication line was put on the plate. Those are exceptional cases. Artists' proofs means the first stage of the plate; proofs before letters the second stage before the title of the engraving is put on. It used to be a common practice, but not by respectable publishers, to put silver paper over the publication line and letters. The "Horse Fair" was painted in Paris. I am having it re-engraved on steel, by Mr. Lewis. To produce the photograph, the print is placed opposite to the camera, and its lights reflected in the camera, which produces a negative on the glass. From a large photograph you can produce a smaller one. [The one bought at the defendant's was a small one.] There is nothing to show whether the photograph produced was taken from another photograph or from the engraving.

The sale of the photographs by the defendant was admitted.

Mr. Coleridge submitted that there was no case. Although the photographs are copies of the engravings in one sense, yet they were not such copies as were meant by the statutes. They were not *fac-similes*.

Mr. Justice Willes.—They are wonderfully good.

Mr. Coleridge.—They are not copies whereby any one could be deceived into believing that they were purchasing original impressions of the engraving. The statutes were intended to protect the inventors and designers. They use the phrase "main design." These photographs are mere abridgments or imitations; they are not copies. Again, it is possible to produce one photograph from another, and there is no evidence that this may not have been so produced. The copy, to be the subject of an action, must have been produced through the medium of the engraving.

Mr. Justice Willes.—The plaintiff, who is a person of great experience, and has given his evidence with great candour, says he believes they are copies of his engravings

The jury said, on the question being put to them, We think they are copies.

Mr. Justice Willes.—I do not intend to decide this question. Photography is a recent art, and could not have been in the contemplation of the Legislature when the statutes on which this action is founded were passed. I know that this question has been much discussed, and that there is a difference of opinion upon it. My present impression is that these are substantially copies, and that the plaintiff is entitled to maintain this action, and I shall direct the verdict for the plaintiff, with the agreed damages of £10, reserving leave to the defendant to move to enter the verdict for him, in case the Court should be of opinion that there was no evidence to support the plaintiff's case on the objections raised.

Verdict for the plaintiff—Damages, £10.

## Proceedings of Societies.

### South London Photographic Society.

The usual monthly meeting of this society was held in the City of London College, Leadenhall Street, on the evening of Thursday, the 11th of December, the Rev. F. F. Statham, M.A., F.G.S., in the chair.

The usual routine proceedings having taken place, the following gentlemen were elected members of the society: Messrs. Jeffreys, Richehouse, and W. Sheppard Townsend.

Mr. Harman, the Secretary, exhibited some fine instantaneous stereographs, and a print from an enlarged negative. The original negative was a stereoscopic view of part of the Tower of London; the enlarged negative was 20 inches by 16 inches, and was well defined, brilliant, and perfect.

Mr. Wharton Simpson exhibited an instantaneous stereoscopic negative by Mr. Hurst, of Mirfield, illustrating some of the advantages and defects of ammonia when used in the development of tannin plates. One half of the plate had a clear good image of a wreck, sea, clouds, &c.; but the other half was covered with opaque granular spots, and the image was imperfectly brought out. A great tendency to this kind of defect Mr. Hurst had found to arise, when using ammonia with pyro for development. Mr. Simpson also showed some very exquisite card pictures, taken with Ross's No. 3 card lens, by Messrs. Southwell, Brothers.

The Chairman called attention to a couple of memoranda placed in his hand by the Secretary, from which it was seen that he had received a sum of £8 10s. 3d., and another sum of

£8 2s. 5d. from Messrs. Johnston and Matthey for chloride of silver and sulphide of silver precipitated from the washing water, fixing solutions, &c., accumulated in a very short time. The importance of recovering waste silver was thus forcibly illustrated.

Mr. VALENTINE BLANCHARD then read a paper on instantaneous photography. (See p. 602). On the completion of his paper, Mr. Blanchard exhibited a camera with the instantaneous shutter he employed, and illustrated its action. He also exhibited some very fine instantaneous London street and river views on paper, and some very beautiful glass transparencies of the same subjects, which were much admired.

After a few remarks from the CHAIRMAN on the excellence of the specimens and the interest of the paper,

Mr. WALL called especial attention to the point of view from which the street scenes had been taken. One great defect, which generally characterized such pictures, was that the horizon was much too high—from the fact that the camera had been placed at considerable elevation, probably on the top of a house, or at some high window. The result was an approximation to a bird's eye view, which gave the pictures an unfamiliar aspect.

The CHAIRMAN said this fact had struck him in looking at the specimens. The scenes were from familiar points of view, and yet it would seem impossible to plant the camera in the desirable position in a crowded street.

Mr. BLANCHARD proceeded to explain his method of obtaining the views in question. Being convinced that street views from lofty windows were unsatisfactory—from the fact that few people ever saw the streets from such a point—he had this summer resolved to remedy this evil by taking the negatives from a position in the streets, as nearly all the best views were quite inaccessible from any other place. He had, therefore, during the summer, employed a cab, working inside, and planting his camera stand on the top. He was thus enabled, with but a pause of a minute or two in any place, to secure a view from any point he desired. He had, on the whole, got on without much trouble or interruption in this novel position, although some laughable scenes had arisen during the course of his operations. The only one which at all promised to lead to serious results arose out of the over-officious stupidity of an Irish policeman in Covent-garden. This foolish fellow, seeing a cab with the windows blocked up with yellow calico, and several persons watching it, demanded of the cabman its nature and purpose. The driver simply stated that he was engaged, his fare being inside the cab. Whilst an altercation was proceeding, he (Mr. Blanchard) emerged from the cab; and as he found the policeman excited, vociferous, apparently drunk, and deaf to explanations, he at once desired him to proceed to Bow Street police-station, to settle the matter by reference to the inspector on duty. The officer at the station, on learning the details, at once decided that the cab was properly engaged, and beyond the reach of the policeman's interference, and reprimanded him for not distinguishing between an unengaged cab, loitering and causing obstruction, and one which, being engaged, practically stood for the time in the position of a private carriage.

After some further conversation,

Mr. HARMAN called attention to two prints from the same negative, illustrating his remarks made at a former meeting as to the fact of negatives intensified with mercury and an iodide gradually becoming harder in course of printing. One print was very soft, and showed the original condition of the negative; the other print was so hard and chalky as to be quite useless, and illustrated the result of exposure to light, whilst producing some thousands of prints. In answer to a question Mr. Harman explained that the negative in question had been intensified with pyro and silver, as well as bichloride and odine.

Mr. WALL had had some experience with negatives, and in one instance only had he found that negatives treated with bichloride and an iodide only became harder. His negatives were all kept in the light.

Mr. HARMAN observed that this was altogether different to direct exposure, whilst printing some thousands. The question was an important one to decide.

Mr. BLANCHARD had never met, in his own practice, with an instance of such change, where bichloride and iodide only were used; but he had found that negatives, in which iodide of silver had been formed, changed during constant exposure. He had known some portraits which, having been treated with the bichloride and mercury, had so changed, and he remembered that the collodion gave a spongy film, and the action of the bichloride and iodide seemed to have passed right through, as the negative was brown at the opposite side. In his own negatives, the change seemed to take place on the surface only, the back remaining unchanged in appearance.

Mr. SIMPSON regretted that his remarks must increase the uncertainty of the bichloride and iodide process; but his own experience, and information from many able men, confirmed the notion that such negatives were liable, in some cases, from long exposure to light, to become denser. He had before stated that some of the negatives of the late Mr. Lacy, who, if not the originator of the process in question, gave it precision and also popularity, had become harder. Since last meeting he had had an opportunity of talking further with Mr. Hughes on the subject, who stated that not only had many of Mr. Lacy's negatives so changed, but that the same thing had occurred in his own practice of the same process, where no pyro or silver were used in the intensifying at all. Mr. T. R. Williams had also informed him that after a twelvemouth's experience of the process, he had come to the conclusion that some of the negatives did become harder. The perplexing part of the business was, that some changed and some did not, and as like causes must produce like effects there must be some difference in the conditions, which difference remained to be discovered. It was important to know exactly what the change was which this method of intensifying effected, and this was a point not well understood. When the bichloride solution was applied, there was of course a deposit of bichloride of mercury, which the subsequent application of iodide of potassium converted into iodide of mercury. But the action of the bichloride solution was not simply to cause a deposit of the salt of mercury; it was very probable that a portion of the chlorine was liberated; and, acting on the finely divided silver of the image, formed a portion of chloride of silver. Again, the action of the iodide solution might be to convert a portion of the silver into iodide of silver. Mr. Blanchard's suggestion that the presence of iodide of silver was the cause of such change would thus be explained, and his statement that it had occurred with porous films would further bear out the idea, as such films, by their easy permeability, would favour such changes. But the whole subject required more careful investigation, as conjectural or hypothetical suggestions would not really settle the question.

A conversation on the subject followed, in which Messrs. Sebastian Davis, Hart, Wall, Blanchard, Henderson, and others, took part, but in which nothing further of importance was elicited.

Mr. HOWARD asked how the transparencies were produced, and if the negative had been cut in order to secure each half in its proper position?

Mr. BLANCHARD said they were produced on wet collodion, by printing in the camera. The negatives were not cut, nor was cutting needed, although at first sight that appeared imperative; he had been very sceptical as to the possibility of avoiding it until his friend, Mr. Simpson, convinced him, by means of a diagram and experiment, in which it became apparent that as two lenses were used in copying, and that each picture was turned round on its own axis, this had a similar practical result to cutting the plate in two, and transposing the halves. (Mr. Blanchard here repeated the experiment, illustrating the nature of the operation.)

After some further conversation, Mr. Blanchard stated, in answer to a question, that he used various lenses, chiefly an old pair, one of which was American, and the other made he knew not where. He also used a pair of Shepherd's lenses, which served him very well. In answer to other questions, he said he used a looking-glass as a reflector for illuminating his negative in producing transparencies. He developed them with iron, toning with a solution of bichloride of mercury, followed by hydrosulphate of ammonia, completing the operation before drying.

Mr. SEBASTIAN DAVIS remarked, in reference to the silver bath for instantaneous negatives, that Mr. Blanchard had stated it lost sensitiveness rapidly. There must be a reason for this. Was it caused by the accumulation of a nitrate of the base used in the iodide with which the collodion was prepared, or from an accumulation of organic matter derived from the collodion?

Mr. BLANCHARD could not speak with certainty. He did not think that the accumulation of ether and alcohol was the cause, as he had placed the bath in an open dish in the sunshine to evaporate these, and had still found the bath, even after correction, less sensitive than at first.

Mr. Davis asked the ratio of loss of sensitiveness.

Mr. Blanchard said, perhaps the exposure was a fourth longer.

Mr. Martin suggested, that if Mr. Blanchard used a coloured collodion, the minute portions of nitric acid liberated by the free iodine would gradually cause loss of sensitiveness.

Mr. Blanchard said Mr. Martin was overlooking the fact that he had already said that he always used oxide of silver to correct the bath and neutralize any free acid, and that it was after such correction that the bath remained less sensitive than before.

Mr. Simpson said it was more probably from some effect produced by the accumulation of ether and alcohol. Although Mr. Blanchard had tried to remove these by evaporation, it would be but partially effected, as, even if a bath were boiled down to dryness, the characteristic smell of ether would remain almost to the last, showing that it was difficult to eliminate that body from the nitrate bath.

Mr. Harman suggested that the use of collodion made with methylated spirits would cause this.

Mr. Blanchard prepared his collodion with pure spirit; and Mr. England, who also used pure spirit, found the same loss of sensitiveness.

Mr. Hart said the presence of organic matter was recognized as causing loss of half tone, which was equivalent to loss of sensitiveness, as longer exposure was necessary to get the half tone.

Mr. Leake always commenced by treating his bath with carbonate of soda, and he found such baths gave more sensitiveness and better negatives after having been used a short time.

Mr. Blanchard said that he had observed, that the bath, when discarded for instantaneous work was in prime order for portraiture.

Some further conversation on the subject followed, in which Messrs. Leake, Wall, Harman, and others took part. A conversational discussion ensued, on the cause of increased actinism prevailing when light winds and white clouds were present, rather than with a clear blue sky.

The quality of yellow glass was the next subject of conversation.

Mr. Simpson said he believed it quite possible to get non-actinic glass. The guarantee Mr. Blanchard had received from a shopman who sold him a sample could scarcely be held as ensuring him the most perfect sample made. He had met with samples of silver-flashed glass and of orange pot metal, which not only were shown to cut off all actinic rays in the spectroscope, but gave no reduction on] plates coated with bromo-iodized collodion and developed with iron after thirty seconds exposure to strong light, in absolute contact with the glass.

Mr. Foxlee said the difference in the thickness of the flashed surface, even with silver flashed glass would make a difference in results.

Mr. Martin said it was clear that Mr. Fry had a very non-actinic glass in his dark-room, the window in which had four 12 by 10 panes in it.

After some further conversation on this and other subjects,

The Chairman called attention to a communication he had received from the Photographic Society at Marseilles, soliciting the interchange of papers and general reciprocation of good offices. An exhibition of that Society was also about to take place to which photographers were invited to contribute.

The proceedings then terminated.

---

### American Polytechnic Society.

We extract the following from a Report of this Society in the *Scientific American*:—

*Photographic Printing Machine.*

Mr. Fontaine.—This is a machine for printing photograph positives from the negative. It looks, you see, something like a small wooden trunk. The negative is secured in the upper part of the lid directly below an opening through which the light enters, the light passing through the negative as usual and forming a reversed copy or positive upon the sensitive paper below. The sensitive paper is wound on this shaft and is turned under the opening by a crank. The negative is secured by a spring at one edge, and is pressed down in contact with the positive paper for a moment while the paper is stationary, and at the same instant the orifice for the light is opened by the hole in the revolving plate above it coming over the orifice. It will print four pictures a second, which is at the rate of 14,400 per hour. These sheets were printed with the machine, and I will pass them round for inspection. By condensing the light with a lens, 30,000 pictures per hour may be printed.

The President.—I see Professor Seely present; will he please to give us his opinion of this machine?

Professor Seely.—I admire the mechanical ingenuity displayed in the construction of the machine. The process employed is that which Talbot employed in 1840. It has been repeatedly tried, but is not now used to any extent.

Mr. Fisher.—How much time is occupied in changing the sheets?

Mr. Fontaine.—With one assistant (my daughter who is eighteen years old) I can print and finish 350 positives per hour.

Mr. Stevens.—Could this process be used for illustrating a book? I ask this question in reference to a work now in manuscript of an acquaintance who is delaying its publication on account of the illustrations. The work is on physiognomy. Heretofore works on this subject have been illustrated by portraits of different individuals, but the author of this wishes to illustrate all of the passions by a single countenance; showing its expression when in an amiable mood, again when distorted by anger, again in the pomposity of the military strut, and so on. What would be the price of pictures by the quantity if printed on this machine?

Mr. Fontaine.—They can be printed for two cents apiece. I sell them mounted on cards at four dollars per hundred.

Mr. Fisher.—Can you print them on rolls of paper, or is there a limit to the size.

Mr. Fontaine.—By having a slit across the box instead of a circular opening, the printing might be done on a roll by continuous motion. I have a photograph made by this process that is $5\frac{1}{2} \times 7$ feet.

The President.—There would be no difficulty in making a large machine and driving it by a steam engine?

Mr. Fontaine.—There would not.

## Correspondence.

### FOREIGN SCIENCE.

[From our Special Correspondent.]

*Paris*, 17*th December*, 1862.

M. L'Abbe Laborde, whose suggestions in photography always possess a marked interest and value, remarks that if we add to the positive nitrate bath one-fourth or one-fifth of its volume of alcohol, the following advantages will result:—

1st. A saving of the salt of silver, as equal results may be obtained with a weaker bath.

2nd. A saving of time, and a less scrupulous care in the sensitizing of the papers; for the alcoholic liquid penetrates them rapidly, and they require to be left a much shorter time in the silver bath.

3rd. The sensitized papers retain their whiteness for a much longer time.

4th. The silver bath scarcely becomes discoloured with albumenized papers, and most frequently there only forms on the surface a pellicle of reduced silver, which can be removed without having recourse to filtration. It can be skimmed off by means of a strip of paper.

5th. The gloss of albumenized papers retains all its brilliancy, due probably to the more complete coagulation of the albumen, which is coagulated both by the nitrate of silver and by the albumen.*

Herr Otho von Littrow, the son of the Director of the Observatory at Vienna, has invented and constructed a remarkably ingenious spectroscope, which has already given

* The Abbé Laborde, a high authority amongst French men of science, is here repeating the fallacies which we have recently exposed.—Ed.]

very satisfactory results; it enables the observer to discover many more lines in the solar spectrum than are shown in the instrument employed by M. Kirchoff. It is difficult to give an intelligible description of Herr Littrow's apparatus without the aid of diagrams; but it may be stated, as among other advantages it possesses, that it requires one lens less than M. Kirchoff's instrument, and gives double the effect with the same number of prisms, namely, four of flint-glass of 60 degrees. It is contained in a camera, measuring about twelve inches square by five inches in height. Its price is sixteen guineas.

M. Clerville has given the name of *Eau de Patako* to a liquid which possesses the valuable property of intensifying a negative, and at the same time preserving its transparency so as to yield positives on paper which, after being toned, present pure whites and shades of a good tone. The exposure must be complete, as there is no occasion to regard the veil almost always produced by sulphate of iron. Upon removal from the camera, the negative, developed but not intensified, is fixed by any convenient process, and well washed. It is then carried into the light, and its degree of strength ascertained, and the intensifying proceeded with if desirable. A sufficient quantity of the *Eau de Patako* is put into a glass measure and poured all over the surface of the negative, and immediately poured back into the measure, and then poured on again, until the desired result is obtained; a little solution of hyposulphite of soda now poured upon the plate gives it a fine black tone, and an irreproachable transparency.

M. Gaudin, who has witnessed the experiment, expresses his conviction that the employment of this liquid will be a great advantage to photographers. The negative acquired a remarkable degree of intensity, such as can be obtained only with much difficulty with all the mercurials, sulphides, &c., hitherto proposed for this purpose.

Dr. Goppelsröder, of Bâle, has discovered a very sensitive test for alkalies and alkaline nitrites, in the extract of the petals of the *mauve*, or mallow. The colour of this extract is violet, and it becomes red when acted upon by an acid. Paper is tinged with this red extract, and employed in the same manner as litmus paper. The alkaline bases render this paper violet when the solutions to be tested are weak, and green when they are more concentrated. When a solution contains only $\frac{1}{2000000}$ of caustic soda, this re-agent still colours the paper violet, while the reactions with litmus paper are ineffectual. The same reactions are manifested with the alkaline nitrites; thus, fused nitre and the ordinary nitre of commerce give this reaction, while nitrate of potassa, chemically pure, does not give it. Extract of leaves, crushed pears, tea, coffee, urine, and milk, also give it; hence we may conclude that these bodies contain alkaline nitrites.

The usual test for nitrites is starch, with iodide of potassium, and an acid. The nitrous acid is set free. By means of this test, we find nitrites in water which has been exposed to the air, in the saliva, in extracts of various plants, &c. Other plants contain nitrates. These show the reaction in question only after the expiration of twelve to twenty-four hours, because the organic substance must first reduce the nitrates into nitrites. Such is the case with the common nettle. Other plants contain both nitrates and nitrites. Thus the extract of common salad first gives the reaction of the nitrites; then this reaction disappears, because the nitrites are destroyed, but it reappears at the expiration of twelve to twenty-four hours, when the nitrates have become reduced into nitrites.

It is generally admitted that free iodine always gives the well-known reaction with starch, but it is not so. The protochloride of mercury (corrosive sublimate), and other salts of mercury, possess the property of preventing the colouration of starch, which appears, nevertheless, when we add chloride of sodium, sulphate of potassa, hydrochloric, hydrobromic, or hydriodic acids. So also, when to a solution of iodine, we add potassa in sufficient quantity for there to be no longer any free iodine, and for the starch to become entirely colourless. The colour reappears upon adding chloride of sodium.

M. Jeaurenaud's dry collodion process, which is said to leave nothing to be desired, consists of ordinary collodion, containing five per cent. of a saturated ethereal solution of amber. The plate is sensitized in a bath of nitrate of silver of the strength of seven to eight per cent., to which two per cent. of glacial acetic acid is added. The plate is washed in four or five waters, and developed as usual, either with pyrogallic acid or sulphate of iron. With large plates it is necessary to retain the collodion on the edges by means of a spirit varnish. The plates are as sensitive a month after preparation as on the first day. The exposure required is about double that for ordinary wet collodion, and a little less than for the Taupenot process.

M. Becquerel has published the results of some interesting researches upon the determination of high temperatures by means of the intensity of the light emitted by the incandescent bodies. He employed a thermo-electric pyrometer, formed of platinum and palladium wires, united together without soldering for the space of about $\frac{4}{10}$ of an inch. The intensity of the thermo-electric current developed in this pair is very great; it increases with the temperature in a more regular manner, without the unequal variations observed when other metals are employed; this pair is also available to nigh the fusing point of palladium, 2700°, Fah. By this instrument M. Becquerel ascertained the fusing point of silver to be between 1710° and 1730°, and that of gold scarcely 1962°.

## RESINIZED PAPER.

Dear Sir,—Allow me to be the first to publicly thank Mr. H. Cooper for the boon he has rendered to photographers, in making known the formula for the preparation of the resinized paper. It has so many *good* points in its favour, that I feel confident amateurs will be spared many a shilling, and lots of trouble and annoyance, in the employment of it—even supposing that they do not take the trouble to prepare it themselves, which they may easily do, and without dirting or disturbing the cleanliness of their fingers or clothes; sticky they will become certainly, but that is all. On the 13th ultimo I attended a meeting of the South London Society, and was then much struck with the extreme artistic effect of the prints, as there brought forward by Mr. Cooper. The contents of the paper he read on the subject, and which was so ably reported in the "News" and other journals, induced me, on my return home, to make some experiments upon what I then heard and saw. Having procured the necessary ingredients (which I may here state ought to be of the *best* quality to ensure success), I made my first attempt, but with only partial success; owing, as I afterwards found, to having mixed the gums in the wrong order. Having tried two or three times since, and each time a different way, I am prepared to state that the formula may be mixed in a quantity of 20 oz., and ready for filtration in about a quarter of an hour or 20 minutes.

I find I can employ two sorts of paper: thin Rive for "cartes," &c., thick Rive for large $12 \times 10$ pictures. In the one you require great delicacy, in the other boldness; in both, artistic feeling and an atmospheric effect; this you get in all its glory in the paper in question. As to the preparation of the paper, I proceed thus:—To make 4 oz. First weigh out your chloride of calcium, place in a mortar, pound until fine; add 1 oz. of spirits of wine (56 over proof mine is). When dissolved, powder into the filter, which has been previously placed in a glass funnel in a perfectly clean bottle, previously rinsed out with spirits of wine. Next weigh out your frankincense, place in the mortar, pound fine, add 1 oz. of spirits of wine; continue to use the pestle until all is dissolved, then place in the same filter as the chloride of calcium. Serve the mastic in the same way, only adding the remainder of the spirits of wine by degrees; filter as before; when all has run through, filter again through same filter into another bottle. It is then ready for use.

The paper is prepared by pouring out a small quantity into a flat dish, and laying the sheets in one by one. When all the material is absorbed, drain the paper into a measure and replace in the bottle; dry before the fire. To sensitize, use a 70 or an 80-grain bath; float the *thin* Rive three minutes, the *thick* five minutes; dry quickly. In the exposure in the frame the print must be *considerably* over-done—the whites all but obliterated.

After trimming the prints, wash them quickly in water: then immerse for three minutes in chloride of sodium and water, in the proportion of 1 ounce to 40 ounces; wash again thoroughly, tone and fix as usual.

I find I can get any tone, the same as with the albumenized paper—warm, cold, red, blue, black, purple; in short, it is much easier to work with than many samples of the albumenized paper one gets now-a-days; added to which, the total immunity from spots, stains, blue marks, streaks, measles, and the other diseases of albumenized paper, which all find, and about which so much has been said and written.

The paper is extremely sensitive to light, so much so, that I intend trying it in the summer-time in the enlarging camera; it is, therefore, very useful for printing under-exposed negatives, which can be printed in the shade or by diffused light, and thus get all the detail brought out. Gentlemen must bear in mind that they *must*, in *every* case, print until all the lights are very dark and the shadows bronzed; and in the toning they must "look sharp," or they will be done before you are aware of it. The sensitizing bath, I forgot to mention, must be tilted each time, and before floating the paper.

The bath becomes of a deep red colour after sensitizing, but clear and bright—no sediment; its loss in strength is very slight—about 3½ grains to the ounce. In washing before toning, a larger quantity of chloride is precipitated than with albumenized paper.

In conclusion, I will add that if photographers will only use care, cleanliness, and patience, they *must* succeed.

I will be happy to answer any questions upon the matter. Wishing you the compliments of the season, I remain, dear sir, yours truly, W. H. Warner, Photographer.

*Ross, December* 13, 1862.

---

## COAGULATED ALBUMEN AND MR. DAWSON.

Sir,—Several mis-statements in an article on dried albumen which appeared in the *British Journal* of the 15th instant require correction; and as they have reference to my recent communication on this subject in your pages, the task I think very properly devolves on me.

In the first place it is due to you as well as to myself to deny that I was "instigated, aided, or abetted," in any of my communications, by you or any other person, the only instigation being my own desire for the promulgation of truth. The same reply will suffice for the foolish charge that I feel malice against Mr. Dawson or the *British Journal*. I know nothing of Mr. Dawson, personally, whatever, and very little of the *British Journal* beyond what is necessary to warn me against getting into any controversy with it, if I would avoid being pelted with mud.

Next, the article in question seems to claim for Mr. Dawson some especial immunity from the charge of error. I do not know of any reason why his errors should not be pointed out, the more so as, by the vain-glorious character of his "Lesson for the Learned," he tempts criticism. I may here add, in reply to another cavilling remark as to Mr. Dawson's office, that a man who accepts an office "takes upon himself" its duties, and a man who writes himself "Photographic Teacher" surely cannot deny that he has undertaken the duty of teaching.

Again, Mr. Dawson's words afforded no idea whatever that boiled white of egg was meant by "albumen coagulated by heat;" and now that the explanation is made, the experiments turn out to have still less relevancy than I supposed; for I am not aware that boiled eggs or anything analogous thereto have been used in any photographic operation.

The editor of the *British* next has some confused remarks on the coagulation of albumen, in which it is not quite clear whether he is defending the popular notion, or trying to prove that it is not held. That the notion is common every photographer knows; that it has been promulgated by many authorities, from Mr. Hardwich downwards, I could readily prove by quotations from their published writings. That the notion is erroneous, and therefore mischievous, I have shown in my former letters. The exposure of error is a duty which all photographers owe to the photographic community, whenever they may detect it. The task is not always a pleasant one, but such men as Mr. Shadbolt, by their insinuations of mean or spiteful motives, make the task even dangerous. Is this suspicion of the motives, of others derived from his knowledge of his own habit of mind?

It would require too much of your space to enter into a more elaborate reply to this lengthy attack upon the Photographic News, its Editor, and myself; and I have already written more, perhaps, than the matter is worthy of. I now leave the subject in your hands, to deal with it further if you think well.—Yours, &c., G. Price.

*Mornington Road, Deptford.*

[We have no intention whatever of noticing the outburst of spleen referred to. Mis-statements and mean imputations from such a quarter have very little weight with anybody. We have better occupation for our time, thought, and space, than to answer such imputations.]

---

## Photographic Notes and Queries.

### Coagulated Albumen.

Sir,—Allow me to say a few words concerning the coagulation of albumen. I thought it was generally understood that coagulated albumen was a compound of water and albumen (hydrate); such, at least, has always been my view. Hence, if albumen was first dried, neither heat nor any other agent could coagulate it without water being present. If a plate, coated with the white of egg, was held before the fire, it dried before the temperature was reached necessary to the coagulation. Many years since, before the discovery of collodion, I prepared albumen plates for sale, which were advertised in the *Athenæum*, &c., no Photographic News or Journal then offering a comparative easy road to photography. My process was described in the *Athenæum* and other journals, and in a work on photography by Willets, of Ironmonger Lane. I was then carrying on business in Oxford Street, London. The plates coated with albumen, either wet or dry, were introduced into an atmosphere of steam, which at once afforded both the heat and water necessary; the result was a transparent film, perfectly insoluble in water. The apparatus was very simple—a tin boiler a little larger than the plate, containing water heated by charcoal; the plate was placed horizontal, face upwards, the cover put on, and two or three minutes completed the operation. The iodide of potassium was added previously.—Yours truly, T. Reeves.

*Bedford Street, Plymouth, Dec. 9th*, 1862.

### Substitute for Tannin in the Colonies.

Dear Sir,—Having, through the medium of your valuable paper, been induced to try the tannin process, I thought I would see how a solution of our black wattle bark would answer. I accordingly steeped some, cut up pretty fine, in boiling water for twenty-four hours, then strained, and added a little honey to it, say 12 or 15 grains to the ounce of solution. The resulting liquid is of the colour of dark brandy. After sensitizing and the usual washing, I immerse the plate in a bath, containing the tan, then dry. I find it to answer remarkably well, the results being quite equal to those prepared with the pure tannic acid. I have taken a stereoscopic picture in five seconds—full sunshine. Meniscus lens and half inch diaphragm, development as usual. The dark colour of the preservative does not seem to affect the transparency of the shadows, the picture coming out beautifully sharp, and all the details distinct. Perhaps the above may be of service to some of your readers, to whom tannic acid is not at all times procurable, and I imagine any bark would answer, as long as it contained tan.—Yours truly, R. H.

*Tasmania, Sept. 22nd*, 1862.

## Talk in the Studio.

Parkesine.—A New York paper says :—"This article hardly attracts the attention it merits. It is a substance of gluey aspect, with certain phases of character which suggest cheap and inferior confectionery. From all I can gather, it is destined at some remote day to supersede everything. Parkesine is obtained by condensing oil, chloride of sulphur, and collodion in certain proportions. A hardened mass is the result, which solidifies immediately. It is then capable of being used for nearly every purpose to which india-rubber and gutta percha can be applied, with the additional advantages of being excessively hard and indestructible, besides being in thin plates, perfectly transparent. It is susceptible of being coloured, either with an opaque pigment or a transparent colour. It forms a varnish, coloured or not, which is perfectly hard and impervious to moisture. For buttons, combs, knife-handles, and all other articles for which horn and ivory are generally employed, it is singularly valuable, as it is not only capable of being moulded into any required form, but possesses a hardness equal to iron. Its insulating properties are very great, and it is said to be quite indestructible by damp. The inventor of this 'big thing' has not yet completed his experiments on its uses, but it seems difficult to put a limit to them, especially when it is remembered that Parkesine can be made for a few cents a pound. A patent for a similar production was taken out some time ago in this country. We have not heard to what extent it has been used."

Photography and the Lancashire Fund.—We are glad to know that photographers and photography are contributing freely in aid of our distressed countrymen in the cotton manufacturing districts. On Friday (this day) the London Stereoscopic and Photographic Company devote the gross receipts of their retail sale of Exhibition photographs to this fund. All the employés in the same establishment have been making contributions. We commend the example to others. The forthcoming exhibition will afford many an opportunity of aiding this cause.

Vignette Glasses.—Our correspondent, Charles Derby, who described his mode of making vignette glasses in a recent number, suggests that plates of mica, or Squire's silicious laminæ, may be used with great advantage, instead of glass, for the purpose, as they are easier to use, and incur no danger of breakage.

Patent Albumenized Paper.—Mr. Sutton intends shortly to issue a pamphlet on his new method of preparing paper, illustrated with a photograph on the paper so prepared.

Fine Surface in Card Pictures.—We have been repeatedly asked, by persons who have examined the card pictures of Mr. McNab, to what the extremely fine surface and high glaze were due. The prints have the appearance of having received some especial treatment or varnish after finishing. Mr. McNab informs us that this surface depends entirely upon careful manipulation and good rolling. The paper is highly albumenized and selected with great care, and the surface is not allowed to deteriorate by long soaking or other careless manipulations in any part of the operations. He adds that he considers one of the best tests of careful manipulation to be, the retaining in the finished print of the same amount of surface the albumenized paper possessed before printing.

Manchester Photographic Society.—The following gentlemen were elected officers of the Manchester Photographic Society, at the recent annual meeting. *President.*—The Lord Bishop of Manchester. *Vice-Presidents.*—J. B. Dancer, F.R.A.S., J. P. Joule, LL.D., F.R.S., J. Parry, H. E. Roscoe, B.A., Joseph Sidebotham, W. C. Williamson, F.R.S. *Council.*—The President, the Vice-Presidents, W. T. Mabley, Jas. Mudd, M. Noton, J. Rogerson, H. Thorp, T. Haywood, John H. Gilbert, Wm. Hooper, Ed. Mann, H. Petschler, A. Patterson, J. H. Young, F. C. Tobler, G. Wardley, T. H. Nevill. *Treasurer.*—Edwyn Offer. *Honorary Secretaries.*—Benjamin Consterdine and L. J. Montefiore. We also observe that future meetings will have a social character, tea and coffee being provided at half-past six o'clock, before each meeting.

## To Correspondents.

⁂ Our advertising friends will please notice that new advertisements, or alterations, must be received a day earlier next week, as, owing to the intervention of Christmas Day, we go to press on Wednesday.

Z.—There are two distinct physical faults in the collodion film which are sometimes classed under the common head of craping. One arises from the pyroxyline giving coarse ridges or lines, and yielding a film like morocco leather. Age, alkalies, or considerable dilution with ether and alcohol, may prove remedies to some extent; but nothing that we know of will cure it. The addition of a few drops of chloroform used at one time to be recommended as a cure, but we never experienced any advantage from its use. The other form of craping, which is more correctly described by that word, arises from the use of solvents containing too much water, and when dry the film is seen to be reticulated, and form a very fine network. Certain kinds of pyroxyline favour the production of this result, but it is always, we believe, caused by water. Allowing the film to set well will lessen the chance of this evil; but there is no real remedy. You may sometimes work the collodion off by mixture with an anhydrous sample.

B. G.—A coarse ground glass is an effectual preventive to perfect focussing. Your only remedy is to get a piece of finer ground glass. Most dealers, and all camera makers, can supply you. The common, or cheap French cameras, are generally supplied with this coarse, useless glass.

A. B.—Any copy of a copyright picture, whether produced by painting or photography, is a piracy. The Act makes use of the phrase "by any means whatsoever," and therefore any mode of reproduction without permission is precluded.

Cur Nescire Pudens.—In using bichloride of mercury and iodide of potassium for intensifying, the strength of the bichloride solution is unimportant. A saturated solution is often recommended, but a weak one may be used, about 10 grains to an ounce of water being a convenient strength. The operator must be guided by the colour of the film produced by the action of the mercury rather than by any rule as to its strength. It should not pass the stage of a uniform dark grey; if the whitening action commence, the intensification will not be right when the iodide is applied. The solution of iodide of potassium should be about one grain to an ounce of water, and this may be applied longer, pouring off and on until the right amount of intensity is gained. Always wash carefully between the application of every fresh solution. On the subject of intensifying with mercury and iodide, see discussion at the South London meeting, reported on another page. You may intensify old negatives with pyro and silver, if previous to applying the solution you treat the film with a solution of iodine. The silver will readily deposit then, and give you any desired intensity. See a chapter on intensifying in our Year-Book of Photography for 1863.

A. B.—The rules for exhibitors at the approaching Exhibition of the Photographic Society were inadvertently issued without correcting the address; 5, Pall Mall, used to be the proper place in former years; Suffolk Street Gallery is the proper place to address for this Exhibition. The "front of each picture" may mean either the card mount, or the glass. All that is meant is that the description of the picture shall be placed where it can be read.

A. T. P.—We have not heard Mr. Spiller state the exact quantity of caustic soda that should be added to the water for boilers; the quantity of lime salts in the water would, of course, somewhat affect the question. "A little" is spoken of: try an ounce to a gallon of water.

J. F. N.—In the formula to which you refer the writer had inadvertently omitted to subjoin at the conclusion "then add 12 ounces of water;" this would make a total of 16 ounces for the 480 grains, or 30 grains to the ounce.

C. P.—We cannot, with fairness, recommend particular makers by name in this column.

J. F.—The irregular supply of your copy of the News is due to the provincial agent. It is published in London regularly every Friday morning at 12 o'clock. Messrs. Smith receive a large number regularly, so the fault is not with them, but with their provincial agent.

A Young Photographer though a Matured Man.—The combined fumes of the dark room are not beneficial to breathe, and it is desirable, therefore, to secure good ventilation. But unless gross carelessness be used in leaving bottles of acetic acid, cyanide of potassium, ammonia, hydrosulphate of ammonia, ether, collodion, &c., &c., unstopped, there is not much danger of injurious consequences to an amateur. Many operators spend the whole day there constantly, and yet enjoy good health. Take care to avoid the unnecessary presence of fumes, and preserve as much ventilation as possible, and you need not fear injurious consequences. The symptoms you describe are those of dispepsia.

G. L.—We believe there is no limit to size or number of contributions, provided they are good. Contributors receive a season ticket.

C. T. G.—We have, as you suggest, but without inconsistency, spoken highly of Mr. Dawson as a photographer. We have reason to believe that he is a good photographer, and a careful experimentalist; but all men are liable to error or mistake, and therefore subject to correction. We would not willingly do any one injustice, and an opponent least of all; and in the present instance we have scrupulously avoided it, nor shall taunts tempt us into further retort. The weak and foolish only cry out loudly, and reiterate hard words.

J. J. F.—Constant change of water, and the use of a sponge, are much better than long soaking. If you have time to rub the surface of each print with a sponge, or a piece of cotton wool, it will materially aid and hasten perfect washing. A final rinse in warm, or even hot water, is valuable, but we do not like boiling water; it seems to reduce the brilliancy of a print. The use of a hot iron does not darken a print, unless there be sulphur present. We have noticed that gold-toned prints sometimes look a little redder after the use of a hot iron.

M.—We prefer a gold mount for coloured prints generally. Gold harmonizes with almost anything, and generally adds richness to the picture.

H. J.—We believe that the adjudicators of the prizes have not yet been appointed, nor is it decided who will undertake the duties. The medals are silver. One side will have for design, "Phaeton in the Chariot of the Sun;" the other is not determined.

Several articles, reviews, and letters in type are compelled to stand over until our next for want of space.

Several correspondents in our next.

All Letters, Works for Review, and other Communications for the Editor, should be addressed to the Office, 32, Paternoster Row, London.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 225.—*December* 26, 1862.

## REGISTRATION OF PHOTOGRAPHS.

We have received from various correspondents statements of a difficulty experienced by provincial artists as to the registration of their photographs for the purpose of securing the copyright. Many of our readers very naturally supposed, after the instructions we gave some months ago, that nothing further would be necessary than to fill up the proper form and forward it to the registering officer at Stationers' Hall, with the amount of the fee for registration in postage stamps. They are met at the outset, however, by this answer from the registering officer :—" The form must be brought to the office ; no forms are received by post, and no stamps are taken for fees." This decision, which may at first appear arbitrary and unreasonable, as causing much inconvenience to residents in the country, is really not intended to be uncourteous by the officer. It is a simple statement of the fact : there is no provision made for other than personal attendance. If forms were received by post, it would often lead to explanatory correspondence, which is no part of the duty of the registering officer.

To meet this difficulty, we have determined to act upon the suggestion of a correspondent, and undertake arrangements for the registration of photographs for our readers. In order to facilitate these arrangements, it will be necessary that those of our readers who desire to avail themselves of our agency should adhere as closely as possible to the instructions which follow.

We refer our readers, in the first place, to articles on pages 374, 380, and 398, containing the fullest information on the subject of the new Copyright Act and Registration. It will be seen that the details for registration are to be supplied in a given manner, in a form, the blank copies of which are to be purchased, at a penny each, of the registering officer at Stationers' Hall. The briefest distinctive description is desirable, together with a copy of the photograph—a spoiled one will do—to be registered. We will now specify the steps to be taken by our readers who wish us to undertake the registration of their pictures.

The form, properly filled up, and with the photograph attached, should be forwarded to our office, addressed to "The Publisher of the Photographic News," with a memorandum outside of the envelope, "Photograph for Registration." Each photograph must be accompanied by fifteen penny postage stamps, twelve of which will be required, as the registering fee, by the officer at Stationers' Hall, and three for contingent expenses.

In order to avoid unnecessary correspondence, the reception of all prints will be acknowledged, and the registration notified, from week to week, on the last page of the Photographic News. We trust that this arrangement for facilitating registration will prove satisfactory to our country friends.

We may here add, that our publisher is just about making further arrangements for the convenience of provincial readers and photographers generally. From many communications, we learn that photographers frequently experience some trouble in obtaining various works connected with the art. The publisher of the Photographic News will, therefore, undertake to supply, post free, any work in photographic literature, on receipt of the price of the work in postage stamps or post office order. Other arrangements, in connection with the printing, publishing, and sale of the literature of photography will be made, and duly announced in our advertisement columns. We hope that these arrangements will also be found convenient and satisfactory to photographers.

## The International Exhibition.

### FOREIGN APPARATUS—A FEW FINAL WORDS.

Before taking final leave of photography in the International we must add a few closing words. We endeavoured from time to time, during the period that the Exhibition was open, to give a tolerably comprehensive description of the British Photographic Department ; and we have also called attention, from time to time, to the specialities in which foreign photographers displayed peculiar excellence. We have noticed the magnificent enlargements of Ghemar, Disderi, Wothley, Albert, and others ; the enamels of Camarsac ; the silk prints of Madame Lafon ; the noble direct prints of Angerer, of Ken, and others ; the exquisite instantaneous pictures of Warnod ; the carbon prints of Fargier, Charavet, Camarsac, and others ; and various other photographs which, by the perfectness of the process, or the beauty of the result, claimed the attention of photographers. We have not entered into detailed or systematic description of the various foreign pictures, simply because so little information was obtainable regarding the method used ; and an extended notice of pictures regarding the production of which we could give but uncertain information, did not appear to us a mode of filling our pages profitable to our readers.

We have given still less attention to foreign apparatus, and for various reasons. After a careful examination of the various examples of apparatus exhibited by foreign manufacturers, guided by the best information we could obtain concerning them, we were confirmed in a conviction which we had before held, that in real excellence and efficiency, English apparatus generally was unrivalled. Many articles of continental manufacturers display considerable ingenuity and skill, and it is probable that in some matters of arrangement our own makers may have gathered a few hints for future use. But for thorough excellence of material and workmanship, and real usefulness, we much prefer the products of English makers. In one feature alone the contributions of continental manufactures appeared to take precedence of those in the British department—they were apparently much cheaper. Possibly in some respects there might be some reality in this ; but for the most part we believe this appearance of cheapness was delusive. That in some cases a real saving of cost was effected by disregard of that nice finish, without which the better class of English manufacturers would regard their work as imperfect, we have no doubt. But we know that in many instances, an impression most erroneous in itself, and unfair to dealers and makers in this country, was created by the prices marked on objects contributed in various continental courts. We will mention one illustration :—A correspondent recently called our attention to certain articles in glass ware in the Austrian Court, and asked very naturally why articles equally good in quality, convenient in shape, and moderate in price, could not be procured in this country. For the purpose of obtaining really correct information on this subject, we gave especial attention to this individual illustration. On examining the contributions in question, we found it consist of certain glass vessels, which for years past have been imported constantly, and have been in regular use in this country, the only difference being that the examples in question were perhaps picked specimens. The list of prices attached, however, appeared marvellously low, and much cheaper than English photographers were in the habit of paying for the self-same articles. This led us to inquire further, and we met with a tolerably clear solution of the enigma. The prices attached for public guidance, and which photographers would naturally base their opinions upon, did not afford the slightest idea of the real prices at which the articles would reach the public. They were manufacturer's prices, not retailer's prices. The dealer in this country wishing to supply these vessels to English photographers, must order them in given quantities, probably dozens, of the agent appointed by the manufacturer. They are invoiced to him at the prices quoted in the Exhibition; but with 25 per cent. added for breakage, carriage, etc., in bringing them to this country. To this added 25 per cent., the retailer must add his profit, and charge for risk and breakage. The result is that the price of each vessel, when it reaches the photographer, becomes nearly double that quoted in the list referred to.

We have mentioned a single instance; but we have reason to believe that it is by no means an isolated case. The motive suggested for affixing the manufacturer's price to articles intended for public inspection we cannot determine with certainty; but it has been suggested that as cheapness was to be regarded as an element of merit, many continental manufacturers, not only of photographic apparatus, but of various other articles, ticketed their various productions in the way we have described, for the purpose of giving them an appearance of cheapness not justified by their selling prices. Whatever may have been the motive, we believe that the fact is as we have stated it, and that some injustice to dealers and consumers was the result of the misleading prices displayed.

The final pageant, which was to have concluded the business of the Exhibition by a formal distribution of prizes, is not, it now appears, to take place. The prizes are, we believe, ready for distribution; but when and how they will be distributed we cannot with certainty say. We regret to state that the final proceedings of the Commissioners appear to be as objectionable as much of their conduct has been from the beginning. Such of the goods as were not taken away by exhibitors have been packed up and sent home, with an exorbitant demand for cases, package, &c., the original cases having been confiscated. This demand has not only been excessive in amount, but imperative and offensive in its tone in the last degree. Such enterprises are doubtless difficult to manage so as to give entire satisfaction to everybody; but we fear this has been so mismanaged that it will be difficult, at least until the lapse of years shall have dimmed the memory of annoyance, to persuade the nation into another similar undertaking.

## THE STEREOGRAPH AND THE STEREOSCOPE.*

Having arrived at a breathing place in the discussion which has occupied my attention for the last few months, I feel myself called upon to express *my* opinion on a subject on which opinion is divided among the scientific both of England and France. I refer to the twin figures of Chimenti.

The following extract from a paper by Sir David Brewster, published in the 119th number of the *Photographic Journal*, will introduce the reader at once into the subject in question :—

"In 1859, when Dr. John Brown and his brother Dr. Alexander Crum Brown were visiting the Museum of Wica at Lille, their attention was called to two pictures of a man sitting upon a low stool, and holding in his left hand a pair of compasses, and in his right hand a line reaching the ground. These two pictures appeared to be exactly the same, as if the one had been copied from the other. They were each about *twelve* inches high and *eight and a half* broad, and were placed close to one another like the pictures in a stereoscopic slide.

"Dr. A. Crum Brown, on his return to England, sent me, through Principal Forbes, the following account of these two pictures, which I think was read in his presence at a former meeting of this Society.

"'These two drawings,' he says, 'are by Jacobo Chimenti da Empoli, a painter of the Florentine school, who was born in 1554, and who died in 1640. They are drawings of the same person from points of view slightly different. That on the right hand is from a point of view slightly to the left of that on the left hand. They are so exactly on the same scale that, by converging the optic axis, I succeeded in uniting the two so as to produce *an image in relief.* They united so easily and completely, that I could not help thinking that they had been drawn for the purpose of being looked at in that way. So far as I could judge, the difference between the pictures was greater than would be produced by a change of the position of a spectator equal to the distance between the two eyes; so that the *steroscopic effect was somewhat exaggerated.* I think, if we had a photograph of the pictures, it would be much easier to prove the stereoscopic character than merely by referring to them; and if the photographs were of such a size that they could be *transposed*, and put in the stereoscope, anyone could see it.'"

Immediately after the above suggestion was made, the *Photographic Journal* issued in the 120th No. a lithograph of the two drawings diminished to the ordinary size of the stereographic slide; and on the 15th of June last we find an engraved helioplastic reproduction of these two figures in the *Moniteur de la Photographie* reduced to the stereographic size. The latter form is the more reliable of the two from which to draw correct conclusions.

In all our text-books on natural philosophy we are taught that gravity is a property of matter *universally*, namely, that there is no exception; in like manner in stereoscopy, the gradual *increase* or *decrease* of distance from corresponding point to corresponding point in the two photographs or drawings, from anterior gradually to posterior objects, or *vice versâ*, according as stereograph is *strabonic* or *lenticular*, is a *universal* property; if this property be wanting, there is no authority for any mathematician to argue by the formulas of probability that any twin figures were intended to be stereoscopic; just as little as we should have no right to assert that the laws of gravity would account for all the phenomena of astral mechanics if these laws had exceptions.

Let twenty different artists take duplicate copies of any single object or engraving as accurately as the eye and the pencil can perform the operation, of the stereographic size, and let the duplicates be mounted on cardboard as stereographs. The result will be, *undoubtedly* be, that these copies will possess relief, an *irregular relief*, more or less, when viewed either strabonically or lenticularly; but this relief will be *different* in each of the mounted duplicates. This irregularity or difference of relief arises from the fact that the *gradual increase* or *decrease* of distances does not exist, and not existing, we are authorized to conclude that such duplicates are not *stereoscopic*.

Let us now put Chimenti's drawings to the test. For this purpose I use the figures as reproduced in the *Moniteur* by Poitevin's process.

### *Chimenti's Figures Analyzed.*

If we place a living object so as to represent the figure in Chimenti's drawings, we shall be convinced that the toe of the left foot will be the nearest point of the figure to the artist or photographer; the knee of the left leg will be the next; the compasses in the left hand the next; probably

* From *Humphrey's Journal*.

the left shoulder the next; the back of the coat at the shoulders, or on the stool, will probably be the most remote.

HORIZONTAL DISTANCES.

Anterior Objects.

| | | |
|---|---|---|
| From left toe to left toe | 2.13 | inches. |
| From left shoe-string to left shoe-string | 2.73 | ,, |
| From left tibia to left tibia | 2.18 | ,, |
| From left knee to left knee | 2.27 | ,, |
| From left garter to left garter | 2.18 | ,, |
| From left hand to left hand | 2.22 | ,, |
| From left wrist to left wrist | 2.205 | ,, |
| From left shoulder (right line) to left do. | 2·28 | ,, |
| From left shoulder (left line) to left do. | 2.28 | ,, |
| From left collar to left collar | 2.22 | ,, |
| From left side of coat near the elbow to do. | 2·23 | ,, |
| From button on the left knee to do. | 2.21 | ,, |
| From right leg of compasses to do. | 2.27 | ,, |
| From left leg of compasses to do. | 2.29 | ,, |
| From lower end of black line on shoulder to do. | 2.26 | ,, |

Posterior Objects.

| | | |
|---|---|---|
| From right toe to right toe | 2.19 | inches. |
| From right shoe-string to right shoe-string | 2.14 | ,, |
| From right heel to right heel | 2.20 | ,, |
| From right elbow to right elbow | 2.17 | ,, |
| From right wrist to right wrist | 2.18 | ,, |
| From right shoulder to right shoulder | 2 205 | ,, |
| From back of the neck to do. | 2.23 | ,, |
| From back of right shoulder to do. | 2.20 | ,, |
| From prominence on back of coat to do. | 2.23 | ,, |
| From back of stool to back of stool | 2·19 | ,, |
| From back of right leg to do. | 2.20 | ,, |
| From button on the right side to do. | 2.19 | ,, |
| From upper angle of right knee to do. | 2.115 | ,, |
| From lower angle of right knee to do. | 2.14 | ,, |
| From leg of stool to leg of stool | 2.205 | ,, |

| | | |
|---|---|---|
| Nose to nose | 2.20 | inches. |
| Chin to chin | 2.21 | ,, |
| Mouth to mouth | 2.21 | ,, |
| Ear to ear | 2.20 | ,, |
| Occiput to occiput | 2.22 | ,, |

*General Observations on these Distances.*—The greatest difference between the extremes is a little more than one-sixth of an inch, a difference *vastly greater* than ever occurs in the stereograph of a human being. If we regard the drawings as a lenticular stereograph, then the lines on the left shoulder are shown to be far behind the back of the right shoulder; also the left knee is behind the prominence on the back of the coat, etc.; if we regard the drawings as a strabonic stereograph, the distortions are equally manifest; in fact, since the distances are so irregular, the relief arising out of them will be equally irregular, and consequently offensive to the eyes to behold. We are certainly authorized, from a comparison of the above distances, to conclude that the pictures, if intended to produce stereoscopic effect, do not in any way whatever succeed. Another evidence of this conclusion is manifest from a comparison of the following vertical distances:—

VERTICAL DISTANCES.

Left Figure.

| | | |
|---|---|---|
| From nose to toe of left figure | 2.3 | inches. |
| From lapel on shoulder to foot of stool | 1.62 | ,, |
| From wrist to chin | 1.1 | ,, |
| From left knee to waist-belt behind | 1.59 | ,, |
| From right knee to tip of toe | 1.37 | ,, |
| From middle button to opposite of body | 0.6 | ,, |
| From highest prominence on the head to foot of stool | 2.49 | ,, |

Right Figure.

| | | |
|---|---|---|
| From nose to toe of right figure | 2.42 | inches. |
| From lapel on shoulder to foot of stool | 1.76 | ,, |
| From wrist to chin | 1.15 | ,, |
| From left knee to waist-belt behind | 1·7 | ,, |
| From right knee to tip of toe | 1.485 | ,, |
| From middle button to opposite side of body | ·68 | ,, |
| From highest prominence on the head to foot of stool | 2·715 | ,, |

From this comparison it appears that the right figure is about one-quarter of an inch taller than the left, and all the other proportions are nearly in the same degree as regards size. Such a discrepancy is never found in a stereograph.

The difference in binocular vision was known before the time of Chimenti, and it is supposed that, having read the works of Baptista Porta and Leonardo da Vinci, Chimenti may have received some idea of the superimposition of two pictures so as to produce relief. Not having succeeded in producing true stereoscopic effect by the figures under discussion, we cannot argue therefrom that he was ignorant of stereoscopicity, or that these figures were *not intended* to effect stereoscopic relief. We can alone maintain that the figures fail of their object, if such was their object; and, failing of this object, they do not indicate that Chimenti was acquainted with stereography.—*Humphrey's Journal.*

## A SHORT LESSON IN CHEMISTRY.—No. 6.*

In the first place, I will call your attention to the following table, which contains the per centage of iodine, bromine, and chlorine, in the salts which are or may be used in photography, and I will afterwards make some application of this table.

| | | | | | | | |
|---|---|---|---|---|---|---|---|
| 100 | parts of iodide of | lithium | contain | 95.1 | parts of iodine. | | |
| 100 | ,, | ,, | magnesium | ,, | 91.4 | ,, | ,, |
| 100 | ,, | ,, | ammonium | ,, | 87.6 | ,, | ,, |
| 100 | ,, | ,, | calcium | ,, | 86.3 | ,, | ,, |
| 100 | ,, | ,, | sodium | ,, | 84.7 | ,, | ,, |
| 100 | ,, | ,, | iron | ,, | 82.0 | ,, | ,, |
| 100 | ,, | ,, | zinc | ,, | 78.4 | ,, | ,, |
| 100 | ,, | ,, | potassium | ,, | 76.0 | ,, | ,, |
| 100 | ,, | ,, | cadmium | ,, | 69.3 | ,, | ,, |
| 100 | ,, | ,, | barium | ,, | 64.8 | ,, | ,, |
| 100 | parts of bromide of | lithium | contain | 92.5 | parts of bromine. | | |
| 100 | ,, | ,, | magnesium | ,, | 91.3 | ,, | ,, |
| 100 | ,, | ,, | ammonium | ,, | 81.6 | ,, | ,, |
| 100 | ,, | ,, | calcium | ,, | 79.6 | ,, | ,, |
| 100 | ,, | ,, | sodium | ,, | 77.7 | ,, | ,, |
| 100 | ,, | ,, | iron | ,, | 74.0 | ,, | ,, |
| 100 | ,, | ,, | zinc | ,, | 70.8 | ,, | ,, |
| 100 | ,, | ,, | potassium | ,, | 67.8 | ,, | ,, |
| 100 | ,, | ,, | cadmium | ,, | 59.0 | ,, | ,, |
| 100 | ,, | ,, | barium | ,, | 53.2 | ,, | ,, |
| 100 | parts of chloride of | lithium | contain | 84.4 | parts of chlorine. | | |
| 100 | ,, | ,, | magnesium | ,, | 74.7 | ,, | ,, |
| 100 | ,, | ,, | ammonium | ,, | 66.3 | ,, | ,, |
| 100 | ,, | ,, | calcium | ,, | 63.9 | ,, | ,, |
| 100 | ,, | ,, | sodium | ,, | 60.7 | ,, | ,, |
| 100 | ,, | ,, | iron | ,, | 55.9 | ,, | ,, |
| 100 | ,, | ,, | zinc | ,, | 52.2 | ,, | ,, |
| 100 | ,, | ,, | potassium | ,, | 47.5 | ,, | ,, |
| 100 | ,, | ,, | cadmium | ,, | 38.8 | ,, | ,, |
| 100 | ,, | ,, | barium | ,, | 34.0 | ,, | ,, |

Collodion is sensitized with one or more of the iodides in the preceding table, or with a mixture of the iodides and bromides. The collodion film owes its sensitive character to the iodine or bromine, or to both, and not to the metal contained in these salts; therefore, it is evident that those salts will be the most efficacious in photography which contain the largest quantity of iodine and bromine in comparison with the metals entering into the formation of the salts.

* From *Humphrey's Journal.*

Now, if all the preceding salts were equally expensive, equally soluble in alcohol and ether, equally easy o decomposition by nitrate of silver, and equally permanent as salts under all ordinary circumstances, then we should have no hesitancy whatever in pronouncing the iodide and the bromide of lithium as the best sensitizing salts in the manufacture of collodion. Such is found to be the case, even although the metal lithium is somewhat rare and consequently expensive.

But in the performance of chemical operations for practical purposes, we must pay regard not alone to the immediate effects produced, but to a whole chain of facts, in order to effectuate the best results with the least expenditure of material in all the operations combined.

The silver bath contains, when freshly prepared, a solution of nitrate of silver saturated with iodide of silver. After it has been in use for some time, it holds in solution, in addition to the above, the nitrates of all the metals that have been employed in the collodion, as well as a large quantity of alcohol, ether, and organic impurities. In consequence of this accumulation of extraneous salts and unnecessary substances, the bath becomes utterly useless long before the nitrate of silver is exhausted. If we had any chemical means of separating the solution of nitrate of silver from this mass of unnecessary materials, without decomposition of the nitrate, the bath might be used for an indefinite time, and always comparatively in a normal condition. Now let us see if this can be done. The ether and the alcohol can easily be separated by distillation—the organic matter by filtration. Now, about the rest? The bath probably contains nitrate of ammonia, nitrate of potassa, nitrate of soda, nitrate of lithia, and nitrate of the oxide of cadmium; it may, as a general thing, if collodion has been employed from different manufacturing houses, contain all these salts. If these salts could be converted into other salts of the metal mentioned, and which salts are insoluble in a solution of free nitric acid and nitrate of silver, then the difficulty might be solved very easily; but we are acquainted with no means of doing this under the circumstances in question; so that a spoiled bath cannot be remedied.

As an exercise in photographic chemistry, I will now teach you how to separate the different materials from each other in an old sensitizing bath; these different materials being those already mentioned. In the first place, I will distil the bath at the low temperature of about 120 deg. Fahrenheit; by this treatment the ether is distilled over into the receiver. As soon as ether ceases to be condensed, raise the temperature of the bath to about 180 deg.; the alcohol will now distil over. When this fluid has ceased to pass over, the bath may be raised to the temperature of boiling water, and then allowed to cool. By this process you observe that a quantity of a dark substance has subsided; this is a mixture of silver and organic matter from the alcohol, ether, and collodion, and can be separated easily by filtration. The solution now contains only the nitrates above-mentioned. By adding to this solution hydrochloric acid, as long as any white precipitate is formed, the silver subsides in the form of chloride—an insoluble substance. A second filtration separates this chloride from the liquid thoroughly. Whilst it is still on the filter, fresh water may be repeatedly poured upon it, whereby it becomes washed; after this the white sediment may be placed in a warm dry place in the dark room, and dried. This chloride contains all, or nearly all, the silver in the bath. Our next step is to precipitate the cadmium, which we can effectually do by passing a current of hydrosulphuric acid gas through the bath; the current must pass for some time. The liquid, after standing for a number of hours, is raised to the boiling temperature, which is continued until all smell of hydrosulphuric acid has been driven off; it is then filtered for the third time; the yellow sediment on the filter is sulphide of cadmium, containing also a minute portion of sulphide of silver, which had remained after the action of hydrochloric acid. The solution now contains the alkaline salts alone. By evaporation to dryness we obtain the nitrate of ammonia, the nitrate of lithia, the nitrate of soda, and the nitrate of potassa. Dissolve this amorphous mass of salts in a very small quantity of water, and then add a strong solution of bichloride of platinum and a little alcohol; this will precipitate the salt of potassa in the form of minute crystals, which can be separated by filtration.

The superfluous platinum salt is afterwards removed by hydrosulphuric acid gas in the same way that the cadmium salt was obtained. When this operation is performed, we have left the three remaining salts in the solution, which is again evaporated to dryness; the residue is then fused, and kept at this temperature as long as any gas is given off; by this process the nitrate of ammonia is converted into protoxide of nitrogen and the vapour of water. The residue contains the salts of lithia and soda. By adding sulphuric acid in proper quantity, and by heat, the nitrates are converted into sulphates, and the nitric acid is expelled.

These sulphates are now dissolved in water, and decomposed into their corresponding chlorides by means of the careful addition of chloride of barium in solution, and afterwards separated by filtration from the sulphate of baryta thus formed. The filtrate now contains the chloride of sodium and the chloride of lithium, which is now to be evaporated to dryness. The residue is now placed in a well-closed vial containing a mixture of absolute alcohol and ether, and put aside for a few days, at the end of which time the whole of the chloride of lithium becomes dissolved, whilst the chloride of sodium remains undissolved, and may be obtained by filtration. If it had been an object to obtain the ammoniacal salt in the form of ammonia, the process would have been different, which I will not now describe, because the present lesson is rather long already.

## Proceedings of Societies.

### North London Photographic Association.

The monthly meeting of this association was held on the evening of Wednesday, December 17, Mr. G. Shadbolt in the chair.

After the usual routine proceedings, the following gentlemen were elected members of this society: Messrs. Dallmeyer, May, Bockett, and Lock.

In the absence of any paper, the Chairman called attention to some enlarged photographs by Mr. Wenderoth, of Philadelphia. They were enlarged by the solar camera; but instead of the use of the mirror, the camera *itself* was directed to the sun, a ¼-plate Voigtländer being used as the enlarging lens. The pictures were printed direct, and the time of exposure required was stated to be about two hours. The prints themselves were wanting in definition, and altogether not of sufficient excellence to demand especial description. The Chairman pointed out the unsatisfactory nature as regards definition, &c., of these prints, reiterating his own objections to the principles of the solar camera, and expressing a conviction that the best mode of enlarging consisted in producing from the original negative a suitable transparency, and from this obtain an enlarged negative, and print in the usual way. He was of opinion that even if one copy only were required, that this was the proper course to pursue. He especially directed the attention of photographers wishing to enlarge, to his suggestion of first *reducing* the picture to be enlarged, and then at once to enlarge the same to the required size. He observed a gentleman present, who, if he would, could throw considerable light on the subject.

Mr. Dallmeyer, who was thus called upon, made some observations on the principles of the solar camera, in which he concurred in the main with the observations made by the chairman; but remarked that he had lately seen some photographs enlarged by the aid of the solar camera by Mr. Stuart of Glasgow,* which certainly took him by surprise, for as regards definition, these pictures left little, if anything, to be desired. Before seeing these pictures he himself had always strongly recommended the production of an enlarged negative, from which

* Mr. Dallmeyer had seen the pictures by Mr. Stuart we recently described, see p. 590.

to print in the ordinary way, in preference to the use of the solar camera; but photographers generally appeared to prefer obtaining an enlarged *print* direct, as it involved one operation only. It appeared to him now that all that was required to attain a perfect result in the direct printing process, was further to perfect the mechanical appliances of the solar camera, and use a perfect enlarging lens, which he was happy to say he had completed, and hoped shortly further to describe.

Some discussion then followed as to the best mode of using the sun as the luminary, either by pointing the camera direct to the sun, or using a reflector. The Chairman preferred the latter mode of illumination.

Mr. Bockett asked whether there was not more loss of light in using a glass mirror for the solar camera than a speculum?

Mr. Dallmeyer observed that the loss of light by speculum reflection was much greater than by the silvered mirror; in fact, silver was the best reflector.

Some observations by Mr. Burr, Mr. Hislop, and others, on the respective merits of mirrors, mode of illumination, &c., followed, after which

A conversation arose on a singular incident, related by Mr. Hill, in several negatives he had taken the image of the white crossbars in a shed, were reproduced about half an inch above the original image. Various suggestions were offered, but no satisfactory solution arrived at.

The use of methylatic spirits and ether, for collodion, was next discussed, the chairman strongly condemning its use. Some members, confirmed by Mr. Martin, expressed a conviction that much of the methylic ether could be removed by heat. Mr. How stated that the disadvantages chiefly arose from the use of old pyroxyline in methylated solvents.

The Chairman exhibited some prints of machinery, &c., taken by Harrison's new globe lenses; but there was nothing extraordinary in these specimens, or tests, as to the capabilities of the lens. He also exhibited some specimens of American card pictures, which scarcely came up to the best English standard.

Mr. Hill handed round the Society's album containing some beautiful specimens, by himself and others, and stated that members could have the loan of the same for one month in turn.

After some further desultory conversation, the proceedings terminated.

### Photographic Society of Scotland.

The ordinary meeting of this Society was held December 9th, Mr. George Moir in the chair.

After the usual routine, the Chairman announced that Mr. A. F. Adam, the Honorary Secretary, had felt that press of other duties compelled him to resign, and that Mr. T. B. Johnson had accepted the office. He then announced that the Council had, for various reasons, although with great reluctance, come to the resolution that there should be no Exhibition of Photographs this season. The experience of last year's Exhibition had not been encouraging, as the receipts had not nearly covered the expenditure. This season had not been a good photographic one, whilst the attractions of the Great Exhibition had prevented the greater number of amateurs from doing anything. Then there was considerable commercial distress in the country; and above all, it was not possible to procure an exhibition-room of sufficient size in a good locality. But he looked forward with confidence to the removal of all, or at least the greater part of these difficulties before the return of another Exhibition-season. In lieu of the regular Exhibition, there would be, in February or March, an Exhibition of photographs to the Society, of works competing for the various medals which the Council had resolved to award, as usual, to the successful competitors. The Secretary would advertise shortly in the various journals the subjects for which medals would be awarded, and the time when the pictures would require to be delivered.

A letter from Mr. Pouncy, in answer to a request to him to forward to the Society specimens of his more recent carbon prints, was then read. Mr. Pouncy willingly would comply with this request, upon condition that negatives be forwarded to him, so that his carbon prints may be directly compared with silver prints from the same negatives. This was agreed to, and the Secretary was requested to send such negatives as would afford a satisfactory test of the matter.

The Chairman then called attention to a collection of photographs of ancient Rome which covered the walls, by Mr. M'Pherson, of Rome, who was called upon to give descriptions of some of the views, and also to explain his mode of working.

Mr. M'Pherson stated that his views were all taken by the collodio-albumen process, which he found, from long experience, to be best adapted for subjects requiring long exposure. The exposure depended entirely upon circumstances; for a distant landscape, in a good light, five minutes was enough; for near objects, ten or twenty minutes; and in some of the sculpture-galleries, where the light was deficient, two hours were often required; and in one or two cases, even an exposure of two days was necessary to produce a good negative.

In answer to the Chairman, Mr. M'Pherson stated that he had not been induced to continue working his process of photo-lithography for views—not from any want of confidence as to the result, but simply from the difficulty of procuring lithographic stones and other materials in Rome, and also from there not being such a thing as a good printer, accustomed to fine work, in that city.

After some other proceedings the meeting was concluded.

## Correspondence.

### FREE NITRATE IN DRY PLATES.

Sir,—About a month ago, being confined to the house through indisposition, I betook myself to trying some experiments with tannin and honey, and tannin and gum, and using free nitrate of silver in the preservation; but the unfortunate continuance of bad weather prevented me from getting out to expose the plates I had thus prepared. However, not be done out of trying the effect, I resolved to expose some of them as transparencies, and (to use an old phrase) was agreeably disappointed with the results. The tone was a rich purple brown, soft and delicate, having somewhat the appearance of stained glass, and gave me every encouragement for further experiment when time and opportunity afford. I will not trouble you with any lengthy detail, but briefly state my method of procedure, which is as follows, much the same as Mr. Hannaford used in his Fothergill modification:—Sensitize the plate in the usual manner, and wash in one or two changes of rain water. Apply the preservative at one corner; let it flow evenly over the plate, and off; repeat a second quantity, and allow it to remain on for a few seconds, keeping the plate in motion; pour off, and wash under a tap, or other convenient way. This must be well effected, or stains and markings will be the result of neglecting this precaution. Set up to drain awhile, and remove to box to dry, on clean slips of glass with blotting-paper under.

The preservative I used was made as follows:—Equal parts of a 15-grain solution per ounce of tannin and honey, or tannin and gum (the gum solution to be sufficiently thin to flow freely), to which is added a ½-drachm of a 30-grain solution of pure nitrate of silver, containing ½-grain citric acid, and used when newly made. To develop the plate, moisten with distilled water, and apply a 1-grain solution per ounce pyro only, until the image make its appearance; wash, and apply 2-grain solution of pyro, 1-grain citric acid, and a few drops of 30-grain solution of nitrate of silver, until the development be completed.

I should apologize for now troubling you; but as your journal had just come to hand, I was pleased to find (although I thought it strange) that another gentleman had been experimenting in the same direction as myself; and, though in a somewhat different way, yet I believe to the same end. However, the above facts are at your disposal, should you think them of any service.—I am, sir, yours very respectfully,

John Frew.

7, *Railway Terrace, North Shields*, 8*th Dec.*, 1862.

P.S.—I exposed some of the plates on Saturday, having much c earer weather; but previous engagements prevented me from developing them until to-day, when I only got one done, which was very good. The exposure was the same as for wet; the collodion was bromo-iodized. J. F.

## Talk in the Studio.

Photographic Piracy.—Another prosecution under the new Copyright Act was heard at Marlborough Street, on Monday. Wm. Peter Haywood, of Great Portland Street, appeared to answer a summons under the Amended Copyright Act, for, without the consent of Messrs. Southwell, photographers, of Baker-street, offering for sale copies of the photograph of Miss. Lydia Thompson in Scotch costume, in which there is a subsisting copyright to the said Messrs. Southwell. Evidence having been adduced, the magistrate said that, as the defendant had given up the whole of the copies, a fine of 5s—though he was liable to a fine of £10—would do. William Milford, of Dorset-street and Oxford-street, was next summoned for a similar offence, the proceedings, as in the preceding case, being under the Amended Copyright Act. Mr. Greenwood, who appeared for the complainants, said he should press for the full penalty, as the defendant was the person who had sold the photographs. The case having been proved, Mr. Tyrwhitt said he should not impose the full penalty, but order the defendant to pay 40s. and costs. Mr. Gambart has written the following letter to the daily papers on this subject :—Sir,—In your police reports of this day I see that Messrs. Southwell Brothers, photographers and publishers, have obtained prompt justice against Mr. Hayward, of Great Portland Street, and Mr. Milford, of Dorset Street, both being convicted of selling spurious copies of Miss Lydia Thompson's portrait, and that they were fined by Mr. Tyrwhitt for the offence. I have often heard of two weights and two measures; but, although a foreigner, I still cling to my belief in English justice. I cannot, however, help looking with disappointment on the different manner in which cases were received in other courts where I have sought remedies against like offenders. I am not, indeed, the publisher of charming portraits, but I do try to protect works of art, such as "The Light of the World," by Holman Hunt, and Rosa Bonheur's "Horse Fair;" and what is my experience? I appear under the same Act, 25th and 26th Victoria, before Mr. Corrie, and am told it will not do, and must go to another court. I appeal to Justice Willes, when, after much talk by eminent lawyers, points are reserved, and I am left in suspense as to whether my property belongs to me or not. But this is not all. Twenty years of residence in England have thoroughly imbued me with English ideas, and admiration for the laws and institutions of the country; and, when speaking of these with praise to my brother publishers of the continent, they cry out, "What about the International Copyright Treaty between France and England? Come to France; travel from Calais to Marseilles, and you will not find any pirated copies of English engravings offered for sale, or, if any occur, you have instant remedy against the offender; but all over London we see infringements of our copyrights, and are told that we have no remedy except at enormous expense, and then with a doubtful result. *Perfide Albion* has done us again."—I am, sir, yours, &c.,

*December* 23. E. Gambart.

The Sleep of Sorrow, &c.—Monti's exquisite group in marble—"The Sleep of Sorrow and the Dream of Joy," has been purchased by the London Stereoscopic Company. They have also become the possessors of the charming statue of Daphne, by Marshall Wood.

Photographic Gift Book.—Amongst a number of books and pictures on our table waiting for review we have one which claims immediate attention, as being one of the best Christmas Gift Books which a photographer can present to a friend. We refer to an edition of Scott's "Lady of the Lake," just issued by Mr. Bennett, of Bishopsgate Street. The various charming scenes in which the action of the poem is laid are illustrated by photographs, executed by G. W. Wilson and by T. Ogle. Few poems could present a greater number of scenes which, apart from the associations of the poem, present so much of picturesque beauty to the camera, whilst the stirring descriptions of the poet impart to them a peculiar interest which will be readily appreciated by every lover of the poem. Who, for instance, that has read the poem—and who has not?—can gaze on the charming photograph of Coilantogle ford without picturing to himself the terrible combat between James Fitz-James and Roderick Dhu? or on Ellen's Isle, without fancying the little skiff of the Lady of the Lake skimming the surface of Lock Katrine with stately Benvenue beyond? The majority of the photographs are, moreover, very fine and full of atmosphere. Adverse criticism of any part of a work so well intended and so well worked out would be somewhat ungracious, otherwise we would suggest that some of the prints are a trifle dark, and that the square shape is not the best for such pictures. The work is beautifully printed on tinted vellum paper, and very handsomely bound, and altogether a very beautiful book.

## To Correspondents.

*** Owing to an unusual pressure in our printing office, the intervention of Christmas Day, and the preparation of an elaborate index, we have been compelled to delay the publication of the Photographic News to Saturday, instead of Friday. The four pages extra, rendered necessary by the title-page, index, &c., are given without extra charge.

A. T. P.—Mr. Spiller has kindly furnished us with some further hints as to the use of caustic soda for preventing, or removing, the incrustation in steam boilers. From two to three pounds, for 1,000 gallons of water, are used in the Royal Arsenal. Mr. Spiller's "Memorandum on the Prevention of Incrustation in Steam Boilers" appeared in the proceedings of the Royal Agricultural Society. It is extracted at length in an article on "Boiler Explosions," in *The Engineer* of the 21st of last month.

J. W.—We have not used the formula of M. Schuatz. It will be very easy to try whether a less proportion of platinum will answer the purpose. We do not see any advantage to be gained by toning after fixation, although some operators prefer that method. The process is more difficult, and requires a stronger gold solution. Mr. England fixes in a saturated solution of hyposulphite of soda, and then tones in a bath of hyposulphite of soda and gold You may fix first, and then, after a very thorough washing, tone in the ordinary alkaline gold solution; it will generally require, however, to be much stronger than if the print were toned before fixing.

E. J. T.—All prints, and especially those on albumenized paper, such as card pictures, should be prepared for receiving water colours. Newman's "preparation" for the purpose is the best material we know. 2. Ordinary good water colours are used. 3. It is not customary to use any varnish, or other final coating, after colouring. Some persons use an encaustic paste, after touching, to give uniformity of surface. You will find Mr. Wall's work, a "Manual of Colouring Photographs," price 6s. 6d., or "Newman's Harmonious Colouring Applied to Photographs," price 1s., a new edition of which is just published, of great service to you in colouring.

W. B., a New Subscriber.—Gum and treacle would not make a suitable preparation for application to photographs. There is no lens capable of producing more than one impression at once.

P. M —We have not used the lens in question, but should not recommend it for card pictures.

G. M. Redaway.—It is difficult to determine the cause of the dull, red, poor effect of your prints. Had you not stated the direct contrary, we should at once, from their appearance, have concluded that the silver bath was much too weak. Possibly it is too acid, or possibly the paper is in fault. In any case much deeper printing would have been desirable, and longer toning. We should think that the negatives were very good.

P. M.—Your toning bath contains right proportions. In order to get blacker tones, you must print considerably deeper.

An Amateur.—You do not state sufficient particulars to enable us to form an opinion of the cause of the red tone in your print. It may have been inactivity of the gold bath, or it may have been insufficient time of immersion; or it may be bad paper.

Vaissier et Verey.—We will make enquiry of Mr. Fry as to where his yellow glass was obtained; but we must warn you that, without testing the sample you purchase, there is very little certainty of obtaining a truly non-actinic glass.

Geo. Fielder.—We have received many complaints recently of the difficulty of obtaining deep tones; probably the cold weather, in some degree, affects the question. Print deep, and slightly warm the toning bath; this will probably aid you.

Globe Lens —We have seen several pictures produced by the globe lens, but none that give the slightest evidence of its alleged superiority. It is not likely that it will be manufactured in this country, as it is patented. We have seen the specification of the patent, with diagrams, but cannot perceive anything in its construction which can justify the claims made for it. The field must be very much curved indeed; to render it at all available, it appears to us, that it must be used with an extremely small stop, which would make it very slow. We do not imagine that it will ever come much into use, as it appears very dear, without any real compensating qualities that we can ascertain.

N.—The use of freshly precipitated oxide of silver is the most philosophical mode of neutralizing free nitric acid in a bath; but bicarbonate of soda may be used with perfect safety, and sometimes, indeed, with greater advantage than anything else; as, when added slightly in excess, a precipitate of carbonate of silver is thrown down, which often takes with it other impurities and improves the bath

W. Atkins.—If the toning bath be decomposed by the immersion of prints, it generally indicates the presence of free nitrate of silver in the prints. Try washing the prints, as well as immersing them in the acetate solution. Slow or unsatisfactory toning, at this season of the year, is often removed by warming the solution.

Studio.—If you make your sitter face the south, and shut out direct sunshine by means of blinds, you will lose more light than by making him face the north, without blinds. 2. We do not quite understand what you mean by the half circle over the head, but it is probably due to other causes than the lens.

Nitrate of Silver.—A correspondent, whose letter is mislaid, asks how to make nitrate of silver from the metal recovered from his waste, may be converted into nitrate. He will find full instructions in an article on page 6 of the fifth vol. of the Photographic News.

Erratum.—In Mr. Stewart's paper on the Solar Camera, p. 595, the sixth line from the bottom of the article, he is made to say that he is "satisfied with the apparatus. The word should have been "dissatisfied."

Several correspondents in our next.
