THE

# PHOTOGRAPHIC NEWS:

A WEEKLY RECORD

OF THE

# PROGRESS OF PHOTOGRAPHY.

VOLUME VI.

EDITED BY G. WHARTON SIMPSON.

" *Nulla recordanti lux est ingrata.*"—MARTIAL.

LONDON:
PRINTED AND PUBLISHED BY THOMAS PIPER, 32, PATERNOSTER ROW.

1862.

# PREFACE.

In completing our Sixth Volume, we have the pleasure of addressing some hundreds more readers than we did at its commencement. This is, to us, a circumstance especially encouraging, as affording the best practical assurance that our earnest desire and continual efforts to render the Photographic News a worthy exponent of the Photographic Art, and the recognized organ of Photographers, have not been fruitless; and suggesting the certain hope that continued exertion in the same direction will meet with like appreciation and similar success.

As each year's record of progress is completed, each year's history chronicled, we feel deeply impressed with the growing importance of the Art we represent. During the year which has just passed, Photography, in its every phase, has been pre-eminently successful: its processes have been improved; its art results have assumed a higher character; its applications have been vastly extended; its commercial prosperity has been unprecedented. The success of the Art, whilst it makes the labours of the journalist more satisfactory, also renders them more responsible, and claims a more conscientious and sole devotion to their right discharge. The growing experiences, discoveries, and suggestions of Photographers throughout the world, have to be collected, winnowed, verified, condensed, garnered. Whatever tends to the advancement of Photography, either in science or practice—whatever tends to its elevation as an Art, whatever tends to extend its scope and applications, and thus increase its economic value and commercial success—demand from the Photographic Journalist not simply record, but advocacy and encouragement.

In the prosecution of our task, we have preserved an abiding sense of the responsibility attached to it; but we must add that this consciousness has not made it the less a labour of love, into which we have entered heart and soul. Our task has also been cheered and lightened by the augmented confidence of our increasing constituency, and the aid and information we have received from every quarter. To a large number of friends and correspondents we here tender our thanks for very material and constant assistance in advancing the Art in various ways, and enabling us to present, in the Volume for 1862, a complete record of everything worth remembering in the year's results.

We need to add but few words as regards the future. Where mutual confidence exists,

but few pledges are necessary. Where we have striven to be the pioneer of progress, either in the artistic or scientific aspects of the Art; where we have aimed to initiate improvements, as well as to record them and give them publicity; where we have maintained the interests of Photography and Photographers in every way in which we could perceive their advancement was possible, we shall "walk by the same rule, and mind the same things." No existing feature of interest in the PHOTOGRAPHIC NEWS shall be removed or diminished, and no opportunity shall be neglected of adding to its usefulness to Photographers—professional and amateur. We conclude these brief after-words with wishing to all our readers a joyous Christmas and a prosperous and happy New Year.

32, PATERNOSTER ROW, *December* 24, 1862.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 174.—January 3, 1862.

## A GLANCE AT THE PAST YEAR.

In glancing at the progress of photography in the year 1861, we cannot exclaim *annus mirabilis!* There have been no wonders to chronicle; no startling discoveries to reveal. But the year has been, nevertheless, one of progress in the more important aspects of the art. There has been a decided improvement in the quality of the pictures produced, and a higher standard of excellence is obtaining recognition amongst photographers generally. Better pictures are appreciated, better pictures are aimed at, better pictures are obtained. A better understanding prevails of what pictorial excellence demands, and a more perfect mastery over the means to that end, is gradually being attained.

A few years ago, if a picture were clean, and sharp, and brilliant, it was unhesitatingly deemed to merit praise as "excellent photography." If it were out of focus, blurred, hazy, and not all made out, it was deemed "artistic and suggestive." Now, however, a picture to merit the praise of being good photography, or of being artistic, must be something more than either of these we have described. A photograph to be good and artistic must be soft and properly graduated, as well as sharp and brilliant; it must be made out, and properly defined in all its parts as well as atmospheric; it must be harmonious in tones, and balanced in forms. No immense patch of white paper for a sky, cut from the landscape by a hard horizon, will now satisfy the aspiring photographer. Natural clouds if possible, or at least a tint with some suggestion of atmosphere must now supply the bald white space we used to see. The increased number of good pictures we see produced, the still more increased interest in, and desire to produce such pictures, gives us strong assurance of the great artistic progress of photographers and photography.

Another phase of the progress of artistic photography is to be found in the increased production of instantaneous pictures, especially of marine and atmospheric effects. That such effects were amongst the first productions of the collodion process we well remember. But the effects attempted, the results obtained, and the proportion of successes were not to be compared with those of the present day, in either number, variety, or excellence. The daring and exquisite effects of Wilson, in sun, and cloud, and water, and atmosphere, no longer stand alone; but have been produced by so many amateur and professional photographers, and in some cases with such success, as to render it necessary for Mr. Wilson to look to his laurels, or content himself with the credit of initiating what others are now successfully imitating. We have before us at this moment some slides, which for grand effects of atmosphere and chiaroscuro we have never seen surpassed.

Another question which has reference almost entirely to artistic effect, has recently occupied the attention of photographers, we refer to the wide angle in landscape pictures. If no other result were to arise from the discovery of the panoramic lens, it has at least done good service in originating the discussion on the value of a wide angle of view. That there are many cases in which the beauty of the scene can only be rendered by including a wide angle we have already affirmed, and that for the production of such landscapes there is no doubt the panoramic lens will come into use; but apart from its own special advantages, we repeat, the discovery of the panoramic lens has rendered good service to photography in showing the possibility and the excellence, on many occasions, of securing something more than an angle of forty degrees, and suggesting the production of such exquisite photographs as the recent 7 by 5 landscapes of Wilson, which include an angle of nearly sixty degrees.

No great optical discovery has been made during the year; no especial novelty has been introduced. But we conceive there is decided tendency to the improvement in the lenses used. Instantaneous photography demands quick acting lenses; album portraits demand a flat field, with perfect definition and quick action; a wide angle of view demands lenses with excellent marginal definition: and from the perfection of the results we have seen during the year, we conceive that these characteristics in lenses have been secured by the best makers in a degree not before attained. We also notice that the improved taste amongst photographers generally has created a fresh and increased demand for appliances of the best quality, the users and producers thus reacting beneficially upon each other.

We have been somewhat disappointed in the tardy progress made by the solar camera, or other means of enlargement. That the system of producing large proofs from small negatives will eventually become popular, we have not a doubt. The facility for producing perfect instantaneous small negatives, either in portraiture or landscape, and the pictorial value of such pictures, when well enlarged, possess advantages too palpable to be lost sight of. To what cause the slow progress of the enlarging system is due, in this country, we cannot with certainty say; the absence of direct solar light during a great part of the year, most probably. Be that as it may, it appears certain that we are far behind our continental neighbours in this respect. We have not anything like the productions of Ghemar of Brussells, or of Disderi, or Alophe, in Paris; and if a tithe of what we hear be true, we shall in this respect, at least, have to hide our diminished heads at the forthcoming International Exhibition.

In the chemistry of photography comparatively little discovery has been made. In the wet collodion process the chief noticeable fact is the all but universal use of bromo-iodized collodion, iron development, and intensifying processes. During the spring some hope was raised of the possibility of dispensing with a nitrate bath by combining the sensitive salts of silver in one vehicle, by which means a plate would be ready for exposure as soon as it was coated. A similar idea had been mooted in these pages during the preceding year, but had not been vouched by results.

The first intimation of the discovery by Captain Dixon, was accompanied by two or three excellent negatives as specimens of the process. *If* the negatives shown to us were produced by the method then described, and subsequently patented, the discovery was a most important one. All the subsequent results shown to us, were, however, decidedly inferior to what we ourselves produced in the same manner. The patent was abandoned, and the process belongs to photographers generally, or such of them as may be disposed to experiment further in the matter. Captain Dixon's method simply consisted in adding a small quantity of nitrate of silver, dissolved in alcohol, to iodized or bromo-iodized collodion. All questions of exact proportions remained undecided. The pictures were developed either by iron or pyrogallic acid. In our own hands the chief difficulty was to obtain sufficient density without fogging. We found no difficulty in making and keeping a preparation sensitive to the action of light, which yielded an image in the usual time. The process being patented deprived it of sufficient interest at the time to induce us to continue our experiments;

but we believe the matter is well worthy of further attention, M. Gaudin also gave some attention to the subject, with, as he announced, successful results. The conditions on which his success depended have not been published.

In dry processes we have had many modifications and novelties suggested, some of which have been worthy of attention, but all have left something to desire. The points which remain to be secured are rapidity and simplicity. With the exception of these qualities we think everything as regards excellence and certainty are to be found in the collodio-albumen process as practised by Mr. Mudd. The chief objection consists in the number of operations involved in preparing the plates. Even rapidity may be obtained by the use of hot developers. If the same quality and certainty of results could be obtained with more simplicity, the process would be perfect. The tannin process, invented by Major Russell, is a great stride in the direction of simplicity, and the results are of excellent quality. Photographers are highly indebted to such men as Major Russell, who, with the ability, leisure, and means necessary, steadily apply themselves, month after month, without weariness or impatience, working out definite results by careful experiment, and then unhesitatingly laying them before the public for the benefit of photographers at large.

Perhaps one of the most important steps towards the improvement of existing dry processes is the new mode of development suggested by Mr. Wardley, and that by M. Roman. The use of hot solutions of pyrogallic acid for developing, as suggested by the latter gentleman, was not, indeed, a novelty, but its great value in reducing the exposure had never before been so fully brought under public attention. The development, without free nitrate of silver, was quite a new idea, and its value in securing softness and detail cannot be overrated. As our readers know, we have been successful in applying the principle to plates by several dry processes, and have reason to believe it is available in the majority, if not in all cases.

In apparatus generally, a variety of improvements have been made, and some novelties introduced, but none of sufficient importance for recapitulation here.

We believe on the whole the commercial aspects of photography have never been better. Although some branches have suffered, considerable impetus has been given to several others by the rage for what, although never used for the purpose, people will insist on calling *cartes de visite*. We believe, moreover, that better, softer, more delicate photography has been rendered necessary by these pictures than used to suffice in the eyes of many for larger portraits.

The applications of photography have not been in any way notably extended. The processes which would aid this in some directions, such as photo-lithography, carbon printing, &c., have not made such advancement during the year. One of the directions in which the application of the art has been extending is to us a source of regret rather than of congratulation. We refer to book illustration: many of the recent attempts of that kind, although bearing the names of good men, have been simply a disgrace to the art. Bad reproductions of imperfect photographs can never do the art any credit.

Perhaps no subject has excited more attention during the year than the probable position of photography in the forthcoming Exhibition. It would be worse than repeating a thrice told tale to recapitulate the history here. As all our readers know, the thing has been badly managed; it has been one huge blunder. The only thing which now can be done, is for photographers to endeavour, as far as possible, to retrieve the error they could not prevent. They will very shortly receive, what all other trades and professions have long since received, the notifications of space allotted. They will be required, we believe, to state positively whether they can undertake to fill the space allotted to them, and also to nominate gentlemen in whose judgment they can rely as jurymen in their department. We trust every photographer will now do his best to aid in producing a successful issue.

There have been a few losses by death from amongst the known ranks of photographers, and two valued gentlemen have publicly withdrawn. We trust, however, that every year we gain—it is impossible to speak of the devotees of the art except as a fraternity, with the strongest bond of a common interest and sympathy—some fresh enthusiastic, able, earnest recruits to aid in forwarding the perfection of the art in all its branches. Such men are needed. Let us all put our shoulders to the wheel.

## A NEW RAPID DRY PROCESS.

In another page will be found a communication from an old and valued correspondent, Mr. Bartholomew, of Fareham, in which he gives the formula of three new dry processes. The two first involve nothing new in principle, but claim attention on the score of simplicity, and, we believe, efficiency. The third process involves, however, the recognition of a novel principle in photography, and claims a rapidity equal to that of wet collodion.

The conditions for which Mr. Bartholomew challenges recognition are, in several respects, antithetical to those deemed imperative in the wet process. For the most successful operations with wet collodion we require the absence of organic matter, acid reactions of bath, &c., and the presence of free nitrate of silver. In the dry process proposed, the absence of free nitrate of silver, the presence of organic matter, and *alkaline* reaction, are laid down as the bases of success. The last-mentioned condition is, of course, contrary to all experience. The plentiful use of acetic acid has always been, with dry operators, a *sine qua non*. There is no reason, however, why the new suggestion should not receive a careful trial. Mr. Bartholomew says it has proved eminently successful. We can readily see how immunity from the chief evil of an alkaline reaction is avoided. As our readers well know, alkalinity is favourable to sensitiveness, but it is, unfortunately, at the same time, the sure source of fog from unrestrained reduction. Fog, however, is generally, if not always, surface deposit, and arises from the too rapid reduction of the free silver present. If, then, the development proper be effected without the presence of free nitrate, the danger of fogging is removed, and the rapidity of an alkaline condition secured, whilst the evil is avoided.

Assuming for the present that this principle will work, its applications may no doubt be varied, and it may lead to very important results. It at once suggests the value of the notion, originating with Mr. Wardley, to the working out of which we have recently given some attention, namely, development of dry plates without the presence of free nitrate of silver.

Mr. Bartholomew is, as we have said, an old and intelligent correspondent, and our readers are indebted to him for many valuable suggestions, amongst which we may mention the use of silver in the albumen solution for Fothergill plates, recommended about the same time, independently, by Mr. Hannaford. The latter gentleman and Mr. Bartholomew are always associated, in our minds, as typical of a valuable class amongst photographers, whose communications, however short, always contain important hints and pregnant suggestions.

## IRREGULAR TONING.

There is no evil which has caused more annoyance to the photographer of late years than the mealy, mottled, irregular result which some samples of paper yield under the action of the alkaline gold toning bath. An irregular mixture of slaty grey and reddish brown spots cover the print, and in the case of delicate pictures, such as album portraits, ruin the effect. Various suggestions have appeared in our columns from time to time for the removal of this annoyance, and the use of acetate of soda in the toning bath has, in many hands, either entirely or partially removed the defect. We have just had out attention called to what is styled a "perfect cure." In the Photographic News for Dec. 6th, a letter from "A Cure" appeared suggesting that, before immersion in the toning bath, all free nitrate should be converted into acetate of silver by submitting the print, for at least ten minutes, to a bath containing four drachms of acetate of soda dissolved in ten ounces of distilled water. Mr. Samuel Fry, whose letter will be found in another page, recently showed us two prints from the same sample of paper. One was as bad a case of mealiness as we have seen, the other entirely free from this ruinous defect, its immunity being solely due to the use of the acetate of soda bath he had seen recommended in the letter to which we have referred.

We shall not enter into the matter further here, as Mr. Fry has promised to bring the subject before the next meeting of the South London Society, when it will, doubtless, be fully discussed. The matter is, however, of so much importance to many of our readers, that we feel it important to call their attention to a remedy so simple, for an evil so disastrous, without loss of time, and shall be glad to learn the results of their experience on trial.

## SOME ADDITIONAL HINTS ON THE TANNIN PROCESS.

BY MAJOR RUSSELL.

The following results of a recent investigation of various means of fixing the collodion film for use with tannin may be of interest to some of your readers. Two methods appear to be quite satisfactory:—

First. Coating the glass with gelatine solution, prepared with acetic acid. This solution is much improved by adding for every 10 grains of gelatine, 2 grains of iodide of cadmium, 1 grain of bromide of cadmium, and a very small quantity of iodine, dissolved together in a few drops of water. Besides other advantages gained by this addition, the gelatine film is protected from fungus, and the gelatinized plates may be kept without any extraordinary precaution against damp. Gelatine prepared in this way does not in my hands diminish sensitiveness. No alcohol is required in the solution.

Second. Using a thin solution of india-rubber in the following manner:—Soak thin slices of raw india-rubber in benzole, one grain to each fluid ounce, for twelve hours, or as much longer as is convenient, and filter. After cleaning the glasses, warm, to ensure dryness, and allow to become cold again. Then pour the solution in the same manner as collodion, and before the liquid has ceased to drip, hold vertically at a short distance before a fire. As soon as the plate appears dry, it may be set up before the fire, near enough to keep hot and complete the drying whilst others are coated. The film thus produced is so bright that it is almost impossible to tell by inspection which side is coated, and no lines or irregularities are formed. Collodion does not flow so freely on india-rubber as on gelatine, but well polishing with a velvet rubber much improves it in this respect.

This thin film of india-rubber does not, like a thicker coat, cause cracking of the collodion, but it will not always secure sufficient adhesion, unless diluted alcohol is used instead of water to moisten before development.

The treatment with alcohol so much diminishes the tendency to loosening of the film, that most collodions may be used in this way without any previous coating, but not quite satisfactorily, as the film sometimes becomes loose, and breaks in the final washing. I am indebted to a correspondent of the Photographic News for a knowledge of this valuable property of alcohol. One part of ordinary alcohol (not methylated) to two parts of water, or equal parts of each, answer well; the exact proportion does not seem to be material. The liquid flows so freely that it may be poured on the plate and spread over it by blowing gently. The same portion may be used for many plates. After pouring off, distilled water should be poured on and off till oiliness is removed. A film on india-rubber treated in this way is not detached even by a boiling developer.

Old collodion may be much improved by adding ten or twenty drops of benzole to each ounce, or as much as can be used without rendering the film too impervious. After adding the benzole, shake up well, and introduce some slices of raw india-rubber to digest a few days before use. This treatment does not seem to alter the sensitiveness, but by hardening the film renders old collodion available for printing transparencies, or other purposes where quickness of action is not necessary; no previous coating will usually be required if dilute alcohol is used to moisten for development.

Complaints are often made that tannin plates are insensitive, generally, I think, because an unsuitable collodion is used; one sign of this may be mentioned—the appearance of the sky before development; this never occurs in my experience, on a properly exposed plate, when the collodion is even moderately sensitive.

## Scientific Gossip.

The eclipse of the sun—total in some parts of the world although but partial in England—which happened on Tuesday last, the 31st of December, has not attracted the attention which such an occurrence seems to deserve. In London it commenced at nine minutes to two in the afternoon and ended at eight minutes to four; the time of greatest phase being at seven minutes to three, when nearly half the sun's diameter was obscured by the moon's intercepting body. Being small compared with several eclipses that have lately occurred it has been little thought of; it is one, however, of considerable interest to science, and it is to be hoped that some of our readers will not have allowed to pass so favourable an opportunity of showing the eminent adaptability of their art in recording, permanently and unerringly, a photographic record of this important natural phenomenon. In other parts of the world the eclipse was total, the line of central shadow having passed, successively, over the Carribean Sea, the Island of Trinidad, and the North Atlantic Ocean; entering the the west coast of Africa, near Cape Verd, traversing the Sahara or Great Desert, Tripoli, and the Mediterranean Sea, but having been lost in sunset just before reaching the Morea. It will thus be seen that although the totality was invisible to all the great observatories and centres of civilization, it passed over several spots where ready access could be gained by astronomers and photographers, or where they were already located. At Trinidad, one of the first places where the totality would become visible there are many amateur photographers, and the important West India Islands are not very far distant for an astronomical excursionist, considering the importance of the object. The next land which it would touch would be near Cape Verd; this is readily accessible from several flourishing settlements on the coast, and also from the Islands of the same name; whilst it would scarcely be considered too far by sea from Teneriffe, the scene of Piazzi Smyth's important labours in physical astronomy. Perhaps, however, the most important station to Europeans is Tripoli; a short sea voyage from Malta, and also readily accessible from the important cities and states bordering the Mediterranean, this town would offer peculiar faculties for the observation of the phenomena of totality, whilst it would not occur at too late an hour in the afternoon to render its observation, both astronomically and photographically, a matter of difficulty, owing to the low altitude of the sun; we understand, indeed, that arrangements were made to observe it in this neighbourhood by the Moorish astronomers, who so carefully noticed the phenomena of the eclipse of July 1860, in the same country. We may, therefore, anticipate with confidence that this total eclipse will not have been allowed to come and go without having been amply scrutinized by competent scientific observers.

Reichenbach has lately shown that phosphorescence, or the continuous emission of light in darkness, is a much more common phenomenon than is usually supposed. His experiments tend to prove that phosphorescence is a usual consequence of all molecular phenomena, and not the result of combustion or oxidation. This last point has been previously proved by Dr. Phipson. According to Reichenbach, there is phosphorescence during fermentation or putrefaction, crystallization, evaporation, condensation of vapours, the production of sound, and the fusion of ice; a considerable glow is remarked when a galvanic pile in activity, a block of ice undergoing fusion, or a solution of sulphate of soda in the act of crystallizing, are observed in the dark. The human body itself is not devoid of phosphorescence; in a healthy state it emits a yellow glow; when in ill-health the glow becomes red. The author considers that this observation may possibly be of use in diagnosis. To perceive these phenomena, the eye ought to have been previously rendered sensitive by remaining some hours in perfect darkness; and even then all eyes are not equally impressionable. But if several persons unite in performing the experiment together, there will always be a certain number who are able to see the phenomena. Some of our readers will doubtless be reminded by these observations of the strange announcements mode some years ago by the same author, of the existence of a new force in nature, which he termed the Odylic force, and which apparently formed a connecting link between physical and vital forces. It was stated to be seen by some persons only in the form of a luminous glow, issuing from the poles of crystals and magnets, and streaming from the fingers and other parts of the body. Little credit was given at the time to these extraordinary statements, although made by a man of established scientific reputation, and the subject seems to have since been quite forgotten. Probably it will be found upon reinvestigation, that the phenomena of phosphorescence, which are known to be general, will account for most of the luminous glows said to be seen by Reichenbach's patients. These "occult" researches well deserve further investigation, and would doubtless reward an enquirer. Amongst others, we remember a fact which photographers might easily verify; a horse-shoe magnet was placed in a box, and opposite to its poles, near, but not touching, was arranged a sensitive daguerreotype plate. The whole was then enclosed in a feather-bed, or some such contrivance for keeping it in perfect darkness, and it was put away. After the lapse of some considersble time (whether weeks or months we do not remember), it was examined, and the daguerreotype plate developed with the vapour of mercury. On the spot opposite to each pole of the magnet there appeared a white patch, which Reichenbach considered was due to the light issuing from its poles. This experiment could be repeated at the present day with more chance of success than at the time it was tried by Reichenbach, inasmuch as the exquisite sensitiveness of the collodion film would be likely to record any action in much less time than would the metal plate. Even if the result were found to be the same as described above, it would by no means show that it was due to *light* issuing from the poles of the magnet. The different conditions in which the various parts of the sensitive plate were in, with respect to *heat*, consequent upon the contiguity of a mass of iron, might in time cause one part of the plate to darken under the reducing agent; and, moreover, it is not improbable that magnetism itself might have a disturbing action on the exquisitely balanced affinities in the sensitive collodion film.

An interesting fact is mentioned in the transactions of the Physical Society of Bombay, just published. In a typographical and geological sketch of a portion of the province of Jhalawan, the writer took with him a photographic apparatus, stereoscope, and slides. The instrument was, as might be supposed, a source of extreme wonder to the people. The Marwarree Sidar of Kholwar, coming one day to obtain medicines for his sick son was shown some stereoscopic pictures of the neighbourhood. He was vastly astonished and delighted, and not a little mystified as to how it was managed to get the fortress of Gwujjuck shut up in so small a space as the stereoscope. The author states that there is a vast difference with the natives as to their capability of understanding pictures. A man, to whom a stereograph was shown and who had never seen a picture of any sort in his life before, detected at once the little figure of a man standing at the door of a Mosque; while an intelligent native officer, on being shown a large portrait of her Most Gracious Majesty, naïvely asked if it were a camel.

In a previous "gossip," when giving the results of an examination of some coloured glass in the spectroscope, we took occasion to suggest that photographers should not confine their attention solely to glass, but should endeavour to find some other illuminating medium less liable to fracture and equally efficacious in filtering off the chemical rays of light. Acting on this suggestion, a correspondent, W. R., has forwarded to us three pieces of coloured fabric, which appear from our examination to be a considerable advance in the right direction. They apparently consist of muslin, thoroughly saturated with a hard, dry varnish, and coloured with different shades of orange red. No. 1 is too pale to be of service, as it allows large numbers of the active rays to pass through, the green, blue, and indigo rays suffering but little obstruction. No. 2 is the darkest of the three, it cuts off in a most perfect manner all the active rays, but unfortunately obstructs the greater part of the light at the same time, so that to properly illuminate the dark room it would require a considerable area of this translucent material. No. 3 is intermediate in colour between Nos. 1 and 2. In the spectroscope it is seen to allow the red, orange, yellow, and some of the green rays to pass through whilst it cuts off all above. In very brilliant light we have been able to detect a few struggling rays of the upper green (active on bromide of silver), which passed through; but these were very feeble, and for all ordinary purposes might be safely disregarded. The medium is tolerably translucent. and would suit admirably for the windows of the photographic laboratory. It is, however, open to two objections, being extremely brittle, and also (as the colouring matter is organic) likely to fade on long continued exposure to sunlight. We shall add a few words on the method employed in the preparation of these samples in our next.

## THREE NEW DRY PROCESSES.

BY WM. BARTHOLOMEW.

Dear Sir,—On a former occasion you were good enough to publish a formula of mine in the Photographic News, so I again send you some more, which, I believe, have the merit of novelty, and will be found upon trial to be worthy of the attention of your readers.

I have three separate dry processes to describe, one of the usual sensitiveness, and two of unusual rapidity. To begin with the first:—

*First.* Coat a perfectly washed and sensitive collodion film with a solution of caramel; the exact strength is immaterial; I have used it about the tint of brown vinegar, or brown brandy; dry, and expose as for a tannin negative, moisten, and develop with pyro and water, then with pyro, acetic acid, and silver; this formula produces clear, vigorous, rich brown negatives, with a good stable film.

*The Second* formula is to finish the preparation of a Fothergill plate with a coating of the same solution; dry, and expose for about one-sixth the usual time (according to my calculation), and develop as usual; the like results, or nearly so, are produced with Petschler and Mann's, the hot-water, and I think, the collodio-albumen, and very likely the albumen simple processes.

*The Third* formula involves the recognition of a principle in dry plate photography, which has hitherto not been noticed: it occurred to me that if in the wet collodion process we require free nitrate of silver — acid reaction — and no organic matter; so probably in the dry collodion process we require—*no* nitrate of silver —alkaline reaction—*and* organic matter. I forthwith put it to the test, and was gratified to find that the applica- of this principle enabled me to produce a plate, which when dried, is as sensitive as *wet collodion*. I have selected gelatine as the most suitable organic compouud, and soda as the most suitable alkali, although other organic substances answer, and you can obtain a picture with potass, solution of magnesia, lime water, &c. I have not tried the *alkaloids*, and cannot state their effects. It appears to me that this principle can be successfully applied in a variety of processes, for instance, for solar camera pictures. the waxed paper process, washed calotype papers, and I am sanguine enough to believe that by its means *dry* plates will, ere long, be prepared far more sensitive than *wet*. I have not tried it on chloride of silver in place of free nitrate, but it deserves a trial. I think I will now state my formula.

Gelatine, 1 drachm, distilled water, 10 ounces, dissolve and filter; coat an unlimitedly washed sensitive collodion film with it: dry, and apply a solution of carbonate of soda (sub-carbonate); I have used from two to ten grains to the ounce; dry and expose as for wet collodion, well moisten the film, and develop with iron and acetic acid, with some acid nitrate of silver added on using. Intensify, if required, with pyro and silver, *sec. art.* The alkali can be dissolved iu the gelatine solution, and will produce the same results; but reasoning theoretically, the film would appear to be less liable to disturbance, by adopting the second wash.

I hope you will pardon such a long letter, for I have endeavoured to state what I wanted in as concise a manner as possible, and, in conclusion, allow me to assure you that there *is* a certainty of success in either of the above processes, if carried out as I have described.

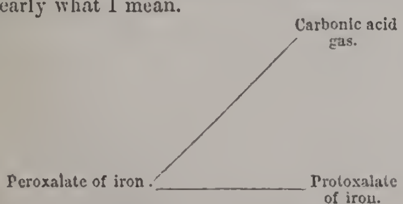
*Fareham, December* 21*st*, 1861.

## ON A NEW IRON PROCESS OF PHOTOGRAPHIC PRINTING.

BY EMERSON J. REYNOLDS.*

In the commencement of the present year accideut led me to the study of the composition and properties of the oxalates of iron. In the course of my experiments, I observed the peculiar power which light exerted on them, namely, that of reducing the oxalate of the peroxide of iron to the state of protoxalate. On this property, possessed by these compounds, I have based the process for photographic printing, which I propose to have the honour of bringiug before you this evening. Before entering ou the description of the process itself, you will allow me to speak briefly of the mode of preparation of some of the leading characters of two oxalates of iron—the proto and per-oxalate. In this way I hope to render what will follow more intelligible to you.

For our preseut purpose, then, it will be sufficient for me to say that two oxalates of irou exist which are convertible one into the other under certain conditious. The oxalate of the peroxide may be prepared by dissolving hydrated peroxide of iron in a solution of oxalic acid; when excess of acid is present, a very soluble salt is formed, the solution of which has a sweet taste, and when exposed to the action of the solar rays, is decomposed into carbonic acid gas, which flies off, protoxalate of iron being simultaneously deposited in the form of a yellow powder. The following diagram will explain more clearly what I mean.



* Read before the Dublin Chemical Society.

This yellow oxalate appears to be identical with the salt produced by adding oxalate of ammonia to a solution of proto-sulphate of iron. Now, let me direct your attention to the fact, that the peroxalate of iron is very soluble, while the protoxalate is insoluble, or nearly so. To apply this principle to the purpose of printing by light, all that requires to be done is to saturate paper in the ordinary way with a solutiou of peroxalate of iron, to dry it in the dark, and expose it under a uegative photograph. When sufficiently exposed, it may be removed from the printing frame, and on being examined will be found to have acquired a *dark* colour wherever the light has acted, that is, in the shades and semitones of the picture. It may be remembered, as I stated before, that the colour of the protoxalate of iron, which is the result of the action of light, was yellow. Then, it may be asked, how is it that this deposit is of a dark colour? The auswer to this is very simple. Protoxalate of iron, when formed uuder the influence of light, without the presence of moisture, is deposited in the anhydrous state; when in this condition, it has a dark colour, but the moment it is brought into contact with water, the light yellow hydrated salt is produced; it is precisely the same with a picture; for the moment it is immersed in the water the dark outlines disappear, and instead, there is a yellow impression observed. So far, however, the picture is almost invisible, consequently some means must be had recourse to in order to develop it. There are several ways in which this object can be accomplished; perhaps the simplest is by the use of the red prussiate of potash or ferrocyanide of potassium. When the picture is immersed in a solution of this salt, the parts exposed first become green and then blue, of course the deposit is prussian blue. Although this reaction was useful, in the first instance, for the purpose of showing me how far the actinic action had gone, yet it is evident that the colour produced would not do for the production of regular pictures. Hence I was obliged to find some other developer by means of which a grey or black photograph could be obtained. After some search I fouud a developer which accomplished everything I wanted, and this was, ammonio-nitrate of silver. By treating the print with a solution of this salt, I get a deposit containing metallic silver in a finely divided state, which being black, gives the picture its proper intensity of tone. All that now remains to be done is, to wash well, dry and mount, when the picture is finished.

I have now given, step by step, the various means by which I have worked out the process; there are some modifications which I have since introduced that I will now proceed to notice.

I frequently observed that the prints produced by the process I have just described, were wanting in the beautiful accuracy of detail, observable in pictures priuted by the chloride of silver process. I immediately set to work in order to find out the reason of this, and at last came to a correct conclusion as to the cause of failure. I found that a solution of the peroxalate of iron was capable of dissolving a very considerable quantity of the protoxalate. Here lay the solutiou of the difficulty. The explanation was just this—when the print was immersed in water after coming out of the printing frame, the peroxalate is dissolved, which in turn attacks the finer and more minute deposits of protoxalate, dissolving them before it gets too much diluted to exert its solvent power. The question now arose as to the best measures to be taken iu order to prevent the details from being lost in such a manner. After a great number of experiments, I found that the difficulty might be overcome in either of two ways—one being to substitute the combination of peroxalate of iron with oxalate of ammonia for the plain peroxalate, this compound salt not having any action on the protoxalate. The second way was to wash the print immediately on coming out of the printing frame, with a solution of acid oxalate of ammonia, which immediately formed the double salt above referred to. By either means the desired ends may be accomplished, and pictures obtained with their full amount of detail. It is almost needless for me to add that the picture can readily be toned with gold by means of the alkaline gold toning, both generally in use amongst photographers. There now remain some questions to which I wish to draw your attention. In the first place, a query which naturally suggests itself is, whether prints can be produced as rapidly by this process as by the old one. I can easily give an affirmative answer to this question, for I have repeatedly taken prints from a negative on a fine day with as short an exposure as if I were employing a sensitive surface of chloride of silver. I have compared the relative action of the solar spectrum on paper prepared with a solution of peroxalate of iron, and with the usual sensitive surface of chloride of silver, and I find that the oxalate is acted on from the green up to a considerable extent beyond the visible violet rays; in this respect somewhat resembling chloride of silver.

Now from what I have said, you will see that my process possesses two great advantages over the ordinary one, in being both very cheap, and the prints produced by its aid requiring a very slight amount of washing. The same operation of washing has been the bane of photographers ever since the art was discovered. We may form some idea of the trouble incurred in producing, or endeavouring to produce, a stable picture, when an eminent writer on the subject states that no picture can be considered at all safe unless it has undergone at least eight or ten hours continuous washing with running water. I think no one will deny that my process contrasts very favourably with this, when I state that a picture, by its means, can be printed, developed, washed, dried, and mounted, all within two hours, on a fine summer's day. So far as their permanency is concerned, I can only say that I have exposed a picture during a period of three months, on every opportunity, to direct sunshine, and up to the present time I have not observed any indication of fading. I may remark that the cost of the production of a hundred pictures, by my process, is something ridiculously small when compared with the considerable outlay incurred in printing the same number of pictures in the ordinary way.

In conclusion, I may say, that I trust photographers will try this process for themselves, and ascertain whether it is worth following or not. It must be remembered, however, that it is as yet in a very imperfect state; but I hope in the course of the ensuing spring and summer to be enabled to continue my experiments in this direction, and if it is not found to be capable of practical application, at least it affords a curious instance of the use to which the knowledge of an apparently abstract scientific truth may be applied.

The society then adjourned.

## THE ORIGINAL FOTHERGILL PROCESS.

BY S. BOURNE,*

Perhaps no process in photography has had more said or written about it than that which we term the "Fothergill process." At one time the journals were filled continually with papers, discussions, and correspondence in reference to this popular discovery; and I confess that I am most reluctant to add to what has been written, and to trouble the Society with another paper on this almost threadbare subject. But as I was requested to do so by our worthy President, and as Mr. Hill would not let me escape, I must make the best of it, promising that if any member should feel disposed to compose himself for a comfortable nap until the reading of it is finished, I will not disturb him. *Apropos* of this I may remark, *en passant*, that a photographer living in the provinces, and unaccustomed to attend the meetings of any photographic society, has doubtless an imperfect idea of the feelings which sometimes pervade these meetings. The reports in the journals, I fear, do not always give a correct notion of the kind of reception a paper meets with; and the intimation at the end that a vote of thanks was passed to Mr. So-and-so, for his "interesting paper," gives but a faint idea of the inward grumbling and uneasiness, the gaping and listlessness, manifested by the majority while this same "interesting paper" was being read. In such a case the author of a paper has an advantage in being absent, since he is likely to gain a more flattering idea of the reception it meets with from reading the report of the meeting in the journal than he would have done had he been present. But if I may be allowed such a digression, I should like to wake up some of the gentlemen who attend meetings simply as critics or listeners, and ask how it is that they do not take a more active part in furthering the progress of our art? How is it that, in a Society numbering over a hundred members, photographers in the country get the impression that it contains only some twelve or fifteen? Why are the names not seen, nor the voices heard, of the great majority? Has nothing occurred in *your* photographic experience capable of interesting or benefitting your fellow students? Why not, then, throw it into the common stock, and instead of ceaselessly ringing the changes on a few well-known, cherished, but over-worked names, step forward yourselves and put a shoulder to the wheel, and you will not only receive the thanks of President, Secretary, and Committee, but of hundreds whose isolation from all photographic intercourse causes them to look forward to the proceedings of these meetings with great interest.

The object which, in this paper, I have specially in view, is not to introduce a new "modification," or to carry you through a labyrinth of experiments to determine the value of this or that "suggestion." My object is of a mere practical and, I hope, useful character. It is simply to describe the exact method by which the specimens now before you were produced, and which method, I think, will be found to differ little from the simple and excellent formula originally published by Mr. Fothergill.

In these days, when so-called photographic discoveries succeed each other with such startling rapidity, we have scarcely time to test the value of each new candidate for our suffrages before we are summoned with a great noise to throw it up and pay our devotion at the shrine of one more worthy than all, and guaranteed to give universal satisfaction. If we are young enough in photographic experience, and green enough to obey the call, it is, most probably, to find ourselves in a short time perfectly ready to relinquish even that for the next new comer. Amidst this ceaseless change and accumulation no wonder that the old and generally best processes lie buried, if not forgotten. Such being the case, if one can be found who, through all this change and universal thirst for novelty, has remained faithful to an old, tried, but now neglected favourite—and who, when the new dodges begin to pall on a satiated public, comes forth and disentombs it, and exhibits its sterling worth before his perplexed and disconsolate contemporaries, confers as great, yea a greater, benefit upon them than the hero of some new modification. If the writer of this paper can, in some measure, succeed in accomplishing this to-night as regards the process in question, he fancies that neither his nor your time will be thrown away, and that some at least will not regret that they listened to yet another paper on this "dry" subject. You will judge, then, that I am not about to describe a process that I have only just taken up. My connection with the Fothergill process dates from the day of its publication in *The Times* by its discoverer, and since then I have attentively watched its history, have tried it under a great variety of conditions, have now by me more than 200 large negatives taken by it—many of them excellent, and all, I believe, tolerably good—and up to this hour I have never felt, nor still feel, any wish to change it for another, or for any of its recent modifications. My method of manipulation is as follows:—

I always use patent plate glass on account of its superior flatness and smoothness of surface—indeed, for *large* pictures, it is indispensable unless you choose to incur the ceaseless risk of breaking your negatives in the pressure-frame. I always use for this, as I would for all other processes, a bromo-iodized collodion. It possesses two advantages over the simply iodized, viz., it will bear a more thorough washing without materially impairing its sensitiveness, and it is more impressible to feeble rays of light. That which I almost invariably use, and which produced the pictures in question, is Perry's, of Sheffield. It may not, perhaps, be better than some others, but when it has been iodized two or three months, it appears to be the exact thing required, of a consistency suitable for large plates, producing a film perfectly uniform, and while sufficiently porous in structure, adheres firmly to the glass. I may here remark that in my humble judgment collodion should never be used soon

* Read at the North London Photographic Association, Dec. 16th, 1861.

after iodizing, especially for a dry process. When it has had time to settle and become clear as sherry, it not only works free from all specks and comets, but far more cleanly and vigorously. The silver bath is of the strength of forty grains to the ounce, and in precisely the same condition as required for wet plates—faintly acid, with acetic acid. Here an advantage is possessed by this process over some others; if you wish to take the portrait of a friend, you do not require another bath. I frequently take both positive and negative portraits with the one I use for Fothergill plates. In preparing a batch of plates, I first of all put my operating-room in the best possible order, having a place for everything, and everything in its place. This having been done, the bath filtered, the washing-bath filled with distilled, or rain water, by its side collodion carefully decanted, clean blotting-paper arranged on the drying shelves, muslin tied over the tap to regulate the force of the water, and all *intruders* shut out (if any be present), I commence operations. The plates, of course, have been cleaned and polished in another room, with a mixture of ammonia, spirits of wine, and tripoli—no water being used. When the plate is attached to the pneumatic holder, I take a broad camel-hair brush, kept for the purpose, and remove every particle of dust from the surface, coat with collodion, and sensitize in the usual way. After draining well on the dipper it is immersed in the washing-bath. For this purpose I use a vertical bath, precisely like the one containing the silver solution, as this is by far the most convenient, there being no necessity to remove the plate from the dipper. As to the amount of washing required, I have always contended that it should be regulated by the time the plates are required to keep. I generally, in the summer, take out a large number of plates for a fortnight's excursion. I begin the preparation of them a week or more before starting, and another week elapses after I return before they are all developed. Here you see they are required to keep at least a month—a fortnight before and a fortnight after exposure. Now in the heat of summer no "four drachm" system of washing will do this; and even for shorter keeping no advantage is gained, but great risk incurred of stains and decomposition. I formerly washed the plates under a tap as freely as in the collodio-albumen process, and the negatives I obtained, though requiring a little longer exposure, were of a very clean and vigorous character. But the plan I now adopt, while being more convenient and taking less time than the tap-washing, possesses all its advantages with increased sensitiveness. It is simply immersing the plates in the vertical bath as described above, moving up and down until the water flows freely, and changing the water after every six plates.

The plate having been thus washed and allowed to drain the albumen mixture is poured on. This is composed of white of egg, one ounce; distilled water, two ounces; ammonia, eight minims; chloride of sodium, two grains. The whole is beaten into a froth and allowed to subside, and, when bottled, will keep for any length of time—the older it is the better. I am aware that many operators use albumen much more diluted than this, while others adopt Mr. Hannaford's modification of adding nitrate of silver to it. The advantage of using a somewhat concentrated solution of albumen consists in the tenacity and binding effect it imparts to the film, making it almost as hard and indestructible as a Taupenot plate. I shall not contest the matter with Mr. Hannaford as to the advantage of adding silver to the albumen. I have but little opportunity for making experiments, and when I have become familiar with the formula which succeeds to my satisfaction I have little disposition, as I said before, to change it; and in this instance, not having experienced any of the drawbacks which Mr. Hannaford proposed to remedy, I must own to not having tried his suggestion. I am somewhat undecided as to the beneficial effects of a chloride in the albumen, having obtained equally good pictures without it. The chief advantage, perhaps, lies in its imparting additional keeping properties, by converting the unstable nitrate of silver left in the film into the more stable chloride. I formerly thought it increased the density of the image, but longer experience inclines me to believe that it rather diminishes it, and gives a softer picture. To proceed with the manipulation:—When the albumen has been made to flow well up to every edge of the plate for about a minute, it is washed off freely under the tap. For a 12 by 10 plate I continue this washing about three minutes, holding the plate by the corners. The more thoroughly this operation is performed the better; and the reason why so many find these plates slow in developing is attributable to the preservative not being sufficiently removed. Washing in a dish in two or three changes of water will not do: a moderate force must be employed either from a tap or jug. The plate is then set to drain on one corner, and removed to fresh blotting paper in ten or fifteen minutes, after which it should not be removed until quite dry. Any irregular action in drying—such as completing the operation by artificial heat when the surface is partially dry—will leave a spoiling mark between the two actions, soon rendered visible by the developer. I do not know that I need describe my mode of developing. It is done in the usual way. I use pyrogallic acid, 1½ grains; citric acid, ¾ grain; and 1 oz. distilled water—adding the smallest possible amount of silver, until the details are all out, when I intensify to the proper extent. This plan is analogous to that described by Mr. Simpson at the last meeting, while I think it has an advantage in reducing the time. So much, then, for the manipulation.

It will be observed that the process, as I have described it, differs not from that originally published by Mr. Fothergill, and, as I hinted before, I more than question whether any of the "modifications"—or, perhaps, more correctly, complications—since published are any improvement on his most simple and excellent formula. I have tried several myself, but have always gone back to my "first love;" and, until something turns up in dry processes altogether different from what we have at present, I shall not forsake it again. I do not wish to disparage other dry processes, and there is little fear that those who, like myself, are accustomed to work one in particular, and succeed, will change it through anything I may say; but I cannot help remarking, for those who are undecided, that no process appears to me so simple as this—none can give finer results when properly manipulated, and it possesses advantages which some others cannot claim. I have already mentioned one or two, such as no special silver bath or collodion being required; and I may mention, in addition, that none of the horrid blisters which sometimes disgust one with the otherwise excellent process of Taupenot ever show themselves here, and its keeping qualities are greatly superior. Over its new rival (the *tannin*) it still holds its place. It is more sensitive, and there is no fear of beholding your beautifully-chosen and developed picture meet with instant destruction in the final washing; neither have you to give the plate a preliminary coat of gelatine to avoid it—a most undesirable and uncalled-for operation. The possibility of seeing the picture, after all the labour and anxiety it has cost, leave the glass, piecemeal, in the very last operation, is to me a fault of such magnitude, that I would never have anything to do with a process, however excellent in other respects, that rendered one liable to this contingency: hence the great recommendation possessed by those processes in which albumen is the chief preservative agent. But I fully concur in the statement we often meet with in the journals, in "Answers to Correspondents," that it is not in the *process* but in the *man* that the cause of non-success must be sought for. It is undoubtedly true that good, if not equally good, pictures may be produced by any sensible dry process, when worked with intelligence and careful attention; but it is equally true that the most simple and certain of them must fail in the hands of many—shall I be wrong in saying the majority—of those who dabble in them. From what I have seen of the manipulation of amateurs generally, I frequently wonder how most of them ever get a presentable picture at all. The dirty, slovenly, *unthinking* way in which they go about their work is most unpardonable, and becomes ridiculous when it is expected that from such an abuse of all that has been written on photography, and such a transgression of its delicate and inflexible laws, they shall produce something worthy of admiration. I must confess that I have often been disgusted at the sight of negatives that have come under my observation, and from persons, too, who had the reputation of great achievments, and whose frequent communications to the journals led one to suppose that they at least had attained an eminence beyond the reach of ordinary aspirants. It is no uncommon thing to see negatives marred or spoiled by long-tailed comets, caused evidently by dried pieces of collodion falling from the mouth of a dirty bottle when coating the plate; others defaced by a huge stain or two from the corners, caused by dirty fingers; in others, an inch or more of the picture lost by the thumb-hold; others covered with black specks and sundry embellishments (the sure products of an unfiltered bath); some even varnished before the iodide of silver has been removed; while, to crown the whole, some adorn their negatives with a few beautiful scratches, and, if the improvement be not sufficiently marked, dab a few touches of black varnish on the same places, which give to the resulting priut fine coutrasts of black and white. The pictures which I have the pleasure of presenting to the Society, I believe will generally be found free from theso defects, and on tho whole, perhaps, equal to the average of dry collodion pictures. One fact about their production I must not omit to mention, and that is that those measuring 12 + 10 inches were taken with one of Grubb's lenses for 10 + 8 pictures. Wishing to get a much wider angle of subject than usual I procured one of these lenses, and was pleased to fiud that with it I could cover a 12 + 10 plate very satisfactorily, and that, too, with a ⅝-inch stop. Unfortunately these specimens do not exhibit the capabilities of this lens to the best advantage, as most of them were taken in dull and even wet weather, which, of course, greatly interferes with the sharpness as well as general excellence of the pictures.

This paper, I fear, has already extended beyond the usual length; but if in closing I might be permittad another remark, it would be this: that although I have to-night been describing, and in somo measure advocatiug, an excellent and useful process, I would prefer to advocate one capable of producing still better results. The day, I think, has arrived, when all our dry processes aro weighed in the balance and found wanting. However much we may admiro the beautiful productions which some of them havo wrought in the hands of skilled workmen, we have seen some yet far above them, and of such surpassing excellence as we can never hope to attain by any dry process as at present known. Those who have seen the marvellous productions of Mr. Wilson—who have been thrown into ecstasies of delight as they beheld the wondrous beauty, the delicacy, and harmony which characterize nearly all of them—who have felt as if transported amid the real scenes there depicted, as they saw the charming landscapo spread before them, and its distant horizon melt almost imperceptibly into its own natural sky, or the flood of mellow light which beamed from behind the golden cloud in which the sun was sinking to its rest—who have felt a pensive silence as they stood by the shores of an Aberdeen lake as the shades of evening fell upon, and wrapped all surrounding objects in its deepening gloom—must have turned from the contemplation of such pictures, or rather I should say such realities, to their own poor productions, with a feeling of dissatisfaction and almost disgust. These have now lost their charm and their power to please, and henceforth we can be content with no process that does not give us all the gradations of a distant landscape in true and softened perspective—that does not reproduce on the sensitive tablet every cloud that may adorn the sky the moment our view is taken—that does not fix the dashing waves and rising spray of the ocean, and at the same time carry our eye over its wide expanse, till it rest on the diminutive bark which serves to mark the otherwise imperceptible horizon as it touches and merges into clouds—and which does not catch those transient beauties which frequently flit over the face of nature like smiles o'er the features of a beautiful damsel. When a dry process can accomplish this we will not bo undmindful of its claims; but with anything short of this Mr. Wilson has taught us to be dissatisfied.

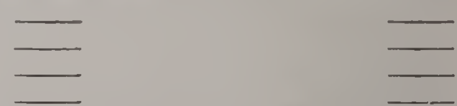
## ON AN IMPROVEMENT IN THE LENTICULAR STEREOSCOPE.

BY PROF. E. EMERSON.*

The lenticular stereoscope, in its common form, has certain imperfections as an instrument which more or less detract from the pleasure which would otherwise attend its use. Nor are these imperfections of such a character as only to be recognised by adepts in its use; on the contrary, they are well known to almost every one who possesses one of these popular and iustructive instruments. The causes of these imperfections are not so generally known. A common result of one fault is the difficulty which is experienced in endeavouring to unite the dissimilar right and left pictures; this is, indeed, sometimes quite impossible, and the observer, after a series of exercises, exceedingly straining to the organ of vision, gives over the effort in despair. Another imperfection is the inability of the instrument to exhibit a stereoscopic view of pictures much larger than those ordinarily furnished by the dealers in Enrope and America. Negatives including a much larger angle are readily obtained, but the positives taken from them are either reduced in copying, or the negatives are cut down to the size of the ordinary stereoscopic picture, when they are printed by contact; thus, oftentimes, some of the most beautiful details in the view are absolutely sacrificed.

We propose, in the present article—1st, to account for these imperfections in the stereoscope, and 2nd, to describe a simple modification of the instrument, which will remove them completely.

The difficulty experienced in uniting the right aud left pictures of certain stereoscopic slides may be occasioned either by the lenses being improperly mounted; or the picturesbeing arranged on the slides at improper distances from each other; or because the eyes of one observer are naturally wider apart than those of another, and therefore the same instrument fails to afford an equally good view to each. Let us examine briefly each of these cases. It sometimes happens that the lenses are so adjusted or cut as to occupy improper positions; as a consequence, one of the pictures is thrown a little *higher* than the other. If this defect operated only in a horizontal position it would not be so serious, as, within certain limits, the eyes can accommodate themselves to a horizontal strain; which accounts for our ability to see certain views, after a considerable effort, which at first gave us more or less difficulty. But when the discrepancy is one measured on a perpendicular line, it is much more serious; the eyes are not accustomed to move in this direction independently of each other; so that if the imperfect mounting of the lenses causes a variation on this line of from one to two-tenths of an inch it will be almost impossible for the observer to unite the views. An easy method of testing an instrument for this fault is to draw upon a piece of white paper, the size of a stereoscopic slide, two series of short lines, each series being 2·6 inches from the other, aud the lines in each series being drawn at corresponding distances from each other, thus:—



Upon placing this in the stereoscope, and looking at it, if the lines unite instantly with no variation, it proves the absence of this fault; but if, on the contrary, we obtain as a resultant a view of more thau than four lines, thus:—

we may be certain that the lenses are not properly mounted, aud will give in usage little or no satisfaction. The instrument, however, may be perfect as to its lenses, and a difficulty still be experienced as to certain pictures or by certain persons. When the imperfection consists of a want of proper relation between the lenses and the slide, it usually results from the complementary pictures beiug mounted at too great a distance from each other for the power of the fixed lenses to unite them; but the same result may be the effect of an individual peculiarity in the observer, the eyes being naturally wider apart than is common.

The variation in the mounting of stereoscopic pictures is very great. In carefully measuring a lot of nearly three hundred different views, on glass and paper, French, English, and American, the actual variation was over an inch between the extremes; some being mounted only 2¼ inches apart, and not a few of them over 3¼ inches from

* From *Humphrey's Journal.*

each other. Moreover, as might be expected from the variation in practice, there is considerable difference in opinion, among those who have endeavoured to settle this point, as to what should be the standard distance between the right and left pictures. Some say "the same distance the eyes are separated;" others, "2·6 inches," and a recent writer, Mr. Shadbolt, says — "There being two variable quantities involved, viz., the width between the eyes of different observers, and the lateral displacement of rays by the prisms used, it is necessary to obtain something like an approach to an average of the amount of these inconstant qualities, and, after careful consideration of the matter, we fixed it at 2·75 inches." The same writer, however, finds the distance required by Smith and Beck's achromatic stereoscopes very constant at 2·8 inches. It does not seem that there is a clear apprehension of the truth in regard to this point, which is, that the distance the pictures should be mounted apart will depend entirely upon the deflecting power of the lenses employed to unite them. And as there does not appear to be any standard for this power of the lenses, there is, consequently, none to regulate the distance the right and left hand pictures should be separated. It is easy to see, therefore, that a stereoscope which will enable us to see, equally well, different views which vary more than an inch in the mounting is a desideratum.

The lenses of the ordinary stereoscope are so mounted that the eyes of the same observer always look through the same portion of each lens, which, of course, always causes the same amount of deflection, and answer perfectly to unite pictures which are separated from each other a certain uniform distance.

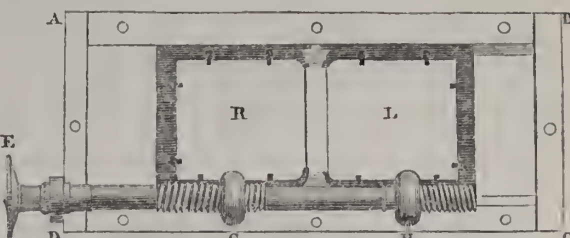
In order to measure this distance for any particular instrument, take ten or fifteen pieces of white paper or cardboard, the size of a stereoscopic slide, and upon the first draw two lines one quarter of an inch in length, perpendicular to the lower side of the card, and parallel to each other, thus :—

increase the distance between the lines upon each successive card one-tenth of an inch until the lines upon the last card are three and one-half inches apart; now look at each of these in the stereoscope with a rather hasty glance, and it will be easy to determine at what distance the lines should be apart to coalesce perfectly and instantly. This will be the distance the centres of the right and left pictures should be separated *for that instrument.*

But further, the ordinary lenticular stereoscope does not permit the view of a picture measuring over three inches from one side to the other; *i.e.*, it affords a view of nine square inches as a maximum.* Sir D. Brewster, in his work on the Stereoscope, pp. 162, 163, declares that—"the *size* of the picture is determined," that nothing can be gained by using larger pictures," &c., &c. This is true with regard to the ordinary form of the stereoscope. But this renders it, none the less, a very desirable thing to be able to see larger pictures: and by larger pictures we do not mean the same pictures magnified, for then, indeed, nothing would be gained, but pictures including a larger angle, and affording a view of more than twenty square inches as a maximum.

Before proceeding to a description of an improvement which accomplishes this result, it will be necessary briefly to remind the reader that the lenses employed in the stereoscope, while they are constant as to their focal length, vary exceedingly as to their power of deflecting a ray, increasing it regularly as we proceed, from the centre of the lens to its thin edge; so that pictures which can be easily united when seen through the thicker or central portion of the lenses, require to be separated more and more from each other as we separate the glasses, and thus force the eyes to use a more highly deflecting portion of the lenses. The modification we propose, in order to give the instrument a general character and adapt it to all sorts of views, is an adjustment by which the lenses are rendered moveable in a horizontal direction, so that they can readily be approached near to each other until the edges touch, or separated from each other as far as the distance between the eyes will allow; *i.e.*, the distance travelled by each lens will be measured by the distance between the thickest and thinnest portion of that lens, which will be a little over an inch.

To operate properly the lenses should move simultaneously, at uniform rates and in opposite directions. As the right lens moves towards the right, the left lens moves towards the left, and *vice versâ.* By this means the lenses are made equivalent to prisms with variable angles. An easy method of accomplishing this is shown in the following diagram exhibiting the *under side* of the lenses and their mechanical attachment.



This apparatus takes the place of the lenses in the various forms of the lenticular stereoscope. We have adjusted our own to a common hand-stereoscope merely flanging the sides so as to afford a view of glass and paper slides measuring ten inches in length by four in width.

By means of this instrument, whatever the distance between the eyes, pictures may be easily and perfectly united which are mounted at any distance apart between two, and four and a half, inches from centre to centre; and this, too, with the ordinary stereoscopic lenses; if achromatic lenses are used, it is quite practicable to unite pictures which measure five inches from centre to centre, affording a view filling twenty square inches, which is considerably more than twice as large as the ordinary slides.

* The reflecting stereoscope of Wheatstone will exhibit larger pictures, but it is not adapted to popular use.

## Photographic Tourist.

### PHOTOGRAPHIC PENCILLINGS OF AN EASTERN TOUR.

Taking a pleasant, hurried, final leave of my few good friends and true, one briskly invigorating, and hearty December morning, after duly superintending the stowing away of luggage, I sprung into the railway carriage, and away I went, feeling that I really was, *at last*, on my way to quit dear old England for a long-promised tour amid scenes associated with so much that is dear to the Christian's heart. That night I stowed myself away, horizontally, in one of the berths on board the boat which conveyed me across the channel, and woke up to go ashore and be horridly annoyed by the suspiciously overhauling of my various traps, especially the photographic. This trouble over—I had to pay duty, by-the-bye, for such glass as I took with me—I was speedily in the streets of Paris.

Paris is said to be the home of art, and I have seen, in the pages for which I am now writing, that photography is regarded as superior in artistic quality there than here. Now I am no artist myself, although an amateur photographer, but I must say that while no one can deny that art is more widely understood and appreciated in Paris than in London, French art, in all its applications, including photography, is, after all, wanting in the elements which we English best understand. It is brilliantly attractive in all the more popular qualities, but does not indicate much thought or feeling. Its paintings are almost gaudy in colour, and their subjects seem always to be more or less melo-dramatically treated; and as to its photography, I have no patience with those who would compare, detrimentally, the productions of Robinson, Heath, Mudd, Bedford, Rejlander, and other eminent English masters, with works of a similar character by their French representatives. With reference to portraiture, however, although I think we have as many *good* photographers devoted to this branch of the art in London, whose pictures at least equal those of their French brethren, I certainly think the French have not so many of those hideous libellers of "the human face divine" as we, unfortunately, tolerate or encourage. In France, as a rule, the people would laugh to scorn productions which here find admirers and imitators. In short, while *their* art is more widely spread, *ours*, to my thinking, at least, has greater depth, or, in other words, while the French have less bad art, we have most good art.

I was very much struck, during the few days I remained in Paris, with its numerous street improvements, apparent in every direction. Grand new boulevards seem to have sprung up with magical rapidity, and although but a few years had elapsed since my previous visit to this mighty city, the changes and improvements were something to wonder at. I looked in vain for many of the narrow streets once so numerous beside the Seine, and with no little interest upon the many new *cités* reared by private speculation encouraged by Government aid.

Starting by the Lyons railway, I was duly conveyed to Marseilles, from whence I embarked for Malta. I will not say much of the voyage. I did not see much of our progress; the more prominent memories of those days at sea are not pleasant ones—in fact, humiliating though the confession may be, I—wasn't *quite well.* I certainly have certain indistinct remembrances of a swaying and rolling, a creaking and jolting, a rising and falling of the vessel; of a torpid state of mind, and a limp colapsible state of body; but can recall little else until we reached our destination, and, to my inexpressible satisfaction, I landed and found myself in the streets of Valetta. I thought, as we entered the blue waters of the harbour (containing vessels from most of the nations of the world), and looked upon the pale-faced, strongly-fortified rocks, caught glimpses of the imposing-looking city, gazed upon the grand fort of St. Elmo, and perceived the other fine buildings reposing under a bright clear sky, I had seldom seen a more pleasing sight.

The day of my arrival being Sunday, I attended divine service in a large plain-looking church, erected by the late Queen Adelaide, the congregation being largely composed of the civil and military officials of the Government.

The streets of this fine city are very picturesque, and although I had not intended to unpack my apparatus here, I was unable to withstand the temptation they offered. So I secured several views, including the ancient palace of the Governor, which of old was that of the Grand Master of the Knights of Malta, and one or two of the somewhat dilapidated, but still stately and grand, old *Auberges*, together with some of the forts; one of a little road-side chapel, stumbled over on my ramble to the reputed scene of St. Paul's shipwreck (situated five miles from the city), &c. &c. The houses and streets combine favourably in a picture, but the latter are very frequently far more pleasant to an artist's eye than an artist's legs, a walk up some of their steep ascents being verily "sich a getting up stairs." But these streets of stairs, and the novel aspect of the houses, which, although of nearly equal height, are of the most varied and irregular kind of architecture (chiefly Moorish), and have a variety of huge overhanging balconies, with projecting windows of ornamental sand-stone, giving all that variation of line and chiaroscuro which we seek in making pictures. My street views are also most agreeably enlivened, where instantaneous, by the variety of costume among the figures and groups they contain, and in other cases by a carved stone fountain or two, none the worse in my negatives for being time-worn and dilapidated. I have two of these photographs now before me, one in which may be traced the sombre figures and curious triangular turned up hats of a couple of priests, the negligently worn caps of some labouring men, sitting and talking on the steps, a monk, an English soldier, some women with their heads by no means ungracefully draped in the folds of their mantillas, and a party of Greek seamen, quite dramatic looking characters, sauntering indolently on their way; the other is of a more crowded and animated character, and was taken from the water-gate, with its stairs, and stalls, and its thickly crowded variety of men and women in all sorts of widely different costumes. Beggars, and boatmen, soldiers and sailors, monks and priests, fish-stalls and fruit-stalls, half-naked vendors of all sorts of eatables, some dirty makers and street-vendors of cigars, may all be traced in the latter photograph if you have patience, and eyes good enough to separate the component figures of this confused crowd of forms and figures which make one of the most interesting and successful mementos of my visit to Malta. M. H.

(*To be continued.*)

## Correspondence.

### FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

*Paris, 1st January*, 1862.

THREE proofs of large dimensions, obtained by M. Fargier's process, were lately exhibited at our Photographic Society, accompanied by positives obtained from the same negatives by the ordinary process with salts of silver. It was remarked, that the proofs obtained by M. Fargier's process, although obtained from the same negatives, were evidently of much smaller dimensions than those furnished by the salts of silver. This effect is easily understood, as it is due to the shrinking of the gelatine in the several baths communicating to the carbon proof a remarkable degree of sharpness. M. Fargier has made some important modifications in the original process; he found the sensitiveness of the bichromate of potassa so great, that one or two seconds exposure was sufficient to solarize the proof; he then substituted nitrate of uranium, bichromate of ammonia, &c., for the salt of potassa, and then obtained better results. The exposure could then be prolonged several seconds without danger. The manipulation of the collodion films is also performed with much more freedom.

It was announced, a few months ago, that M. Wothly, of Aix-la-Chapelle, had discovered a method of obtaining positive proofs without the use of salts of silver. He recently sent some specimens to Paris for presentation to our Photographic Society, accompanied by a note in which he stated that these proofs are obtained by means of chlorides of copper, of iron, of molybdenum, of cyanide of potassium, of ferrocyanide of copper, and of a substance which he designates under the name of catechu acid, encountered in certain varieties of catechu, and which is analogous to tannic gallic, and pyrogallic acids; he concluded by remarking that this process realized, upon the ordinary method, an economy of ninety per cent.

The administrative committee, struck with the extreme beauty of many of these proofs, and of the analogy of the tones they exhibit with those obtained with silver, requested M. Girard to make a summary examination of them with regard to their chemical composition. He recognized that these beautiful proofs contain no salt of silver, and that they appear formed principally of ferruginous compounds; but this composition is not satisfactory to him with respect to permanence. In observing the extreme facility with which these proofs disappear, not only in the mineral acids, but even in acetic acid, M. Girard could not omit to remember that proofs of analogous composition alter very readily by contact with the atmosphere, especially in the half tones, in consequence of the transformation of the ferruginous compounds into carbonate of iron.

The Tremont prize for 1861, has been unanimously awarded by the commission to M. Niepce de Saint Victor, in preference to the claims of other candidates, for the following reasons:—

The *debut* of M. Niepce de Saint Victor was very remarkable. The object of his first effort was to take copies of engravings or of designs in black on a white ground, by exposing these engravings or designs to the vapour of iodine. The iodine attaches itself to the black lines of the engraving, &c., and when the design so iodized is placed in contact with a sheet of starched paper, the lines of the engraving &c. are produced in blue on the paper, because the iodine abandons the black lines of the engraving, &c., to unite in preference with the starch of the white paper.

M. Niepce gave a considerable impulse to photography by his application of iodized albumen to glass plates: when this film becomes dry, he immersed it in a solution of aceto-nitrate of silver, and then exposed it to the action of light in the camera. He thus obtained a *negative* proof from which any number of positives could be afterwards taken on surfaces impregnated with substances sensitive to the influence of light.

M. Niepce demonstrated the remarkable fact that certain bodies receiving the rays of the sun, possess the faculty of afterwards acting in the dark upon matters sensitive to light, as if the first bodies were themselves luminous, the sun communicating to them a power of action which they retain for entire months in the dark.

M. Niepce starting from the beautiful researches of M. Edmund Becquerel on the colouration of matters sensitive to light, also recognized a very remarkable action in chloride of lead, under the two-fold relation of the whiteness, and of the duration of the colour of the image submitted to the influence of light. This discovery M. Niepce will soon lay before the Academy.

M. Niepce is an example of what a decided vocation can accomplish. Educated at the cavalry college of Saumur, he early made himself a name in science, by researches marked by originality; the academy always received them with sympathy, independently of the interest inspired by the author of them, then a stranger to every scientific body, and whose first researches, commenced at a distance from the capital, were successfully carried on in a barracks, amid the distractions of military duties, always faithfully performed. When M. Niepce generously abandoned his discoveries to the public, he never entertained the idea of deriving the least personal advantage from them, and he executed most of his researches at his own expense. Therefore the commission unanimously award him the Tremont prize of 1861.

Attention has been directed to a new principle, extracted from the *pinus larix*, which Dr. Stenhouse calls *larixinc acid*. This substance is remarkable for its resemblance to pyrogallic acid. It is obtained by digesting the bark in water at 176° F., and evaporating this infusion to a syrupy consistence. The residuum is submitted to distillation; the larixine acid passes over with the aqueous vapour, one portion crystallizing on the sides of the receiver; the other portion, the largest, is found dissolved in the aqueous liquor, from which it may be withdrawn by cautious evaporation. When purified, the acid appears under the form of beautiful white crystals, possessing a peculiar odour, which sublime at 200°. The solution of this acid precipitates neither lime nor acetate of lead, nor the salts of potassa or silver. But at ebullition it reduces nitrate of silver: it colours the persalts of iron purple, and, like pyrogallic acid, it readily oxidises in contact with the atmosphere, or an alkali.

Chloride of lime is particularly obnoxious to insects and vermin. A small quantity of the chloride spread on a board in a stable drives away all the flies which are so troublesome and irritating. Gardens watered with a solution of chloride of lime are freed from caterpillars, bugs, moths, snails, etc. If a ring be formed round the trunk of a tree, of a mixture of chloride and fatty matter, insects will not pass it. It has been remarked that rats and mice quit places where chloride of lime is kept.

## ON MOUNTING PRINTS.

Sir,—Seeing the many enquiries about mounting in your interesting periodical, I take for granted that some of your amateur photographic correspondents are unacquainted with the ordinary artist's sketching frame, by the use of which they would effectually avoid all chance of cockling in their mounted prints. To those who have never used such an useful and simple article, I would say, that they have only to thoroughly damp the mounting paper on both sides with a sponge or large hog's-hair tool and cold water, and to press it tightly into the frame on the central board. Having previously dissolved some gelatine in hot water, give the back of the proof a coating of it, lay it on the stretched and damp sheet, and press it down firmly with a large sponge, squeezed tolerably dry from water as hot as it can be borne by the hand, and the thing is done. Of course the proof may be mounted with the help of any other adhesive material, if thought more desirable. The picture should now remain in a warm room until quite dry, perhaps four-and-twenty hours, and there will be no more trouble experienced from cockling.

The proof should have been previously squared by a T square, which will guard against all risk of its being cut askew or on the squint.—Believe me, sir, yours very truly,

Henry H. Hele.

*Teignmouth, Devonshire, Dec. 30th*, 1861.

## PHOTOGRAPHIC EXCHANGE CLUB.

Dear Sir,—Before the commencement of the third mouth of the existence of this Club, and the second exchange, I wish to address a few remarks to members as to the working. In the first place, I must impress upon members the necessity of numbering or giving some distinctive description to each negative that may belong to a series, thus, "1, 2, 3, 4, 5, 6, Westminster Abbey, &c.," or else, "North view, south view, east, &c.," "North door, west, east, &c." The same remarks apply to "Landscapes, rural scenes, &c.," as "Shady lane, No. 1; Cold Blow Farm, No. 3." In many cases four or five photographs of the same subject (from different points of view) being named or distinguished in the same manner. If no attention is paid to this, great confusion will arise hereafter.

A few words on the financial part of the question. I must beg to inform gentlemen who, remitting *one* postage stamp, are under the impression that because their letter or parcel comes for one penny, I can send it back for the same. That I cannot do; explanatory or admonitory letters, pens, ink, and paper, a book for the entries, &c., are all necessary, which the extra penny is intended to cover.

To avoid sending mounted stereos, if possible, as the same amount which sends fifty or sixty will not distribute them, and send explanatory letters. A little consideration paid to these matters will, I think, make the new rules a great success—Yours respectfully,

Frank Howard.

*December 31st*, 1861.

# Photographic Notes and Queries.

### A Perfect Cure for Mottled Toning.

Dear Sir,—A recent number of your paper contains a "jotting" from "A Cure" recommending a weak bath of acetate of soda, as a remedy for mealiness, and red spots in toning. Allow me to emphatically confirm the high value of the suggestion.

I tried it on an exceedingly bad sample of paper, which with all ordinary toning appliances gave a mealy mottled print. The acetate of soda bath at once removed all tendency to mealiness. It therefore appears to me to ensure a perfect immunity from the above evils, and to be well worthy the attention of practical photographers.—Yours truly,

Samuel Fry.

## Talk in the Studio.

SOME NOVELTIES.—A correspondent forwards us the trade circular of a suburban artist, which he appears to think contains novelties which should not be confined to a small suburb. It runs thus:—"All the new improvements in the science of chemistry, will be found concentrated in the original Photographic Gallery of——. Light and shadow fully developed by the new process, removing from the surface of the picture all superfluous matter. Portraits in memory of, for rings, charms, or brooches, highly finished, commencing at 0s. 0d. each. The Newly Introduced Envelope Portrait, for transmission by post, for birthday or wedding presents, and elaborate works of art. N.B. Families and public institutions waited upon for invalid and group pictures."

PORTRAITS OF PRISONERS.—The aid of photography in identifying criminals has been, for some time, fully recognized, and in many gaols of the country photography is one of the recognized institutions. However convenient to the authorities, it can scarcely be expected that the prisoners themselves enter amicably into the arrangement. The professional thief has an especial antipathy to any proof that he has been "in trouble" before. The bright idea that they can by moving, grimacing, etc., entirely frustrate the aim of the photographer has, however, gained currency amongst them, and the moment the lens is uncovered, a jerk round of the head, or an effectual twist of the features, spoils plate after plate. In this dilemma it has become necessary to adopt a *ruse*, and foil the convict by his own weapons. Every preparation being made the sitter is placed in his chair, and asked to sit still. If he be tractable a portrait is secured without further trouble. If, on the other hand, he attempts to defeat the object of his sitting by movement, he is told that he had better take a seat elsewhere for a short time, so that he may overcome his nervousness, and be able to sit still, and that in the meantime another portrait will be proceeded with. Another sitter takes his place, and he takes the seat indicated for rest. There he watches with deep interest the operations on his fellow, and whilst thus engaged he sits motionless and interested, another camera peeping through a convenient aperture, has its eye upon him, and registers on the faithful tablet the true presentment and natural expression of the unconscious victim, who is exulting in having thus baulked the authorities, and rejoicing in the anticipation of a similar piece of management on the part of his "pal."

BOOK POST TO FRANCE.—Under the provisions of a new postal convention with France, on the 1st of January next, and thenceforward, photographs on paper, commercial and legal documents, as well as other papers in manuscript, not of the nature of a letter, may be transmitted by the post between the United Kingdom and France, or Algeria, under the same regulations, and at the same reduced rates of postage, applicable to printed papers, viz.:—For a packet not exceeding 4 oz., 3d.: above 4 oz., and not exceeding 8 oz., 6d.; above 8 oz., and not exceeding 1 lb., 1s.; every additional 8 oz., 6d. This postage must be paid in advance. From the same date proof sheets, printed, engraved, or lithographed works, or sheets of music, bearing corrections, manual notes, or any writing not of the nature of a letter, may be sent by the post to France or Algeria at the same reduced rates of postage. All the regulations now in force, other than those which prohibit any writing in packets of printed papers, must continue to be observed. The present arrangement is confined to packets addressed to France or Algeria, and does not extend to those addressed to the foreign countries, the correspondence of which is forwarded through France.—By command of the Postmaster-General, ROWLAND HILL, Secretary. General Post Office, Dec. 27.

"PHOTOGRAPHIC WARE BATHS."—We find continual allusion and constant praise given in the American journals to a new material for baths. "At present," observes a writer in *Humphrey's Journal*, "probably, the most popular bath is known as the photographic ware, an invention of George Mathiot, an electrotypist, of Washington. The invention grew out of a want in Mr. Mathiot's business, viz., a cheap ware which will hold acid solutions, and consists simply in soaking the vessels of unglazed and porous porcelain in melted wax. Thus Mr. Mathiot killed two birds with one stone, and did a very handsome thing for photography as well as for electrotype. Such ware costs but a trifle, is neat, handy, and durable. Would not paraffin be a useful substitute for the wax? There is no compound known which is so little affected by corrosive matters."

## To Correspondents.

*** Our readers are informed that the FIFTH VOLUME of the PHOTOGRAPHIC NEWS, containing the whole of the numbers for 1861, will be ready in a few days. Cases for binding the volume will also be ready at the same time. No. 123 is now reprinted.

OXIDE.—As a general rule a chamois leather or wash leather is not sufficiently clean, in the condition in which it is bought, for polishing glasses for negatives or positives. We generally prepare them as we used to clean skins for Daguerreotype buffs; namely, by washing in equal parts of spirits of wine (methylated will do) and water. In drying, keep stretching and shaking the skin until it is dry.

H. W. BALL.—The cause of the stains on the negative sent is the use of a damp or imperfectly cleaned glass. It appears to us that the plate had been used before, and had not been perfectly cleaned before use again. In winter weather we prefer alcohol, tripoli, and a little nitric acid or old collodion for cleaning glasses. If you use water, dry the plate before the fire just before coating it. The use of a collodion with more body would help you in cold and damp weather, as then collodions readily show stains unless the plate is very clean. There is no reason to suppose your bath is out of order. 2. The "Photographic Dictionary," by Mr. Sutton, is out of print at present. We believe a new edition is preparing.

H. COOPER, jun.—Printing by development has never, we believe, been very successful with albumenized paper. The manipulations are the same as for plain paper; but it is difficult to obtain good tones when albumen is present. 2. We do not know where the enamel colours used in M. Joubert's process are sold. If you select some of the tints given by Mr. Hannaford in a recent number, you can probably get the materials at your chemists.

THOMAS CUMBERFORD.—A portrait lens consists of a combination of achromatic lenses. The front lens is an achromatic meniscus placed in a tube with its convex side outwards, the back lens consist of a convexo-concave and a double convex, one of flint, the other of crown glass, not quite in contact with each other. The convexo-concave is placed with its convex side towards the front lens; the double convex being placed outwards. The distance the lenses are to be placed apart depends on the relative foci, &c., of the lenses, and these relations depend on a variety of matters into which we cannot enter at length here. Each optician has his own plan. The focus of the front lens is generally shorter than that of the combined focus of the two forming the back lens; sometimes about half. The construction of a portrait lens is a matter in which you will scarcely be successful as an amateur without being well and practically skilled in optics. For landscapes an achromatic meniscus is considered best, the concave side being placed outwards The moveable tube is used to aid in focussing.

ALPHA.—You do not say at what stage you obtain the white deposit. We presume after taking the proper steps to dissolve the half sovereign in aqua-regia you find this white deposit, which is chloride of silver, formed from the presence of that metal with the gold After diluting the solution this may be removed by filtration.

W. D. B.—Major Russell Gordon's pictures at the Paris Exhibition consisted of large pictures as well as stereoscopics, and each kind were equally good.

UN PETIT GARCON.—The usual size of the "pistolgram" is about one inch square; the camera is about three inches long.—2. The lenses in the pistol camera are more rapid than common portrait lenses. 3. We are not in possession of any particulars as to when the catalogues of the International Exhibition will be ready.

W. R.—You will find a report on your transparent calico in the usual column. 2. We do not think the albumen process so well suited to instantaneous work as wet collodion. We do not know that any advantage is gained by using iron development with albumen plates. Hot gallic or pyrogallic acid is better.

JUSTITIA.—We like the appearance of No. 2 best, but it would require a careful trial to determine absolutely. Possibly there might not be much difference in result, and both are probably good. The chief impurity present in pyrogallic acid would be metagallic acid, which being insoluble would render it necessary to filter the solution to remove it.

S.—The chief cause of the evil in your print appears to be a somewhat fogged negative, which always increases any tendency to "mealiness" in the paper. See letter from Mr. Fry, and article on the subject in another column.

G. L.—The addition of a bromide sometimes improves old insensitive collodion.

N. N.—The chief objection to lenses of very long focus for album portraits is, besides slowness of action, that in thick weather there is so large a space of hazy-foggy atmosphere between the sitter and the camera that it is almost impossible to get a brilliant negative. So far as definition all over is concerned, the long focus is an advantage.

C. H. R. F.—The price for binding the volumes of the PHOTOGRAPHIC NEWS strongly in cloth, will probably be about 2s. or 2s. 6d.

F. G. C.—We prefer for the first washing, in preparing dry plates, a vertical bath with distilled water. After the first washing, common water may be used.

G. C.—The Taupenot process and the collodio-albumen process are the same. The first term is from the name of the originator, and the second describes the materials employed.

N. J. F.—See a recent article on Iron Negatives for strength of iron developers. See also PHOTOGRAPHIC NEWS ALMANAC.

COLEMAN SELLERS.—Mr. Hannaford will be very happy to hear from you as you propose.

ALPHA.—We do not know of any place to which we can recommed you in the neighbourhood you name. The most suitable place for obtaining lessons that we know, is the photographic department of King's College. Mr. Dawson, the lecturer, who is an able photographer, gives private lessons. If you write to him, he will furnish you with terms.

Several correspondents in our next.

All Letters, Works for Review, and other Communications for the Editor, should be addressed to 32, PATERNOSTER-ROW.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 175.—*January* 10, 1862.

## PHOTOGRAPHY AND THE INTERNATIONAL EXHIBITION.

We have received repeated enquiries of late as to the allotments of space to exhibitors in the photographic department of the forthcoming International Exhibition. Allotments in every other department have been completed some time since; but as yet the committee appointed to take charge of the interests of photographers have made no sign. We fear that the mismanagement which has characterized this department is now about to reach its culmination. We have reason to believe that no allotment whatever will be made; but, instead, an arbitrary selection of such pictures as will be forwarded for exhibition. If the space at present intended to be devoted to our art be not extended, the photography of the world will be displayed in an apartment which would not afford space for the legitimate contributions of a single province. We have not space to say more now. But unless some active steps be immediately taken, the interests of the art and its devotees will, in this exhibition, be betrayed without remedy.—*Verb. sap.*

## DRY PLATES WITHOUT PRESERVATIVE.

One of the greatest boons which could be conferred on photographers would be a dry process which should only require the removal, by washing, of the free nitrate of silver from the exacted collodion plate. If, to this simplicity of preparation could be added extreme sensitiveness, cleanness, brilliancy, and certainty, the boon would be complete, and the process would stand acknowledged as one of the greatest discoveries since that of Archer. For many years past, at intervals, we have been promised at least part of the boon, and on more than one occasion the whole of it. Collodion plates, simply washed, have repeatedly been tried, and frequently with sufficiently good results to justify considerable hope of ultimate complete success. Dr. Hill Norris, whose careful and fruitful researches on the subject of dry collodion are well known, has always maintained that the generally received opinion as to the importance of a preservative forming an organic compound of silver in dry plates, was an error, the only legitimate purpose served by preservative preparations, according to his view, being a mechanical one—that of rendering the film permeable by the developing solution. To this end he recommended the application of preparations of gelatine, gum, &c., to the thoroughly washed film, which permeating its structure and being easily soluble in, or absorbent of, water, allow the ready action of an aqueous developing solution. Some years ago the idea occurred to the Abbé Despratz, of adding to the collodion itself some body which should keep open the structure of the film, and prevent it acquiring the horny and repellant state of dessication. With this view he suggested the use of resin in the collodion, and the process has been pursued with more or less of success by some skilful photographers for years; although how the presence of a resin insoluble in water could keep open the film, so as to allow the more ready action of an aqueous developer did not adequately appear.

How far the position is true, that the organic element is unnecessary in the sensitive dry plate, we do not undertake to determine; but it unfortunately happens in many of the cases brought to prove that it is unnecessary; some organic element is used, and it remains to be proved in such cases that an organic compound of silver is not formed. In Dr. Norris's plates, there is gelatine or gum, in the Despratz process there is resin; and it is worthy of remark that in the latter process it is important that the bath should have the addition of acetic acid. In a paper by Mr. Hislop, recently read at the North London Photographic Society, he advocates the use of simple washed collodion, as giving all the results desirable in a dry process, without the use of any preservative whatever. It turns, however, quite incidentally that although Mr. Hislop applies no preservative preparation to the excited and washed collodion film, he coats the plate with a dilute solution of albumen prior to applying the collodion. This is done with a view to prevent the film leaving the plate, and without any idea that it would play any chemical part in the subsequent operations. The fact, however, that albumen forms a compound with silver readily acted upon by light would at once suggest that the impossibility of the film of albumen remaining inert in Mr. Hislop's plates, and the actual experience of all who have worked in that direction prove that it plays a most important part in the formation of the negatives.

Mr. Hislop's paper has recalled to our mind an interesting letter we received at the beginning of last summer from a very able correspondent, who suggested a similar process, with the difference that much more was claimed by our correspondent for his process, which he affirmed will produce results in all respects equal to wet collodion, with a degree of sensitiveness scarcely at all inferior. The matter was brought under our attention in confidence, in order to learn our opinion regarding its practial value; finally it was placed at our disposal for use in any way we thought proper. Our first experiments were not altogether satisfactory, the matter was laid aside for further examination; and until it was recalled to our mind by Mr. Hislop's paper, it had been overlooked.

We have just received a letter from our correspondent, again referring to the matter, and briefly re-stating the details of his process. We give the letter just received now, and shall probably, if we have space, give some extracts from a former fuller communication in an early number:—

"Dear Sir,—As attention appears to be turned just now to the subject of rapid dry plates, probably some of your readers would like to try the process I mentioned to you about a twelvemonth since. I had hoped to find time to carry out some further experiments before publishing it, but I have lately been exclusively occupied on other subjects.

"The process is of the simplest manipulation. A highly bromidized collodion is required; with this a plate is coated and sensitized in a neutral or slightly acid bath, as for ordinary negative portraits, 30 or 35 grains of silver to the ounce. It is then well washed, and placed for a minute in a 2-grain solution of chloride of ammonium, or of common table salt, to convert all the remaining nitrate of silver into chloride. After another washing to remove the salt, a solution of gallic acid, 5 grains to the ounce is poured over the surface (care being taken that it flows well to all the edges), and allowed to remain upon it for about 30 seconds, when it is poured off, and the plate stood up to dry.

"The plates so prepared are of the most extraordinary sensitiveness, half a second being sufficient exposure to produce a dense negative of a well sun-lighted view with Dallmeyer's stereoscopic lens, No. 2 stop. The pictures are of exquisite softness, and possess a definition of minute detail in the dense shadows, rarely met with even in wet collodion.

"I used to develop with pyrogallic acid, citric acid, and silver, or with gallic acid and acetate of lead, but probably it would be advantageous to use Mr. Wardley's method, which was not published at the date of my experiments. Unlimited washing *after* the application of the gallic acid appeared to rather increase the sensitiveness, but I think that the extreme cleanness and brightness of the picture, which are characteristic of the process, are less certain when this is done.

"These plates have no great keeping qualities. They are often spoiled at the end of a week; but I have kept some good a month.

"Upon the publication of the tannin process, which took place shortly after I had concluded my experiments, I imagined from the analogous nature of gallic acid and tannin, and the manipulations being precisely similar, that the processes would also turn out to be similar in result; but the contrary appears to be the case, as tannin plates I understand keep well, and are slow in being impressed with the image; while gallic acid plates do not keep well, but are remarkably rapid.

"The question which I wished to investigate more fully was the proper kind of collodion to be used, as I have met with some unsuited for the process. But probably all who wish to try these quick plates will find at least one specimen in their laboratory suited to prepare them, as those which are not are the exception.—I remain, dear sir, yours faithfully,

*January 6th*, 1862. F. R. Window."

We may here observe, that in his former communication Mr. Window informed us that he always gave his plates a preliminary coating with dilute albumen. We entertained a decided conviction that the preliminary coating of albumen played some part in the subsequent chemical operations. As that part of the question is an important one, we shall in our next give some interesting details on the subject communicated to us by Mr. McNab, who has much experience in the use of albumen as a preliminary coating.

In the discussion at the North London Meeting, Mr. Martin observed that the point upon which success chiefly depended in using simply washed plates, appeared to be the selection of the collodion. Our own experience entirely confirms this observation, and we believe that it is in this direction experiment will be most successful. We made several experiments last summer after receiving the letter to which we have referred. We did not find much difficulty in obtaining very sensitive dry plates without any preservative, but they were accompanied by some other difficulties, which our engagements at the period did not allow us time entirely to overcome: these were extreme thinness of the image, and stains. Some subsequent experiments led us to believe that these defects were chiefly due to the use of an unsuitable bath. We used a silver bath, which was giving good results, with wet collodion and iron development; but we remembered afterwards that it was an old bath, and contained a little free nitric acid, but no acetic acid. The use of the latter acid we believe to be of great importance in experiments in this direction, and we had reason to believe it would have materially modified the results if we had had time to follow out our experiments.

Soon after the discussion at the North London Society we received an interesting letter from Mr. Ward, of Stratford-on-Avon, stating that he had for some years past used dry collodion plates without preservative, with complete success, adding:—"According to my own experience dry collodion is two-thirds more sensitive than any of the albumen processes, and much less trouble in preparation and development. I have not found that difficulty which some of your correspondents seem to have had in keeping the film on the glass, although I have never used any foundation for the collodion."

Mr. Ward's letter was accompanied by the best of all arguments, a couple of very excellent prints from negatives produced by the process. The pictures are ten by eight, and appear fully exposed. One, a view of Shakespeare's House, was exposed two minutes and a half, with a lens of 15-inch focus and five-eights stop: the other, Ann Hathaway's Cottage, had three minutes exposure. It will be readily seen that the exposure is less than that of most dry processes. The prints were so perfect that we wrote to Mr. Ward asking him to oblige our readers with further details, an application to which we received a prompt and courteous response. We subjoin his letter:—

Dear Sir,—According to your request I forward you my method of manipulating the dry collodion plates.

I use a powdery collodion which will bear almost any amount of washing with ordinary care, and is comprised as follows:—

| | |
|---|---|
| Powdery Pyroxyline *quantum suff.* | |
| Ether ... ... ... ... | 4 ounces |
| Alcohol ... ... ... ... | 4 " |
| Iodide Cadmium ... ... .. | 1 grain |
| Iodide Ammonium ... ... | 2½ " |
| Bromide Ammonium ... ... | 1 " |
| Liq. Ammonia ... ... ... | ½ minim |

In the first place I coat the plate with collodion, when *well set* it is immersed in the nitrate bath of the usual strength, with a large proportion of acid; afterwards well drained and washed in four separate dishes of filtered rain water, and placed on one corner to dry spontaneously, when it is ready for exposure.

After being wetted with distilled water the plate is developed with the following solution;—

| | |
|---|---|
| Pyrogallic Acid ... ... ... ... | 3 grains |
| Citric Acid ... ... ... ... | 1 " |
| Water ... ... ... ... ... | 1 ounce |

and fixed with cyanide or hypo. I prefer the former as it requires less washing afterwards.—I am, dear sir, yours truly,

J. F. Ward.

*Stratford-on-Avon*, 17*th December*, 1861.

It cannot require one moment's argument to prove that if satisfactory and certain results can be obtained by means of a process so simple, the use of preservatives will soon be deemed as unnecessary complications. We shall be glad to learn the further experience of our readers.

## SUBSTITUTES FOR YELLOW GLASS IN THE DARK ROOM.

Since we have undertaken to test the samples of yellow glass of our readers, as to their suitability for dark room windows, we have received for examination, from time to time, samples of varnished silk, muslin, &c. The mode of preparing the various specimens of translucent fabric has not generally been stated. This is to be regretted. In our reports upon various samples of glass, the chief gain is to individuals, the only advantage derived from their perusal by the mass of our readers is the incentive to examine their own arrangements, seeing that those of so many are defective in this respect. Where the method of preparing a translucent fabric accompanies a sample, the report upon it may become valuable to every reader of the paper.

In our last we reported upon three samples of varnished muslin, with the mode of preparing which we are furnished. Two of the samples were prepared by coating muslin with glue, described as of a consistency about half as thick as that used by carpenters. To this solution of glue, nitrate of silver was added. In one sample the proportion was one-eighth of a grain of nitrate of silver to each ounce of solution. This sample was too light in colour to be efficient; many of the actinic rays passing without difficulty. Another sample contained one grain of nitrate of silver to each ounce of solution. This was perfectly efficient in repelling the actinic rays; but it cut off a large portion of the illuminating rays as well. It is probable that a proportion of nitrate of silver midway between the two, say two-thirds of a grain might be efficient in obstructing the actinic rays, without reducing the amount of light to an inconvenient extent.

A third sample, also prepared with glue, appeared to be tolerably efficient, not cutting off too much light, and yet repelling the greater part of the chemical rays. It was, however, coloured with annatto, and would, we fear, be liable to fade on exposure to sunshine.

There was one other objection to these samples, which might, however, be easily remedied: they were very brittle, arising from the large quantity of glue used. The mode in which the muslin was prepared, was by applying repeated coats of the solution of glue, and finishing with a coat of varnish. Possibly the second sample would have been just right, with fewer coats of glue, and two coats of varnish; it would not have been so dark nor so brittle. Another mode of rendering glue less brittle, is to add a little treacle to it, assimilating it to the elastic composition used by printers for making rollers.

Muslin or silk, treated with a coloured varnish of boiled linseed oil and orange chrome, would probably be very efficient.

The frequent complaints we have heard made of the difficulty experienced in getting suitable samples of glass, renders it worth while, we think, to endeavour, if possible, to find a simple, certain, and efficient substitute. We shall be glad to receive and report upon the experimental samples of non-actinic translucent fabrics of our readers.

## THE ACTION OF IODIDES ON EXPOSED PLATES.

It has been commonly maintained that in preparing collodio-albumen plates, the first part of the process—coating with collodion, sensitizing, and washing—might be performed in daylight, as any action produced by white light would be obliterated, and sensitiveness restored in the subsequent operations, either by immersion in a solution of an alkaline iodide, or by the application of the iodized albumen. This position has, however, often been combatted by skilled operators in this process. Some years ago we remember Mr. Sidebotham stated in the Photographic News that a slight amount of fogging was the general result in his practice, of white light falling on the plate after it left the first silver bath. Mr. Wardley, in a recent paper on the collodio-albumen process, read before the Chorlton Society, maintained a similar view, stating that the effect of white light falling on a sensitive collodion film could not be obliterated by the after application of an iodide solution, nor by the action of the iodized albumen. A contemporary editor slightly demurred to this statement, referring to the action of iodine in restoring an exposed daguerreotype plate to its sensitive condition; and adding that a solution of *iodine* had a similar effect upon an excited collodion plate. *Prima facie*, he should have anticipated, he stated, that an actinic impression would have been removed by an *iodide* also, and invited Mr. Wardley to detail the experiments upon which he based his conclusion.

As the subject is an interesting one, we subjoin Mr. Wardley's statement at a recent meeting, as reported in the organ of the society. He says:—

The question at issue is:—Can the action of a ray of white light be obliterated from a sensitive collodion film by means of an alkaline *iodide*, provided such film be free from organic matter, except that which may be contained in any ordinary collodion bath solution? In consequence of an offer made to publish my experiments to prove the position I took, I now respond to the call; but bear in mind that these experiments were not intended to be applied to photography generally, but simply to have a bearing upon the successful working of the Taupenot process. During my long practice of this process, I have been assailed by various operators declaring that the first preparation could be conducted in open day-light. I therefore tried several lots of plates so prepared, but I must confess I never obtained a satisfactory negative upon any one of them: all were more or less foggy and stained: some would not yield any kind of picture. In consequence of my non-success, I went in for a series of experiments, one or two of which were so conclusive that I discontinued them. In the first experiment I coated a plate with collodion, sensitised it, exposed one-half to daylight, carried it to the dark room and washed it well with water, immersed it in a solution of iodide of potassium for two or three minutes, drained and albumenised it in the usual way, and dried. This plate was then sensitised in the acid silver bath, washed, dried, and exposed in the camera. When developed, the two halves of the plate exhibited a great difference. That portion which had been exposed to light during the first preparation was foggy and stained; the other half, which had been protected from white light, was bright and satisfactory. This experiment may not be conclusive or correct, owing to the presence of organic matter: to meet that objection I tried another plate *without* the albumen. The transparent slide before you was coated with ordinary collodion, sensitised and exposed, then removed to a dark room, well washed with water, solution of iodide of potassium poured on half of the plate, the excess removed with a little water, and afterwards developed in the ordinary way. I think you will say the iodide has *not* had the least influence upon the image to which it has been applied. You see it is equally intense, and as full of half-tone as that portion which has been treated with the solution of iodide. This fact was published years ago. I am afraid that photographers of the present day are apt to underrate the value of papers written by men whose names have disappeared from the pages of our present photographic publications. On looking over the photographic literature of our day we are often startled by some grand new process or invention. Some of these may be of great value, and not a few can be traced to early experimenters. Pardon this digression; and in conclusion, and in support of what I have to-night advanced, allow me to quote from a paper by Mr. J. G. Berry, *On the Theory of Photographic Development*, published in *The Liverpool Photographic Journal*, February, 1855:—"We will take a plate of glass, collodionize and excite in the usual way; we will wash it in water, to remove the free nitrate of silver; we will then expose it in the camera; we may again plunge it into water, or even a solution of iodide of potassium, and replace it in the camera, exposed to a fresh object; and then, on the application of the pyrogallic solution, mixed in the usual way, with a small portion of silver, we shall evolve both the images impressed. They will be quite uninjured by the rough usage they have undergone, and are in every respect equal to what they would have been if manipulated in the usual way." This quotation shows that theoretically I am not alone in this matter. We have very much to learn of the theoretical part of photography, which necessitates or imposes a duty on those who have time and opportunity to pursue this department, in preference to inventing or adopting some trivial affair that can well be dispensed with. More theory will lead to greater things.

Other members of the society had arrived at similar conclusions to Mr. Wardley, and had met with countless failures from fog, stains, &c., when they had prepared the plates in daylight.

Mr. Griffiths, vice-president of the society, made some remarks full of interest and importance. He said:—

It was an undoubted fact that some operators conducted the first preparation in daylight and obtained good results. How could that be accounted for? He suggested that it might be owing to their *probable* use of free iodine in the iodized albumen, which most photographers acknowledged would remove any actinic impression made during the first preparation. Referring to that part of the editorial leader in which it is stated that "if anything approaching reduction has taken place on a plate which has received an actinic impression, an iodide will not restore its normal condition," he said the integrity of this statement was not borne out by facts; but he might ask—Does not reduction invariably occur when a sensitive surface is exposed, for however short a time, to white light? He was one of those who believed it did; and with a view to satisfying himself on that point he had, some twelve months since, undertaken a number of experiments, one or two of which he would briefly describe. A collodionized plate was sensitized in the ordinary way, and exposed wet in the camera for such a time as was considered sufficient to impress a negative. After thoroughly washing off the free nitrate, a solution of pyrogallic acid (without free acid) was poured over it for an instant. It was again washed, and the iodide of silver removed by cyanide of potassium. Nothing was visible on the plate after this treatment; but on the application of the usual pyro developer, mixed with a few drops of nitrate of silver solution, a faint, but perfect negative made its appearance. Another plate, similarly prepared and exposed was, after well washing, treated with dilute nitric acid (one part acid to twenty of water), again washed, and a solution of pyro, without free acid or silver applied for a few seconds. It was then washed, fixed with cyanide of potassium, and pyro developer mixed with silver poured over it; but not a trace of an image could be seen. Other collodion plates were prepared. After being taken from the silver bath they were well washed by allowing a stream of water from a tap to run over them for at least ten minutes, when a drop from them gave no precipitate with a chloride. They were then dried and exposed in the camera for times varying from two to four minutes. Previous to developing one of them, a camel-hair pencil, dipped in the dilute nitric acid, was drawn across the middle of the plate. They were then all treated exactly like the first plate mentioned—that is, first with plain pyro, then fixed, and finally with pyro developer and silver. The result was that a picture was produced on every plate except that which had been touched with dilute nitric acid not a trace of a picture could be obtained. One remarkable fact remained to be noticed, namely, in every case in which a washed *dry* collodion plate had been exposed in the camera, and treated as described, the result had invariably been, not a negative, but a faint *transparent positive*. In the explanation of this singular fact is involved the proof that actinic light acts essentially as a reducing agent. Take, for example, the sensitive wet collodion plate, and represent the film chemically, as containing before exposure, Ag I + (Ag I, Ag O, $No._5$), + Ag O, $No._5$ After exposure the parts acted on by light become Ag I + Ag O + Ag O, $No._5$ + $No._5$ (set free) + Ag O, $No._5$—the picture being formed by Ag O, subsequently reduced by the developer to the metallic condition. In the case of the dry collodion plate previously adduced, where no free nitrate or other salt of silver is present in perceptible quantity, the film contains Ag I + (Ag I, Ag O, $NO_5$); and in that condition he believed it was more readily susceptible to actinic influence than when wet—an instantaneous exposure being sufficient to produce the change represented by Ag I + Ag O + Ag I + (N $O_5$ set free). A long exposure would have the effect of partly reducing to the metallic condition, the newly formed Ag O, and thus produce the effect known as solarisation or reversed action of light. These views were offered not altogether as his own, but rather as the result of his study of the works of Hunt, Miller, Barreswil, Davanne, and others.

The exact nature of the change produced by light on the film of sensitive salts of silver remains, at present, a curious and important, but still unsolved problem. We think, however, there can be little doubt that it is desirable to conduct all the operations, with an excited film, by the aid of non-actinic light. If glass of the proper colour be selected for the window of the dark room abundance of light may be admitted.

## PHOTOGRAPHIC CHEMICALS.

### THEIR MANUFACTURE, ADULTERATION, AND ANALYSIS.

*Hyposulphite of Soda.*

THE manufacture of this salt offers good illustration of the laws of supply and demand. Before photography became a widely diffused and popular art, hyposulphite of soda was a mere chemical curiosity, occupying in laboratories a similar position to that which the corresponding hyposulphate does at the present time. It had been investigated as a chemical compound, and its leading properties were tolerably well known; but no practical use having been suggested or made of it, it remained almost unknown except as a museum specimen, and we doubt if all the laboratories of England could have furnished a pound weight of it. No sooner, however, did there arise a demand for it amongst photographers, than this salt found its way into commerce, and at the present time its manufacture gives employment to a vast number of hands, and has assumed somewhat important dimensions, South Lancashire alone producing three tons weekly, the bulk of which is consumed by photographers, and by paper-makers, and bleachers, as an *Antichlor.* Hyposulphite of soda is formed under several different circumstances; but chiefly:—1, when sulphites are treated with an excess of sulphur; 2, when a sulphide or polysulphide is submitted to the action of sulphurous acid; 3, when polysulphides are exposed for some time to the air. This latter method is, however, seldom made use of. According to the method first mentioned, crystals of crude soda are saturated with sulphurous acid until they are converted into bisulphite of soda. This bisulphite is then dissolved and neutralized with soda until it is converted into the neutral sulphite. It is placed in a large iron boiler, and an excess of flour of sulphur added; the liquid is then heated to the boiling point, and kept in ebullition until no more sulphur is dissolved. 100 parts of soda crystals, saturated with sulphurous acid, require for this purpose about 12 or 15 parts of sulphur. When the action is terminated, the solution is filtered through linen to separate the excess of sulphur, and the filtrate allowed to cool in shallow iron pans, when it soon deposits hyposulphite of soda in large crystals. These are generally purified by recrystallisation.

Another method of preparing this salt has lately been successfully carried out. It depends upon the mutual re-action of sulphurous acid upon alkaline sulphides. As a starting point, nitrate, instead of carbonate of soda, is used, by which the fluctuations in price of carbonate of soda are avoided.

Finely-ground native sulphate of baryta is mixed with carbon and calcined in a reverberating furnace out of contact of the air. The sulphate is reduced, and the whole becomes a greyish mass of sulphide of barium. This is then exhausted with water, and filtered. The clear liquid, after concentration to the requisite strength, is then mixed with an equivalent quantity of nitrate of soda (Chili saltpetre). A double decomposition thereupon takes place, by which the nitric acid goes to the baryta, and the sulphur to the sodium, thus:—

$$BaS+NaO.NO_5=NaS+BaO.NO_5.$$

The nitrate of baryta thus formed, being of very slight solubility, soon deposits from the solution in the form of crystals, whilst the sulphide of sodium, being very soluble and deliquescent, remains in the liquid. The whole of the baryta is removed by successive crystallizations, and the mother-liquor evaporated nearly to dryness, when a solid mass of sulphide of sodium is obtained. This moist mass is then broken up into coarse pieces, and placed in a large upright rectangular box ten or twelve feet high, lined with lead, and standing on a leaden cistern provided with a tap. The interior of the box is provided with wooden shelves pierced with holes, on which the moist sulphide of sodium is placed. At the lower part of the box, below the sulphide but above the cistern, a leaden pipe enters, which conducts a stream of sulphurous acid from a furnace, where it is generated, into the box (which acts as a chimney to the sulphurous acid). By contact with this gas the sulphur of the sulphide of sodium oxidises in the following manner:—

$$2NaS+3SO_2=S+2\ (NaO.S_2O_2).$$

The hyposulphite of soda ($NaO.S_2O_2$), as soon as it is formed, dissolves in the small quantity of water contained in the sulphide, and the solution trickles down into the cistern placed beneath the box. From this it is drawn off from time to time, concentrated, filtered from the precipitated sulphur, and purified by crystallization. The nitrate of baryta formed in the first re-action is commercially valuable, both for pyrotechnic purposes, and also for the manufacture of precipitated sulphate and other salts of this base.

The above methods of making hyposulphite of soda are, however, manufacturing operations, rather than processes which the amateur photographer could conveniently adopt, if it were necessary for him to prepare this salt on the small scale. If he have conveniences for the preparation of sulphurous acid or sulphite of soda, he may, indeed, make use of either of the above plans with advantage; but, otherwise, it will be more advisable to adopt the following method:—Take one pound of very pure, crystallized carbonate of soda, and dry it as perfectly as possible. When dry pulverise, and mix it intimately with five ounces of sulphur. Place the mixture in a shallow dish, and gradually heat it to the melting point of the sulphur, keeping it at that temperature for some time, with constant stirring, so as to bring every part in contact with the air. At first sulphide of sodium is formed; this absorbs oxygen from the air, and is converted with feeble incandescence into hyposulphite of soda.

'he mass is then allowed to cool, when it is dissolved in ater and boiled for some time with sulphur. It is next to e filtered, and the filtrate evaporated to the crystallizing oint. If the heat has been raised too high, part of the ılphur is burned off, and there remains an excess of caronate of soda undecomposed, which will have to be removed y a second crystallization. Very fine and pure crystals are btained in this manner.

Hyposulphite of soda crystallizes in different states of ydration. according to the temperature of the solution rom which it is deposited. From a hot solution it comes own quite anhydrous, but from a cool, less concentrated olution, it crystallizes in large clear oblique prisms, beonging to the right prismatic system, and containing 5 quivalents, or 36·23 per cent. of water. It is inodorous, nd has a cooling, saline taste, passing into a bitter and ulphurous flavour. It is quite neutral to test paper, and emains unaltered in the air. Upon heating, it fuses in its vater of crystallization; at a higher temperature it loses, vithout decomposition, all the water of hydration. Upon eating it still further it burns with a blue flame, evolving ulphur, and leaving a brownish mixture consisting of ulphide of sodium and sulphate of soda. It is insoluble in lcohol, but extremely soluble in water. Its aqueous soluion undergoes gradual decomposition on keeping, being onverted in close vessels into sulphur and sulphite of soda nd if air have access, into sulphur and sulphate of soda. The aqueous solution has extraordinary solvent powers over various chemical precipitates. Its action upon chloride of ilver is well known; in addition to this it dissolves in he cold, chloride of lead, subchloride of mercury (calomel), odides of mercury, silver, copper and bismuth, cyanides of ilver, lead, copper, uranium, zinc, cadmium, and bismuth, errocyanides of copper, lead, silver, uranium, cobalt, and bismuth, and the ferricyanides of copper, silver, manganese, cadmium, and lead. In addition to the above, it dissolves more sparingly, iodide of lead, cyanides of manganese and cobalt, and ferrocyanide of iron. Of these solutions, some appear to undergo spontaneous decomposition, but others appear more stable. The solutions of the chlorides are more stable than those of the iodides. It will, therefore, be seen that hyposulphite of soda is an energetic solvent for many bodies, and might possibly be advantageously employed in photographic processes which may be hereafter devised, in which any of the above salts play an active part.

## A FEW WORDS ON THE MANUFACTURE OF PHOTOGRAPHIC VARNISHES.

By H. R. Nichols.

To make a good varnish of any kind requires great care, much experience, and proper vessels for the preparation of the gums. In the latter lies the chief secret of varnishmaking; for if even the right gums be used, if they are not used in the proper condition the varnish will be useless.

The first consideration, then, is the selection and preparation of the gums, according to the purpose for which the varnish is intended. A negative varnish is required to be clear, hard and tough; not to become soft or sticky, or to crack under the influence of the sun's rays, and to bear a decent amount of handling without injury. It appears to be the impression of many photographers that the mere solution of a gum in spirit is a varnish. So it is, but a very bad one, and one which will very soon spoil a good negative. Those who will follow my directions will have a firstclass article, which will answer every purpose to which a negative is exposed.

*Negative Varnish.*

Take gum benzoin, broken into small pieces, from which select the *white* portion only. Put about four ounces, or other convenient quantity, into a conical vessel of copper or glazed earthenware, and insert this vessel about one-fourth of its depth into an iron lamp chimney. Apply heat from the flame of a lamp just sufficient to melt the gum. If scum arise, remove it. Keep it in fusion a quarter of an hour, then pour it on to a slab to cool. If this is nicely managed, the gum, when broken, will be glassy and slightly coloured. Put two ounces of this into one pint of spirits of wine. This should not be stronger than 50 over proof, nor should it be weaker than 40 over proof. This is of great consequence; for if the spirit be too strong, entire or partial solution of the film will occur. Add ten grains of the gum sandarac of commerce. Dissolve without artificial heat.

When perfect solution is effected, add fifteen drops of mastic varnish, prepared as follows:—Put one ounce of picked gum mastic into a glazed pipkin: melt it over a clear fire, stirring with a wooden spatula, continually. When perfectly fluid, remove it from the fire, and add, in small portions at a time, one gill and a half of turpentine, stirring it all the time. When cold and settled, it is fit for use. This forms, also, a good varnish for prints, &c., which must be first sized with parchment or gum size.

The benzoin varnish, with the mastic added, must now be boiled in a flask for a few minutes, and left to clarify. When clear, it is fit for use. The trouble of making this varnish is well repaid by its quality.

I have a few words to add on the use of shellac, from its frequent recommendations as a constituent of negative varnish. However useful shellac may be for other purposes, it is much out of place here, being decidedly injurious to spirit varnishes applied to glass. In my experience with shellac, no matter in what form it is used, the results are the same; a rough and freckled surface always ensues. If it is not so on its application, a few exposures to the sun's rays generally make it so, soon rendering the negative unfit for printing purposes. The cause of this is partially due to the spirit used with it containing so much water (from 45 to 50 over proof.) The remedies in this case are however, in my opinion, worse than the evil. With a spirit at 90 over proof these appearances are very slight; but the negative is much weakened, if it be not entirely destroyed by solution of the film. This may be prevented by sizing the film with gelatine before varnishing; but this practice ought never to be used without absolute necessity. When the use of gelatine is required, after the film is dried, a clear cut round the plate should be made with a sharp knife, about an eighth of an inch from the edge of the glass, so that the varnish may come in contact with the clear glass. If these precautions are not taken, the destruction of the negative soon follows: the moisture arising from many causes to which a negative is subject attacks the gelatine, causing it to swell, and the film becomes detached from the glass. This is, of course, followed by cracking of the varnish and the spoiling of the negative. I think these troubles far outweigh the trouble of manufacturing a varnish which will stand against all mishaps, and bear a very large amount of rough usage.

*Positive Varnish.*

An excellent varnish for collodion positives on glass may be made on the following formula:—

| | |
|---|---|
| Gum dammar ... ... ... | 2 ounces |
| Benzole ... ... ... ... | 16 ounces |

Dissolve and add

| | |
|---|---|
| Mastic varnish ... ... ... | 4 drachms. |

Stand the bottle in hot water half an hour; when fine it is fit for use; this varnish will never crack.

*Varnish for Positives to be Coloured.*

| | |
|---|---|
| Gum dammar ... ... ... | 1 ounce |
| Benzole ... ... ... ... | 12 ounces |

Dissolve, and then take

| | |
|---|---|
| Amber resin ... ... ... | 1 ounce |
| Turpentine ... ... ... ... | 4 ounces |

when both are dissolved, mix together, and let the mixture stand a few days. Then pour the clear portion off for use.

*Varnish for Paper Pictures.*

| | | |
|---|---|---|
| Picked gum mastic | ... ... | 2 ounces |
| Turpentine ... | ... ... ... | 10 „ |

when dissolved, add half a scruple of Canada balsam. Size the picture first with vellum size, dry it perfectly before the fire, and then varnish and dry in a free current of air.

*Liquid Enamel, or Polish for Paper Pictures.*

| | | |
|---|---|---|
| White shellac | ... ... ... | 1 ounce |
| Sandarac ... | ... ... ... | 1 drachm |
| Mastic ... | ... ... ... | ½ drachm |
| Spirits of wine | ... ... ... | 8 ounces |

Dissolve with slight heat.

*Black Varnish for Positives. No. 1.*

| | | |
|---|---|---|
| Asphalte ... | ... ... ... | 4 ounces |
| Tar naptha ... | ... ... ... | 8 ounces |
| Boiled linseed oil | ... ... ... | ½ ounce |

No. 2.

| | | |
|---|---|---|
| Asphalte ... | ... ... ... | 4 ounces |
| Benzole pure | ... ... ... | 6 ounces |
| Mastic varnish | ... ... ... | 2 ounces |
| Vegetable blacks | ... ... ... | ½ drachm. |

No. 3.

| | | |
|---|---|---|
| Shellac ... | ... ... ... | 2 ounces |
| Water ... | ... ... ... | 8 ounces |
| Biborate soda | ... ... ... | 5 drachms |

Boil till dissolved, and add

| | | |
|---|---|---|
| Vegetable blacks | ... ... ... | 1½ drachms. |

This in a more dilute state forms a good ink for the laboratory. The copy of this article is written with it. It has no bad smell, and stands unrivalled in many respects.

Good writing-paper coated with No. 2. I have often used for collodion positives, instead of glass; it answers well.

*Transfer Varnish.*

| | | |
|---|---|---|
| White shellac | ... ... ... | 1 ounce |
| Water ... | ... ... ... | 5 ounces |
| Biborate soda | ... ... ... | 2 scruples |

Boil until dissolved.

Coat the positive, and dry before the fire two or three times, using a camel's-hair brush. Coat, also, a piece of black paper, press both together wet: when partly dry, the picture easily leaves the glass.

## MICROSCOPIC PHOTOGRAPHY.

BY M. GIRARD.

As a member of the Jury of Admission of the Universal Exhibition of 1862, I had occasion a few days ago to visit the ateliers of M. Dagron; and in seeing the interesting results obtained by this operator, I promised myself that I would communicate to the Photographic Society an account of what I had seen. Since then I have learned that M. Dagron's processes were the subject of important suits with respect to the priority of patents; this circumstance caused me to hesitate, but remembering that the Society, according no official value to the communications made to it, is in the habit of leaving all responsibility with their authors, without wishing to appear in any manner as a judge between the parties, I have thought, therefore, that it would be permitted me to make this communication, without in this case, more than in others, our erecting ourselves into a tribunal.

I know that for a long time, in England especially, microscopic photography has been practised, and that to enlarge these proofs, use has been made of the microscope. I am also aware that in France, M. Marion on the one part, and MM. Angé and Picard on the other, have suggested the placing one of these proofs in the little telescope lorgnettes, which are employed as *breloques de montre;* but it seems to me that there is an important difference between these isolated attempts and the great development given by M. Dagron to the introduction of microscopic photography into current jewellery; and it is precisely in consequence of this development that the subject has appeared to me worthy of interesting our Society.

M. Dragon's pictures are obtained from transparent plates prepared by the Taupenot process, by means of apparatus which appeared to me no special novelty, except in an ingenious and intelligent arrangement of the several parts. These proofs are taken in any number on small glass plates, by means of multipliers placed at the extremity of the camera. Being afterwards made into little squares of three millimetrés each, they are ready for mounting. This latter can be effected in four different ways. The first two will not occupy us long, besides they are now seldom employed by M. Dagron; one of them is applicable to the case in which it is desired to obtain a single proof; the other very curious case is that in which we wish to place two different ones in the same apparatus. In the first case, at one of the extremities of a little copper tube we place one of the little combinations, known as the *Stanhope lens*, at the microscopic proof at the other extremities. In the second case, the system is composed of two little apparatus of the same kind, opposite to each other, and placed in a tube furnished with a longitudinal aperture, by which penetrates a quantity of light sufficient to lighten the proof; but this method, like the other, is not much employed by M. Dagron, who prefers the following methods:—

To mount single proofs he cuts little elongated rectangular prisms out of crown glass, then passes one of the ends of this prism through the flame of a lamp, so as to give it the desired curvature. The proof is simply glued into the other extremity, then the asperities and edges are rounded and smoothed at the lapidary's wheel. When it is desired to obtain two opposite proofs, mounted end to end, we proceed by an extremely ingenious process, invented by M. Barquille, one of M. Dagron's workmen. It consists in taking a quadrangular prism of crown glass, well squared at its two extremities, and gluing a proof to each, and afterwards passing each of the glasses bearing these proofs to the lamp, so as to transform the plane surface into a curved surface of the desired curvature, employing a magnifier to view the opposite proof enlarged, while that nearest the eye is too small to be perceptible.

Such are the methods which have permitted M. Dagron to make of microscopic photography and its application to jewellery an extensive branch of industry. His ateliers are occupied by one hundred and fifty workmen, and I thought the Society would be interested in knowing the importance thus acquired by an application of the art to which it has devoted all its cares, and of which it always receives tidings of its progress with pleasure.—*Bulletin de la Soc. Franc. de Photographie.*

## THE CAUSE OF ACTINISM.

BY S. D. TILLMAN, A. M.*

The clear and succinct statement of the principles of the Undulatory Theory, contained in Sir John Herschel's "Essay on Light," may be accepted with a modification of the last proposition, which is, "That as in the doctrine of sound the frequency of aerial pulses or the number of excursions to and fro, from the point of rest made by each molecule of air determines the *pitch* or note, so in the theory of light, the frequency of the pulses or the number of impulses made on our nerves in a given time by the ethereal molecules next in contact with them determine the *colour* of the light; and that as the absolute extent of the motion to and fro of the particles of air determines the loudness of the sound, so the amplitude or extent of the excursions of the ethereal molecules from their point of rest determines the brightness or the intensity of the light." The first part of the statement seems to imply that the

* Read before the American Photographical Society, Nov. 11, 1861.

optic nerve is impressed by the increasing number of undulations so as to excite a sensation of colour, gaining in luminosity by regular gradations, as the auditory nerve is impressed by increased frequency of aerial waves so as to produce a sensation of sound of higher pitch.

In papers heretofore presented for the consideration of this Society, I have endeavoured to show why the darkest ray is not found at one end of the solar spectrum, and the lightest ray at the other. From both the ratios which express the relative number of undulations, and the mean length of all the undulations producing white light, we can determine the position of the yellow ray in the spectrum. Assuming that it has been satisfactorily shown, in the papers alluded to, that the degree of luminosity depends on the laws of harmony, as to other forces we find there is a resemblance between those undulations which produce heat, and the waves of air which give a downward progression of pitch; also between those undulations which produce actinism and the air waves which give an upward progression of pitch.

The interesting problem is now before us: how can undulations of ether or eeth waves having no distinguishing characteristics but a relatively increasing curve, and an accelerated transversal motion, produce such instantaneous and peculiar effects when brought in contact with the class of sensitive compounds used by the photographer? Of the manner in which such chemical changes are produced we know but little experimentally. Between the cause and the wonderful result there is a vast void as yet unbridged by observation.

Adopting the view of Ampere, that ponderable matter is composed of molecules, each of which is formed by a group of atoms, both atoms and molecules being prevented from actual contact with each other by an intervening fluid, vastly attenuated and elastic, which we may assume to be identical with, or a portion of, the all-pervading eeth, the inquiry is presecuted, whether a series of wave forces generated by the sunbeam, when acting upon certain kinds of highly sensitive matter, can so modify the forces of cohesion and chemical affinity as to produce all the phenomena under consideration.

Let *a b c d e f g h* represent molecules whose centres are in the same right line. If the longest eeth-wave producing the invisible and least refrangible rays of the solar spectrum includes in its length all these molecules, the wave of half the length will include four, the wave of one-quarter the length two, and the wave of one-eighth only one; in the whole distance there will be one wave including eight molecules, two waves of the octave each including four molecules, four waves of the double octave, each including two, and eight waves of the triple octave each including one.

It would be, perhaps, too great a digression to illustrate the action of these waves by diagrams, and give the formula for estimating the comparative effects of wave forces. It will be readily seen if transversal velocity increases with the increasing number of waves; the molecule *a* will receive a transversal impetus from the series of shortest wave, vastly greater than from the longest wave.

A crude conception may be formed of a transversly-increasing circular undulation, by comparing the exterior of a half wave with an ordinary bell, in which the tongue, hanging at rest in its centre, shows the direct force. An infinite number of perpendicular radial lines, from any point of the central line of the tongue will represent the sum of the transversal forces in the wave, at the altitude or amplitude marked by the circle of intersection. The direct line measuring the length of the half wave may be taken as the measure of the force of compression and the radial line measuring the amplitude of the wave as the measure of a disintegrating force. The latter predominates as the diagonal line representing these two forces approaches a perpendicular to the line of direct action.

The range of octaves here presented is really within the limit already recognised. Esselbach's calculations based on acknowledged data and confirmed by the deductions of Muller, measure four octaves within the fluorescent and thermal spectra; the length of the extreme fluorescent wave being 0.0003 millimetres, and that of the extreme thermal wave being 0.0048 millimetres.

It is evident the shortest wave, assumed to embrace a single molecule, will exert an effect in strong contrast to that of the longest wave, which takes within its sweep the whole group. We can easily comprehend that the action of the latter, being the wave of greatest force, tends to expand the mass of a solid, and if further increased in amplitude, to make it assume a vibratory movement, and become a centre of radiant heat, as a sonorous body vibrating in air becomes a centre of sound.

On the other hand the shortest eeth-wave may effect the normal condition of only one molecule, by changing its relative position and motion and polarity. Every molecule of the mass is subjected to this isolated action of an eeth-wave, and hence the chemical effect, now defined as actinism.

Surface exposure is an essential condition to this action as solution is to that of chemical affinity. Actinism increases with the increasing number of transversal departures of eeth from the direct line of action within a given length. The greater the number of such departures the smaller is the group of molecules affected. Actinism becomes the prominent power in that portion of the sunbeam where the path of each undulation includes but a single molecule, and has its maximum effect when the length of the undulation does not exceed the distance between the centres of two atoms. Actinism is most apparent in bodies which absorb a portion of the light passing through them, or, more accurately, in the presence of a so-called elementary substance, whose atoms acquire sympathetic vibrations in unison with a passing eeth-wave, and which in turn sends forth like an Æolian harp a similar series of eeth-waves, thereby causing its characteristic colour. The most prominent of such elements are included in the haloid class of salt-radicals. Knowing only the fact that the violet ray has a higher actinic power than any other primary, we would select the violet coloured volatile iodine as the most sensitive of the haloid class. Knowing farther that the extreme violet ray, produced by an increased frequency of undulations, gives increased rapidity to actinic action, we should be led to add to the iodine salt a small portion of a salt containing the red coloured volatile bromine.

It should be borne in mind, however, that the chemical power of the sunbeam extends through a wide range of undulations of different velocities, whose action upon a given substance depends upon the relation between such velocities and the molecular arrangement of such substance. The action of similar rays upon different kinds of matter is well illustrated by the Daguerreotype and the collodionised glass plate. In one case the eeth-waves have effected a partial decomposition, in the other only a change in the position of component parts, which allows the waves to pass unbroken and makes the collodion film as transparent as the glass. The intensity of actinism, like that of heat, depends upon the amplitude of the wave which, when increased, tends to bring both molecule and atom more completely under its influence by a relative increase of transversal velocities.

The diverse effect of undulations of the same medium may be thus briefly stated:—the longer eeth-waves have the power of giving an undulatory motion to the whole molecular chain; the shorter waves the power of moving each particular link of that chain. The longer waves penetrate and disturb the whole substance, thus evolving heat; the shorter waves act superficially, yet they change the original motion and position of the minutest component part of the surface, thus generating actinism. If the views here advanced are tenable, we may dispense with the ingenious three-wave theory of Sir David Brewster, to which the late Prof. Nichols presented insuperable objections.

## PERMANENT PRINTS: FIXING BEFORE TONING.

SIR,—Photographers generally have begun to look with grave doubt, if not with suspicion, upon any silver printing process for permanency. They have seen their pictures rapidly produced, and almost as rapidly disappear, that they have come to the conclusion that the process for securing permanency is still looming in the regions of future discovery. But why should not a silver print be as permanent as a glass positive? In each case the image is produced by metallic silver, and the method of production is almost identical, and yet they are so different in their stability, that the cause of fading cannot be attributed to the agents employed, but rather to the way in which they are used.

Photographers generally aim to produce deep blacks on their prints, in imitation of a steel engraving, and the public like to have them so. To preserve these blacks intact, I think may be attributed one of the chief causes of fading. The prints are removed from the fixing solution while they are being rapidly reduced, before the unreduced silver is removed. Hence it follows that rapid decomposition sets in, because there is a sufficient quantity—it may be an infinitessimal quantity—of silver, or sulphide of silver in the print, capable of being acted on by light. Hence we find the the first symptoms of decay are perceptible on the highest lights of the picture. But why should the highest lights of the picture be attacked first? Because there is the largest quantity of unreduced silver. It is a remarkable fact, that prints are never attacked first in the deepest shadows, and this confirms my opinion that one of the chief causes of fading is due to the presence of unreduced silver, because in the deepest shadows the silver has been reduced by the action of light, and need not the prolonged action of the hypo bath. I may be wrong in this opinion, but observation and experience has led me to this conclusion. It sometimes happens, in fixing a lot of pictures, some of them stick together, and the hypo bath imperfectly acts on some portions of them, and this may not be seen until the prints are mounted, and then it is perceived by disagreeable yellow patches. Now, I think that these yellow patches are identical (only in a greater degree) to the yellowing over of the lights of the print after a short exposure to the action of light. It is a known fact that prints more rapidly fade by being exposed in shop windows, or suspended in rooms, than those do that are placed in albums. It is worthy of notice (and worth an experiment), that when prints are placed in the fixing bath, for the first ten minutes they are rapidly reduced, and for the next ten minutes they are very much less so; and, if allowed to remain an hour, the reduction is not perceptible. Now, if a print that is still being reduced by the fixing solution be removed and washed, and mounted beside one that has been removed from the fixing bath, when it could no longer be reduced in any perceptible degree, the former will rapidly turn yellow in the lights, while the latter will retain its purity and brilliancy. I saw some *cartes* the other day that had been sent out by a respectable London establishment (the name was on the reverse of the carte), and they had only been out a few weeks, and the lights had turned to a dirty yellow. I feel certain from a careful examination that they could not have presented such an appearance had they been properly fixed.

I attribute the permanency of prints, fixed and toned by this process, to the prolonged action of the hypo, and their thorough fixation. Before referring to details, I may say a word or two in reference to the quality of the paper used. It is not at all likely that if the photographer can produce prints that will bear the test of ages, that the paper on which they are executed will remain entire. It is a known fact that for years the quality of paper has been deteriorating. The cause of this deterioration appears to be the excessive use of sulphate of lime in the manufacture, for the purpose of giving it a good colour, and apparent firmness of texture. The president of the Royal Scottish Society of Arts, at the last meeting, referring to this subject, said "that our books, some of which are called standard, are falling to pieces, and the deeds, which were intended to be permanent exponents of their writers' wills, are now so faint as to be scarcely legible." If printers' ink so rapidly fades through the bad quality of the paper, how can we expect any other than a silver print will fade from the same cause, if everything else is conducive to its permanency? No doubt this is the cause of the rapid discolouring of the paper, after excitation. The French papermakers, I think, use chlorine gas as the bleaching agent, which no doubt is an advantage, as no lime can remain in the pores of the paper. In order to preserve the keeping qualities of the paper as long as possible after excitation, I use a large quantity of nitric acid (½ drachm to the pint of silver solution), and place the papers in a close box. Some samples of paper will remain pure for a week; others under the same circumstances will not keep above three days. The difference I attribute to the sizing, or bleaching agents employed by the makers.

I need not say a word on albumenizing, as most parties buy their paper ready prepared. I excite the paper on an 80-grain solution of silver to the ounce, from three to five minutes, according to the thickness of the paper. I think there is no perceptible difference in the colour and vigour of the print, if a 60-grain solution is used, or if it is allowed to be the strength of 90 or 100 grains to the ounce. I think the silver solution should be regulated by the quantity of salt in the albumen. Makers of albumenized paper would confer a boon on purchasers, if they would state with each parcel sent out the quantity of salt used in albumenizing.

I almost invariably print in the shade, and deepen with a minutes exposure in the sunshine. The proofs should be printed several shades deeper than they are required, as they are considerably reduced in the subsequent processes of fixing and toning. But not more so than they are in the carbonate of soda bath, the printing that does for one, will do for the other. The prints should then be washed in three waters, then placed in a large pan of water, in which has been dissolved a handful of salt, allowed to remain there five minutes, then washed in another change of water, and they are ready for the fixing bath. My object in getting rid of the free nitrate is to preserve in working condition the fixing bath for a longer time; as it may without danger to the prints be used several times over. The fixing bath is composed as follows: six ounces of hypo to half a pint of water. Allow the prints to remain in this bath about twenty minutes, then wash rapidly in two changes of water, and they are ready for the toning bath, which is made as follows: dissolve four ounces of hypo in a pint of water, add gradually two grains and a half gold, dissolved in two ounces of water, stirring while it is being added. Let it stand twenty-four hours, as in the acetate of soda bath, then test for acidity; if no trace of acid is perceptible, add two or three drops of acetic acid. The bath should never be alkaline, and only slightly acid. The prints first assume a red colour, then a deep brown, then a purple, up to a blue black. This last colour named, frequently takes some hours. But the time varies according to temperature from half an hour to nine or ten hours. The bath tones better after a few prints have been toned. But it is necessary to add gold occasionally, whenever the bath tones slowly. When it ceases to tone satisfactorily it should be thrown away.

As regards the washing of the prints, I wash them very rapidly for the first half hour in several changes of water, then allow them to soak for four or five hours, changing them occasionally.

As regards the advantages and disadvantages of the process, they may be summed up in a very few words. The only disadvantage (if you are pressed for time) is the slowness of toning compared with the alkaline toning processes. But the certainty of the results in the purity of whites, the agreeable tone, and the permanency of the prints, more than compensate for this little drawback. I had intended sending a series of prints with this letter, to show you the capabilities of the process, but I have had no time to get them ready; but will send them on when I may have occasion again to refer to this subject.

Enclosed is half of a stereogram, done nearly five years ago, in fact, it was one of the first that I toned by this process, and it does not appear to have changed in the least degree, although it has been thrown about in every conceivable way. (The scene is a village inn, Devon.)—Yours respectfully, THOS. TEDRAKE.

*Appledore, North Devon, Jan. 4th*, 1862.

[The picture received is of a purple brown tint, and shows no sign of fading. The slight amount of acidity extracted would, however, undoubtedly lead to the decomposition of the hypo, and induce sulphur toning.—ED.]

## Critical Notices.

### A MANUAL OF ARTISTIC COLOURING, AS APPLIED TO PHOTOGRAPHS. By A. H. WALL. Second Notice.

WHEN we first introduced Mr. Wall's Manual to our readers, we had not time or space to enter into any detailed examination or analysis of the work. From what we had seen of the book, and what we know of its author, we felt perfectly safe in expressing our hearty commendation. A further examination more than confirms our first expressed opinion, and induces us to give a brief *resumé* of some parts of the work which possess especial interest.

Having duly introduced the subject and purpose of his work, in a chapter from which we quoted in a previous notice, Mr. Wall says, that regarding the photograph as the drawing upon which the colours are to be applied, it is of no small importance that it should at least be "perfect in resemblance, and pleasing in its general effect," and that it may be so, he points out the methods which the photographer should adopt in posing, grouping, lighting, &c.; pointing out certain important principles of art in relation to such matters, and boldly asserting that a bad photograph can never, by colouring, be made a good picture. We are then, by way of commencing at the beginning, initiated into the abstract qualities of colour in its optical relations, from the consideration of which we glide harmoniously enough into the principles of artistic colouring, and the peculiar qualities of colours as pigments, in reference to working, drying, body, permanence, purity, transparency, &c. in water and oil, and in their dry condition, both when alone and in combination. But even then the author checks the ardour of the young colourist, and bids him put aside his new brushes and colour-box for yet a little time longer, while he lays before him "one hundred maxims" carefully selected from the writings of eminent painters on the subject of colouring; for, says the author, "There is no 'royal road' to art," adding, "It were very little use to supply the means of travelling if there were no roads, and roads themselves might only confuse and delay if they were not provided with direction posts," which he regards these precepts as supplying.

The student is then initiated into the method of painting with dry colours, how to treat defects in glass positives, &c.; after which follow in succession touching in black and white, colouring in water and in oil colours, lessons in chalk, and in painting water-colour landscapes, &c. &c.

In reference to "touching" photographs, we find the following remarks:—"The native truthfulness of a good photograph is so superior to the meretricious smoothness and laboriously stippled prettiness of an india-ink drawing, that creating the last upon the first seems to me a display of the most erroneous judgment and bad taste. The excuse generally tendered for the 'touching' of photographic portraits, or, in other words, making them resemble india-ink drawings, is, that it gives them '*finish*,' by which is evidently meant smoothness." These are followed by a quotation from a work by an artist, once a very active member of one of our photographic societies, Mr. F. Howard, which states that finish "does not consist, as appears to be a prevalent notion of the present day, in smoothness of surface, or tea-boards would be the most finished productions of art. Sir Joshua Reynolds could not be said to have finished any of his pictures. Texture would be worse than of no value; but varnish would be the artist's best friend. Nor does finish consist in another kind of smoothness which results from the careful blending and softening of all the touches, so that the method of execution shall not appear. Nor does it consist in minute detail, but in *the complete expression of character*." In this sense, asks Mr. Wall, "What can be more finished than a perfect untouched photograph?"

That portion of the volume before us which is devoted to colouring in crayon will prove of no small value now that the solar camera has introduced life-sized portraits.

The most novel, and certainly not the least interesting, portion, however, is that devoted to lessons in colouring photographic landscapes. By the method here suggested, we see no reason why the most exquisite results should not be realized, combining the truthfulness of the photograph with all the qualities of a first-class water-colour drawing. We are not aware that we ever saw a coloured photographic landscape that was not inferior to a *coloured* engraving or lithograph, and judging from our own personal practical knowledge of painting, we easily recognized the great difficulties by which an artist, desiring to make of such really effective coloured pictures, would be met; but these difficulties are all overcome by the method here suggested, and we hope that what colour has done for our portraits will prove to be as readily done for our landscapes. Not long since Mr. Hannaford, a clever amateur landscape painter, better known to our readers as a very ingenious photographer, obtained a very charming effect by the use of oil colours on a photographic sea view, but stated that were it possible he should much prefer colouring the same in water.

It has just struck us to ask, how it is that some of the beautiful composition pieces of Rejlander and Robinson have never been translated into colour.* Surely such sketches would make glorious paintings if the colourist were only the peer of the photographer as an artist. What sunny gaiety might not be infused into the "Holiday in the Woods?" what sentiment and power might not the sombre gloom of the "Lady of Shalott" gain? in short, are there any of these photographs that would not, *in able hands*, make paintings of high rank and worth? We dedicate the hint to Messrs, Robinson, Rejlander, and Wall, the first an amateur painter, and the latter two both painters by profession, the last named gentleman we heard only the other day very enthusiastic in his praise of the "Lady of Shalott" as a subject for colour. Why does he not paint it?

### INSTANTANEOUS STEREOGRAPHS, OF VARIOUS SUBJECTS. By G. W. WILSON, Aberdeen.

WE have recently received a parcel of Mr. Wilson's charming stereographs, including a variety of subjects, landscape, marine, and street views, and interiors. It is now late in the day to say, that each one of these pictures, no matter what the subject, is little short of perfection. In conversation with a friend the other day on the subject, we found ourselves somewhat at a loss for a word which, in any especial sense, characterized these pictures. They are delicate, they are vigorous, they are perfectly defined, they are clean, they are atmospheric; the subjects are well chosen; they have all these characteristics and many more; but it is difficult to say that any one of these takes precedence of the others. We were obliged to fall back on a somewhat negative term, and speak of their entire faultlessness; of the absence of anything we would wish different. The landscapes are so well composed, so full of gradation and of atmosphere; the interiors are so perfectly rendered, so full of detail, and yet so grand and forcible, free alike

* Since writing the above, Mr. Rejlander has informed us that it is no uncommon thing for his pictures to be copied by painters without alteration or acknowledgment; and mentioned, that one which was hung, and received high praise, at a recent exhibition, was simply a copy of his exquisite "Night in London."—ED.

from heaviness and chalkiness; the marine pieces are so marvellous in light and shade, and cloud and water; the street scenes are so perfectly defined and free from either under exposure or blurring of the moving figures; all are so harmonious and well chosen, that it becomes easier to declare them free from fault than to point out the especial sources of their excellence.

Amongst the most recent are a series of views of some of our principal war vessels. Amongst these are to be found, perhaps, the most perfect specimens of instantaneity which have yet been produced. Some of the vessels are engaged in "great gun practice," and the plate has been exposed the moment when the cannon has belched forth its cloud of smoke, the immense volume of which is as crisp and perfectly defined as if it had been perfectly stationary, instead of a curling, wreathing, rapidly-changing mass of vapour. With all this the ship is perfectly made out in every part, hull and cordage, without the slightest trace of under exposure in any part. "H.M.S. Cambridge, No. 316," is an admirable example of this perfect instantaneity. There are two, we observe, of the same subject, and with the same number; but that presenting the broadside of the vessel is the most perfect.

We may here call attention to a useful practice adopted by Mr. Wilson in mounting. The paper containing the name of the subject extends over the whole of the back of the slide, and has the advantage of counteracting any tendency of the card to curl from the mounting of the prints on the other side.

---

INSTANTANEOUS VIEWS OF LONDON, &c. C. E. Elliott, Aldermanbury Postern.

We have had the pleasure of seeing and reviewing many hundreds of instantaneous stereographs; but we must candidly confess that we have never felt greater surprise and delight, than we have experienced in examining some of the slides now before us. The subjects are of two kinds; street scenes, and views of cloud and water. Regarding the former we must express some qualification with our praise. Whilst they are very good considering the difficulties of producing instantaneous views of the streets of London, owing to the smoky condition of the atmosphere even at favourable times, they have some faults which scarcely belong to that cause. Some of the views have been taken from a great altitude, with the camera tilted, so as to look down on the scene, and the result is a peculiarly tumble-down kind of effect in the buildings. We may mention "No. 57, St. Paul's from the foot of Ludgate Hill," as a specimen of this defect, which ought certainly to be avoided. Some of the pictures are also a little chalky and under-exposed. Having said this much, we may add that they are, notwithstanding, decidedly beyond the average of such productions: the scenes well chosen, and the photography clean and vigorous.

When we approach the marine and atmospheric effects we can adopt entirely another tone of comment. Here all are charming, and some are perfect. We observed last week, in some remarks on the progress of instantaneous photography, that Mr. Wilson would have to look to his laurels. We had these pictures before us at the time we wrote, and in the photographer who produced them we believe Mr. Wilson will find his most formidable rival, if that rivalry can be considered formidable which simply comprehends a friendly struggle as to who shall best illustrate the great powers of a great art, and is conducted with the respect and esteem which we are sure must characterize the feelings of the neophyte competitor, and are certain will not be absent in the veteran.

The views before us comprise scenes chiefly on the Thames and the Solent; and have been produced under such conditions of light and atmosphere as we have rarely seen secured. In some there is a marvellous weird effect, which almost fascinates the spectator with the apparent vastness and solemn grandeur of the scene. A fine illustration of this is "123, Sunset at Ryde." The sky here is the charm, as the water in one part is a thought chalky: but what a sky! The horizon is surmounted by one immense bank of cloud which stretches across the entire picture; the sun has just sunk behind this cloud, but a rich warm glow of light radiates from it, and illumines the whole arch of the sky. The picture at once suggests colour, and we see the deep purple black of the cloud dense, but yet full of vapoury form and texture; and we see the golden light running through various tints and gradations into the blue of the upper sky. We should like an inch cut off the lower part of the negative, and the remainder enlarged to about twelve by ten. If well done, such a picture would be one of the finest things the art has produced. Even more perfect and quite as picturesque, but without the weird grandeur of the last is "No. 82, Sunset at Greenhithe." This is perhaps one of the most satisfactory specimens of chiaroscuro we have ever seen in a photograph: both foreground and sky are perfect. The sun has just descended behind an immense bank of dark cloud, the jutting fleecy edges of which it fringes with silver; a rift in the clouds shows the clear sky, and above the rift is a mass of cirrus cloud, the lower edges of which are illuminated by the sinking sun. The only bit of pure white in this picture is the delicate fringe of illumination to the clouds; all the rest consist of various gradations of demitint and shadow, in the most harmonious arrangement. We commend this slide to those of our readers interested in the matter, as a study of chiaroscuro. One of the most perfect studies of cloud we have met with is "No. 89, A study of clouds at Southsea." Here a mass of cumulus clouds, which cover the sky, possesses modelling and roundness, sufficiently perfect to give apparent solidity. This is not obtained at the expense of other parts of the picture, for a square rigged vessel in full sail is perfectly made out in every detail, as is also the water. We have not space to particularize further, or we might mention several others, each very fine indeed in their kind. We may especially refer to Nos. 87, 83, 51, 93, and 106, all of which are nearly perfect.

We have not received from the publishers definite information on a subject we always like to mention in notices of this kind. We refer to the name of the photographer who produced the pictures. We are strongly inclined, however, from internal and other evidence, to us satisfactory, to award the credit to a gentleman who, some eight or nine years ago, was a pupil of our own in the Daguerrotype process—Mr. Valentine Blanchard. If our conjecture be correct, we have pleasure in congratulating Mr. Blanchard on his success in producing stereographs which rank as high in artistic merit as any which have come under our attention. We would suggest to him the high value which many of these would possess if enlarged; and as he and the gentlemen with whom he is allied in business are proficient in the use of the solar camera, we hope to have an opportunity of seeing some of these stereoscopic negatives reproduced in large-sized pictures, which, if we are not mistaken, would take the photographic world by surprise.

---

EUCLID IN THE STEREOSCOPE.
By G. F. Sams. London: The Stereoscopic Company.

This is a highly ingenious and useful application of the principle of binocular vision to an educational purpose. The diagrams of the first twenty-one propositions in the eleventh book of Euclid, treating of planes and solids, are produced on stereoscopic slides, so that when viewed in the stereoscope the geometrical figures are seen in their proper relief and solidity. Many of our readers will remember the interest excited a few years ago by the publication of a stereoscopic slide drawn from Cruikshank's "Bottle," by Mr. Sang. The principle on which slides with the proper stereoscopic relief could be produced from one picture was first promulgated, we believe, by Mr. Sutton, and Mr. Sams acknowledges his obligation to that gentleman for the method by which these diagrams are produced. The slides are neatly engraved, and the stereoscopic effect very perfect. They are interesting as illustrations of the principle of binocular vision, and cannot fail to be welcome aid to the mathematical student.

# Proceedings of Societies.

## London Photographic Society.

The usual monthly meeting was held on the evening of Tuesday, January 7th, at King's College. The Lord Chief Baron in the chair.

The Chairman said he need not remind them that since they had last met there, on the first Tuesday in the month of December, there had occurred perhaps the greatest calamity almost which had ever befallen this or any other country at any time. It was proposed by the council that they should do no other business at this meeting than what was absolutely essential, such as reading the minutes and going through the usual forms. He should have then the honour of proposing an address of condolence to her Majesty on her recent heavy bereavement. They were not a chartered body; the society consisted of the members, who themselves appointed their council to conduct their affairs, and a president to preside over their meetings. It appeared to this council that it would be better if the address of condolence was presented not merely from the council, but from the whole body of the society, as the sentiments which belonged to them generally. It was not the council, but the society to whom her Majesty the Queen and the late Prince Consort were patrons; it was the society who had the advantage of that honour, and who benefitted by the countenance, advice, and assistance which the late Prince had rendered. Every member was interested in expressing his sincere sympathy with the bitter bereavement suffered by her Majesty, and in expressing the deep loss of the country in being deprived of the services which had contributed so largely to its welfare. It was proposed, therefore, that they should at that meeting do no business which could be dispensed with; but let their sole duty be to pass an address of condolence and sympathy to her Majesty, which had been already approved by the council. After hearing the address read it would be for the meeting to say if he should append his name to that address as their president.

The Secretary then read the minutes of the previous meeting which were confirmed.

The Chairman remarked, before reading the address of condolence, that of course if any member thought, on hearing the address, that anything could be added which would make it more acceptable to the entire society, and make it more expressive of their feelings in relation to the connection which had subsisted between her Majesty and the late Prince Consort and the society, it was open to such member to make any suggestion. The address was to the following effect:—To Her Gracious Majesty. We, your dutiful and devoted subjects, the president, council, and members of the photographic society, urged by feelings of the deepest gratitude to your Majesty and his Royal Highness the late Prince Consort, our patrons, humbly venture to address your Majesty to express how deeply, in common with all the nation, we deplore the inexpressible calamity which has befallen your Majesty and the entire nation. We, especially, who have been guided by the practical judgment of his Royal Highness, assisted by his liberality, aided by his advice, stimulated by his example, cheered and encouraged by his presence, deeply lament the irreparable loss this society has sustained. We humbly express our sincere share in the sympathy of the whole nation, and pray that, by the blessing of the Almighty, you may receive the only real consolation which so great a bereavement will admit of; and that your Majesty may derive satisfaction from the happiness, prosperity, and honour of the countries you govern, and from the universal esteem and devotion of the subjects who have benefited by your Majesty's reign.

The address was carried unanimously, and the proceedings terminated.

# Correspondence.

## FOREIGN SCIENCE.

[from our special correspondent.]

*Paris, 8th January*, 1862.

A retrospect of the progress of photography during the year that has just passed away, naturally induces the inquiry, "In what does the future of photography consist, and in what direction does it lie?" This question becomes more difficult to respond to every year, in proportion as photography advances on the road to perfection. With such results as are now attained by so many eminent artists we might reasonably be satisfied, were it not the disposition of the true artist to remain content with nothing short of absolute perfection. But the greater the strides toward perfection during the past, the more timidly we look to the future. "What further improvement can we hope for?" is the question that even the most ardent and sanguine must frequently ask.

We would gladly accept a more certain or less capricious medium than collodion, but the various substitutes for it hitherto brought into notice have found so little favour, that the empire of collodion remains unshaken.

But dry collodion, that much coveted desideratum, is far from having received its last improvement, and, perhaps, no element of photographic operations is more worthy of study and experiment than this. We have recently witnessed the effects due to the tannin process; we have yet to see what can be effected by the addition of resinous bodies to collodion, for the attempts hitherto made have lacked persistence and method. Yet enough has been achieved to satisfy the most sceptical of the resources lying dormant in resined collodion.

Closely allied to this part of our subject is the consideration of "washed collodion." Our views in this matter have been very excursive, and experience has reversed many formulæ insisted upon with singular pertinacity, even after their empiricism was fully proved. That collodion can be freely washed, without in any degree losing its sensibility, is a fact now fully substantiated, it being well proved that the presence of nitrate of silver on the collodion film is entirely unnecessary during exposure, as was once so strongly insisted upon. Besides, washed collodion pictures are developed much more rapidly under the same circumstances than are those on unwashed collodion.

M. Garneri's mineral collodion has a very tempting aspect, and it is to be hoped that experiment will realize all the results expected of it. It seems to be specially applicable as a dry collodion, and to occupy an intermediate position between albumen and ordinary collodion.

It is probable that the resources available in developing agents, or in modification of those in use, are far from being exhausted. Temperature, it has been shown, greatly modifies the results of this operation, especially in winter; but in all seasons, the reaction is accelerated by heat, while at the same time the proportion of nitrate of silver may be reduced; and thus it happens that purer images may be obtained by duly regulating the temperature of the developing solution.

The difficulty in causing collodion to adhere to the glass plate, although not insurmountable, cannot yet be said to be fully overcome. We know that it depends upon the chemical composition and cohesion of the collodion: both extremely variable conditions. And yet the importance of possessing the means of securing this adherence is very great under all circumstances. Coating the plate with albumen is a remedy, it is true, but one not quite satisfactory: another less objectionable, consists in covering the edges of the plate only with albumen, which has the effect of causing the most troublesome collodion to adhere. This simple application is very quickly performed, and fully compensates for the slight trouble it involves.

It is not very long ago when great distrust attached to positives on paper. Fading was so general, that few persons had the courage to look upon their proofs as permanent. But no sooner was the extent of the evil recognised, than a remedy was found, and, perhaps, in no branch of the art of photography has more satisfactory progress been made. It is, however, highly probable that the next step in advance will be to find a reliable substitute for the salts of gold in toning, among which, doubtless, platinum will take the first rank.

Carbon printing cannot as yet pretend to vie with printing with salts of silver; yet the success obtained by M. Fargier encourages the hope that still further progress will soon be achieved. The true path of carbon printing consists, it appears to us, in obtaining a photographic picture on stone from which any number of lithographs may be printed. The efforts yet made in this direction are very far from producing gradation of tone in the impressions, and it is not improbable that this fact will present insurmountable difficulties. For designs in outline, photolithography is fully available, but when it attempts designs in chiaroscuro the resulting picture presents no harmony: there is no relief, but a disagreeable flatness instead.

It is now generally admitted that the perfection of photographic portraiture depends principally upon the rapidity with which the picture is taken, assuming a natural attitude to be attained. Probably no style of portrait is so satisfactory as the little full-length now so popular as *cartes de visite;* certainly none other has ever been so popular. In a portrait the figure is as characteristic of the individual as the face, and if it has not hitherto been appreciated at its full value, it must be attributed to the conventionalities and short-comings of the portrait-painter. Thus it happens that the popular *cartes de visite* constitute one of the most valuable and important contributions, I might say *the* most valuable and important, to the science of anthropology.

Extremes will ever meet. Full life-size portraits would doubtless enjoy great popularity, if the difficulties to be overcome in producing them were not so great; but to be tolerable, portraits on this scale must be enlarged from very small negatives taken in the fraction of a second. Between two portraits of the same person, one taken in a quarter of a second, and the other in ten seconds, there is always as much difference in expression as between the living face and a mask taken after death.

## Talk in the Studio.

The Tannin Process.—Mr. E. Borda, writing to one of the American journals, says that tannin plates give more softness and delicacy when developed with a warm solution of gallic acid than with the pyro developer, especially for subjects having much contrast, such as dark foliage, and water, &c.

Louis Napoleon has given Professor Bunsen the decoration of an officer, and M. Kirchoff the Cross of the Legion of Honour, in recognition of their valuable discoveries in spectrum analysis.

Startling Discovery.—We, in the metropolis, are decidedly behind the age. Whilst we have deemed a certain thing as scarcely possible, in the provinces it is done; and photographic portraits in their natural colours are a regular article of commerce. A correspondent sends us a trade circular issued in a provincial town, from which we make the following extracts:—"New and important discovery! Photographic portraits in their natural colours. The ——— established for the purpose of supplying the public with large-sized, highly-finished, everlasting family portraits in their natural colours; to be taken daily, and in the evening by the chemico-electrical light, in a style hitherto unequalled." The announcement of the natural colours is not deemed sufficiently attractive alone, and as an additional inducement, an immense amount of valuable property is to be given to the patrons of the establishment. The munificent intentions of the artist are thus announced:—"Christmas presents, and New Year's gifts, of great value, to be positively given away at the commencement of the New Year, consisting of magnificent electro-silver tea service, elegant gold and silver watches, superb gilt ormolu time pieces and clocks, under glass shades; ladies' gold guards, lockets, and brooches; albert chains, and numerous other costly articles, some of which are now on view in the shop window of Mr. ——— jeweller." With a sly touch of prudence it is intimated that the quantity of "costly articles will be increased or *diminished*, according to the number of subscribers."

## To Correspondents.

*** The Fifth Volume of the Photographic News, neatly bound in cloth, is now ready, price 15s. Covers for the Volume are also ready, price 1s. 6d. No. 123, for which numerous inquiries have been made, is now reprinted, and may be had at the Office, or of any bookseller.

C. Scarfe.—The contamination of the atmosphere in the immediate neighbourhood of a gas-house will tend to discolour unvarnished collodion positives. The only way to avoid it is to varnish the films or keep the plates in boxes which exclude the atmosphere as much as possible. Some samples of collodion produce a greater tendency to discolour than others. Collodions of what is termed the "organic" character favour this discolouration most.

J. P.—In asking "what colours are most suitable to make a dark background," are we to understand you as referring to the colour for your background screen, or to the colours for applying to the background of a picture? We will presume the screen. In that case it will depend upon whether you wish to paint in oil flatting, or distemper. If the former, use white lead with just sufficient drop black to make it a dark grey, and dilute with turpentine. If in distemper, use ordinary whiting, with lamp-black added to the desired tint. Some operators prefer a stone colour of about the colour of brown paper. Common whiting and brown umber may be used to produce it. In mixing distemper colours, remember they look several shades darker whilst wet than when dry. It is well before applying them to a screen, therefore, to try first, allowing the colour to dry, on a piece of paper.

G. Price.—There can be no doubt that an analytical index would be very valuable. We have several times contemplated making one to the whole of our volumes yet published; but we fear the cost of production would scarcely be repaid. In order to derive the full value of a series of volumes containing such diversified information, we think it is highly advisable for readers to keep a "common-place book," in which should be registered alphabetically the place of every fact or formula worthy of further note or reference. In articles such as appear in our pages, it often happens that important ideas, allusions, recipes, &c. &c. occur incidentally in the article which cannot be even indicated in the title. The matter appearing under the general head of "correspondence" is full of such information. Our last issued index, got up at a very considerable cost, and given to our readers gratuitously, is the most copious we have issued, but no ordinary index can refer the reader to a tithe of the information the volume contains. Many of our readers keep such a common-place book as we have described, and we recommend the plan to all who wish to have a ready means of finding all the information bearing on all important subjects at a single glance. We will hear your suggestion as to the reference to the No., as well as page, in mind. We never dream of taking offence at well-meant advice; but aim, as far as we can, and see right, to profit by it 2. We have never met with any of the samples of paper giving mealy prints in our own practice; but have seen many mealy prints in the hands of others. Mr. Fry will, doubtless, be willing to supply you with some of that we referred to last week, if you call at his establishment in Gracechurch street.

J. A. F.—If the lenses are required for stereo work only, the stereoscopic lenses will answer perfectly. If for *cartes de visite* as well, the No. 1 B. The first cover well and work very rapidly, but cannot always be worked with full aperture. The second would have an advantage for instantaneous work, inasmuch as they will cover the stereo size very perfectly with full aperture.

An Admirer is thanked.

B. F.—If you are certain the landscape lens you speak of buying is a "Ross," you may purchase it with safety, with full assurance of its quality.

G. H. C.—We have met with a similar difficulty to that you describe, when using bichloride of mercury as a strengthening agent, the image becoming thin and transparent. It is doubtful whether in that stage there is any certain remedy; the best chance will rest in the use of pyro and silver. Dry plates are better strengthened by that means, at any time, than by bichlorides. If the latter be used, they should be very dilute.

R. Atherton.—We forwarded the letter to the proper address.

O. B.—The arrangements you require are those of the solar camera. The 9-inch condenser will answer very well. It may be placed, plano side next the negative, at such a distance from the portrait lens that its focus falls upon the front lens. The distance of the negative from the portrait lens will be regulated by the amount of enlargement. See table in our Almanac. Your mirror must be so placed that the image of the sun is always directed to the centre of the condenser, and will, if you print out instead of developing, require constant attention. See various articles on the solar camera in our last volume. The same remarks will apply to your arrangement throughout.

Subscriber.—The probability is that your collodion now contains a considerable excess of ether, and by rapid drying may cause you the lines complained of. When you require to dilute collodion, do it with equal parts of pure ether and alcohol. If the streaks arise from the collodion at all, the excess of ether is the most probable cause. Sometimes such fringes arise in the course of development from irregular draining of the solution, whilst the negative is being examined.

1862.—We do not know of any other. We have not seen the set to which you refer; but it is much too low in price to be worth anything. In photography there is nothing so delusive as mis-called cheapness. For a beginner a very low-priced set might serve for first experiments, but it would require replacing in a few months.

G. F. L.—The ebonite continues perfectly satisfactory in our hands.

X. Y. Z.—The late Mr. Lacy used the No. 2 B lens of a well-known English optician in the production of his card pictures. He had tried the lenses of several makers previously, but finally he only used those we have named.

Several articles, letters, and answers are compelled to stand over until our next.

All Letters, Works for Review, and other Communications for the Editor, should be addressed to the Office, 32, Paternoster Row, London.

THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 176.—*January* 17, 1862.

## PRELIMINARY COATINGS FOR GLASS PLATES.

NE of the great difficulties which have attended various forts to simplify the use of dry collodion, has been a ndency, in the hands of the majority of operators, to the osening and destruction of films. The fact that in the ands of some photographers this difficulty is either never lt or easily overcome, cannot, we presume, be accepted as vidence against general experience. In our own hands ich a thing as a lost film is an occurrence so rare as not to nter into our list of casualties. Mr. Ward, whose process ppeared in our last, uses simply washed collodion, with ntire immunity from this evil. Some others give similar stimony. But in spite of all this, one of the most common omplaints amongst those who use simply washed collodion, annin plates, or plates prepared by any similar process, is, hat the films loosen, expand, crack, or blister. This evil it s clear is sufficiently general to demand some consideration f the remedies proposed.

These remedies consist chiefly of the application to the lass of some preliminary adhesive coating, gelatine, india-ubber, or albumen being the substances proposed. Major Russell, whose opinion is entitled to some consideration, ives the preference to gelatine; but although its use is, omparatively speaking, unobjectionable, it does not seem to ave become a favourite with the majority of photographers; robably owing to the fact that the aid of heat is necessary o prepare and keep the gelatine solution in a condition for se, and that the layer of gelatine is apt to decompose in the resence of damp atmosphere. A sub-stratum of india-ubber is strongly recommended by some operators. Major Russell, in a recent article in our columns, speaks of its value f certain conditions be observed. Mr. Glover, in a recent ommunication to our Liverpool contemporary, gives very ecided preference to india-rubber as a preliminary coating, nd adds some information as to the best mode of using it. We make some extracts from his remarks. He says :—

"After careful experiments with all three substances, I find a olution of india-rubber, of such a consistence as will readily ilter, to be the most effectual and easy of application, flowing vith all the readiness of collodion. In coating with gelatine or lbumen the glass must be chemically clean, or either will be epelled by the surface, and cause subsequent difficulty and nnoyance to the operator; but the solution under notice lows equally well on the glass, even after unlimited contact vith the fingers, and without affecting the resulting nega-ive. Not that any sane individual would either practise r recommend anything but strict cleanliness, but it is sola-ing to be enabled to ensure a perfect and adhesive surface vith the minimum amount of trouble. Both Major Russell nd many others complain that india-rubber films contract nd split up on applying the necessary heat to varnish he negative. This difficulty may be entirely obviated by ubjecting the coated plate, as soon as surface dry, to a consi-lerably greater heat than is required, previous to using spirit arnish—bearing in mind not to continue it to such an extent s to produce decomposition, but sufficiently long to dissipate ll traces of the solvent, leaving nothing but a coating of pure ndia-rubber to receive the collodion. The error of previous xperimenters has been the subjection of the negative to a reater amount of heat than the foundation previously under-vent. An addition of about one grain of common resin to each unce of solution is also a further preventative against the evil n question, and it is then less dependent upon the thorough eating than without such addition. I find the best solvent or the purpose to be common coal tar naphtha—or equal parts f it—and spirits of turpentine. Benzole, although more agreeable to the sense of smell, is too volatile; which is also the case with chloroform, producing lines or streaks of unequal thickness, similar to collodion containing too great a proportion of ether.

"What I wish to urge is the superiority of india-rubber as a support for collodion, on account of the following reasons :—The great facility with which it is prepared and applied; its un-changeable qualities, as after it is once properly filtered it never deposits sediment, and keeps indefinitely; its complete neu-trality, however long in contact with nitrate of silver; its insolubility in water and very slightly in collodion, so that the thinnest possible coat is only necessary; and, lastly, its inde-pendence of the state of the glass surface."

Probably the plan suggested by Mr. Glover of applying considerable heat to the film of india-rubber, when on the glass plate may, by slightly melting it, cause it to adhere more firmly to the glass than it does when the film is simply dried by the evaporation of its solvent. If this were not the case, we should not expect the layer of india-rubber to adhere more firmly to the glass during the processes of wash-ing, then a film of glutinous collodion. Indeed, we have used both india-rubber and gutta-percha as a preliminary and an efficient aid in transferring the film. In preparing a solu-tion of india-rubber it may be well to mention that the pro-cess may be materially facilitated by the use of a portion of chloroform. In either benzole, mineral naphtha, or turpen-tine, the india-rubber requires digesting for some time, and sometimes the aid of heat before perfect solution is effected. If, however, the strips of india-rubber be immersed in a little chloroform, it is rapidly dissolved, and may then be diluted with any of the other solvents which may be chosen. It should be remembered that both mineral naphtha and tur-pentine leave some residue behind after vaporization, the pre-sence of which is scarcely desirable.

The preliminary coating which has been most largely used, and most generally preferred is albumen. The use of a substratum of albumen has been recommended as having under some circumstances a very important chemical action, as well as for its mechanical aid in preserving the film. Some years ago the Rev. Mr. Laws suggested its value in giving vigour and richness to the negative image, a result to which it undoubtedly contributes. Mr. Hislop, whose paper on washed collodion was recently read at the North London Society, invariably uses a coating of dilute albumen solely with a view to its mechanical effect. Incidentally, however, there can be no doubt it plays a part in the chemi-cal part of his process. Against this view it was urged at the meeting, that Mr. Hislop coagulated his albumen by ex-posing the coated plate before a brisk fire. We at the time ventured to affirm that no coagulation would take place under such circumstances. It has been asserted also that the film of albumen is coagulated by the application of the collodion. We venture to doubt this also, as we feel satisfied that a film of dried albumen is not coagulated by ether or alcohol. But even supposing it were coagulated, that would not prevent it exercising an important action in the forma-tion of the negative image.

That this should be the case is not, however, by any means necessarily a disadvantage if it can be proved that plates so prepared do not injure the bath. This is a point on which much contradictory experience has been promulgated. As we were anxious to lay the best evidence we could obtain on this subject before our readers, we have taken some pains to collect some facts and opinions from trustworthy sources. So far as we can ascertain, general experience is corroborative of the views of Mr. Hislop, to the effect that collodionized plates, having had a preliminary coating of *dilute* albumen may be excited in silver baths containing *acetic* acid without injurious results. Mr. McNab, of Glasgow, who has had very extensive experience in the use of plates so coated, gives us a very full, lucid, and satisfactory statement of his own practice in the matter from which we make the following extracts:—

"I have been much interested in the discussion going on in the North London Society, on the preliminary coating of the plates with albumen. I had thought its use had been a settled question, and no new light could be brought to bear upon it. If I may be permitted to give my experience upon it, it is more or less in unison with that of Mr. Hislop. The cleaning or preparing of the plates is at the threshold of all our other operations, it is not the most pleasant: it is too often the Slough of Despond to many; it is tedious and often irksome in the extreme. How often have our tempers been ruffled and soured in endeavouring to prepare them fit for use, the testimony of the thousand and one failures, mishaps, comets, spots, and all the innumerable ills to which dirty plates are liable, not to hint at cracking and rising of the films, and other evils too numerous to mention, can testify.

"I think I am within the mark when I say that more failures have arisen from this cause, than all the fogging baths, and tender and bad collodion put together. One is apt to treat the matter lightly, and think there is nothing easier than to clean a plate fit for good work: this is a great mistake, to the bitter experience of many who have abandoned it as a great bore. If it is difficult with small plates, it is worse with larger ones. How very many would be up and doing, but they *hate* the cleaning of these abominable plates, and shove it off from day to day, and dodge it fifty ways rather than begin it. If they could speak, many neglected cameras, and dusty lenses, and deserted apparatus, could bear testimony to all I now say, arising from the drudgery of washing, drying, and buffing glass plates. To get over the evils complained of, a friend of mine recommended me to try a preliminary coating of albumen. I did so, and found it to work well, and had it constantly in use for a considerable time, when I had the pleasure of a visit from Mr. Shadbolt. I mentioned the matter to him, that I used a bath for positives and negatives; he said it was somewhat singular that he had a communication from Manchester, in type, on the same subject. He suggested to me the use of iron to coagulate with, which I have constantly used with much satisfaction.

"First of all, a flattened sheet is carefully selected, free from kiln smoke, or crown glass, this effects a considerable saving in the price. They are washed in water strongly acidulated with nitric acid, and afterwards in a copious stream of pure water from a tap; and then put into a rack to drain a little. In the wet state they are coated with albumen in the same way as you coat a plate with collodion, the superfluous albumen is drained through a filter into a wide-mouthed bottle to be ready for future use; the plates after draining are put upon a rack before a brisk fire to dry, and then to be stowed away in packages, to be ready at any future time to be coagulated ready for use. In this state a great many are prepared at one time, and generally two hands are at work on them at the same time, the one to wash, the other to coat with albumen.

"When wanted for use they are taken out of the packages, and one after the other wetted all over under a flowing tap. A saturated solution of sulphate of iron acidified with sulphuric acid is now poured over the plates, the same as if you were developing the plate, the solution is made to flow over the plate in one continuous, unbroken wave, and kept floating upon the plate for a short time, and afterwards washed in abundance of water. It is now placed in the rack before a brisk fire and dried. After they are dried they are carefully cleaned upon the back and marked, as it would now be difficult to find out the prepared surface. I have never experienced any difficulty in covering the plate with collodion.

"In preparing the albumen, I take white of eggs with the germs carefully taken out, and beat them up in a bason for some fifteen to twenty minutes till it gets into light, white froth. It is allowed to settle, and three parts of water to one of egg is added and filtered into a large bottle: liquor of ammonia is added till it sensibly smells of it. This helps to preserve it.

"The advantages of a preliminary coating of albumen to the glass is cheapness in the price of flattened sheet for large plates. The collodion, however tender, adheres with tenacity, and is with difficulty removed. Less labour and more certainty in the preparation of the plates; freedom from blemishes of every sort; the negatives will stand much rougher usage, and is somewhat firmer in texture; and I do not find the bath more liable to get out of order than with plates in common use. I have worked with baths until they were unfit for use from the large quantity of ether and alcohol they contained, without having a foggy plate. I have thought that after long use they showed symptoms of loss of sensitiveness, but I am not quite sure but that the same may be said of a bath somewhat improved from constant use, when it begins to show symptoms of coming age.

"To all who are in the habit of using large plates for out-door work or copying, or printing large transparencies, it offers many advantages, not the least being a temper unruffled by losing films from off the plates, and perfect immunity from spots and blemishes, so far as the preparation of the plates is concerned.

"I have thus given in my own way my method of working plates so prepared. I do not know if I may have shown it as you wish that I should have done it—it is the best way I can explain myself.—I am yours, dear sir,

"ALEX. MCNAB."

Mr. McNab's conclusion, it will be seen, after perhaps more extended experience in the matter than any other photographer we know, is in the highest degree favourable to the use of this preliminary *couche* of albumen. Mr. Hughes, who at one time tried the same plan with marked success, so far as the negatives are concerned, was obliged to give it up from the gradual injury to the bath, which resulted in fogging. There was this difference in Mr. Hughes' mode of proceeding: he used undiluted albumen, whilst in all the successful cases of which we have record, the albumen is used in a considerably diluted condition.

Before leaving this subject, there is another curious discrepancy of experience to be noted. Mr. Glover, in the article to which we have referred, says:

"Finely-ground glass gives a more sensitive film than its natural surface does. On the contrary, gelatine and albumen surfaces have a decidedly retarding influence. This is not the case with india-rubber, as may be demonstrated by the following experiment:—Coat the halves of three plates with each of the substances in question; make them into dry plates by any of the processes; expose and develop as usual, and observe the result.

"The appearance of the half covered by the albumen is that of being less exposed than the half left bare; the gelatine presents a greater contrast still; while the india-rubber seems not in the least to have affected the result."

Mr. Hughes, Mr. Hislop, and all from whom we have received any communication, state on the contrary, that the use of an albumen coating gives a very decided accession of sensitiveness. The only mode of reconciling this discrepancy is to refer it to some varied condition of the other chemicals used by the gentlemen in question, as it is well known that organic matter, in some circumstances, acts as an accelerator, whilst under other conditions it materially retards actinic action.

## Notes and Jottings.

No. 11.

### "NEW" IRON PROCESS BY MR. REYNOLDS—"NEW" CARAMEL DRY PROCESS.

WE have before us the paper read by Mr. Reynolds, before the Dublin Chemical Society,* together with some remarks thereon by Mr. Shadbolt, in the last number of *The British Journal of Photography*.

The term "new," as here applied, reminds us of the way in which the same word has been so frequently used in claiming originality for slight modifications of well known dry and preservative processes. Mr. Shadbolt himself would have some difficulty in informing us of the number of "new" processes his introduction of honey, as a preservative, has originated. Brown sugar, white sugar, burnt sugar, "hard-

* See p. 5 of the present vol.

bake," treacle, golden syrup, are only a few of them. This printing process is equally "new;" for Sir J. Herschel long ago stated that persalts of iron were reduced by light to protosalts, which latter, as is well known, precipitate the salts of gold and silver.

He says: "If paper prepared with the ammonio-citrate, or ammonio-tartrate of iron, and impressed with the latent picture, be washed with nitrate of silver, a very sharp and beautiful picture is developed of great intensity. . . . . The picture may be fixed by the hyposulphite of soda, *which alone, I believe, can be fully depended on for fixing argentine photographs.*"

Now, the use of peroxalate in lieu of the salts of iron given above, is as original as the employment of treacle instead of honey, just alluded to, so that nothing "new" can be claimed on that score; and the same may be said as regards the reduction of silver by the protosalt of iron.

Mr. Burnett, too, has, we believe, given very similar suggestions, although we cannot at this moment recollect where and when; but some of his communications state the results of numerous experiments with the proxalate of iron.

His Uranium process in its action and manipulation is identical with that given by Mr. Reynolds, save in the difference of the sensitive agent. Thus:—

Persalt of *uranium* is reduced by light to a protosalt: persalt of *iron* is also reduced by light to a protosalt. When the print is placed in solution of silver or gold, the protosalt of uranium, again becomes oxidized, silver or gold, as the case may be, being deposited.

The iron print, on immersion in gold or silver, likewise becomes again per-oxidized in the reduced parts, the metals being deposited.

In each case the sensitizing salt is removed by water.

It will thus be seen that in principle Mr. Burnett's uranium, and Mr. Reynolds's, or rather Sir J. Herschel's iron processes, are the same; the difference of one salt being used instead of the other, being, theoretically, about the same as developing the image on a collodion plate with one deoxidizing agent in preference to another.

But Mr. Reynolds says, as regards fixing, after immersion in silver solution:—"All that now remains to be done is to wash well dry and mount, when the picture is finished." Mr. Shadbolt endorses this statement, saying, "it then remains but to wash the print in distilled or rain water, and the operation is finished." Now Mr. Hardwich in similar cases has objected that all papers contain chlorides in their composition, chloride of silver being thereby formed, the lights of the picture suffering in consequence. In our quotation above, from Sir J. Herschel, we have italicised his assertion that the use of hyposulphite of soda is necessary, and Mr. Burnett after full trial, very unwillingly had to fall back on the same agent.

We do not remember to have heard of a like statement to that of Mr. Reynolds respecting the weakening of half tones in consequence of the reduced protosalt being partially dissolved by the persalt, and for this hint we must certainly give that gentleman our thanks. Mr. Shadbolt we know has always been of opinion that bichromate prints do not present half tones equal to silver, that is, that the number and minuteness of particles of reduced silver would be greater than those of the bichromate. Without waiting here to discuss that point, we purpose giving a trial to his suggestion as to whether the reduced bichromate is not in a similar manner partially dissolved by the perchromate.

---

Mr. Bartholomew's caramel, or burnt sugar process is also not quite new. Sutton in his dictionary says:—"It has been tried instead of honey, &c., in preservative processes. It was found to lessen sensitiveness, but was less inclined to crystallization." In short it is the honey process of Mr. Shadbolt, slightly modified.

Of his third "new" process we shall be glad to hear something more. Michael Hannaford.

## REMARKS UPON SOME OF THE APPARATUS EMPLOYED IN PHOTOGRAPHY.

BY F. R. WINDOW.

It is easy to find fault. It is far from my intention to do so. In the following remarks upon some of the apparatus employed in photography, my aim is simply to pass in review a few of the contrivances that are generally in use; and, keeping in view the object for which they are intended, to ascertain whether each particular form is the one most suited to its purpose, offering occasionally such suggestions as may from time to time be prompted by my own experience.

Every one who has practised photography has probably at some time discovered that the instruments at his disposal, that is, those generally manufactured for sale, were not quite suited to some particular object he wished to attain, and he has had to exert his own ingenuity to remedy the shortcoming. Descriptions of many of the modifications so designed have appeared in these pages; and this class of practical information has mostly been well received by photographers, who are always anxious to seize whatever may tend to the improvement of their art, whether it be a chemical, an optical, or a mechanical detail, or a lucid illustration of its higher capabilities to "hold the mirror up to nature."

In the following "remarks" I do not propose to deal with exceptional cases, like the above, which photographers have generally proved themselves perfectly capable of dealing with, but I intend to confine my observations solely to those instruments which are required for the ordinary daily practice in the laboratory, the studio, and the field.

It is worthy of remark that, with the single exception of the optical portion of the lenses, the mechanical appliances for producing photographic pictures have suffered scarcely any important modification in their various details, since the date of the first introduction of the now universal process on collodion: and while our eminent opticians and chemists, by dint of hard labour and minute investigation of the various requirements of the art. have furnished us with lenses and chemical formulæ which can compare with those of 1850 as "Hyperion to a Satyr," we have still the same cameras, the same baths, the same dishes, stands, boxes, and other apparatus, with but slight modifications, that were used at that date.

Does this arise from the absolute perfection of this apparatus, and the recognised impossibility of improving it, to keep pace with the optical and chemical departments? I think not. I believe that if a dozen intelligent practical photographers, competent by their mechanical knowledge for such a work, were separately requested to furnish a design of their idea of a perfect camera for the studio, for instance, they would very probably produce twelve designs each differing in its details distinctly from the others; but I feel equally certain that each would likewise differ quite as widely from that in general use. Indeed, this opinion is corroborated by the fact that a large number of our principal artists use cameras and other apparatus made after their own design, differing materially in many points from those which continue to be manufactured for sale to the general public.

We must, therefore, reject the idea that our present photographic apparatus has undergone so little alteration during the past twelve years, because it was at first designed perfect, and scarcely susceptible of improvement. I believe the real cause will be found in the fact that it is no one's business to study the matter with a view to improvement. The photographer is engaged in the production of the best possible pictures, with the appliances at his command; and it is evidently not the interest of a manufacturer to risk the introduction of new types and innovations into his business, entailing a fresh education of his workmen, so long as the articles he is accustomed to produce meet with the approbation of his customers.

Another cause, also, nearly allied to the above, may probably be traced in the fact, that photographers generally may not be sufficiently conversant with mechanical operations to enable them to offer really *practical* suggestions for the defects which they may recognise in their apparatus; and that the manufacturers have seldom that intimate practical acquaintance with the art of photography which would alone enable them to judge of its real merits.

It may be urged that our apparatus cannot be very defective, because we are able to take with it very excellent pictures. This is true; but our aim should be *perfection*, an unattainable goal in art, but which, I take it, is nearest approached by a consciousness of imperfection, a diligent study of its cause, and a steady desire to progress. We ought to be dissatisfied with our work if, at the end of a year, our results do not show an improvement upon those produced twelve months ago. We should always be striving to move forwards. In such an art as photography, how slight, how apparently insignificant, may not be the cause of a great effect? Yet, if each trifling cause or source of recognized error, when remedied produced an amended effect but in a ratio to its minute self, we should not neglect it, but—however small the apparent step—rather set it down as a great profit, as another round gained in our climb towards perfection.

A remark by one of the most eminent photographic artists that this country has produced—alas! no longer among us—was registered in this journal a short time since, and is so singularly illustrative of my argument that I cannot refrain from quoting it. In reply to a question respecting the worth of a toning formula he had purchased at rather a high figure, Mr. W. G. Lacy, replied, "In aiming at perfection, a very slight step is a great deal, and is worth *anything*." And the enlightened editor aptly comments—"Such an answer was a key to his success."

So, if in the "remarks" which I propose to make, and the propositions I may have to offer respecting the mechanical appliances used in photography, I am successful in advancing the art but one very slight step, I shall be content, and count it a great deal.

(*To be continued.*)

## Scientific Gossip.

Composition of the Photographic Image—Ruby Gold and Silver—Minute Divisibility of Matter.

The recent discussion on the composition of the photographic image, first started by Mr. Malone's lecture on this subject, at a late meeting of the Photographic Society, has caused attention to be directed in several quarters to the almost infinite extent to which matter may be subdivided. The idea that a dense metal like gold or silver *could* be precipitated in so minute a state of subdivision as to allow of the passage of rays of light, appeared incredible to some writers on the subject—one contemporary, indeed, going so far as to question the statement of the ruby or purple colouration of Mr. Malone's liquids being produced by solid suspended matter at all, unless the said particles could be seen floating about in the liquid when examined under the microscope. Now undoubtedly neither Faraday nor De la Rue, could detect the slightest symptoms of resolvability of the ruby gold liquids into separate particles, but this only shows that the compound microscope has but limited powers, in spite of the perfection to which it has been brought, and must not be used as an argument to limit the powers of nature. Indeed, Faraday has shown that in his ruby fluid there is only one volume of gold diffused through about 750,600 volumes of water; and that whatever the state of division to which the gold may be reduced, still the proportion of the solid particles to the amount of liquid through which they are dispersed must be of that extreme proportion. This accords perfectly with their invisibility under the microscope; for it is only necessary to calculate what is the minutest fraction of a drop of the ruby coloured liquid which can be seen under the microscope, and the above proportion proves that the size of the solid particles must be at least 750,600 times smaller.

This would appear to prove that the ruby colour of the liquid was due to *solution*, and not to suspended solid matter. It is not so easy to disprove this, but still upon attentively examining the subject, the arguments in favour of the latter explanation appear so convincing as to amount to little less than absolute proof. Thus if sunlight be concentrated by a lens on to the ruby liquid, the path of the cone of rays will be distinctly marked out through the liquid by the copious reflection of light of a golden character. This even takes place when the ruby liquid is so diluted with water as to show scarcely any trace of colour, and can only be explained on the assumption that it contains solid suspended matter. Another proof is that upon allowing the liquids to stand at rest for some weeks a ruby or purple deposit settles at the bottom, whilst the supernatant solution has become of a lighter colour. If this liquid be carefully poured off from the deposit and allowed to stand by itself for a month or two, a fresh deposit will be formed, and the supernatant liquid will be almost or quite colourless. If these deposits are shaken up with pure water, they will again become diffused through it, and will reproduce the ruby liquid, from which they will settle a second or third time if allowed to stand undisturbed. All these phenomena are inexplicable, on the assumption that the ruby fluid is a true solution, whilst they appear perfectly consistent and natural, if we assume, with Faraday, that the colour is due to finely divided particles of gold suspended in the liquid.

Immediately connected with this question, as proving the almost incredible degree of subdivision gold can be reduced to, by the comparatively coarse method of mechanical division, are some experiments and calculations which have recently been made on the divisibility of matter. They strikingly show the wonderful resources of mechanical and chemical subdivision, and also of microscopic science, whilst they at the same time prove the hopelessness of attempting to detect the ultimate solid particles in a ruby-gold fluid by the present instruments; for notwithstanding the almost incredible minuteness of the particles into which gold is capable of being cut by mechanical means, it is certain that the chemical subdivision of the ruby or violent precipitate far exceeds anything obtained by artificial means. In the first place, an ordinary sheet of gold leaf is taken, measuring 3·375 inches square, and weighing about one-fifth of a grain. In Faraday's paper, "On the Relations of Gold to Light,"* he shows how a leaf of this kind may be reduced very considerably in thickness, whilst its metallic continuity remains unbroken. This he effects by breathing on a clean plate of glass, and then gently placing it on a piece of gold leaf; the latter will adhere to it, and if distilled water be immediately applied at the edge of the leaf, it will pass between the glass and the gold, and the latter will be perfectly stretched; upon now draining the water out, the gold leaf will be left extended, smooth, and adhering to the glass. If after the water is poured off, a weak solution of cyanide of potassium be introduced beneath the gold, the latter will be gradually dissolved away, becoming thinner; but at any moment the process may be stopped, the cyanide washed away by water, and the attenuated gold film left on the glass. If towards the end, a washing be made with alcohol, and then with alcohol containing a little varnish, the gold film will be left cemented to the glass. The film in this condition, although consisting of pure gold, presents none of the ordinary appearances of the metal, being perfectly transparent and resembling a delicate film of pale green varnish more than a dense metallic body. Its thickness has been reduced to about one-twelfth part of what it was originally, weighing about the $\frac{1}{600}$th of a grain per square inch, and being no more than the $\frac{1}{350000}$th of an inch in

* "Researches in Chemistry and Physics," p. 391.

hickness. Let us now see what is the extreme degree f subdivision to which this film can be reduced. Some nonths ago in our "Scientific Gossip" we gave a brief acount of some observations by Messrs. Wormley and Sullivant n a Nobert's test plate. From this it was found to be possible to rule, with a diamond point on glass, lines so lose together that upwards of 90,000 of them were comprised in the space of one inch linear. It was, however, een that the limit of vision in the best microscopes s at present made, will not resolve lines closer together han $\frac{1}{55000}$th of an inch, which does not widely differ from the heoretical deductions of Fraünhofer and others, based upon he physical properties of light. Applying this to the plate of glass supporting our gold film, it will be seen that ines may be ruled across it not more than the $\frac{1}{80000}$th of an nch apart, and if at right angles to these other similar ines be drawn, we shall have a single square inch of gold ilm cut up into 6,400,000,000 separate pieces, each of which s capable of being distinctly seen under adequate microscopic power. What, now, does each piece weigh? The gold eaf with which we started measured 3·378 inches square, and weighed the $\frac{1}{5}$th of a grain; a square inch therefore weighs the $\frac{1}{57}$th of a grain. After being reduced in thickness by the action of cyanide of potassium, it therefore weighed (in round numbers) the $\frac{1}{600}$th of a grain. This being cut up nto 6,400,000,000 separate pieces, it is evident that each piece weighs no more than the $\frac{1}{3840000000000}$th of a grain; or, n other words, we have actually cut up by mechanical means a single grain of gold—a piece about as large as a good-sized pin's head—into three billion, eight hundred and forty thousand million parts, each recognizable to the assisted eye! The proportion which each separate piece bears to the original grain being about the same as a thimbleful of water bears to a building six times the size of St. Paul's. How purely conventional do the terms large and small appear in the presence of such overwhelming figures as these: they are seen to be merely relative, and to depend for their significance upon some artificial comparison instituted in our own minds, which has no connection whatever with the absolute amount of substance regarded in the abstract.

## MEALINESS IN TONING.

BY SAMUEL FRY.*

It really seems to require some apology for writing a paper on a subject so well worn as toning; but my excuse must be, that notwithstanding all the communications made on this matter, and the deep and valuable researches of scientific enquirers, more failures still occur in toning than ought at this period of the history of photography to be the case. Alkaline toning, whilst giving longevity to the print, has also produced a new disease, that of mealiness, and red spots caused by the refusal of certain isolated spots of the picture to acquire the same tone and colour under the influence of gold as the main body of the print.

It has not unfrequently occurred that samples of otherwise excellent paper have been necessarily rejected, from the impossibility of getting rid of this most objectionable dotting, and streaking with red spots on a surface otherwise neutral or black in colour.

It has necessarily occurred that the nature of the positive proofs required has considerably modified the resultant image; for example, a sample of paper which would give perfect, brilliant, homogeneous proofs of a landscape negative, abounding in details of trees, rocks, &c., would possibly give impresentable proofs for a portrait negative whose smooth surfaces and delicate gradations would render painfully perceptible every aberration from the main surface colour of the picture. I think I am not exaggerating when I state as my opinion, that the once vital question of "Whose collodion do you use?" has been considerably superseded by the more modern query of "What paper do you use?" Various remedies have been proposed, but although mostly founded on correct principles, they have not, to my knowledge, proved invariably, or even generally successful. Slow toning undoubtedly mitigates the evil to a certain degree, and the use of a toning bath containing acetate of soda to a still greater extent; but when using either or both of these, it is far from unusual to come upon a batch of paper with which nothing can be done satisfactorily.

The remedy I now propose to bring before you is not of my own originating, having appeared lately in a letter in the Photographic News; but I was so impressed with the results obtained in printing on a very indifferent class of paper from negatives for album pictures, which require the highest qualities of paper, that I determined to go into a few experiments, in order to ascertain certainly if samples of paper rejected from their unsuitability could be effectually brought into use, and I am now fully satisfied that any albumenized paper of ordinary excellence may be used with complete success by adopting the method indicated below.

Wash the print with great care, to thoroughly remove all the chloride of silver, but do not immerse in salt and water finally, as has been customary hitherto, but instead place for five minutes in acetate of soda 10 drachms, water 1 pint. This solution may be used three or four times over.

After five minutes has elapsed, pour off the acetate solution, and rinse the prints with water before toning, which may be done either with chloride of gold and acetate of soda, or chloride of gold and carbonate of soda; I now generally use the latter from preference, perhaps from fancy more than anything else. Fix as usual in hypo of 4 oz. to the pint of water.

In order to thoroughly investigate the matter, I took some prints on paper, which I was sure would, under ordinary treatment, turn out mealy and poor; then I cut in half, and toned one piece as usual, the other as above, and in every case with a complete removal of the unpleasant symptoms, and the substitution of the most even agreeable colouration that would be desired.

Further practice in the ordinary way of business has convinced me that the method of treatment I have indicated invariably gives good results. There may be undoubtedly irregularities of surface arising from paper kept too long, or having been in contact with foreign substances, such as a flat surface of wood, or any other disturbing agency; but the practical photographer will readily distinguish between these and, if I may be allowed the expression, the social evil of printers.

* Read at the meeting of the South London Photographic Society, on Thursday, January 9th, 1862.

## ON THE EFFECTS OF AFFINITY IN PHOTOGRAPHY.

BY DR. SCHNAUSS.

For the practical photographer, the true road to future progress consists less in reading and experimenting upon new formulæ, than in the study of the laws of nature, for they are eternal. What may appear to be a new discovery is only a manifestation of laws which have existed from the beginning most frequently already known, but under another form, only the proper practical application was wanting. There are still thousands of hidden treasures to be discovered; but to attain them requires a watchful eye, and a profound study of physics. And even these will not always suffice to make discoveries; something also is due to accident or chance, by way of suggestion. Although photography has been enriched by many important discoveries, to apply them we must possess a knowledge of natural laws, or at least of the most important facts in physics and chemistry. We shall endeavour to throw some light on many of the obscure phases of our art, and expose whatever is false or characterized by the empiricism of charlatanism, and in a series of articles explain the most important natural laws in their application to practical photography, adding various remarks on the improvement of photographic agents, and on the means of attaining successful results with certainty; first occupying myself with the various kinds of attractive force. Almost all the necessary chemical experiments have been made specially for this object in the writer's laboratory.

ATTRACTION, one of the most powerful natural forces manifests itself in various ways. The attractive force which bodies exercise upon each other, according to their mass is called *gravitation*, and it is chiefly the attractive force exercised by the earth that is understood by this designation. *Gravity* is, therefore, the force by which various bodies are attracted by the earth; it is their absolute weight which is measured by the balance. But a great number of much smaller masses also attract, as may be seen upon examining bodies floating in water. A ship, for instance, will attract a boat with a force proportioned to its size.

Gravitation also acts at great distances, as is seen in the motions of the celestial bodies. *Cohesion*, another kind of attractive force, acts only in the case of immediate vicinity, that is in contact and between the molecules of the same body. According to the degree of this attraction relatively to the repulsion between the molecules of a body, so its form differs; it is *solid*, *liquid*, or *gaseous*. In the first case, cohesion prevails; in the second, cohesion and repulsion are in equilibrium: in the third case, repulsion prevails.

Heat is antagonistic to cohesion; consequently it can change solids into liquids and gaseous bodies, and the body submitted to the action of heat experiences a great expansion of volume. Cohesion acts also during the crystallization of bodies, because they pass from the gaseous, or the liquid state, to the solid, and assume a symmetrical form; but there are many bodies which do not crystallize, hence they are called *amorphous* bodies. The resistance opposed by a solid body when torn or broken, arises from cohesion, and constitutes its solidity. If cohesion consists in the attraction of the molecules of the same body. We know also of an attraction which exhibits itself in the contact of *heterogeneous* bodies, which is called *adhesion*. If a liquid remains attached to an insoluble solid body, immersed in it, it is in consequence of their adhesion; polished plates of glass, copper, or zinc, adhere so strongly together upon pressure being applied, that it requires great force to separate them.

Another attractive force between the molecules of heterogeneous bodies, very different from adhesion, and which is of the greatest importance in photographic operations, is *chemical attractive force*, or *affinity*. Wherever it appears, heterogeneous bodies are united to a homogeneous body, possessing entirely different properties. On the present occasion we shall occupy ourselves chiefly, and merely mention in passing two kinds of attraction, *magnetic* and *electric*. They differ essentially from the others in two different forces attracting each other in consequence of the polarity which electric and magnetic bodies acquire.

The force of chemical attraction is the basis of all photographic operations: it causes the formation of iodide of silver in the collodion film; of chloride of silver in the positive paper; the development of the latent image; the solution of the iodide and the chloride of silver in hyposulphite of silver during fixing; and the toning of the image formed by the metallic agent.

Now, to understand all these changes, we must first speak of some other fundamental doctrines of chemistry. Bodies may be separated, or they may not. In the first case they are called *simple* bodies or *elements*. We must here explain the difference between mechanical and chemical separation, in order to appreciate a chemical composition. Suppose we wish to mechanically separate the parts of a piece of marble, we pulverise them in a mortar. Marble is a compound of lime and carbonic acid. Let the pulverisation be ever so long continued, it is only possible to separate the pieces of carbonate of lime into anything but carbonate of limes, never the lime from the carbon. To effect the separation of the carbonic acid, which is a *chemical* separation, it is necessary to apply the force of chemical attraction, or the tendency carbonic acid possesses of passing to the gaseous state at an elevated temperature. In the latter case, the marble is submitted to the action of a strong acid, nitric acid for example, which combines with the lime, displacing the feebler carbonic acid, which is liberated in the gaseous form. In heating the marble in a strong fire, the same result is obtained, the carbonic acid is liberated, and the lime remains. Both the lime and the carbonic acid can also be decomposed by the chemist, the lime into a metal, *calcium*, and a gas, *oxygen*; the carbonic acid into *carbon* and *oxygen*. Calcium, carbon, and oxygen, are the elements of which the marble is composed, and are indecomposable into other matters. No one would suppose upon looking at a piece of marble, that it is composed of a gas, a metal, and carbon. From this example we see how the properties of simple bodies are changed in their combinations. From the appearance of iodide of silver the photographer would scarcely expect to find in it the bright metal silver, and the violet-vapoured element iodine.

The force of chemical attraction is so powerful that it completely changes the nature and aspect of bodies. But there is no irregularity in the relative quantity of the matters which unite chemically, for they combine in exact proportions, which remain the same under every condition, and which expressed in numbers the weight of the compound or the *equivalent*. It would lead us too far astray to relate all that concerns this subject of equivalents, which is to be found in every treatise on chemistry. By means of a greater affinity, a body (simple or compound) can separate another body, simple or compound, from its combinations, and be the more easily effected if the decomposition takes place in a liquid, or if the newly-formed compound is insoluble. In such cases, a body possessing very feeble chemical affinity can even displace a body possessing a much greater affinity.

As an interesting illustration of this law of affinity, derived from practical photography, I shall first describe the toning of photographs on paper by means of a bath of a solution of gold.

I have studied the process so precisely, by the following chemical experiments, that I entertain no doubts on the subject.

(*To be continued.*)

## ON THE MANUFACTURE OF PHOTOGRAPHIC PYROXYLINE.

BY MR. NICOL.*

PHOTOGRAPHY, the child of but a few years, has astonished all who have taken the trouble to think of it, by the rapidity with which it has attained its present position; but this it owes as much to the time and circumstances, as to anything of inherent expansive power in itself. Had the chemist, in his never-ending search after something new, not accidentally or otherwise discovered pyroxyline, and through it collodion, and, having discovered it, had he not been ready with his long list of iodides and bromides, photography would have been in a very different position. An analysis of last season's photographic exhibition will perhaps show more clearly the relative position which collodion holds. It contained altogether 764 pictures: of those, one was by the calotype or iodized-paper process, six by the albumen process, 72 by the wax-paper process, and the remaining 620 were by collodion in one or other of its various forms. It will be evident that an article which plays such an important part is very likely to have been the subject of much attention; and such is indeed the case, more having been said and written on collodion than on anything else connected with photography, lenses, perhaps, excepted; and yet I believe there is nothing which the photographer uses about which less is really known, or of which less is thoroughly understood.

Now it is not at present my intention to attempt anything towards the removal of this obscurity, but simply to indicate,

* Read at the December meeting of the Photographic Society of Scotland. Mr. Nicol explained that the paper had been written more especially for the Pharmaceutical Society, and he had been hastily called on to lay it before the Photographic Society.

rst, the necessary conditions of a really good photographic llodion, and secondly, a certain and simple method of proicing at will those conditions.

The collodion should flow from the plate in a smooth oilke sheet, without any appearance of running in streams or lges, and as it begins to set, or become slightly dry, there ould be no trace of a clotted or gelatinous appearance. If at is stage the finger be passed across the surface, it should not ar the film from the glass in shreds, but remove only as uch as it comes in direct contact with, leaving at each side raight and not jagged lines. It must not be contractile, so as leave the edges of the glass, or be pulled into a state of inute network on hardening. When properly dry it should resent a hard glassy surface, which is not affected by a pretty rm rub with the finger, be perfectly transparent, and show no ace of structure under the microscope with at least a quarterich object-glass.

You will notice that the conditions indicated are mechanical, ot chemical; and although photography is essentially a chemid operation, yet I have no doubt whatever that the absence f those mechanical conditions is the cause of a large proporon of the failures which so provoke and dishearten the photorapher. A good collodion is absolutely necessary to success; nd after an experience of seven years in its preparation, I am onvinced that the quality depends entirely on the pyroxyline, nd that the iodizing material is a matter of very little importnce. Almost every conceivable iodide and bromide have been ecommended; and our French neighbours especially have xercised their ingenuity in mixing them by the dozen; but I m perfectly satisfied that one is just as good as another, or as ny combination—all that is necessary being a sufficient uantity of some soluble iodide, to charge the film with iodide f silver.

No doubt, some of the objectionable qualities to which I have eferred may be produced by impure solvents, such as acid, ther, or an undue amount of water in the alcohol; but ordiary care will be sufficient to guard against these causes, and I ay therefore assume that, with good pyroxyline, good colloion is easily obtained.

Pyroxyline, or gun-cotton, is generally obtained by the action f nitric acid of a certain strength on lignine or cellulose, or, ore correctly, on both, as the former term is applied to the ubstance of which the walls of the cells are built, and the tter to the substance with which the cells are filled. They re, however, so much alike, that one term will answer very ell for both. Lignine, then, consists of carbon, hydrogen, nd oxygen, and exists in a state of considerable purity in aper, and almost perfectly so in cotton. What we know as medicated cotton" is generally employed for the production f photographic pyroxyline; and though many other things, uch as paper, cloth, and sawdust, have been tried, it is on the hole more generally successful. If a tuft of cotton be imersed in ordinary commercial nitric acid, or even in acid of a pecific gravity of 1·500, it gelatinizes and dissolves. If, howver, sufficient sulphuric acid be added to withdraw a quantity f water from the nitric acid, no such change takes place, the otton remaining apparently unchanged. It is only apparently o, however, as on being washed and dried it exhibits properies of which it was not before possessed: its weight has inreased, sometimes by more than half; it is soluble in acetic ther, and in a mixture of ether and alcohol; and on the appliation of flame, it explodes with considerable violence, or burns vith great rapidity.

Pyroxyline thus obtained differs to a certain extent from what we are in the habit of considering a definite chemical ompound, and belongs to the class of substitution-compounds —a certain portion of the nitric acid, or rather peroxide of itrogen, taking the part of a certain portion of hydrogen; hich will perhaps be more readily explained in this way—

$$\text{Lignine}\left\{\begin{array}{l}\text{Carbon}\\ \text{Hydrogen}\\ \text{Hydrogen}+\text{nitric acid}=NO_5\\ \text{Oxygen}\end{array}\right.$$

$$\text{Pyroxyline}\left\{\begin{array}{l}\text{Carbon}\\ \text{Hydrogen}\\ \text{Peroxide of nitrogen } NO_4+\text{water}\\ \text{Oxygen.}\end{array}\right.$$

n atom of peroxide of nitrogen taking the place of an atom f hydrogen, leaves an equivalent of oxygen, which combining with the displaced atom of hydrogen forms water. It is imortant to keep this in mind, as it explains what would otherwise be obscure when I come to speak of the practical operation. A peculiarity of this change of substance by substitution is the fact that, although it seems to take place atom for atom, the extent to which it goes is dependent on certain conditions. Thus, the quantity of peroxide of nitrogen which pyroxyline contains, depends on the strength of the nitric acid, and the temperature at which it is when the lignine is introduced, the maximum being obtained by the strongest acid, and *vice versa*.

From this it will be evident that, if the range between the maximum and minimum be great there will be considerable variety in the products; practically, however, we may divide pyroxyline into three classes — one highly explosive and scarcely, if at all, soluble in a mixture of ether and alcohol; one entirely soluble in that mixture, and leaving a structureless transparent film when allowed to dry on a plate of glass; and, thirdly, one which is almost entirely soluble, but which leaves on drying a film more or less opaque. The first and last being useless in a photographic point of view, I will confine myself to an indication of the method which I have adopted for the production of the intermediate quality, which possesses not only solubility and transparency, but also all the other essentials of a really excellent pyroxyline for photographic purposes. It will be evident, from what I have already said, that the *desideratum* is to obtain a nitric acid of the proper strength: this is very easily done by adding a certain quantity of sulphuric acid, when the former, in consequence of its great affinity for water, withdraws that body from the latter, and, provided the proportions and specific gravities are properly arranged, it gives us exactly what we require.

For a long time I experienced considerable difficulty in getting commercial sulphuric acid of sufficient strength, the samples ranging from 1·816 to 1·834: the latter, although theoretically strong enough, did not on mixing raise the temperature sufficiently high; and, from some cause which I cannot explain, the temperature raised artificially failed to give the desired result. Latterly I have had no difficulty in obtaining it from 1·840 to 1·850 which leaves nothing to be desired.

Into a well-glazed porcelain dish, considerably deeper than an evaporating-basin, and holding about 30 ounces, I put 10 ounces by measure of sulphuric acid of specific gravity of 1·840; on this I pour five ounces by measure of nitric acid of specific gravity of 1·370, and then two fluid drachms of water; the temperature at once rises to above 150°; and if the cotton be immediately immersed, it gives what is known as "powdery" collodion—a state similar to what is produced by age, and very suitable for certain "dry processes;" but for general purposes, I let the temperature fall to 140°, and then, being armed with two glass rods, an assistant adds, tuft by tuft, 5 drachms of good cotton; as each tuft is added, it is pressed into the acid and the whole kept moving about to ensure equal action: when the whole of the cotton is in, the dish is covered with a plate of glass, and left so for ten minutes; it must, however, be carefully watched during this time: the acid being not much above the dissolving-point, actual solution occasionally begins, but is immediately stopped by a press with the rod.

Although the five drachms of cotton does not absorb the whole of the acid, that quantity must not on any account be exceeded: the change taking place being the conversion of portions of the hydrogen of the cotton and of the oxygen of the nitric acid into water, the addition of a single half drachm is sufficient to change the nature of the product, and occasionally to produce solution of the whole. I, as rapidly as possible, press the cotton between two strong strips of glass, and plunge it into a large quantity of water, where it is immediately teazed out and rapidly moved about to diffuse as quickly as possible the adhering acid throughout the whole volume. Nothing then remains but to wash till every trace of acid is removed: this is conveniently and effectually done by packing in a percolator, and turning on a stream of water for a few hours; and dry by steam or otherwise.

It may seem that the quantity of material operated on at a time is small (but experience shows that larger quantities considerably affect the result); but that is really no great objection, as with two dishes and an active assistant, the pyroxyline may easily be turned out at the rate of 5 ounces per hour.

The sulphuric acid which I have recently been using has a specific gravity of 1·850, to each ten ounces of which I find an addition of three drachms of water to be necessary. And I commenced a series of experiments some time ago with the view to determine whether this held good throughout—that is, whether it might be taken as a rule, that success would be insured by the addition to the formula already given of six minims of water for each additional unit of specific gravity above 1·840 of the sulphuric acid. I regret, however, that want of time has prevented the carrying out of the experiments; but probably I may have an opportunity on some future occasion of again bringing the matter before you.

## Photographic Tourist.

### PHOTOGRAPHIC PENCILLINGS OF AN EASTERN TOUR.*

During the earlier portion of my stay at Malta the days were bright and fine enough, but the very morning on which I made up my mind that my previously arranged three weeks stay here was quite long enough, there came a change in the weather. A fierce wind from the north-east roared over the troubled waters of the Mediterranean, making the harbour white with foam, and bearing the spray of the yeasty waves, thundering against the foundations of the fortifications, right over their lofty walls. Drenching showers fell at brief intervals, and looking out to sea at that vast restlessly moving plain of indigo, so liberally bespread with its changeful patches of fleecy foam, I felt quite qualmish at the bare idea of a voyage in such weather, and resolved to defer my departure until there was a prospect of a more comfortable journey. So I remained wandering about the steep broad hilly streets, examining the effigies of saints and virgins stuck up here and there at their corners, or trying to make out the partially traceable arms on the defaced old shields over some of the doorways, or wandering to the more interesting localities in the island. Photography being, of course, out of the question, I did not relish the delay, although the friends with whom I was staying made time pass very cheerfully.

Not to occupy too much space with this stage of my tour, I will briefly describe a few of the places I saw, &c. Visiting the interior of the governor's palace, I found much that was interesting and curious. I greatly admired the fine staircase: it is said the grim knights, clad in complete mail and mounted on their heavy war-steeds, have gone thundering up these stairs, which certainly seemed strong and wide enough for the feat, although I cannot see why these stern old jokers should indulge in such eccentric equestrian experiments. I here saw many mementoes and relics of these famous warriors, in the shape of paintings, tapestry, old suits of mail, and weapons, which either once belonged to celebrated members of the order, or else were relic-spoils, won in battle from the gloriously defeated infidels. The cathedral church is another place which well repays one for a visit. It is dedicated to St. John of Jerusalem, and stands not far from the palace; its exterior is plain enough, but when inside I found much to admire, and still more to interest a curious visitor like myself. Some massive handsome metal work, said to be solid silver, is shown as having escaped being carried off by the French during their brief possession of the island by being painted black; but many other appointments, scarcely less valuable, were sacrilegiously borne away. The decorations of the aisles and chapels, as they are termed, are very rich and elaborate. On the day I saw the cathedral I also visited one of the convents, and some of the fortifications.

At length the boisterous wind subsided, and the clear expanse above grew deeply blue and cloudless; the waves of the Mediterranean again splashed their clear waves in playful sport against the rocky foundations of the fortifications, over the walls of which its spray and foam had been so fiercely hurled a few days before. Some young bathers and fishers were laughing joyously as they sported in or with the placid element, of which the natives seem at all times so passionately fond; the gaily painted boats with their bright clean awnings moved swiftly on their way, or lingered near the shore in search of hire. The wide, well-paved, pallid-looking streets were bright with sunlight, and the Maltese were again out upon the flat, terraced roofs of their oriental-looking houses. So I once more brought out my camera and tent, and hiring a trap, started off along the main road (a very good one) in a direction opposite to that by which I sought the bay of St. Paul. After a ride of about seven miles or less, and passing the country house of the governor, I reached Civita Vecchia, or as it used to be termed, I believe, Citta Notable, the ancient capital. It occupies very high ground, and must be, as I calculated, very nearly in the centre of the island. It is a quiet insignificant little place enough; almost entirely occupied by numerous religious establishments. There are a few celebrated paintings in the cathedral; beyond which. however, it contains little that is particularly inviting or attractive. The streets are exceedingly narrow, and are full of ragged mendicants, who either plague you to buy coins which they represent as being dug up, but which look suspiciously like modern manufactures, or beseech you to employ them as guides to the lions of the poverty-stricken little place, chief amongst which are the catacombs and St. Paul's Cave. The former are excavated from the rock on which the town stands, and are entered by a low narrow passage winding downwards. As you pursue this labyrinthine way, it gradually widens until you find the tombs, hewn out on either side, and niches here and there for lamps. Reaching a small apartment, with an arched roof, about 10 feet high, I was informed that here the early Christians assembled for worship in their hour of persecution and danger. St. Paul's Cave, situated beneath a church dedicated to the saint, is a small circular low-roofed place, with the walls and ceiling thickly covered with autographs, in which stands a somewhat dilapidated marble statue of the apostle, brought originally from Italy.* It is said that after his shipwreck, the apostle lived in this cave three months, and there is a miraculous tale of how this dark rocky apartment always retains the same size and appearance despite the efforts of those who are carrying away the rock piecemeal to sell or preserve as relics. Before leaving the island, I also visited the village of Mosta, to see a somewhat celebrated church, built literally by the inhabitants themselves. I also went to the small town called Creudi to view the ruins said to be those of some ancient places of religious worship pertaining to the Phœnicians, of which I was delighted to obtain photographs. These remains of this ancient people are situated some little distance from the town, and stand on a wild looking rocky slope near the sea. The barren aspect of the spot harmonizes well with the sentiment of these huge masses of stone, forming a rude, lofty, massive entrance gateway, a number of smaller apertures, and some elliptical shaped compartments. The remains of several altars are easily recognized, and their form would, I should think, indicate that they were made for sacrificial purposes. Artists tell me that my photographs of these most interesting relics are extremely picturesque and valuable, and that my views of St. Paul's Bay are the most dreary and unpicturesque subject of the whole; and agreeing with them, I congratulate myself upon not leaving the island without seeing this portion of it.

I must here pause to note a very singular ciacumstance, which I do not remember ever experiencing before or since, and which I never heard or read of as occurring in the experience of any other photographer in any part of the world.† I had been getting a view of Fort Angelo, and found the light very energetic in its photographic action. The wind was westerly, and the sky cloudless and clear—it is here, as is well known, remarkably so. Suddenly there was a change, and a plate exposed immediately after one which had been unusually successful, did not show anything but the very faintest ghost of an image. I gave the next twice the exposure of the first—worse and worse! A fourth

* Continued from p. 9.

* And since removed, I believe, for more careful preservation.

† The author of this paper is evidently not aware that Mr. Rejlander mentioned a similar circumstance at one of the earlier meetings of the London Photographic Society. The incident certainly seems very unaccountable.—Ed.

I gave four times the exposure of the first, but with no better result. Perplexed and alarmed, I tested my bath, and prepared a fifth plate, giving it a longer exposure than ever. The result was as fine a fog as I ever witnessed; the over exposure was tremendous. So I prepared a sixth, which I exposed half as long as the *first*, and found it a very good negative, slightly, perhaps, *over exposed!* I have often thought about this, and puzzled myself with attempts to account for it. I could not then, nor can I now, conceive that there was anything like a positive cessation of actinic influence in the light itself; but to what can such a mysterious change be attributed? I have put this question to many, and I here put it again; for never yet has it been answered to my satisfaction. I left Malta at the latter end of January. M. H—N.

## Proceedings of Societies.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting of the Society was held in St. Peter's School Room, Walworth Road, on the evening of Thursday, January 9th. Mr. SEBASTIAN DAVIS in the chair.

After the usual routine proceedings

The SECRETARY announced that one of the presentation prints had been decided upon by the Committee, and congratulated the members on the circumstance that they would receive one of the most artistic and beautiful photographic landscapes which had ever been produced: he referred to Mr. H. P. Robinson's "Early Spring." Before sitting down he would take the opportunity of stating that he conceived he had been unfairly dealt with by one of the journals, in which a very imperfect report of his remarks on the subject of the Photographic Committee of the International Exhibition had been given. His conclusions had been given without the reasons by which he justified such conclusions, a mode of proceeding which in this especial case did him much less than justice, and it would have been only fair either to have entirely withheld his remarks, or given them in such form as expressed his views. He wished to add also that since the last meeting he had been told the Earl of Caithness was an able photographer and an energetic man. If anything he had said did that gentleman injustice he now expressed his regret.

Mr. G. WHARTON SIMPSON said that Mr. Fry, who promised a paper for this evening, had called upon him to say that he would be unavoidably absent, and asked him (Mr. Simpson) to express his apologies to the meeting, and to read a brief paper on "Mealiness in Toning" (see p. 29). Mr. Fry had intended he believed to bring some prints with him, showing the irregular toning in its worst form, and some produced from the same paper, in which, by adopting the proposed remedy, total immunity from any sign of mealiness was secured. He (Mr. Simpson) had seen the prints, and in the absence of specimens the meeting must take his word and that of Mr. Fry for the fact.

The SECRETARY stated that he had recently had three printers employed, from none of whom he had been able to obtain anything but mealy prints from a certain sample of paper. His present printer was using the remedy suggested in Mr. Fry's paper, and he had not had one mealy print from the same lot of paper. He thought this spoke highly for the efficiency of the proposed remedy.

The CHAIRMAN asked if Mr. Fry had arrived at any conclusion as to the theory upon which the remedy was based.

Mr. SIMPSON believed not. Mr. Fry simply concluded that the conversion of the free nitrate into an organic salt of silver removed the tendency to irregular mottled toning. He found a bath of phosphate of soda acted in a similar manner to the bath of acetate of soda. He (Mr. S.) thought that, prior to forming a theory as to the operation of the remedy, it was important to arrive at definite conclusions regarding the nature of the cause of mealiness, which, however, appeared at present to be little understood.

The CHAIRMAN thought it would be interesting to ascertain the colour produced by the conversion of the free nitrate after exposure with various salts of silver. Some time ago he excited some plain paper without any other chloride than that contained in the size of the paper; after exposure he submitted the print to the action of an alkaline chloride. The result was that the purple tone produced by light was changed to a salmon colour. It would seem from this that the action of salt was to redden the print. In gold toning, however, he always found it advantageous to submit his prints to a salt bath before toning. He thought that much of the irregular toning was due to the paper being unequally absorbent. If we had a paper of a more homogeneous and uniform texture, less difficulty would be experienced.

Mr. SIMPSON said doubtless the quality of the paper affected the question; but it could only be one part of the cause. In the old method of toning with hypo and gold, this evil was unknown with any sample of paper. Its existence was unfortunately coeval with the alkaline toning system. The great advantage of that method was somewhat marred by the prevalence of this evil. In searching for the cause of the evil, it must not be forgotten that it was in some way essentially connected with this method of toning, and although the nature of the paper might aid in producing the effect, it was the toning which absolutely brought it about. They had to discover both a predisposing and an exciting cause.

Mr. HENDERSON, (who, it was explained, first suggested the remedy of an acetate bath in a letter to the PHOTOGRAPHIC NEWS,) said he would have pleasure in detailing the results of some experiments in toning.

*In the first experiment* he washed a print in boiling water for ten minutes. It was then toned in a bath of gold and acetate of soda. The time required for toning was sixty minutes, and the result was very poor and mealy. The toning bath gave no precipitate of acetate of silver.

*Second experiment.*—The print was washed for fifteen minutes in cold water, and then toned as the last. The time required was forty-five minutes, and the result was somewhat better.

*Third experiment.*—The print was washed ten minutes in cold water and toned. The time required was twenty minutes. The print was of moderate quality, and a slight deposit of acetate of silver was thrown down.

*Fourth experiment.*—The print was washed for five minutes in cold water and toned. The time required was ten minutes. The print was good, and considerable precipitate of acetate of silver was thrown down.

*Fifth experiment.*—This print was not washed at all before toning, and the tone was best of all.

After these trials, he mixed the various toning baths used, which had been fresh for each print, and filtered out the precipitate, which had been greater in each succeeding experiment. He then divided the solutions into two parts, and added a little fresh gold to one portion, which produced a little of a yellow precipitate. A print placed in this toned very slowly. A print placed in the other half remained for an hour without the slightest toning action. He then added to this half a little fresh acetate of soda, and placed in another print. In about ten minutes, this print and the one which had remained an hour unchanged, were toned perfectly. His experiments led him to the conclusion that a print placed in the toning bath direct from the printing frame, without washing, gave the best and most rapid results, but it precipitated the gold largely. Also that a toning bath which appeared exhausted or inactive, might sometimes be made to tone satisfactorily on the addition of a little acetate of soda. The paper he had used gave him mealy results with every formula he tried, except that with the acetate, which had been described, and with the old hypo bath. When he had tried the chloride bath before toning, the results were worse. A mixture of chloride and acetate was equally bad. It appeared to him that the acetate acted in some way on the albumen, so as to induce a more regular reduction of the gold. Whatever might be the theory, practically, he believed, the bath of acetate was a cure for the multitude of evils alkaline toning had been found heir to.

Mr. PRICE called attention to the diversity in different formulæ, as to the amount of acetate of soda which should be added to the gold.

Mr. HANNAFORD said it was quite unimportant, so long as there was enough. He had used various proportions, from 30 grains to 160 grains to one grain of gold. It was best to have it in excess, as in that case it would be unnecessary to add more to cause renewed activity.

The CHAIRMAN asked if Mr. Henderson had tried other acetates, and if he always found that they removed mealiness as well as facilitated toning.

Mr. HENDERSON said he had tried other acetates, but preferred that of soda. The preliminary acetate bath always removed mealiness. It was necessary for all the free silver to be converted into acetate. The presence of chloride of silver was injurious. In the old hypo bath the chloride was dissolved before toning commenced, whence there was not the tendency to mealiness.

Mr. Hannaford said there were two kinds of mealiness. One kind he did not altogether dislike, as it gave a certain amount of atmosphere to the background, similar to that given by the texture of the paper in water-colour drawings. When he had first made use of acetate of soda in the toning bath, it was simply for the same purpose that Mr. Hardwich recommended the citrate of soda, as giving a richer purple bloom than could otherwise be obtained. It was incidentally that he discovered that it gave immunity from the mealiness which he found many others were complaining of. He was in the habit of washing the prints in one or two waters, but not in a chloride solution, before toning, and he was never troubled with mealiness. A print which had been salt washed had chloride of silver formed in the cavities in the surface of the paper, and when toned mealiness ensued. So far his experience confirmed that of Mr. Fry. The use of an acetate did not, however, entirely prevent mealiness without careful washing. He had found a hot solution of hypo entirely removed mealiness. There was another source of mealiness to which he might advert. It arose from a certain amount of greasy repellant condition of the surface, which prevented the washing water from coming in contact with it. In such cases a little oxgall added to the washing water would be found useful.

The Chairman thought that Mr. Hannaford's experience seemed to confirm the idea that chloride of silver was more difficult to tone than an organic salt of silver.

Mr. Fitch had observed more tendency to mealiness when using thin papers. Thick paper was generally free from it.

Mr. Simpson thought it important to remember that this difficulty was not observed in plain paper. It was confined to albumenized paper.

Mr. Hart said that at one time having unlimited command of distilled water he always used it for washing, and at that time he was free from any troubles with mealiness. Subsequently he had nothing to use but hard water, he then had nothing but mealy prints. Recurring next to the use of a soft river water, he again got rid of this trouble.

The Chairman said that doubtless the use of distilled water, preventing the formation of insoluble salts of silver, would tend to remove the tendency to mealiness.

Mr. Simpson said there could be no doubt that water containing carbonates or chlorides forming insoluble salts, largely contributed to the production of mealiness; but these were not the sole cause. It should be remembered that this troublesome defect occurred on prints treated in every respect the same as those upon which it did not occur where other samples of paper were used, and even on parts of the same sheet of paper. He did not think, therefore, that it was solely attributable to the water. He would again direct attention to the fact that mealiness was not found to arise with plain paper, but always on albumenized paper. It was clear the albumen was connected with this evil. There was another circumstance which had not been named; he had observed that a weak, thin negative increased the tendency to mealiness, but where the action of light was the most complete there was the least mealiness. Perfect reduction seemed to prevent it.

Mr. Hannaford thought it was probable that the acetate of soda acted in some way on the albuminate of silver.

Mr. Martin said that as the acetates and phosphates were weak reducing agents of the noble metals, their action in preventing mealiness might be due to this action. He thought this view of the matter was singularly confirmed by Mr. Simpson's statement, that where deep printing and perfect reduction by light had taken place, mealiness did not occur.

Mr. Price mentioned that a correspondent to one of the journals had recently stated that he got rid of mealiness by using pure chloride of sodium in his washing water instead of common salt.

Mr. Leake found recently a batch of prints completely spoiled with mealiness. He ascertained on enquiry that the youth who assisted him, had, in order to get quickly through his work, placed the prints in salt and water direct from the printing frame, without previous washing. He had tried the process recommended in Mr. Fry's paper now for a week, and had not found the slightest tendency to mealiness when it was used. He put an ounce and a half of acetate of soda into half a gallon of water, and used this again and again returning it to the bottle when done. He found that working in this way no extra trouble was involved, whilst very valuable results were gained.

After some further conversation on the subject, in which Mr. Wall, the Chairman, Mr. Simpson, Mr. Martin, Mr. Hannaford, Mr. Hart, Mr. Henderson, and others, took part, the subject was concluded by votes of thanks to Messrs. Fry, Henderson, and Simpson.

The report on the subject of a meeting-place was then laid before the meeting, and on the motion of Mr. Simpson, seconded by Mr. Hannaford, it was resolved that future meetings should be held in Sussex Hall, Leadenhall Street.

Mr. Vernon Heath, Mr. Henderson, Mr. F. W. Hart, and Mr. Farringdon Lane, were then proposed and duly elected members of the society.

After which the proceedings terminated.

## Correspondence.

### FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

*Paris, 15th January*, 1862.

The observatory of Wilna is situated on the fourth story of an old Jesuit's college, and therefore is deprived of the advantage of being able to place its instruments on an immovable foundation. Under these circumstances, the best course to be pursued appeared to be that of directing the industry of the establishment to special investigations which should recommend themselves by their importance, and the observations for which can be made with apparatus which does not require to be placed upon an immovable foundation. After a careful discussion upon the various branches of science coming within this category, Messrs. Sabler and O. Swave decided upon those whose object it is to study the physical constitution of the sun. Of all the instruments at present employed for this purpose, Mr. De la Rue's photoheliograph at Kew Observatory is, without doubt, the apparatus which promises the best results. The photographic operations of this apparatus require only the fraction of a second, and, consequently, the perfect immobility of the observatory is not an indispensable condition.

Mr. De la Rue has announced that he is ready to furnish a photoheliograph of similar dimensions to that at Kew, in the course of six months, for the sum of three hundred pounds sterling.

The second object of study at the observatory of Wilna will be the photometry of the fixed stars. The labours of Schwerd and Seidel have recently thrown a new light upon this subject. It appears that the apparatus invented and constructed by Schwerd very satisfactorily fulfils the object to which it is applied. M. Sabler is therefore desirous that after the observatory is supplied with the apparatus necessary for studying the sun, that the surplus funds be appropriated to the acquisition of the photometer of Schwerd.

M. Reynaud has communicated to our photographic society the results of a great many experiments upon iodide, bromide, and chloride of silver. He shows that if the iodide of silver derived from the iodide of potassium is slowly acted upon by light, it yields very dense and extremely fine negatives, and is especially adapted for those of small dimensions.

The cadmium iodide is one of the quickest to receive the action of light, but the negatives it gives are frequently fogged. To remedy this inconvenience M. Reynaud adds 1 to 2 per cent. of chloride of zinc to the collodion.

The ammonium iodide of silver is less sensitive, but it gives excellent negatives in an artistic point of view. M. Reynaud is of opinion that the sensitiveness of the iodides is in the same ratio as their solubility in alcohol.

To obtain the maximum sensitiveness the collodion must contain little iodide.

A neutral silver bath is frequently the cause of fogged negatives. In order to avoid this result a small quantity of nitric acid is added to the bath, about one drop to every three ounces of bath solution. Hyponitric acid added to the bath instead of nitric increases its sensitiveness. Carbonate of soda or of lime is an excellent agent for neutralizing baths that are too acid.

EXCHANGE OF PHOTOGRAPHS WITH AMERICA.

DEAR SIR,—I have relatives in the United States and in corresponding with them, I always make my letters up to the weight with stereograms trimmed ready for mounting, and from their replies I gather that the enclosures form quite the most interesting part of the letter. They are not photographers, and consequently I receive no "exchanges." On reading the article by Coleman Sellers extracted into a recent number of the NEWS, it struck me that an Exchange Club, similar in principle to the English one, might easily be formed between photographers in this country and in America, and there can be no doubt of the interest that would attach to the exchanges. There would require a secretary in each country to whom all prints for exchange should be forwarded, and who should keep a register of the number of different classes received from each member, return the worthless ones, and forward the remainder to the other secretary for distribution. From either London or New York I presume the parcel of prints could be forwarded in bookseller's parcels at small expense, but even if sent by post, the cost on each print would not be much. The number of prints received from each country would probably not be the same, but the members on the side on which there was a deficiency might be supplied in the order in which the secretary had received prints from them, those last on the list being supplied out of the next batch. At any time an intimation from the secretary that there was an accumulation of prints on hand waiting exchange, would be sure to bring in enough to clear off the score. Doubtless some good photographer here would undertake the office of English secretary, and though Coleman Sellers does not seem to be able to find time to be neat, I have no doubt from the evident gusto with which he handles new prints, that he would find plenty of time for arranging the American department. As I see from your answers to correspondents that he is a reader of the NEWS, should you deem this proposition worthy of consideration, you will perhaps mention it there, so as to bring it before him and other photographers in both countries.—Yours, respectfully, L. LOMAS.

[We commend this suggestion to some of our American readers: to Mr. Coleman Sellers especially, if he can find time to attend to the matter. We have no doubt whatever of finding some gentleman ready to undertake the duties on this side of the water.—ED.]

FIXING BEFORE TONING.

SIR,—I take the liberty to inform you, that some of your correspondents err in taking upon themselves to call fixing before toning a new invention. I must confess it is a very old process indeed, and has long been abandoned by eminent photographers. If you read Mons. Legray's work you will find that he has given and used it as early as 1852; and had he found this process permanent, he would certainly not have rejected it.

I certainly am not surprised that the French deride us when we bring in as new discoveries old methods. On my part I must say that the alkaline process is a very great improvement to our art. If there are some of our professionals who do not know how to use it, they should not, at least, try to bring in old for new. I am perfectly convinced the alkaline process, properly manipulated, is the best of all; and I warrant, by my mode of manipulating, photographs will last a number of years. I have some copies by me in perfectly good preservation, particularly since I prepare my own albumenized paper. I have always considered that the fault is in the preparation of the paper. If you expose certain papers to a prolonged action of light, you will find it change to all manner of colours. The manipulation I have adopted is the same as you have given in many of your columns. I have not made any addition that I know of, but, if you wish it, I shall be most happy to give you the description of my mode of manipulation by which I obtain these tones. If any professional or amateur should like to try my process and paper, I shall be most happy to supply them with it. I shall, in my next, give you a different process. Hoping you will be kind enough to insert this in your journal, I am, yours truly, W. WERNER.

*High Street, Oxford.*

P.S. I shall be pleased to have your opinion on the copies inclosed, which are on two kinds of paper.

[Our correspondent is in error in attributing to the recent contributions to our columns on "Fixing before Toning" any intention to claim novelty for the process. The writers merely reconsider an old subject. It is often wise to examine old methods by the light of new experience. There is some truth in the paradoxical apothegm, "there is nothing so new as what is old." The prints inclosed have a very agreeable tone, and every indication which usually accompanies permanency. We shall have pleasure in receiving practical details from our correspondent.—ED.]

## Photographic Notes and Queries.

VARIOUS QUERIES.

SIR,—If yourself, or any of your talented correspondents, would give, in a condensed form, the changes a plate undergoes from first to last, it would be of much benefit to many of us amateurs.

1. The plate, when coated with collodion and dipped in the bath; how acted on by the solution?

2. The change it undergoes when acted on by the light, and by the iron or pyrogallic solution?

3. Why does the cyanide dissolve off the iodide?

4. Mr. Coleman Sellers says that glass can be got ready in a moment by acetic acid and alcohol, and when the picture is taken it can be flowed with a solution of gum arabic and *aqua ammonia* (What is that?) what strength to make it keep—without washing?

Do you think if the plates, after exposure, were kept in a grooved box of tin filled with thin starch coloured with turmeric, it would answer the above purpose?—I am, Sir, with many thanks for the many hints and valuable papers in your excellent NEWS, your obliged and faithful servant,

*Hasle, Dec.* 2, 1861. ROBERT SAWYER.

[To obtain a full and satisfactory answer to all your queries you should study carefully the various articles on the theory of photography contained in our pages, or such a work as Mr. Hardwich's "Manual." We may, however, very briefly answer your questions here.

1. When a plate coated with iodized collodion is immersed in the nitrate of silver, a change called double decomposition takes place. Silver has a great affinity for iodine, and a portion leaves the nitrate solution to combine with it, forming iodide of silver, which is the creamy looking substance you see on withdrawing the plate from the bath. The nitric acid set free when the silver leaves it, combines with the base of the iodide, and remains dissolved in the bath.

2. The change which the iodide of silver undergoes when submitted to the action of light is not understood. It is known, however, that the parts acted on are reduced to metallic silver when the developing solution is applied. Proto-salts of iron, and pyrogallic acid, have a great affinity for oxygen, in virtue of which they have a tendency to reduce the salts of silver and other similar metallic salts.

3. Iodide of silver is soluble in cyanide of potassium, &c. The latter therefore dissolves all except the part reduced to metallic silver, which constitutes the picture.

4. Aqua ammonia is liquor ammonia, which will be supplied by any chemist. We have no further details except those published in the article referred to. The use of starch and turmeric, as you describe, would probably be troublesome and unnecessary.—ED.]

MODIFIED RESIN PROCESS.

DEAR SIR,—I have lately printed several stereoscopic transparencies by superposition, using the modification of the resin process, the details of which I gave in the number for Nov. 8th, 1861; and have found it to answer better than any other process I have tried. They are *untoned*, and are of a beautiful transparent purple brown, and are as clear, sharp, and brilliant as albumen ones. I sincerely hope that your readers will give this modification a trial, as I am assured that it will amply repay their trouble. I advise those who intend to print transparencies to well dry the plates before coating with collodion, and to run a little shellac round the edges to prevent all danger of the film slipping. | Pyrogallic acid ... ... ... ... | 2 grains |
| Citric acid ... ... ... ... | ½ grain |
| Acetic acid ... ... ... ... | 20 minims |
| Distilled water ... ... ... ... | 1 fluid oz. |

As soon as all detail is out, and the picture looks finished, add citric acid *freely* to the developer, and flood the plate with it; wash, and fix in hypo that has been used before.

Begging pardon for occupying so much of your valuable space, I am, yours respectfully, H. COOPER, Jun.

## Talk in the Studio.

PRESENTATION PRINT.—The South London Photographic Society have selected as one of the prints for presentation to members of the greatest gems the art has produced—a 10 by 8 vignetted print of Mr. Robinson's, entitled "Early Spring." For beauty of composition, delicacy, and atmosphere, few photographs have equalled this. We congratulate the members on the prospect of obtaining a picture which is alone worth the amount of subscription. We may here add, as a hint to the forgetful, that the treasurer speaks of members in arrears, for whose benefit it will be impossible to order prints until they have paid their subscriptions. Speaking of presentation prints, we wonder if any one has heard how the three photographs promised to the members of the parent society are progressing. It is nearly twelve months since an announcement was made that the council intended to make such presentation.

IODIDE OF SODIUM.—We have received several enquiries as to the manufacture of this salt. It can be prepared in the same way as the potassium salt, given under the heading "Photographic Chemicals." The easiest way, perhaps, is to form iodide of iron first by digesting an excess of piano-forte wire (the purest form of commercial iron,) under water, with iodine. They readily combine, and form the pale green solution of proto-iodide of iron. Now add solution of carbonate of soda to this until the iron is exactly precipitated, when the soda will take the place of the iron.

$$FeI + NaO,\ CO_2 = NaI + FeO,\ CO_2,$$

forming iodide of sodium and proto-carbonate of iron. Filter off the latter, and evaporate to the crystallizing point.

## To Correspondents.

⁂ ERRATUM.—In the formula for dry collodion, by Mr. Ward, given in our last, the quantities of ether and alcohol should have been each 4 drachms, not 4 ounces.

ROSELLI.—Woodward's solar camera is manufactured by Mr. Atkinson, of Liverpool, and may be had of all dealers. The price is, we believe, about £12. There is not very much definite information as to the best modes of using it. Several articles on the subject appeared in our last volume; and there is, we believe, a little pamphlet issued by Mr. Atkinson. As regards its results, we think very highly of them, and think it very probable that they will come into more general demand. The method of using it may be mastered by any intelligent photographer after a little practice. It requires a room devoted to it, with a window facing as nearly south as possible.

C. E. L.—Plain unsalted paper must be used in the phosphate printing process. If you carefully read the description, you will find that the formation of chloride of silver is to be carefully guarded against. You can procure paper without salt from most of the dealers. We shall endeavour to get some more details of Mr. Reynold's process.

ENQUIRER.—Caramel is burnt sugar. When sugar is submitted to a temperature a little over 400°, its properties are curiously changed. It becomes a brown tasteless mass, readily soluble in water. It is used for colouring spirits, &c. It may probably be had of the druggists.

J. BURNS.—A 9-inch condenser, with a focus of 17 inches is very suitable for the solar camera. Different kinds of lenses may be used for the enlarging, a view lens may be used; a portrait lens, about half plate, is generally used; a triple achromatic would, we think, be most suitable. 2. In a glass room, we should prefer about five feet over the head of the sitter to be dark; about three feet on each side of the background dark; from thence, about six feet on each side, glass to the ground. The sides for the remainder of the length may be glass to within two or three feet of the ground. Avoid glass in front of the sitter. 3. A twin lens camera may be used for card portraits with great convenience, provided it have suitable lenses.

A CONSTANT READER.—We do not know who is the patentee, but will let you know if we learn.

A DRY PLATE.—Barley sugar has not the same properties as caramel. How far it might answer the purpose, we cannot tell. See answer to "Enquirer."

J. H. REDIN.—We are obliged by your letter and specimen, which certainly possesses an agreeable tone, and is free from mealiness. This is probably due to the formation of an organic salt, or organic salts, of silver in the bath, to which it is subjected before toning. The bath would contain lactates, phosphates, cyanates, &c. You will see on referring to the report, in the present number, of the last South London meeting, that the value of organic salts of silver were discussed, and a conclusion, corroborative in some degree of your experience, arrived at.

S. BYRAS.—Bertch's Automatic Camera is not made in this country at all, that we are aware of, nor do we know of any one who keeps it, or has specimens of its work. Some of the enlargements by the solar camera are very fine. The method of enlarging described in the PHOTOGRAPHIC NEWS ALMANAC will answer very well for landscapes up to ten inches.

J. E. B.—Your letters have never reached us. If we remember rightly, we received one upwards of twelve months ago, asking for some advice about lenses. This we answered by post, and have received no communication from you since. We give a formula for the manufacture of iodide of sodium in another column.

H. R. N.—We shall be glad to hear particulars of the instantaneous movement. We are obliged by your recent letters.

STUMPED.—Your difficulty is an unusual one: we have never met with it. The only suggestion we can make is the use of less of the sugar syrup. If you followed the former carefully the film should not leave the glass; the only thing which could give it any tendency to do so would be an excess of syrup in proportion to the albumen. We are very partial to transparencies produced on wet collodion; there is a softness and delicacy rarely to be obtained by other means. If you have any skill as an amateur mechanic you can easily manufacture a box or camera which will answer. A bromo-iodized collodion gives the best results in our hands. We recently produced some with iron development, which have an exquisitely warm chocolate tone. You will find full information on the use of chloride of zinc as a flux, and on soldering, in the article, "Amateur Mechanic," in No. 87, p. 5, vol. 4.

R. ALBURY.—We are obliged by your communication, and glad to learn you find the NEWS so useful and interesting. Your progress appears to have been very satisfactory indeed. The chief faults of any of the prints is a little under-exposure. Some of them will be eligible, we should think, for exchange. We shall have pleasure in receiving a description of your contrivances.

B. B.—Your pyroxyline has been made at too low a temperature probably, if 4 grains gives you a thick, glutinous collodion. You may make use of it for positives, after diluting with ether, until it is of a satisfactory consistency. We say ether alone, as that will make it more fluid than alcohol and ether. Render sensitive with an alkaline iodide, as cadmium would tend to make it still more glutinous.

JAMES WOOD.—There have been about a dozen patents obtained at various times for methods of etching and engraving photographs; but we do not think your process would infringe any of them, even if the patents have been maintained. We shall be glad to see some of your results.

EXCELSOR.—In using a Latimer Clark stereo-camera, you will obtain no stereoscopic effect if the camera be placed in the centre of the baseboard. It must be placed alternately at each extreme. The lathes should be so arranged that the camera traverses the arc of a circle of which the sitter is the centre. The picture will occupy the same position on the plate, no matter in which of the positions the camera may be placed; but by placing it correctly two different views of the sitter will be obtained, so as to give relief in the stereoscope. To use the camera, commence with it moved on the lathes to the right, and the slide containing the plate also at the right; expose, and then cover the lens. Now move the camera to the left, and push the slide to the left, and again expose. You will thus obtain the two pictures in correct relation to each other. If you examine the *principle* involved you will soon see how the arrangement works. 2. On page 131, vol. 4 (No. 97), you will find the description of a lens similar to Jamin's. You will there learn how to use yours.

J. E.—We have not used the lenses you name; but think it probable they are good. It entirely depends upon the purpose for which you require them, as to whether the first or last-mentioned are best. The first for portraits, the second for landscapes.

G. P.—The two writers are not speaking of the same thing. When Mr. Sutton and others recommend 12 grains of salt to an ounce of "pure albumen," they simply mean 12 grains to each ounce of solution. The words, "pure albumen," as there used, mean pure white of egg, which is solution of albumen. The proportion of salt need not be altered, if the solution contained half water and half white of egg. The Abbé Pujo, however, in the remark you quote, is referring to another matter; not the proportion of salt in a given solution, but the relation of salt to albumen, ("pure" in a more exact sense,) as contained in a given quantity of solution. The first refers to the amount of salt to be spread over a given surface of paper; the latter to the proportion of chloride of silver to be formed, as compared with the amount of albuminate of silver.

A. B. C.—The bath of acetate of soda may be used over again until it is exhausted. 2. The cause of the developing solution turning dark whilst on the plate is partly the mixture with reduced silver, and partly the action of the oxygen it is acquiring in the act of de-oxydising the nitrate of silver. 3. In our experience, toning after fixing is more troublesome and inefficient than before.

R. GORDON and others.—We have written to the secretary of the Birmingham Society, and hope to be able to give some information in our next.

W. BARTHOLOMEW.—There was an error, drachms should have been given, instead of ounces. We have no information as to the waters used for washing, but Mr. Ward would doubtless furnish information with pleasure. We will bear your suggestion as to mealiness in mind. See report of the South London Society. 2. We shall have pleasure in trying the collodion when it arrives. We never think your communications a bore but always receive them with pleasure.

H. NEWTON.—If our memory serve us correctly, the name you mention is the one referred to; but we have not preserved the copy. The place is Derby.

H. R. NICHOLS, CHEMICUS, and several other correspondents, as well as several articles, in our next.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 177.—January 24, 1862.

## PHOTOGRAPHY AND THE INTERNATIONAL EXHIBITION.

he final arrangements for the management of the photo-raphic department of the International Exhibition are now made and will shortly be annouuced to photographers. We ar that in many respects the votaries of the art in this ountry are doomed to disappointment without remedy, and at the very best that can now be done will be far from tisfactory. So far as it has been possible in the brief me and with the limited facilities afforded, we believe it is ut justice to the committee appointed by Her Majesty's ommissioners to the control of this department, to say that ey have worked very hard, and striven very anxiously, to ake such arrangements as may give general satisfaction. hey have resolved to allot the space placed at their isposal in such a manner as shall, to the best of their dgment, give the most adequate possible representation of e art, but that they will fail to satify many of the appli-nts must be evident, when it is remembered that the whole ace devoted to photography is less than the amount asked r in some single applications.

We cannot but think, wherever the blame may rest, that ith has scarcely been kept with photographers, in the aintenance of the arrangements originally intended, satisfactory as they were. Whatever section of the uilding or of the catalogue photography was destined to cupy, it was at least intended to exhibit it collectively. e were authoratively informed that it was intended that e photography of the world should occupy one apartment, d thus afford at one glance a general view of the progress the art universally, and admit of the completest facilities r the comparison of international characteristics and excel-nce in the varied branches. This decision is now reversed; d instead of one universal photographic department we all have several minor national shows, each country hibiting its own photographs in its own department. It to little purpose to enquire now the origin of this changed tention, since it is, we understand, without remedy. We lieve it is due to the persistent protest of the French Com-issioners who insisted that their photographs should be hibited in the French department and not in any general llection. In what category within that department pho-graphy will be placed remains to be seen. Possibly this ay have been a shrewd but efficient mode of avoiding, for rench photographers, the mechanical allocation with which e art was threatened. Time will solve this part of the estion.

The fact stands, however. British photography will now exhibited alone; and whatever space, or whatever position, e art may occupy in the displays of our continental ighbours, it caunot take a very conspicuous position with . It will share an apartmeut with numerous objects voted to the purposes of education, such, we presume, as aps, diagrams, models, broadsheets, &c. The space devoted photographs and photographic apparatus in this great cenuial exhibition will be just one-seventh more than that ually filled by the annual exhibitions of the photographic ciety. In this space every phase of photography, historic, ientific, artistic, and economic, must be condensed: land-ape and portraiture, plain and coloured; micro-photo-aphy and life-sized pictures; historic records, illustrations processes, commercial applications, photo-lithography, amel photography, instantaneous photography, composi-on pictures, in short, all the products or results of the art. But this is not all; photographic apparatus of all kinds, from a plateholder to a camera stand, from a paper-clip to a rolling press, have to be provided for, and all this in half of a moderate sized apartment.

All this is now beyond remedy, and it may be asked, therefore, why dwell upon the subject? It is bootless now to ask who is to blame; but we have an object in bringing the matter distinctly before the minds of our readers. It is quite clear that many photographers will have to forego the display of much they had contemplated, the most judicious selection therefore will become imperatively necessary, to give to the exhibition in quality what it must lack in quantity. Further, from disappointed applicants we would bespeak for the committee a fair amouut of consideration. These gentlemen have accepted, at the last moment, a very unthankful task. They have undertaken to make the best of a matter mismanaged from the outset, and to make the most of limited space. We know they have endeavoured to exercise a most judicious eclecticism in the allotments made, and that some of their number have traversed the metropolis to acquire a personal knowledge of the import-ance of claims made by men whose reputation and standing were unknown. In apportioning the claims of artists of recognized position, the duty is, where all must be cut down, invidious enough; but the duty is tenfold more difficult in dealing with those as yet unknown to fame, and who it may be, are waiting to make their mark in the forthcoming exhibition. The difficulty is still more enhanced by the uncertainty which must prevail in many cases as to the size and character of the pictures to be exhibited. The space which would be very ample for the display of stereo-pictures, might be utterly useless to the applicant whose sole contri-butions are intended to consist of life-size solar camera pictures. If the difficulty of dealing satisfactorily with the applications of artists be great, the difficulty of satisfying the manufacturers of apparatus must be tenfold greater. We hope these considerations will be borne in mind when the allotments reach the hands of those concerned, which will now be within a few days at latest.

The precise conditions for the guidance of photographers we cannot yet state. We believe it is intended to exclude such pictures as are retouched or worked up altogether; but where the line is to be drawn which defines the term untouched, we are at this moment uncertain. It was in contemplation to make the term very stringent, involving entire freedom from any kind of "dodging" in either negative or positive. This would at once exclude not only all worked-up pictures, but all with painted out, masked, aud improved skies; and although it might be strictly just, it would be scarcely desirable. Possibly a wide definition and a discretionary power to be exercised by the committee may be productive of the best results, although it can scarcely be hoped, however wisely and well such a power may be used, that everybody will be satisfied.

If the same course be followed here as in other depart-ments—and we presume it will—applicants on receiving their allotments will be required to signify their intention of filling the space awarded to them, and will, at the same time, be required to nominate a certain number of gentlemen as jurors in their department. This will be an important duty; for however inferior to what had been hoped the photographic department of the exhibition may be, the prestige attaching to the award of jurors generally possesses some value. Self-interest will, therefore, prompt the nomina-tion of men at once of cultivated taste, dispassionate judgment, and freedom from bias; equally capable of forming a correct estimate, and free from all influences which might warp their decision.

Thus ends, then, the magnificent hopes which some of us have formed of an exhibition of the photography of the world at one glance. Instead of one grand collection, we shall have several minor collections; the display from English photography a little exceeding in extent, although largely we hope in excellence, the usual annual exhibition. International comparison, such as we had hoped for, with national collections side by side, we can have none. Fine art comparison and companionship, we can have none, as the apartment in which British photographs—in company with the respectable, but by no means picturesque, display of educational objects—will be exhibited, is quite removed from the picture galleries. All this, however, should be simply an incentive to make our department of the exhibition of sufficient excellence to challenge attention and extort admiration, in despite of the absence of all the circumstances which might have given it adventitious claims.

## THE LATE PRINCE CONSORT AND PHOTOGRAPHY.

PHOTOGRAPHERS generally are aware that his late Royal Highness the Prince Consort was interested in photography, and a patron of the Photographic Society. But few are aware, except those who came in contact with him, how warm was his interest in everything connected with the progress of the art, and how thoroughly sound and technically correct was his judgment in every department of photography. We scarcely meet a photographer of eminence who has not some anecdote to relate connected with some transaction which has illustrated the familiar knowledge, zealous interest, and practical skill, in various departments of the art, evinced by Prince Albert.

Perhaps few men know better the extent of this knowledge and interest than Dr. Diamond, and we find in the *Journal* of the Society the following remarks from his pen:

"We cannot pass over the liberal and princely sympathy which he ever evinced in the progress of photography, not only with his purse, but his suggestions—suggestions founded upon a real and thorough comprehension of the chemical and artistic requirements of the art. The words of the Address so ably drawn up by the Lord Chief Baron, where he says, 'We (especially) who have been guided by the practical judgment of His Royal Highness, who have been assisted by his liberality, aided by his advise, stimulated by his example, and cheered and encouraged by his presence and praise, deeply lament the irreparable loss your Majesty and all society has sustained,' are no unmeaning words; they speak the heartfelt sentiments of every member of the Society who has ever paid the least attention to the interest taken in its affairs by the late Prince. We should mention here, that when the committee for the investigation of the permanency of photographs was first mooted, the late Prince was one of the first who came forward and supported it by a donation of £50. Besides this, he regularly attended every exhibition of the Society, in company with Her Majesty, and carefully inspected the merits of each picture, and subsequently, from his marked catalogue, selected a large assortment of those pictures which pleased him. We need hardly say that this was done with the greatest discrimination; and it was frequently found that little, meritorious pictures, which might have been hung not exactly in such places as were likely to catch the eye, were sure to be in the selection.

The collection of photographs made by His late Royal Highness is, we should think, one of the most complete extant. He did not, however, confine himself simply to the collection of pictures; he also availed himself of the assistance of photography to enable him to reproduce everything that would in any way tend to illustrate the history of Raffaelle's works. This collection, several of which have from time to time been exhibited at the Society's Exhibitions, is, we believe, entirely unique. As a manipulator in photography he was unsurpassed: in his practice of the art he was greatly assisted by his former librarian, Dr. Becker; and on the occasion of his last visit to the Society's Exhibition, he spoke of the great loss he had sustained in his photographic pursuits when Dr. Becker removed to Germany. We should perhaps here add that Her Majesty is also a very good photographer. Certainly the art has no reason to complain of want of patronage and support from the Court; so extensive is the collection of negatives which have been taken for and by the members of the Royal Family, that it is necessary to have a private printer to keep them and print them when copies are wanted."

The debt which the art has owed to the late Prince's aid and patronage it is endeavouring to repay by perpetuating his memory. It is quite certain that at no former period of the world's history were mankind so familiar with the personal presentment of their great ones and benefactors in every grade of life as our art has made them in this age. The everyday aspects of royalty are known at every fireside, and a reigning family beloved alike for its domestic virtues, high personal worth, and beneficent influence on the general well-being of the nation, becomes, by the aid of photography, personally familiar, and an honoured presence in the cherished portrait gallery of loved friends and admired heroes.

Amongst the portraits of the late Prince, genuine and pirated, with which the metropolis now abounds, two or three which have been issued since his death take prominence. A very fine 10 by 8 photograph has been issued by Mr. Mayall, from negatives taken a few months before his death. The face is in profile, and is characterized by more than the usual thoughfulness of a face which was always grave and serious. A copy which lies before us, is unimpeachable as a specimen in photography, delicate, round, vigorous, and full of gradation. Its only fault is in the composition, which had the picture been taken in the artist's studio, with every necessary at hand, instead of at the palace, doubtless would not have occurred. There is a want of balance, which might have been remedied by a piece of drapery filling the vacant space behind the chair. In an engraved copy of the photograph just issued this want is filled up in the way we have indicated.

Another portrait of the Prince is a vignette bust on a whole plate, also a profile, by Mr. Rejlander, from a negative or negatives taken upwards of twelve months ago. A copy we saw in the portfolio of the artist, was as perfect a photograph as we have often seen, and a fine portrait; but we regret to say that the majority of those we have seen exhibited for sale are far inferior, and have much the appearance of reproductions.

Another, perfect as a photograph, and perhaps more pleasing than any as a likeness, is a full length sitting figure by Mr. Vernon Heath. This is very satisfactory throughout; the view is about three-quarter face, and the expression very good. This is not yet published, we believe, the demand for the Court absorbing all the copies at present produced. It will doubtless be shortly before the public.

We need not now, since a contemporary has given publicity to it, hesitate to mention, what before we had conceived the artist might not desire yet to make public. Mr. Rejlander has in hand, and intends to complete, if possible for the forthcoming exhibition, a photographic memorial to the late Prince. The design, if carried out as the artist described it to us, will be a most interesting and grateful memento of the august patron of photography, whose portrait will occupy the central position, surrounded by an allegorical group, indicative of the relation held by his late Royal Highness as the patron and promoter of all the arts of civilization.

## PHOTOGRAPHY IN BELGIUM.

THE glowing accounts we have heard from various quarters of the superior figure photography of the Continent, and especially of the magnificent enlarged portraits, which are to eclipse so signally the productions of our English photographers, has excited our interest to learn all that is possible upon the subject from every quarter. We have recently ublished the impressions of one able observer in Paris. Ve wrote the other day to a friend well capable of judging, t present in Belgium, asking him to give us his impressions, especially of the productions of M. Ghèmar, of Brussels, whose pictures we had heard described as amongst the nest things of the kind which had been produced. We ubjoin some extracts from his letters, conceiving that our eaders may feel as much interest in this question as we do urselves.

"I was at Namur a day or so since, and there saw three *very* xcellent enlarged portraits. I should think the best I have een yet. I did not remark the name upon the door; I went n and examined them. They were evidently enlarged from *arte de visite* negatives, and bore every appearance of being uite untouched. The person in the 'show-room,' (*i.e.* shop,) ith whom I conversed, declined to furnish me with any inormation respecting their mode of production; but he showed o little intelligence, and made several remarks so unscientific, hat I am inclined to believe these pictures were not taken by im at all, and had probably been bought at Paris or elsewhere, o hang in his show-room. This is a very common way of aking a show here. I have seen the same whole plate picures exposed in Brussels, Antwerp, Namur, Mons, and Liege. recognise some that are familiar to me in London; some that have seen in Paris.

"I have not examined with care Ghèmar's large pictures, hough I have seen them; but it has always been by gaslight. will make a point of going there shortly, and will give you y opinion of them. Upon first seeing them, my impression as that they were prints from enlarged paper negatives, and hat these *negatives* were a little touched.

"I do not think that very large portraits are likely ever to ecome a source of profitable business, as the expense of such a icture must of necessity be considerable; and probably the ublic would elect to pay a little more, and have it upon canvas y an oil colour artist. But I believe that if photographers ould give their attention to the perfect reproduction of album ortraits, enlarged to about 28 × 18, which they will bear ery well indeed, and have a remarkably fine effect, a large and ew business might be created. I think in a commercial ense, life-size is a mistake, at least at present. I do not hink we know the *dernier mot* about solar cameras yet.

"There is some careful photography to be seen here, as far s the mere mechanical part is concerned; but generally the ictures (in the show-cases) are poor in artistic effect, the pose eing too often either harshly formal, or too theatrical. This may n some measure proceed from the stuff they have to work with; r the natives here are not very refined in our acceptation of e term, and it is not easy to produce a graceful representation f a *gauche* original.

"The pictures seem in most all cases to bear evidence of nferior lenses, a portion of the picture being out of focus, or an ncouth position being adopted to avoid it; and a deficiency of ght may almost invariably be noticed towards the feet, as if a o small *front* stop had been used. This latter defect may erhaps arise from the imperfect lighting in the glass room. n many of the shows, I see the yellow witness of old hypo oning, and in some these are side by side with the bright roofs produced with the alkaline formula, which appears to dicate that this latter is *beginning* to replace the former."

A letter received a few days afterwards says:—

"I called yesterday on M. Ghémar, and had the pleasure of aking the acquaintance of a most agreeable and intelligent entleman, with none of the froth and voluble bluster so unfornately common to scientific men on the Continent.

"I found him very obliging and communicative; he showed e all over his large *ateliers*, and gave me every information at I asked for. Some of his large pictures are extremely ood—one may be termed *perfect*, that of S. A. R. le Comte de landres. They are all of them taken with the solar camera of Voodward, slightly modified, from a thin iron-developed negave, direct upon chlorided paper, the exposure averaging about ree hours. The proofs are toned and fixed in the usual man-r. They are then touched up, but very slightly; not more, fact, than a whole-plate portrait generally requires. After is they are varnished.

"The touching up in the proof I have named of the Comte Flandres, was confined to the light spot upon the eyes, which always too large, and to the details of the several orders upon the breast, which, being composed of gold, silver, and brilliants, were re-produced too opaque in the negative—as it is easy to imagine. The flesh, beard, drapery, and surrounding furniture were pure photography; the 'touching up' did not occupy half an hour in all, so you may conceive it is not great. You will understand the fidelity of the photograph by the fact that a curtain of wool-work, which forms a part of the background, is reproduced with each of its stitches clearly defined, as in the original negative; and the whole will bear looking at as closely as an ordinary sized photograph. The modelling and relief are perfect, and the softest half-tones beautifully preserved. The height of the picture, I should think, is a little over three feet, and of the figure about 28 inches. I state this merely by guess, and from recollection.

"There are no others equal to this one, but several of them possess much merit. They are generally life-size, and from this circumstance have required more touching up; but still, I am told, seldom upon the flesh. They require to be looked at from a distance—the same as an oil painting—when the general effect is good; but, in my mind, scarcely pleasing. There is about them a *je ne sais quoi* of an unfinished appearance, as if the master's finishing touch were yet wanting. This inspection confirms me in the opinion I expressed lately to you, that half-size of life, or a little less, was a preferable style with our present appliances, and it probably always will be so, than the more ambitious full life-size.

"Among other things, M. Ghémar named a fact to me which I had only suspected from my own experience, but had never proved to be true: I daresay it is familiar to you. He says that, beyond a doubt, paper positives taken from weak, thin negatives, however brilliant when first finished, always fade, whatever precautions are taken, in washing them. He never got a proof returned taken from a strong dense negative, but *invariably* those from weak negatives come back to him at the end of a year or so; he furnishes fresh copies from the same negative, and these, in their turn, are certain to fade also. His walls are hung with experimental specimens in cases, placed alternately from dense and feeble negatives, and certainly the latter show all of them signs of decay not visible in the others.

"I think this is all the information I need give you upon the subject of the large photographs of Ghémar. I am glad, however, to announce to you, that you will have the opportunity of judging them for yourself, as he intends to send some of them to the Exhibition."

Our correspondent sums up his impressions by stating that, judging from what he saw exhibited, none of the Belgian artists surpass the English; and that, with the exception of M. Ghémar, none equal them. Mayer and Pierson, who have a house in Brussels, make a much worse show there than they do in Paris. There are two other establishments of about equal calibre, and all the rest are decidedly bad. The good old photographic caricature (unknown to Paris) of the fifty-centime portrait—just worth the money—is rampant; but, thanks to the police, there are no touters! Whatever may be the case as regards other countries, it is evident English photography will not be eclipsed by that of Belgium.

## PHOTOGRAPHIC CHEMICALS:

### Their Manufacture, Adulterations, and Analysis.

*Hyposulphite of soda* (continued).—The ordinary salt met with in commerce is the one which we described in our last article, as containing 5 equivalents of water, and having for formula—

$$NaO.S_2O_2+5Aq.$$

It is liable to be contaminated with sulphite of soda, sulphide or poly-sulphide of sodium, which communicates to it a yellow colour and disagreeable odour; and also, but more rarely, by salts of other sulphur acids. No chemical means, which could be employed by the amateur, are known whereby the freedom of hyposulphite of soda from many of these latter impurities may be ascertained. It will, however, be advisable to test the salt for sulphides by adding to an aqueous solution a few drops of solution of acetate of lead. If sulphides are present, the precipitate will be dark coloured immediately, whereas the pure hyposulphite precipitates lead salts white, which does not discolour until it has stood for some time, or has been heated. The freedom of the salt from other impurities may best be ascertained by the iodine test. This is founded on the reaction which takes place between hyposulphite of soda and iodine, whereby the former is converted into iodide of sodium and tetrathionate of soda.

$$2\ (NaO.S_2O_2)+I=NaI+NaO.S_4O_5.$$

Both the products being colourless salts, the completion of the reaction may be known by the solution remaining coloured when more iodine is added than the theoretical quantity. The proper amount may be easily calculated; from the above formula it is seen that two atoms of hyposulphite of soda. completely dissolve and discolourise one atom of iodine, Now, the atomic weight of crystallized hyposulphite of soda is 124, two atoms, therefore, being 248, and that of iodine being 127, it follows that 127 grains of iodine should be completely dissolved into a clear colourless solution by 248 grains of hyposulphite of soda. As, however, hyposulphite of soda is never absolutely pure, but contains usually a slight excess of water, or a trace of sulphate, (both of which are immaterial,) it is generally considered satisfactory if a rather less proportion of iodine is able to be discoloured by the salt. The method recommended is therefore to weigh out very accurately 20 grains of the hyposulphite of soda to be tested, and 10 grains of pure iodine, (theory would require 10·24 grains of the latter). Dissolve about three quarters of the hyposulphite in half an ounce of water, and add the iodine to it, facilitating the mutual action by grinding the latter with a pestle, or the end of a thick glass rod. The hyposulphite will be decomposed, and the iodide of sodium formed will dissolve the excess of iodine, forming a deep brown coloured liquid. Now add the remainder of the hyposulphite, dissolved in a little water. If the liquid becomes quite colourless, the hyposulphite may be looked upon as sufficiently pure; but if it be still coloured by uncombined iodine, the salt is impure; the amount of impurity is in proportion to the quantity of free iodine left behind, but since this will be in great measure dissolved in the iodide of sodium, the actual per centage of impurity cannot readily be told, as it otherwise could be by filtering off and weighing the residue of iodine.

Hyposulphite of soda, when in the form of aqueous solution, will dissolve about one-third of its weight of chloride of silver, forming a readily soluble salt of the formula,

$$AgO.S_2O_2+2\ (NaO.S_2O_2).$$

In this form, the silver compound has but little tendency to decompose at the ordinary temperature. But when more chloride of silver is added, there soon commences to be formed another double salt—

$$AgO.S_2O_2+NaO.S_2O_2,$$

containing only half the amount of hyposulphite of soda present in the former compound, and very sparingly soluble in water. This salt will therefore be precipitated in the form of minute sparkling crystals; and when this takes place in a fixing bath, there is great danger of the destruction of all the prints which it contains, owing to the tendency which the crystals have to deposit on the surface and in the pores of the paper, where they resist all attempts to remove them by washing, and speedily decompose, with formation of yellowish brown sulphide of silver and sulphuric acid. Thus is occasioned the well-known appearance of yellow curdy patches in positives, best seen by holding them up to the light. When chloride of silver is dissolved in hyposulphite of soda, there is not much danger of decomposition, provided a good excess of the latter be kept in the liquid; but the case is different when nitrate of silver is used, the salt formed in this case being much less stable than the other, and very liable to precipitate sulphide of silver in the prints. For this reason, it is preferable to wash all the free nitrate of silver away from the positives before immersing them in the fixing bath, or to place them in a dilute solution of a chloride, to convert all the free nitrate into chloride of silver. This plan, however, is not adopted by many photographers, as the tones of the print do not turn dark so readily. Since the *toning* properties of the hyposulphite of soda are communicated to it in this case by the ready decomposition of hyposulphite of silver into sulphide of silver and free sulphuric acid, which latter induces a further decomposition and a separation of sulphur, hydrosulphuric, sulphurous, and other sulphur acids from the hyposulphite of soda, it is evident that prints fixed without removal of the free nitrate of silver which is on their surface, are more liable to be "sulphur-toned," and therefore to fade, than prints which only introduce chloride of silver to the hyposulphite of soda.

It is no part of our design in these chapters on "Photographic Chemicals," to enter into the practical details of the photographic processes; but we may here mention that to perform the operation of fixing positives in the manner most in accordance with strict chemical principles, so as to ensure the greatest possible chance of permanency, it would be advisable to adopt a plan somewhat as follows:—

The positive paper, in the first place, should have a considerable excess of free nitrate of silver on it, in proportion to the chloride present, so as to obtain the *density* of image requisite to stand the various lowering influences to which it will be subsequently subjected. The paper should be used as soon as possible after preparation. The printing should not be too dark, and the prints as soon as they are removed from the printing frame should be well washed until all the free nitrate of silver is removed; the last washing being with water, containing a little common salt dissolved in it. It is perhaps immaterial whether the print be toned before or after fixing, but the toning bath should be alkaline, prepared with gold, and should have no hyposulphite whatever in its composition. The fixing bath should be quite new, and consist of one part hyposulphite of soda to five or six parts of water, kept alkaline by a grain or two of carbonate of soda. The prints should remain here until the whole of the free chloride of silver has been converted into the soluble double hyposulphite of silver and soda, when they should be removed and quickly washed in plenty of water. Whether the fixing or the toning be performed first, the prints should be well washed between the two operations. The final washings should be by rapid and copious changes of water, continued for about twelve hours; the last washing or two being with distilled water. Only a few prints should be placed at a time in a bath, and as soon as any solution shows signs of exhaustion, it should be replaced by a new solution—not replenished by fresh chemicals. If a print be not properly coloured in the toning, never attempt to colour it by allowing it to remain in the hyposulphite of soda longer than is necessary to fix it; but either be content to have it of an inferior colour, or re-immerse it, after washing, in the toning bath. By attempting to make the fixing usurp the functions of the toning bath, the former will be rendered unfit to perform its proper offices with safety to the prints. No doubt good colours may be more readily obtained in this way, but it is at the sacrifice of permanency, and a good photographer should think how his prints will look in ten years' time, rather than how they look at the present moment. One permanent print, even though it be of a rather inferior colour, is better than fifty faded prictures.

## REMARKS UPON SOME OF THE APPARATUS EMPLOYED IN PHOTOGRAPHY.*

BY F. R. WINDOW.

### Lenses.

It is not my intention to examine the optical portion of lenses, as that subject has often been treated in these pages by those more competent to do so than myself. I propose merely to notice the mechanical parts which serve to apply them to photographic use.

The mountings of lenses are of three kinds. They are

* Continued from page 28.

her set in rigid tubes, in tubes sliding one within another, in sliding tubes, with a rack and pinion to commuuicate e movement.

Of these, the first or rigid mounting, is decidedly the st, and should always be selected in preference where use is possible; that is, when it is intended to be emoyed with a camera having a sliding or expanding body. ie only utility of a lens having a movement *per se*, is for e purpose of focussing; but if this can be performed in other manner, there is nothing gained by duplicating the eans, except an unnecessary complication, and an useless ldition to the prime cost. A camera, with a sliding body operly made, and to which the rack and pinion movement fixed, with a lens set in a rigid mounting, will be found ry superior in practice to the ordinary form of camera pplied with a lens in a sliding mount.

Of course, those cameras which have no movement, or which the moveable parts, from faulty design or construcon, work with difficulty, irregularity, out of square, or in ch a way as to render them unadapted for focussing purses, require a lens capable of movement. The question the advisability of employing such cameras for poraiture will be examined under the appropriate heading.

Of the two kinds of mounting for lenses with a moveent, that in which the mounted lens simply slides in other tube is to be preferred. This is more particularly e case with single lenses, for landscape purposes; but it so holds good for portrait combinations. The adjustment the rack, which is merely fitted into a slot in the mountg, is a fertile source of the admission of dust into the lens ount, and of light into the camera. It is very liable to t out of order, and it may inconveniently do so just when d where it is difficult to get it repaired; and it adds aterially to the prime cost of the lens.

For out-of-door work with cameras that must be focussed y the movement of the lens, a sliding tube will be found fficient. It is the most economical, not liable to get out f repair, nor inconvenient to use. For portraiture, it is est not to employ such cameras, but rather those with a iding body moved by a rack and pinion, in which case lens with a rigid mounting is best.

The cap of a lens should be made of wood, papier maché, eather, or some such material, in preference to metal. Caps ade of metal are easily bruised by falling down, or by a low, and are thus temporarily rendered useless. It should t easily on to the hood, so that it may be taken off and placed without danger of shaking the camera.

In taking children and animals, it often happens that the ct of taking off the cap attracts their attention, and causes em to move. To avoid this, I have found a great advange in employing a hinged shutter *behind* the lens, moveble from without, instead of a cap: in this way the lens an be uncovered at any moment without any apparent ovement of the operator, or the sitter being aware that a icture is being taken. The artist can wait until the dered expression comes over the features, and make the best se of the time while it lasts.

The stop or diaphragm of a single lens should be placed n front of it, at a distance of about half its diameter. If be placed too far off, it ceases to be a stop, and acts as an bject, and cuts off light from the edges.

The stop of a double combination lens should be about alf-way between the two lenses: the exact position for it epends upon the relative foci of the lenses. In those nses which are not furnished with a transverse slit in the ounting to receive the central stops, they must be placed n position by unscrewing the back lens. A centre diahragm of cardboard well blackened is perfectly effective, nd, if one has to be improvised, it is very easy to make. f cut a trifle larger than the tube its own spring will keep in position. In a double combination the stop should *in o case* be put in front. This is so well known that I hould not have thought it necessary to mention it, had I ot quite recently seen two separate instances where a front stop was used by professional photographers of eminence in London to produce *carte de visite* pictures with a quarterplate lens. This produces a flat picture, and the field is diminished, because a stop so placed does not act as a stop but as an object.

(*To be continued.*)

## ON COLLODION POSITIVES.*

The production of collodion positives has generally been considered by the mass of negative operators as a matter so simple as to be scarcely worth a thought. It is, nevertheless, a fact beyond dispute, that but comparatively few really excellent positive operators are to be met with. To produce a good collodion positive requires as much care and skill, and attention to proper conditions, as to produce a good negative. As the positive process is generally a favourite with beginners, because they obtain results at once, without waiting for printing, we shall give a brief statement of the best mode of proceeding.

The collodion for positives requires to be of an essentially different character to that best suited for the production of negatives. It should be entirely free from any organic or powdery tendency. For those who are desirous of making their own collodion, the method of preparing the soluble cotton with mixed acid is simplest and best. The nitric acid should be of a specific gravity of 1·420; and the sulphuric acid of a specific gravity of 1·840. Of these take equal parts by measure. To six measured drachms of the mixed acids add two drachms of the best carded cotton wool, which has been previously well pulled out into thin tufts for ready and convenient immersion. The temperature of the acids should previously have been raised by placing the jar containing them in a vessel of hot water to about 130° Fahr., which temperature should be maintained during the immersion. The cotton should be immersed as rapidly as possible, being pressed into the acids by means of a stout glass rod, or spatula. When the whole of the cotton is immersed, it should be kept in the acids from five to ten minutes, the thermometer being kept there also, to test the temperature. It is then removed, thoroughly washed, pulled out, and dried.

From four to five grains of this cotton should be dissolved in equal portions of ether and alcohol, the latter about 63 over proof. The formula will stand as follows;—

| | |
|---|---|
| Pyroxyline about ... ... ... | 8 grains. |
| Washed ether... ... ... ... | 1 oz. |
| Alcohol (63 o.p.) ... ... ... | 1 „ |
| Iodide of cadmium ... ... ... | 5 grains. |
| „ potassium ... ... ... | 3 „ |
| Bromide of ammonium ... ... | 2 „ |
| Tincture of iodine, *quantum suff.* | |

The exact quantity of pyroxyline will be regulated by the thickness of collodion it produces, but about four grains to the ounce will generally be found to give a pleasant working consistency. The iodides of cadmium and potassium in the proportions named, and in conjunction with the bromide, give a stable collodion yielding a fine toned positive. The tincture of iodine is made by dissolving ten grains of iodine in an ounce of alcohol. Sufficient of this should be added to the collodion to make it yield fine clear blacks, free from fog. The proportion will vary with circumstances, but sufficient to produce a sherry colour will generally be found to give the best results. American operators are fond of the addition of hydrobromic acid for a similar purpose. A method of preparing this in a pure form was recently given in the articles on the preparation of photographic chemicals in the Photographic News, but as the method is scarcely available to those not familiar with chemical manipulations, we subjoin the rough American method which, whilst yielding a less pure product, is still found to answer for this purpose:—Take an ounce of alcohol, and add to it sufficient

* From the Photographic News Almanack for 1862.

bromide to make it red. Leave it to stand for a day or two, when it will have become colourless. Repeat the operation until it ceases to lose colour, and then add sufficient alcohol to remove the colour. This is hydrobromic acid, not pure, but sufficiently so to answer the purpose. A drop or two added to an ounce of newly iodized collodion rapidly liberates free iodine, and makes the collodion work clean, with fine silvery tones. Too much will, however, diminish sensitiveness.

Those who do not wish to make their own collodion will frequently find the addition of tincture of iodine or hydrobromic acid an improvement to newly iodized commercial samples. It is a good plan to keep two or three different samples of different ages, and giving different results; some giving much detail, and others much vigour. These can then be mixed in such proportions as may from time to time be found desirable.

The Glasses should always be scrupulously clean, as a very slight impurity will mar a good positive. Alcohol and tripoli will render new glasses perfectly clean, but for glasses which have been used a little nitric acid is necessary. It is worth remembering that the use of a full-bodied collodion is favourable to the production of clean pictures, as a thin film makes apparent the slightest dampness in the cloth with which the plate was rubbed, whilst with a thick collodion the same causes would produce no injurious effect.

The Nitrate Bath.—This should be made of pure recrystallized nitrate of silver; the strength, forty grains to each ounce of water, with sufficient nitric acid to give clean brilliant pictures of a silvery tone. The best way to proceed about making a bath is first to mix the quantity of solution of the required strength. It may not be unimportant here to remark that nitrate of silver is sold by the ounce avoirdupois, which contains only 437½ grains; some photographers make an error by mixing an ounce or more of silver just as they have bought it, with a given quantity of water, on the assumption that it contains 480 grains, the amount of an ounce troy, or apothecaries' weight. Care should be taken that each ounce of water contain forty grains of nitrate of silver. A large plate coated with the collodion to be used having been placed in the bath and left there for an hour or two; a picture may then be tried. If it work without fog, it may be assumed that the silver and the distilled water were both free from organic matter. If the plate be covered with fog or streaks, it may be desirable at once to expose the solution for a few hours to sunlight, which will have the effect of blackening and precipitating the organic matter. The solution is then to be rendered sufficiently acid and will be ready for use. This operation of sunning may be dispensed with, as the addition of sufficient acid would in most cases remove the streaks and fog; but as it is very desirable, in order to produce the most brilliant results, that a positive bath should be free from organic matter, the sunning will give more certainty, and tend to the production of better pictures. The amount of acid to be added will depend somewhat on the amount already present in the crystals; but with a forty-grain bath, from one to two drops of nitric acid may be added to each ounce of solution. It is always well, however, to begin with a minimum quantity, and gradually add more, trying plates in the meantime, until the best results are obtained. It must be remembered that since the collodion generally used for positives contains free iodine, every plate inserted in the bath will liberate a little nitric acid, and that hence, a positive bath generally becomes acid from use. When it begins to work very slowly, either neutralize with oxide of silver, or add more neutral nitrate of silver, to strengthen the bath, as the more acid there is present the stronger the silver solution should be.

Lighting.—One word only is necessary on this head. The lighting of the subject for a positive is the same in principle as for a negative, with this difference, that the light and shade on the figure for the positive may have a little more contrast than is desirable for a negative. The camera and dark room should be carefully shielded from diffused light, by the use of every precaution possible.

Developing.—By far the greater part of the beauty of the finished positive depends on the skill and judgment with which this operation is performed. The strength of the developer should be proportioned to the condition of the bath and the temperature, especially to the latter. Stronger developers, with less free acid, will be required in winter, than in summer. If the bath be very acid, the same conditions will apply, a strong developer with little free acid will be necessary. A weak developer, requiring longer application than a strong one, will sometimes have a tendency to accumulate reduction more on the high lights than on other parts. The same tendency will be observed on using a developer over and over again. Some positive operators are fond of this practice as it tends to give brilliancy to the picture. Care should be taken, however, not to carry it too far or there is danger of losing detail in the shadows, or if the development be continued long enough to give drawing in the shadows, both force and detail are lost in the face through over development. Nothing but a practised eye will enable the operator to determine the exact point at which development should be stopped in a positive. And whilst this part of the process is very important in negatives, it is of still more vital importance in positives. In the former a trifle more or less development may affect somewhat the beauty of the resulting print, but does not necessarily spoil the picture; whilst in a positive an error here may be fatal, rendering the picture quite worthless. We subjoin formulæ for two or three developers, each giving excellent, but slightly different results.

| | |
|---|---|
| Protosulphate of iron ... ... | 10 grains |
| Nitric acid ... ... ... ... | 2 minims |
| Water ... ... ... ... | 1 oz. |

This gives a very metallic-looking picture. It should be used fresh each time:—

| | |
|---|---|
| Protosulphate of iron ... ... | 15 grains |
| Nitrate of potash ... ... ... | 10 „ |
| Acetic acid (glacial) ... ... | 15 minims |
| Water ... ... ... ... | 1 oz. |

This gives pictures of very fine tone. It may be used over and over again, taking care to add each time, however, an equal bulk or more of fresh solution:—

| | |
|---|---|
| Protosulphate of iron ... ... | 20 grains |
| Acetic acid (glacial) ... ... | 20 minims |
| Nitric acid ... ... ... ... | 2 „ |
| Water ... ... ... ... | 1 oz. |

This gives a brilliant ivory-like picture with solid whites It should be used fresh each time:—

| | |
|---|---|
| Nitrate of baryta (powdered) ... ... | 1 oz. |
| Nitric acid (s. g. 1·400) ... ... | 3 drms. |
| Water ... ... ... ... ... | 16 oz. |
| Mix and dissolve, Then add— | |
| Protosulphate of iron (powdered) ... | 1½ „ |

A white turbidity will ensue, which will subside in a few hours. Decant or filter, and the solution is ready for use. It should be kept carefully corked, as it rapidly loses developing power on exposure to the atmosphere.

This is a solution of proto-nitrate of iron, with a little protosulphate in excess. When fresh it is of a green tint, but becomes yellow as the iron oxidizes, and is then gradually losing strength. A little fresh protosulphate should then be added. With many first-class positive operators this is a favourite developer, giving very brilliant and silvery tones. In our own experience we have found that to obtain the best results with it, the bath should be strong and acid, and the plates scrupulously clean.

In all these developers a little alcohol must be added, the amount to be regulated by the state of the bath. With a new bath very little; with an old bath, and especially in warm weather, from twenty to thirty minims to each ounce of developing solution.

Fixing.—The unaltered iodide of silver may be removed ther by hyposulphite of soda or cyanide of potassium. The tter is generally preferred as giving a whiter and better ne to the positive. If used at all it should not be used rong, about ten grains to the ounce being sufficient, and it ay be used over and over again with advantage. Hypo- lphite of soda will, however, give very good results, and we commend its use in preference to cyanide, which, on account its poisonous fumes, we should like to see banished from e dark room. Where hyposulphite of soda is used, the ate should receive a very careful washing with hot water, it can be conveniently done.

The black varnish should not be applied on the collodion de; indeed, in many cases its place is well supplied by ack or dark maroon velvet, which gives a very rich effect the shadows. As a general principle a "crystal" varnish peferable to a spirit varnish, which is apt to lower the ne very much.

The process of whitening pictures, if judiciously managed, ten gives a very fine effect, especially for coloured pic- res. Various recipes have been given for producing ese results, the chief fault of all being a tendency to pro- ce a blue, cold effect. We cannot here enter into details, it may remark that the best effect we have seen was pro- ced by the original "alabastrine solution." Whatever ethod be used, the pictures should be backed with dark lvet in preference to black varnish, which spoils such pic- res.

A gold matt or mount gives a much finer effect to a collo- on picture than the immediate contact of either a black or hite *passe-partout*.

## DRY COLLODION WITHOUT PRESERVATIVE.

Dear Sir,—I wish to offer a few words of comment upon article in last week's Photographic News upon "Dry ates without Preservative." It is a subject of growing im- rtance, as it appears almost certain that we must seek in is direction for such an improvement in the preparation dry plates as will enable them to produce pictures with fficient rapidity to convey those transient effects of atmos- ere, cloud, and wave, which are properly looked for now necessary to a good photograph.

It is very desirable that we should base our experiments little as possible upon conjecture, especially when proof possible; and, I think, one of the first points that ought be settled, should be the part played in washed plates by substratum of albumen. Travelling upon the Continent, m not in a position to make any experiment myself just w, but there would be little difficulty in deciding the estion. Half a plate coated with very dilute albumen, d the other half clear, collodionized, sensitized, dried, and veloped, as usual, would settle the matter. The *value* of two halves must be compared, not the *colour*, because s would certainly be different. It should be carefully ertained whether the half tones, and the details in the adows be better in the one than in the other; in short, ether one is a *better* negative. I think I made this expe- nent, and proved the inactive part of the albumen, but I nnot find any note of it.

In some experiments I was making with a certain preser- ive, I found that the more diluted I used it—that is, the s substance I interposed between the collodion and the ect to be photographed, the more sensitive was the plate; herefore occurred to me to place the so-called preservative *der* the collodion to fill up the pores, according to the n received theory, and nothing at all over it. I did this reversing the collodio-albumen process. I laid the col- ion upon an iodized albumen with only 25 per cent. of ter, and got excellent pictures. I then omitted the iodides the albumen, with the only result that the character of negative now partook more of the nature of collodion, l less that of an albumen negative: having the same idity, the same density, and softness, but black instead of brown. I then increased the water in the albumen solu- tion by degrees to six ounces to one of albumen, without any appreciable difference in the picture, but still firmly believing that this albumen was necessary and actively use- ful in filling up the pores of the collodion. One day, how- ever, after developing an excellent picture, I discovered that by mistake I had put the collodion on the unalbumenized side of the glass, which showed it was *not* necessary, and I frequently afterwards took pictures without using it, that were every whit as good in all respects as those upon albumen.

Undoubtedly, the thin layer of albumen does form a sen- sitive compound with the nitrate of silver, which, when developed, adds its mite to the collodion image; but I be- lieve it is infinitely small when the albumen film is so thin as I used it, and that the nature of the collodion negative is not in any way affected by its presence or absence—it is only an almost imperceptible *addition* to it. I continued to use a very dilute albumen in my general practice for washed plates, because the collodion I was then using had a large proportion of water in it, and was very apt to leave the plate.

This brings me to another point that I wish to notice: the supposed necessity for some mechanical means to keep open the pores of the collodion when dried. Is it a fact that any such necessity exists? I am strongly inclined to doubt it. We have received the dictum without sufficiently examining into its truth, and I think it has led our en- quiries in a wrong direction. When the collodion is suffi- ciently set upon the plate to be placed in the bath, it is still combined with a certain quantity of its solvents, ether and alcohol, which in the bath are substituted for water. The film therefore on coming from the bath is composed of iodide of silver, held in a spongy organic body, the pores of which are full of water. These pores may, and do contract or shrink when the collodion is dried, and expand again or contract with water, like a sponge, but it puzzles me to imagine how they can entirely close up, having only water, which is not a solvent of pyroxyline in them, and that sub- stance not welding with itself without a solvent. That the pores do not close up is shewn in the fact that dried plates not only admit a developing solution into these pores, but they produce pictures more like those on wet collodion than the plates whose pores have been filled up with foreign matter. "A preservative" does fill up the pores, and makes many collodions serviceable for dry plates, that would other- wise be useless, but it is *not necessary*, and better pictures can be obtained without it, so our aim should be to deter- mine the qualities of the collodion most suited to dispense with it.

I believed at first, that an addition of water to the collo- dion would have the effect of making it more porous, and in consequence more suited for washed plates; upon trying it I found it gave a marked improvement to the collodion I was then using, with the drawback I have named, that it made it very liable to leave the plate; but in subsequent trials with other samples of collodion they have sometimes been spoilt for the process instead of improved by the addi- tion of water, and I find that most collodions giving good negatives with the wet process are more or less suitable without any addition at all. It would be a very great service if some competent person would carefully investigate the question, and determine what are the requisite properties of a collodion most suitable to be used without the addition of any foreign matter.—I remain, dear sir, yours faithfully,

F. R. Window.

*January 13th*, 1862.

## ON DRY PROCESSES.—DEVELOPERS—FIXING BEFORE TONING.

Dear Sir,—In the News of last week you ask in your leader for the further experience of your readers upon the subject of "Collodion Dry Processes without Preservatives."

In 1857, I commenced photography as an amateur, and after wading through the wax paper process, in which I did some very tidy pictures (so my friends told me), I took up the wet collodion, to which I have directed my earnest attention ever since; in 1859, having become somewhat an adept at "The *Divine* art," I entered it professionally. In this year I had occasion to take some pictures in Bristol and elsewhere, and not being able to make use of wet, I determined upon making an experiment with *dry collodion.* I certainly had read of all kinds of preservatives, but I could not see much value in any, because I reasoned that if the collodion, which in its very nature was air-proof and waterproof, what would be gained by putting over the plate a foreign substance, which would rather mystify the subsequent operations than otherwise, and the gain—nothing?

*Experiment* 1.—I therefore took a simply iodized collodion—(Bolton's, of Holborn Bars)—coated and sensitized the plate in the ordinary way, then well washed it with filtered rain water, and set it up to dry spontaneously. This I kept a fortnight; then exposed it for two minutes and a half, and got on development a respectable negative—a little wanting in density, but this I remedied in experiment No. 2.

In this I followed out the same formula with three exceptions, viz.—that I then used *Perry's* bromo-iodized collodion, and after washing off the nitrate of silver, I immersed it in a bath of phosphate of soda—then washed and afterwards placed it in a dish containing 8 grains of gallic acid to the ounce of water for half a minute, then washed again, and then dried it by hot water; this plate I kept four months. I then exposed it, (subject, a church with trees) for a minute and a-half; I then kept it for two months. Upon developing, I got a very fair negative indeed; my developer was the same as Mr. J. F. Ward's, and in winter I added an extra grain of pyro, and diminished the citric to ¼ grain. I have used both these processes with satisfaction to myself, and I should not come forward now but for the good of your readers, and as a supporter of plain collodion dry plates.

With regard to developers for the dry and wet processes, I have tried several, but none seem to give so much satisfaction and total freedom from stains and abominations as the pyro and citric acid. I here append a very excellent developer I have often used both with the dry and wet processes, and with great success:—

No. 1.

| | |
|---|---|
| Protosulphate of Iron ... ... | 1 ounce |
| Gallic acid ... ... ... | 1 drachm |
| Nitric acid ... ... ... | 1 minim |
| Alcohol ab. ... ... ... | ½ ounce |
| Aqua pump ... ... ... | 4 ounces |

No. 2.—Intensify.

| | |
|---|---|
| Pyro ... ... ... ... | 15 grains |
| Citric acid ... ... ... | 4 grains |
| Aqua ... ... ... ... | 4 ounces. |

I always fix with cyanide, in which a little silver has been dissolved.

If amateurs generally were to make a greater use of citric acid in their developers, we should not hear so much about stains and marks on the plates. I have used it extensively for instantaneous and other views, and for pictures in which clouds or sea are introduced; there is nothing to beat it—not even iron. Indeed with it you can perform greater miracles than with iron; for should your plate, say a landscape for instance, be by accident over-exposed, by a judicious use of the citric developer, you may get a very fine brilliant negative; if an under-exposed plate, you may in some measure force your picture by repeated applications, if the developer with silver added, but they are apt to have a hard appearance. It does equally well for interiors and for architectural subjects generally. There are so many good formulas extant, that I will not recapitulate them here; suffice it to say mine were taken from the first PHOTOGRAPHIC NEWS ALMANAC, and I have personally to thank both Messrs. Crookes and Simpson for much valuable information derived from the pages of the NEWS, to which I have subscribed from its commencement.

Allow me to say one word on the subject of fixing before toning:—

This process of Mr. Tedrake I used for some time, but I gave it up. not because I could not get fine tones, beautiful browns, blacks, purples, but—because I found that while one batch of prints might be, and appeared, perfectly good, still I never could feel sure that they were perfectly safe. The formula was originally introduced by Mr. Hockin, chemist, of Duke Street, Manchester Square, from whom I had it; and there was a London firm who let me in pretty considerably from the sulphurization of this very bath; indeed it is very difficult to tell when the action of the gold stops, and that of sulphur begins. I am sure that we are much indebted to Mr. Maxwell Lyte, to "Theta," and numerous other gentlemen for the very excellent toning baths and processes they have made public, but there is still something wanting—some new fixing agent to render permanency certain. I always give a final washing in hot water, and am pretty successful; 5 per cent. being about the average loss with me throughout the year out of the many thousands that I print.

I am sorry absence from home prevents my sending you specimens to bear out what I have said. On my return I will enclose some with particulars at back.—Meantime, I beg to remain, yours very truly, W. H. WARNER.

*Ross.*

P.S.—I beg to add that I have kept a note book for jottings, from the commencement of the NEWS, which plan I cordially recommend to all.

## Photographic Tourist.

### PHOTOGRAPHIC PENCILLINGS OF AN EASTERN TOUR.*

THE chief purpose of this, my first eastern tour, being the transaction of certain affairs of business, my route was not exactly, so far as regarded myself, a matter of choice, although the time it might occupy was almost an affair of my own. When I left Malta, therefore, it was to seek Constantinople. The voyage was so very short, the sea so very calm and smooth, and the sky above so clear and bright, that I eat well, drank well, slept well, and quite enjoyed the trip. It is clear that these pencillings of mine cannot give details of all I saw, thought, and did, so that you must be content to know that as we went our way I saw the rocky coast of the Morea stretching its gloomy line of barren ridges along the distant blue sea, that soon after the Isthmus of Corinth came in sight with the majestic snow-capped mountains of the Greek coast, that the Isle of Myteline and Mount Ida, and the classic plains of Troy came to, and went from our sight; that at leas the Castles of the Dardanelles loomed mistily through the shades of evening, and that when the sun of the following morning rose grandly over the diamond-crested waves, we had reached our destination, and lay anchored in the far-famed Golden Horn. As the sun rose, brilliant and beautiful, indeed, was the view outstretched before us. Istamboul—as the Turks call Constantinople—grandly throned upon its noble amphitheatre of hills, rose like a gaily decked queen above the deeply and purely blue waters, the radiant beams of the rising day flashing from her jewellery, as one might call the bronzed and gilded domes; and the tall, slender minarets pointing silently to the clear and lovely sky. Rich with brilliant, variegated colours, its gardens, terraces, and kiosks lay grouped in broad masses of glowing light, and soft transparent shadow, with here and there the dense foliage of the symmetrical, but sombre, cypress trees, giving both contrast and relief. I

* Continued from p. 33.

cannot conceive any view more charming than this of that fine January morning, and think I shall always see it as vividly as I now do, although this, my poor description, does as little justice to my imagination as I believe that does to the real scene. Before the city, forming a very capital *foreground*—if I may use the term in speaking of ships and water—were clustered vessels seemingly from all nations of the world, prominently among which were the huge forms of those belonging to the royal Turkish fleet, and Arab boats, not unlike in their general form to the representations of the ancient galleys, such as were seen when—

> "High on the stern the Tracian raised his strain,
> And Argos saw her kindred trees
> Descend from Pelion to the main."

Flitting rapidly in and out among these were the light, frail-looking caïques, small boats with rising stems and sterns of highly polished beech wood, elaborately carved aud tastefully fitted up with cushions, &c.—something between the canoe and a gondola—rowed by one or more pair of sculls, and most commonly the property of Greeks, although not altogether shunned as a speculative investment by the Turks, whose grave and dignified egotism is in strange contrast with the former's more anxiously eager and noisy mode of doing business. You may hire the services and boats of these boatmen, or caïque-gees, for about five piastres an hour.

The preliminary arrangements having been duly made, we were set ashore, and then, indeed, the feeling with which I had first viewed this romantically beautiful city, received a strong blow. The streets are narrow, steep, excessively ill-drained, and dirty to a most repulsive extent. The gates, placed at intervals in the streets, are in a more than half-ruinous condition. The minarets which I had regarded with so much pleasure, were soon after my landing compared to extinguished rushlights; the mosques to things artificial and theatrical; the houses to some tumble-down outhouses, and the gilding and paint of the low wooden residences, looking so picturesque from afar, to the finery of some tawdry show-booth at an English fair. In walking, I every now and then tumbled into mud-holes—the paving was so miserably done, or clapped my fingers to my nostrils to avoid the effect of some awful stench, more than usually offensive, or was nearly run down by porters conveying goods slung upon a long pole, each end being supported by one of these rude stupid bears, who keep steadily on, knocking over, as a rule, all strangers who do not get out of their way, or else I frequently moved prudently aside to avoid the fangs of savage dogs fighting over some filthy offal. I soon found out how strangely new was all I saw. How far—how far I was from my own people, and my own thriving and progressing native land. Alas! the earnestness and energy of wholesome active life were no longer about me. A people whose mental and moral and natural existance made one stagnant pool, full of decay, and filth, and morbid growth of rank and poisonous weeds, became visible in all I heard or perceived. Mothers studiously kept in black ignorance and brute-like degradation, and shut out from all that refines, enobles, purifies, and exalts; or slave-nurses even more degraded, are here the teachers of each rising generation, producing and reproducing mothers like themselves, and fathers who never heard or dreamed of liberty, either in politics or religion; who recognize as virtue nothing so much as passive indolence, whose egotism and bigotry are the only relics of power in their decrepid natures, who, if poor, are the most servile of slaves; and if rich, the most exacting of masters. These form the population here. All mental life seems to have quite died out, little beyond reading or writing appears to be—at any rate publicly—taught, and if here and there the medressis, or colleges, do turn out an occasional thinker and scholar, there is no possible field for the exercise of his acquirements for the benefit of others, and so he lives and dies obscurely, together with the treasures he possesses. Having to make a stay of two months in Constantinople, I had ample leisure to observe and note the characteristics of this ignoble and degenerate race, descendants—one cannot but remember—of a people whose warlike energy, courage, and enterprise threatened to make them dominant over the whole of Europe, and founded one of the mightiest empires named in the history of the world. Sidney Smith once said that—"It is always considered a piece of impertinence in England if a man of less than two thousand a year has any opinions at all on important subjects;" but God forbid we should ever be reduced to such a state as exists in Turkey, where independent opinions upon almost any subject are about the most rare of conceivable things. As to religion, your sluggish Turk would hold it as tempting Providence to give a reason "for the faith that is within him"—"So he believes because he so was bred;" and Charles the Fifth might have here found men far more alike in their thought than his home-made watches were in keeping time. Of the Moslem, oue might fairly say—

> "No problems puzzle his lethargic brain;
> But dull oblivion guards his peaceful head,
> And lazy fogs bedew his gracious bed."

I have before said how new and strange all I saw and heard here appeared to me. The food I took I had never before met with; the language was perfectly strange to me: instead of shaven faces I saw shaven heads: instead of windows which looked *out* of my house I had windows which looked *in;* instead of chatty, pleasant women in the evening hour of rest I met only drowsy, taciturn men, scornful of infidels, and too busy with their long twisted pipes to exchange a single word of cheerful conversation. The modes of salutation were perfectly new to me; in short, all the customs, usages, and conventionalities of society—all the sights, sounds, and *smells*, especially the latter, thank goodness! were perfectly new and strange. I was, indeed, among strangers, and in a strange land.

I must, however, now turn to such adventures as were more intimately associated with my photographic experience; and as I have now about filled the space allotted for my present communication, I must postpone doing so until the next issue. M. H—n.

## MEALINESS IN TONING.

Dear Sir,—In my practice of photography as an amateur, I had until last summer enjoyed complete immunity from mealiness in toning positive prints. During the past season, not only did mealiness make its appearauce, but also a remarkable slowness in toning; my prints sometimes takiug *hours* in toning, and at the end of that time, turning ont anything but brilliant affairs.

I tried all remedies I could think of. but not knowing the cause of disease, my treatment had but little effect.

I had hitherto been using a toning bath of gold and carbonate of soda; but from what I had heard of the bath of gold with acetate of soda, I hoped it would prove a remedy. I gave it a fair trial, and at first seemed to have got rid of my difficulties, in some measure at least; but having begun upon a new batch of paper, I was quite dismayed at seeing the enemy re-appear in overwhelming strength. I did not know what to do. I tried this, then that; no—nothing would do. Amongst other things, I tried a preliminary bath of liquor potassa in water—about ten or twenty drops of the medicinal preparation to a pint of water. This for a time did some good, but did not clear away the evil. Sometimes I got a well-toned print, but the bulk of them were ruined. I blamed first one thing, then another. My silver bath, because it contained a *small* proportion of copper, got condemned, and I precipitated the silver. Since that time, I have been so occupied by business duties as to be prevented from doing anything at my favourite pursuit, but have been constantly torturiug myself with visions of grey spotted prints, and pictures refusing to toue altogether; in fact, I have been in a state of complete despair at the prospect of the coming season.

Mr. Henderson has however relieved my mind very much indeed, and has come to the rescue with his preliminary acetate of soda bath. I think that the unqualified thanks of photographers, both professional and amateur, is due to him and Mr. Fry for bringing forward a remedy which seems to prove so effectual.

Prevention, however, is better than cure, and though we may sometimes hit upon a cure accidentally, yet before we can effectually prevent we must know something of the cause of the malady.

Judging from the experience of others in conjunction with my own, I have no hesitation in saying that the paper, or rather its mode of preparation, is in fault. This is a conclusion that must, I think, have been generally arrived at, but what that fault may be is beyond my ken; most likely it has its origin in the plan of albumenizing, some change *may* have been made in the formulæ in order to produce a highly finished surface; else, why is it of recent occurrence? It did not come arm in arm with alkaline toning, but rather, I suspect, with highly glazed paper for stereo and *carte de visite* pictures. There is no such thing as mealiness in toning plain paper prints, and but little, if any, in slightly albumenized paper prints. I naturally, therefore, conclude that the evil must arise in obtaining a highly glazed surface on albumenized paper for small sized pictures.

Let albumenizers look to their formulæ, and not seek the highly finished surface so much in vogue; then I think mealiness will be less complained of. A finish can be given to the fixed print almost equal to that obtained by the use of highly glazed paper.

I have still something to say about a "new" (?) printing process, in which I propose the use of *water* as a fixing agent, but having occupied so much of your valuable time, I must defer the rest of my intended communication to another time.

If you think there is anything suggestive of good in the above, perhaps you will give it a place in your columns.—Yours truly, T. C.

## Correspondence.

### FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

*Paris, 22nd January*, 1862.

Among the recent important applications of photography, is that of registering the researches of an eminent anatomist into the laws which regulate the external development of the human body. The first measures relating to the object in question were made with the aim of demonstrating the relations existing between the head and thorax, under certain morbid conditions. The results, and especially the relations between the maximum of the periphery of the head of a given individual, and the circumference of his thorax formed the subject of an important work by Dr. Liharzik. Since the date of this publication, the learned author, in order to give a general and incontestable value to the laws he has laid down, has extended his measures to the entire length of the human body.

Dr. Liharzik had no sooner entered upon this path, than he quickly recognized the artistic importance of the results he might obtain, inasmuch as he might be made to establish immutably the four fundamental proportions necessary to the construction of an imitation of the normal human body. These contours given it only remains to fill up a detail according to the rules generally adopted by sculptors.

The first model constructed according to these rules fulfilled all the conditions of harmony between the whole and each of its parts. An eminent sculptor, M. Francis Müller, modelled according to this plan statuettes of a new-born individual and of an adult, and in this manner that art became indebted to science, and placed in a position to determine the proportions of every part of the human body by direct measurements, without having resource to the slow and difficult method of induction. The results of these measures for the two sexes and for various ages were arranged on a synoptical table, by means of which we are enabled to determine, for any absolute scale, the principal dimensions of the human body, and the normal proportions of each of its parts.

M. Müller has cast in bronze a series of twenty-four statuettes, chiselled with the most scrupulous exactness. This series represents the gradual development of two individuals, man and woman, each supposed to be born with normal corporeal proportions, and to have completed their growth under the most favourable conditions. The series represents the normal couple at the time of birth, at the ages of 1, 3, 6, 15, and 21 months, and at 3, 6, 10, 13, 17, and 23 years, always under the *characteristic proportions* of each of these epochs, which nature, in her regular progress, can neither elude nor surpass. M. Auer, of Vienna, whose labours in the Imperial Printing Office of Vienna are so well known and appreciated, has heartily concurred in the object in view, maintained by Dr. Liharzik and his coadjutor M. Müller, and placed all the resources of the Imperial printing establishment at their disposal, both for the chiselling and casting of these type-statuettes, and for their photographic representation. A work is now in course of publication which contains these photographs, their contours, the synoptical tables and explanatory labels of Dr. Liharzik, which will henceforth justly become the universal code of the sound doctrine of the proportions of the human body. Multiplied in plaster, metal, or any other solid substance, the complete series of these statuettes, or at least those representing the principal epochs of development, will supply excellent models wherever art has an interest in reproducing the human form in all its perfection. Your readers will have an opportunity of inspecting this curious and important series of statuettes at the approaching Universal Exhibition, and they will be found worthy of the attention of everyone interested either professionally or by taste, in the progress of art and anthropological science.

Dr. Duchenne, of Boulogne, has applied photography to the illustration of his "Mechanism of Human Physiognomy," an electro-physiological analysis of the various modes of expression, which is based on the following remarks of Buffon, the naturalist:—"When the soul is agitated, the human face becomes a living picture, where the passions are exhibited with as much delicacy as energy; where every emotion of the heart is expressed by a character, the vivid and prompt expression of which outstrips the will, and unveils and renders apparent by pathetic signs, the images of our most secret thoughts."

The soul is, then, the source of expression, which excites the play of the muscles, and causes them to depict upon the face, in characteristic traits, the images of our affections and passions. Consequently, the laws which regulate the expression of the human physiognomy, can be ascertained by the study of muscular action.

This problem Dr. Duchenne had during many years laboured to solve, by provoking, with the aid of electric currents, the contraction of the muscles of the face, to cause them to speak the language of the feelings and passions. This careful study of partial muscular action revealed to the experimentalist the causes of the lines, wrinkles, and folds of the face in motion. Now, these lines, wrinkles, and folds are just those signs which, by their varied combination, serve for the expression of the physiognomy. It thus becomes possible in proceeding from the expressive muscle to the mind that puts it in action, to study and discover the mechanism and the laws of human physiognomy.

Dr. Duchenne does not limit himself to the formula of these laws: he also represents, by photography, the expressive lines of the face during the electric contraction of its muscles. In fine, the doctor makes known by electro-physiological analysis, and by the aid of photography, the art of correctly depicting the expressive lines of the human face—an art which may be aptly styled the *Orthography of the Language of Physiognomy.*

Another photographic contribution to anthropology has been made by M. Severtsof, who has presented to the Academy of St. Petersburg a series of photographs representing Kirghis and Tartars, dwellers in the steppes of the Ural. Special attention was invited by Herr Von Baer to the method pursued in taking these photographs, which gives to them a real utility for anthropological studies. Each figure is represented in profile and in full face, the head uncovered and shaved: thus we can, without difficulty, take the measure of the principal dimensions of the cranium. As it is much easier to photograph a great number of living individuals, than to collect as many authentic crania, it follows that similar photographs will afford good means for arriving at the determination of mean proportions of races, and of the limits of variation in a given type. Her Von Baer considers that it will be useful to recommend this method to the attention of travelling naturalists.

## CARAMEL AS A PRESERVATIVE.

Dear Sir,—Mr. Hannaford's remarks on the caramel process I think are calculated to deter many from giving it a trial, and although it is mentioned in "Sutton's Dictionary," as he states, still I maintain that the properties there ascribed to it, are in direct contradiction to my experience, for it gives the *usual* sensitiveness of dry plates when applied to a simple washed collodion film, and in combination with a Fothergill plate it acts as a *powerful accelerator*, and, moreover, in both cases the vigour of development is augmented. Again, I cannot endorse Mr. Hannaford's statement, that it is a modification of Shadbolt's honey process; in the first place, caramel is not honey, and honey is not the juice of the sugar cane; the high temperature to which sugar is subjected to form caramel, entirely alters the properties of it; no one I think would call gallic and pyrogallic acids identical, any more than honey and caramel, or wood and charcoal. In the honey process, the tendency is to give thin transparent negatives; in the caramel, it is to give vigorous opaque ones, with great rapidity of development. I did not refer to "Sutton's Dictionary" before trying it, or I most likely should have relied on the information there given, and not have done so. Its not being literally a "new" process, I hope, will not operate as a retarder to its adoption, and I willingly give up all claims to such a term; but at the same time, I say that I discovered it independently of "Sutton's Dictionary," and to me it was a "new" process. Many readers of the Photographic News will, I fear, on reading Mr. Hannaford's "Jottings," dismiss the process in the summary way he has done, thinking it only worthy to be classed with honey.—I am, dear sir, yours respectfully,

*Fareham, Hants, Jan.* 17, 1862. Wm. Bartholomew.

[Caramel has been proposed, and, we believe, tried, before, as a preservative; but not with sufficient care or perseverance to secure success. We remember Mr. Sebastian Davis speaking of its use, and remarking that from its hygrometric qualities, it was difficult to obtain complete dessication. We can testify, however, to the excellence of Mr. Bartholomew's plates, and, so far as we have seen, freedom from any tendency to tackiness. The complete change sugar undergoes in becoming caramel, removes it entirely, we think, from the honey or syrup category.—Ed.]

## SUBSTITUTES FOR YELLOW GLASS.

Dear Sir,—Substitutes for yellow glass in the dark room having been frequently noticed, allow me to suggest one, which, for durability and efficiency in arresting the actinic rays, has not been surpassed. It has had the test of *six years*, with a window facing the south, six feet by four. Sensitized plates are dried at mid-day within a few inches of the window, without the slightest injury to them. I use it myself, and have applied it in many instances without having had a single complaint of its insufficiency. The mode of preparing it is as follows:—Make a strong tincture of tumeric; say one ounce to four of alcohol, and with a large camel's-hair brush paint a sheet of *good filtering paper*, which may be laid on a sheet of glass for the purpose. When dry, it is ready to be applied to the dark room window, the squares of which must first be cleaned, and then varnished with mastic varnish; stained with stone ochre, half an ounce of stone ochre, ground fine in turpentine, to half a pint of varnish. Let the stained paper be a quarter of an inch larger than the glass, that it may lap upon the sash bars. Now varnish with the mastic and ochre over the paper; it will take a few days to dry. That completes the operation.—Your obedient servant,

H. R. Nichols.

Sir,—As many of your readers appear to have some difficulty in excluding the chemical rays from their operating rooms, I have much pleasure in making them acquainted, through your columns, with a method which I have always found perfectly successful in keeping my plates free from the least trace of fog, even with a strong beam of sunlight streaming through the window. It is as follows:—Take of Canadian balsam, turpentine, and powdered gamboge, in such portions that when mixed they may form a thick transparent varnish, about the consistence of treacle. Lay this over the glass with a brush by the aid of a gentle heat, and when dry, if the colour does not appear sufficiently intense, apply another coat. I am indebted for this formula to a painter of magic lantern-slides, who usesit for a transparent yellow, and I think for a dark room window, your readers will find it as valuable as it is simple.—I am, Sir, your obedient servant, Chemicus.

*Poole, Jan.* 13, 1862.

# Photographic Notes and Queries.

## Photographic Exchange Club.

Dear Sir,—I quite agree with all that your correspondent J. H., page 597 of the last volume, says respecting the Photographic Exchange Club, and think that the members should in every instance enclose one stamp beyond those required for the postage. If for nothing else, they must be wanted to purchase envelopes to enclose the return photographs. We certainly ought not to allow the gentlemen who so kindly give their time to suffer even in the smallest degree in pocket. I, for one, being able to speak personally of the secretary's courtesy and promptitude in answering inquiries, should be glad to be able, as J. H. says, to express my thanks in "a more tangible form than mere words."—I remain, yours truly,

*Waltham, Dec. 23rd*, 1861. W. Larchin.

## Sherry as a Preservative.

Dear Sir,—It struck me some time back that sherry wine contained all the requisites for a preservative coating. I accordingly coated a washed sensitive collodion film with some good strong sherry, dried, exposed, and developed with pyrogallic acid, and was delighted with the results; clean, sharp and purple toned negatives.

From the colour and brilliancy, I think it would do well for stereoscopic transparencies.—I am, yours respectfully, I. F.

P.S.—I have been trying the modification of the resin process proposed by a correspondont (I think H. Cooper), and have found it to answer perfectly.

## Photographic Exchange Club.

Dear Sir,—I have been much surprised at sundry gentlemen, members of this club, writing to me about the 15th, 17th, 18th of this month expressing surprise that they had not received their prints, which the rule, that all prints received in one month would be sent out next month, ought sufficiently to explain. As all the sorting, entering, arranging, correspondence, &c., has to be done at intervals of business or pleasure by me, I really must beg of them to wait till the month is out before they complain.—Yours sincerely, Frank Howard.

[We trust members enjoying the privileges of the Exchange Club will not render the duties of the Secretary more troublesome than is necessary by needless impatience or inattention to the rules.—Ed.]

## Talk in the Studio.

Photography on the Interior of Glass Vessels.—A patent has recently been obtained by Messrs. Hooman and Maliszewski for producing photographic pictures on the interior of glass and other vessels. The specification runs as follows:—"Our invention consists in printing the interior of any glass or other transparent vessel by the aid of photographic negatives, portraits, landscapes, views, pictures, arms, devices, or ornaments. To this end we take one or more ordinary photographic negatives of the portrait, landscape, view, picture, arms, device, or ornament intended to be printed on the interior of the glass or other transparent vessel upon a pliable substance, such as waxed paper, or mica, or any other pliable and transparent material. We then fix such negative upon the exterior of that part of the glass or other transparent vessel wherein such portrait, landscape, view, picture, arms, device, or ornament is intended to be fixed, and by means of a mould made of gutta-percha or other flexible material completely covering the said glass, or other transparent vessel, with the exception of an aperture of the size of the negative wherein it is placed, the light being thus wholly excluded from all parts of such vessel. We then pour into such glass, or other transparent vessel, a quantity of collodion or other suitable material, and rendered sensitive to light, which we expose to the even light in such manner that the power of light shall act equally around and through the transparency of the vessel upon the sensitized substance fixed on the interior of such glass or other transparent vessel. We then develop and fix such portrait, landscape, view, picture, arms, device, or ornament so produced by the ordinary process of photographing. When dry, we back the interior of such glass or other transparent vessel with oil colours in imitation of marble, alabaster, wood, or any other fancy decoration, by which means the portrait, landscape, view, picture, arms, device, or ornament is rendered permanent, and thus protected on the inside thereof by such body of oil paint, and on the outside it is protected by the glass or other transparent vessel."

Photographic Exchange Club.—One of our readers is desirous of asking the producer of a 9+7 picture of Chelsea New Bridge, by the Fothergill process, and received in exchange from the Photographic Exchange Club, if he will kindly state how he secures such intensity in his skies, and whether he *thoroughly* washes the plate before albumenizing, or not?

The Commercial Aspect of Photography in America.—*Humphrey's Journal*, copying a paragraph from our columns on the commercial position of photography in this country, adds:—"And here in New York we can instance several examples of parties who have taken much money in the business, but they are generally men who spend all they make, and run in debt for a good deal more! We know of but three operators in all New York or Brooklyn who may be said to have laid up money in the business. A large proportion of the operators in the country get a bare living at the practice of the art. Taken as a whole, we do not think photography can be said to be a money-making business."

Stereo-Exchange Club.—Mr. Clifford, of Hobart Town, writing in reference to the Stereo-Exchange Club, says:—I have, eight or nine months since, sent nine prints to Mr. Stafford, North Shields, and, by same mail, nine to Mr. G. B. Shepherd, Hythe. I have never got an answer, and from the circumstance, I suspect they have never been received; and I fear the same fate has been the case with some or all the others, and am very desirous of disabusing the mind of any of the gentlemen who might think I had neglected to return mine for theirs'. I have always sent them mounted by book-post; and some I sent to France in the same way have been acknowledged.

## To Correspondents.

Preliminary Coating with Albumen.—In the article on this subject in our last, some obscurity arises from a misprint in Mr. McNab's letter. Towards the close of the second paragraph, for "I used a bath for positives and negatives," read "I used it both for positives and negatives." In the last line but one of the last paragraph but two of the same letter, read "impaired," instead of "improved."

Truro.—Your print has been too feeble, and slightly fogged, before intensifying. It is very important to begin with clean shadows. In intensifying with bichloride of mercury, it is rarely necessary to flood the plate with it more than once; two or three applications of the iodide solution will give additional intensity. 2. In intensifying with pyro and silver, it is immaterial whether the solution be kept floating on the plate, or is poured on and off. It is desirable to keep it in motion, and if additional intensity be desired in any especial place, it may be obtained by repeatedly pouring on the solution at that spot. So far as we can judge from the print enclosed, your difficulty arises not from the intensifying process, but from having the image too feeble to begin with. This may result from the condition of your bath, or from the collodion. If from the bath, it is probably caused by the presence of too much nitric acid. If that be the case, neutralize it, either with oxide of silver, or with carbonate of soda. Then try a plate, and, if necessary, add either acetic acid or dilute nitric acid by a drop at a time, until it works clean. If the fault be in the collodion, procure another sample of intense negative collodion, and add a little to that you now use. This will probably be your simplest method of obtaining a more brilliant image to commence with; you will then find the intensifying give you less trouble. You are lighting your sitters too much from the front.

M. D.—When the prints turn red in the hypo bath, it is primarily from some fault in the preparation of the paper. It may be, to some extent, obviated when the tendency is observed, by toning much deeper than appears necessary. Deficiency of salt in the original preparation of the paper is a common cause of the reddening in the hypo.

H. H. H.—Statements in catalogues are not always safe guides as to the amount of field covered by lenses, the best makers generally slightly understating, rather than over-stating the power of the lenses they make. The lens described as covering 4×3, would be described by many as covering a much larger field. 2 Focal lengths being equal, the lens of large aperture will be quicker in action. 3. We should give the preference to the first mentioned maker. 4. A glass room, 20 feet in length, would not be long enough for producing card pictures with a lens of 12 inches focus. 5. A swing-back is a great advantage in a portrait camera, but it is not absolutely essential.

Hugh Bellas, Jun.—The rules of the Amateur Photographic Society will be found in the advertising pages of the Photographic News Almanac; or they may be obtained of Messrs. McLean and Melhuish, Haymarket.

Tyro.—The lens of shortest focus to cover a 12×10 plate, and give "upright perpendiculars," or absolute freedom from distortion, is the triple, by maker No. 1 in your list.

Hawke.—We are much pleased with the charming little card portrait. As a specimen of photography, it is exceedingly perfect, and a very agreeable picture withal. The only thing we would alter is the balustrade, which is rather too light in colour; it would have contributed to more perfect harmony if it were a little lower in colour. The general arrangement, the exquisite definition, the delicacy, brilliancy, and tone, are all highly satisfactory. The three prints subsequently received are also equally good; but be careful to keep the accessories subdued. We should be exceedingly glad to have a statement of your process throughout, as it is always desirable to have the precise details of a method giving such fine results.

A Distressed Photographer exposed a plate by the Rev. J. Lawson Sisson's gum process for five minutes, and on developing obtained no sign of a picture. He then exposed over 50 minutes, and obtained universal reduction. We fear he will often be a "distressed photographer," if, in his experiments, he leaps from 5 to 50 without intermediate steps. To have tried 10 minutes when 5 were insufficient would have been a long stride. But he states he developed with iron 14 grains to the ounce; he says nothing of silver: did he add any? If not that may account for obtaining no picture with the first exposure. The specimen enclosed appears to be an illustration of complete and universal reduction from over exposure. We cannot even guess at the cause of the discolouration of the print marked No. 1 without knowing its history. Some chemical action has taken place; but we have never seen a similar result. We have not tried Perry's collodion, but have heard it well spoken of. Great care to have the film perfectly set before immersion in the bath, and the use of perfectly clean and dry plates are the surest safeguards against losing films.

Ada.—We are a little puzzled as to what you require, as you ask for a formula for a developer to give fine-toned positives, from which we infer that you refer to collodion positives; but immediately afterwards you refer to some of Mayall's paper portraits as illustrations of the tone you require. If you require fine toned collodion positives we recommend you to use the protonitrate developer given in the article on positives in another page. You will find much information on this subject and on toning prints in the Photographic News Almanac.

J. Burns.—The No. 1 lens regarding which you enquire, will cover a quarter plate, and the No. 2 a five by four plate, or a little more. For card portraits the sitter will require to be placed about 11 feet or 12 feet from the camera with the No. 1, and about 18 feet with the No. 2. As each of them have a very flat field, either may be used with the solar camera conveniently. You may rely on receiving every attention, and a lens of undoubted excellence on applying direct to the maker; but we cannot undertake commissions to manage any commercial transactions.

S. Clifford (Hobart Town)—Before you receive this you will have seen the new arrangements of the Photographic Exchange Club. If you forward your pictures for exchange and the requisite stamps to cover their return to Mr. Howard, the Secretary, you will duly receive the exchanges. The specimens received are very interesting.

F. L.—The alkaline gold toning bath may be used with plain paper; but care is requisite to avoid over toning, and the production of a cold slaty hue.

J. K. M.—The preparation of Ponting's collodion is a trade secret. It has all the characteristics of a cadmium collodion.

J. W.—The stains appear to have been caused by the splashing of silver solution, caused by pushing down the slide with a jerk.

R. G.—The interiors are scarcely up to the mark. The lens does not appear to have been suitable, as the definition is very imperfect, the chandelier being little more than a blurred mass. No. 1 is the best. We recommend you to procure some of Wilson's interiors as specimens of what may be obtained: especially those of Gloucester and Exeter Cathedrals, where the depth of definition is very perfect.

E. E. L.—Your samples of coloured paper shall be duly examined and reported on next week. Your suggestion regarding albumenized plates might be useful; have you tried it?

E. F.—A sheet of salted paper floated for six minutes on a thirty-grain solution of silver would not be coated with the same proportions of nitrate of silver and chloride of silver, as if it were floated three minutes on a sixty-grain solution. The same amount of chloride may be formed, but the excess of nitrate will be less.

W. Werner., G. P., H. R. N., and several other correspondents in our next.

THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 178.—January 31, 1862.

## MEALY AND IRREGULAR TONING.

The results of a good deal of experience during the last few weeks, as derived from our correspondents, and opportunities of personal inquiry, indicate that the use of a bath of acetate of soda, as a preliminary to toning, has to a considerable extent removed the printer's *bête noire* of mealiness, the testimony of the majority being to the effect, that this method is, as its originator styled it, "a cure" for irregular toning.

It is important to inquire, however, and, if possible, ascertain what is the cause of mealiness, and why the bath of acetate of soda, or other methods which have been proposed, remove the tendency. The suggested causes of mealiness are singularly varied and contradictory. Many believe it is the fault of the paper, but some believe it is caused by the paper being too thick; whilst others only meet with the trouble when the paper is thin. Some attribute the fault solely to bad albumenizing, others believe it to be due to imperfect negatives; some find its origin in an acid silver bath, and some in a weak silver bath; some in the use of acid chloride of gold, and others in the excessive use of carbonate of soda in the toning bath; some to superabundant washing of the print between removing from the pressure frame and toning; some to the use of water containing substances forming insoluble salts of silver, and others to the want of washing. All these causes have been suggested in discussions, or in letters, within the last few weeks, and it is probable that all or many of them contribute more or less to the result, which, we think, is not, however, entirely dependant upon any one cause.

There can be no question that this trouble of mealiness is one of the concomitants of the alkaline toning system. It was unknown under the old hypo *regime*. It would be manifestly unfair to assume that, co-incident with the use of the alkaline toning bath, manufacturers and albumenizers combined to produce a worse paper, and a more careless method of preparing. Yet the fact that every now and then samples of paper are obtained which have no tendency to this defect, and other samples which have excessive tendency, would seem to point to the paper as the origin of the evil. To meet this view, however, comes the fact that the same sample of paper will produce perfect results with a brilliant negative, and the most mealy results with a thin or fogged one; or will, with a certain line of treatment between printing and toning, give mottled irregular results, and with another course of treatment will yield pictures as satisfactory as can be desired.

The most plausible method of explaining these discrepancies was given by Mr. Moens at a recent meeting of the North London Photographic Association, in a paper which will be found in another page. Mr. Moens attributes the tendency to mealiness to the formation of insoluble salts of silver—chiefly the chloride—in the texture of the paper. The washing waters containing chlorides, the free nitrate of silver in the pores of the paper is partly washed away and partly changed into chloride of silver, which is imprisoned in the paper in a mottled and uneven form. Where there is this excess of silver, he says, "the print is speedily toned, but the rest of the print takes a far longer time, so that you have two toning processes at work: the first one is carried on until the latter is completed, thereby you get two results, which constitutes the evil complained of." A variety of reasons in support of this view are added. For instance, in the old process where toning and fixing are effected in one bath, the chloride being dissolved out before toning begins, mealiness never occurs. It rarely appears when water containing nothing which forms an inorganic salt of silver is used for washing; it rarely occurs if the print be toned without washing, and is generally worst in rough, soft, porous papers; and so on with other reasons.

This view of the case appears in many respects reasonable: it is certainly borne out by many of the facts of the case, and is in accordance with a view we had formed of the matter. But it is, nevertheless, open to some objections, and leaves certain points still unexplained. For instance, if the mere formation and imprisonment in the pores of the paper of an insoluble salt of silver were the cause of mealiness, the use of a bath of acetate of soda, forming in the pores of the paper an insoluble acetate of silver, ought to cause, rather than cure, this defect.

But the chief difficulty involved in this view arises from an assumption it involves. It necessarily implies that the aggregation in certain parts of the print of excess of *unreduced* chloride of silver, causes more energetic toning in those parts. The exact nature of the process of toning is not well understood; but this, if not opposed to what *is* known, is at least an unrecognized action of unreduced chloride of silver. Moreover, if increased toning action, more energetic reduction of the gold, take place on parts where unreduced chloride of silver is present, it would be of little service, as the chloride being necessarily dissolved in the hypo, the gold reduced upon it would also disappear. So far as we understand the process of toning, it is only upon those salts of silver which have been reduced by light, and which form the image, that the deposit of gold is effected, and the more complete the reduction of the salts of silver, the more perfect is the toning action of the gold bath.

That mealiness arises from the existence side by side throughout the print, of two different salts of silver in different stages of reduction, colouring under the action of the toning bath with different degrees of energy, we think there is no doubt. The colour of albuminate of silver when reduced by light is always inclined to a reddish brown; the colour of chloride of silver when so reduced is a greyish or bluish black. The latter has a tendency when toning to assume slaty hues; the former passes with difficulty beyond a purple brown; and when, from the proportions in which these salts are mixed, or when from some imperfect combination of them, they lay in particles side by side; or when from the uneven texture of the paper they are absorbed in uneven or irregular proportions, the natural effect is a mottled and irregular colour. If we had albuminate of silver alone, we should have no mealiness, but we should have red prints; when we have chloride of silver alone, we have no mealiness, such a result never being produced in plain paper prints. When the print is fixed before toning, we have no mealiness, partly it may be because there is nothing left in the print but the perfectly reduced silver, all the unaltered chloride, and all the *partially* reduced chloride being removed by the hypo, and partly because in such case much of the toning is probably due to sulphur, which is not so discriminating in its action as gold.

There are several suggestions then, which will tend, we believe, to the prevention of this irregular reduction of both silver and gold, which causes mealiness. In the first place, as regards the paper and its preparation, the use of a fine paper with a hard surface and even texture, which will, to a large extent, prevent irregular absorption of the solution of salt and albumen. In preparing it, the use of a very dilute albumen solution, so as to form almost exclusively chloride of silver when excited; or on the other hand, if a highly albumenized surface be desired, the use of a minimum proportion of salt, which will not only enter into more intimate combination with the albumen, and will result in the formation of a preponderance of albuminate of silver, which will give very vigorous results, but will rarely tone beyond a purple brown. Whatever the quality of the paper, and its preparation, care should be used to secure as perfect reduction in printing, by the use of negatives, which however soft and delicate, have clean, brilliant shadows, and by the use of a strong silver bath, excess of nitrate of silver aiding reduction.

When the tendency to mealiness is present from any of the causes we have named, it appears quite clear, from a variety of evidence, that the presence of insoluble inorganic salts of silver increases that tendency, and that the conversion of the free nitrate into an organic salt of silver materially aids in removing it. Why this is the case is not so clear. In the absence of a better theory, we offer one or two suggestions. The tendency to mealiness is doubtless existing in the print when it comes from the printing frame, although not always very apparent then. Those parts of the print consisting of particles of reduced chloride of silver always tone readily; but those consisting of albuminate of silver, tardily. The presence of unreduced chloride of silver appears to retard still further the reduction of gold upon the albuminate. On the other hand, organic salts have a tendency to aid in the reduction of chloride of gold, and probably thus aid the deposit upon the organic salt of silver, enabling these particles to keep pace in toning with those of chloride, so as to acquire the desired colour before the remainder have become slaty. This is of course but a crude suggestion on an imperfectly understood subject. The practice is after all the important question. It is difficult within the limits of a short article to give all the data in the shape of evidence from competent persons, and from our own experiments; but we feel certain that the hints we have given as to prevention will be found efficient; and where prevention is impossible, the conversion of the free silver into an organic, in preference to an inorganic salt, will be found the nearest approximation to a cure.

## PHOTOGRAPHIC ALLOTMENTS AT THE EXHIBITION.

The allotments of space in the photographic department of the forthcoming International Exhibition are by this time, we believe, in the hands of photographers. The conditions for the guidance of contributors, which are few, simple, and reasonable, are as follows:—

"Conditions.

"1. All plain photographs must be framed and glazed in plain ¾-inch bead frames, and no other description of frame, and no passe-partouts will be admitted. The margin must be kept under moderate limits, not exceeding for large pictures 2½ inches, and for those under 8 by 6 inches 1½ inches. If desired, several photographs may be exhibited in one frame.

"2. No 'touched' photograps will be admitted.

"3. All coloured photographs must be framed and glazed with a careful regard to economy of space, or they will not be exhibited.

"4. All photographs must be numbered, and accompanied with a statement giving the name of the photographer, subject of the picture, and the process employed."

The only condition upon which any question can arise, is that referring to "touching"; and here it evident alarge discretionary power must be left in the hands of the committee. That photographs entirely "worked up in black and white," should be excluded, is manifestly right, and that pictures largely indebted to the improvements of the pencil should be inadmissible, where space is so precious, will be regarded as reasonable by every one. The touching out of a minor and accidental spot or scratch in either negative or positive will not, we believe, be construed into "touching" by the gentlemen to whom the supervision is entrusted. The difficulty will be chiefly experienced in regard to the question of entirely or partially stopping or masking out skies, and the practice of other "dodges" in printing for the purpose of concealing defects, or adding real or imaginary beauties. Intending contributors are warned, however, in the forms containing their allotments, that "All photographs, both plain and coloured, intended for exhibition, will be submitted to the consideration of the Committee, and will have to be delivered at the Exhibition Building, South Kensington, not later than the 31st day of March, 1862."

The "consideration of the Committee" will doubtless be largely influenced by the character of the pictures submitted to them. We must confess that we should feel sorry if, in the rigid enforcement of the rule, it were found necessary to regard as "touched" some of the skilfully managed skies of Mudd, Bedford, and others.

The limited space at their disposal, will, however, compel the committee to be more inexorably rigid in their exclusiveness than would be otherwise necessary. The total hanging space is three thousand feet, and much of that will be of course too high and too low to be of the greatest value. The room is seventy feet long by fifty-three feet wide; the width being reduced in part of the room by a passage to the educational department. The ground space for apparatus, &c., is about five hundred feet. The position will be, we believe, immediately over the entrance to the building.

The forms accompanying the allotment have to be filled in, signed, and returned to the secretary of the Exhibition within ten days of their date, upon penalty of forfeiting the allotment. These forms are four. The first is an undertaking to fill the allotment and conform to all the regulations that may be laid down by Her Majesty's Commissioners. The second form relates to the nomination of jurors. In this three names are to be proposed, so that from the persons so nominated the Commissioners may select three members of the jury in that department. It will be obvious that in addition to all other fitness for the office, the gentlemen so proposed should not be exhibitors, as any exhibitor being also a juror, would be manifestly disqualified for the reception of a prize. It would be a positive injury to an exhibitor, therefore, to appoint him as a juror, and thus destroy his chance of the reward of successful competition.

The third and fourth forms relate to the catalogues. In the shilling catalogue the name, address, and a brief list of contributions will be inserted without charge. In the illustrated catalogue all insertions will be charged as advertisements, the price being £5 per page, or £3 per half page.

From the date at which it is necessary to forward contributions to South Kensington, it will be seen that there are still two clear months for preparation and arrangement. At some seasons of the year two months would have been very valuable; at present, however, they will serve simply to prepare and arrange pictures already in existence, fresh productions at the present season being of course out of question.

We have received, during the week, several letters on the subject of the allotments. Some from disappointed applicants whose claims have been rejected, and some from fortunate allottees who fear they will be unprovided with pictures in time. Regarding the former, it was, as we have before said, impossible to avoid disappointment to many. It is possible that in some cases injustice may be done; but we feel assured that such injustice is in no case intentional. The space is very limited, and the applications very extensive: many must be curtailed; some entirely rejected. Of these may be some whose pictures are highly meritorious, and whose contributions would have graced the Exhibition. But it is impossible for the Committee, however extended their information, and however careful their discrimination, to be familiar with the exact value of all the claims made. They can only be guided by general principles, and cannot, in all cases, be acquainted with individual merits. Those who are unfortunately amongst the rejected applicants, must, with as much patience as they can command, await the next chance. We fear the time is now past for a certain remedy.

Those gentlemen who have received allotments and are unprepared or uncertain as to their facilities for worthily filling them, should, without a moment's delay, inform the Committee of their inability. We earnestly conjure them to do this. In such a course lies the only hope, which we can see, for those now suffering the mortification of rejection. If a number of allotments be returned upon the hands of the Committee it will enable them to reconsider the most urgent and important of those claims which they have been compelled, however unwillingly, to ignore. Time is now of the greatest moment, and not an hour should be lost in resigning allotments which will not be required.

## Scientific Gossip.

SPECTRUM ANALYSIS—THEORY OF THE CONSTITUTION OF THE SUN—TRANSPARENCY OF GOLD—COMPARISON OF COLOUR—ESTIMATION OF COLOUR ON THE MOON'S SURFACE—EXAMINATION OF COLOURED PAPER IN THE SPECTROSCOPE.

THE subject of spectrum analysis is still affording grounds for much scientific debate. It may be remembered that we have on more than one occasion pointed out that there were many reasons, experimental as well as theoretical, for concluding that the sweeping explanation of the cause of Frauenhofer's lines given by the German savans was, to say the least, open to great doubts. This opinion is now gradually gaining ground amongst scientific men. The Editor of the *Chemical News* has taken the same view as ourselves, and the late meeting of the Pharmaceutical Society, Dr. W. A. Miller, in his lecture on this subject, urged the necessity of still considering the views of Kirchhoff and Bunsen as theoretical, there being many points which presented anomalous features. Some spectral lines, he said, were due to the incandescent metals, but others, undoubtedly, belonged to the atmosphere or to the different gases in which the ignition of the metal took place. The rise of temperature, too, evoked different lines from the same substance. Chloride of lithium, in a Bunsen burner, gives a single crimson ray; in the hotter flame of hydrogen an additional orange ray appears; whilst the oxyhydrogen jet, or the voltaic arc, brings out a broad, brilliant blue band in addition: the same takes place with sodium and other metals. Fascinating as the German theory is, it must be remembered that it is still upon trial, and that it does not yet explain the facts known respecting the vapours of hydrogen, mercury, chlorine, bromine, sodium, or nitrogen. It was expected that spectral observations on the corona seen during the late solar eclipse on the 31st of December last would throw considerable light upon this obscure point. Up to the present moment, however, we have not heard what results were obtained. It will be remembered by our readers that, according to Kirchhoff's theory, that the sun consists of a central solid or liquid incandescent mass surrounded by luminous metallic vapours, the partial opacity of which occasioned the black lines of the spectrum—according to this theory, the light from the corona should proceed entirely from this incandescent metallic vapour and that in consequence of there being no more highly illuminated body behind it, the ordinary black lines ought to come out bright and luminous. This, if observed, would be one of the most startling results of the day, and would conclusively prove the truth of this beautiful theory, whilst the non-observance of such a reversal of the Frauenhofer lines would seriously militate against the hypothesis.

A very beautiful illustration of the transparency of the metal gold in thin films is given by Mr. Makins. As it is in some degree connected with subjects which we have recently discussed in these columns, we think a notice of it will be of some interest. Mr. Makins says that the transparency of gold may be elegantly demonstrated by taking some twenty grains of fine gold and fusing it in a convenient shallow vessel: this is to be removed from the furnace in a completely fluid state, when, if watched, it will be observed that just upon cooling, a crust of solid metal will suddenly form, through which the light of the internal red-hot mass appears of a beautiful brilliant green colour.

In the last number of the *Monthly Notices* of the Astronomical Society, Mr. Birt describes an instrument for the comparison of colours. He has for a long time been making observations on the moon, and has felt the want of some instrument by which he could give fixed values to the determinations of the extent of changes which portions of the moon's surface undergo in respect to colour. This he has at last accomplished in the following way:—the apparatus consists of a rectangular chamber having a circular opening, across which traverses a slide containing discs of coloured glass. The slide is moved by rack-work, so that any of the discs may be rendered coincident with the opening. White paper, or some other suitable reflecting surface, receives the light from the flame of a lantern through a condensing lens, and forms the means of illumination. The observer, having his telescope adjusted, brings the spot—Plato for instance—into the field; and then the illuminated discs of of the *homo-chromoscope* are successively brought in front of the circular opening, when the identity of colour, with the spot under observation is judged by the observer. We conceive that this plan cannot be very accurate, everything would depend upon the identity of the illumination from one night to another, and when this is obtained by the very crude means of a white surface illuminated by a lantern it is impossible to be sure of uniform results. A much more perfect method would be to employ the moon itself or a definite portion of the lunar disc as a source of light, and to apply the coloured glasses directly in front of the image of this at the focus of the eye-piece. By suitable arrangements of diaphragms with appropriate holes at the eye-piece and a good clock-work movement to the telescope there would be no difficulty in keeping in one corner of the field of view a standard circular spot of the moon's disc thrown slightly out of focus to render the light uniform, in front of which the coloured glasses could be readily brought up for comparison with any other portions of the lunar surface. The parts under chromatic examination should be surrounded by a circular diaphragm of the same size as the standard one, and the observations should, of course, be only made when the moon is at full, or very nearly so. In this manner really valuable and trustworthy information could be obtained respecting the different states of the moon's surface as regards colour.

A correspondent, E. E. L. has forwarded for examination in the spectroscope two pieces of French tracing-paper coloured; No. 1 with chrome yellow ground up with oil, and No. 2 with cadmium yellow, ground up as water-colour. Our correspondent states that he has found the latter colour more effectual in stopping out defects in negatives than any colour he has ever tried, and, therefore, suggests that it may prove equally useful as a substitute for yellow glass. Experiment does not, however, corroborate this suggestion. Both pieces of paper, when examined in the spectroscope by ordinary daylight, are seen to admit blue light in small quantity as well as abundance of green and lower rays, whilst when sunlight is employed the amount of active rays which are seen to come through are quite enough to injure a sensitive plate. The paper coloured with cadmium is the least *diactinic* of the two, as might have been expected from its dark colour; but even this admits too much blue light to allow it to be used with safety.

The same correspondent says that if colour applied to surfaces should prove unavailing, he would suggest the following substitute:—Coat a plate of glass with albumen containing some iodide and a good quantity of chloride; immerse it in a dish containing some strong silver solution; wash away the free nitrate to avoid the formation of crystals on the surface, and then expose to strong sunlight, till the whole of the silver is thoroughly reduced, then varnish with a good hard varnish. Our correspondent thinks "from albumen being more nonactinic than collodion, and the chloride being the most stable of the silver salts," that this would prove a good substitute for flashed glass. We scarcely think it would prove sufficiently impervious to the chemical rays to admit of its being employed in the manner suggested, but should be glad to receive a specimen so prepared, in order to submit it to an examination in the spectroscope.

## Notes and Jottings.

No. 12.

HONEY *v.* CARAMEL.

IN the last number of the NEWS Mr. Bartholomew, who has recently proposed caramel as a preservative for sensitized plates, takes objection to our remarks in a recent jotting, to the effect that the employment of this substance was but a slight modification of Mr. Shadbolt's honey process. Furthermore, we stated that the modification was not "new," inasmuch as it had been previously recommended; but to this term Mr. Bartholomew has given up all claim, stating only that it was "new" to him.

The only question really at issue is this:—Is the employment of caramel in lieu of honey a modification of Mr. Shadbolt's original preservative process; or does the substitution of the former for the latter substance involve principles of sufficient importance to entitle the "caramel process" to be termed "new?"

First of all let us consider the two compounds from a chemical point of view. Honey is composed of two kinds of sugar, namely crystallized and liquid sugar. In virgin honey there is little or none of the crystallized sort, but on exposure to air some short time, it is gradually formed. In this change the same causes are at work as when cane sugar is converted into grape sugar prior to the formation of alcohol. Crystallized honey is, in fact, "grape sugar," and the liquid portion is isomeric with cane sugar, caramel, golden syrup, &c.; and it will be found that the *sugar* of these several substances in each case contains $C_{24}H_{18}O_{18}$; with water in combination, excepting in the case of caramel.

Liquid honey, may, therefore, be considered chemically the same as cane-sugar, having, however, some sort of "ferment" mixed with it, causing a proneness to change into grape sugar. Solution of common sugar with the addition of a little albumen, gluten, or yeast, would very nearly resemble honey in its photographic properties.

Now, the formula of crystallized cane sugar is $C_{24}H_{18}O_{18} + 4HO$. By the action of heat the four equivalents of water are driven off, leaving caramel $C_{24}H_{18}O_{18}$. Caramel may thus be considered as *anhydrous cane-sugar*. The two substances are isomeric, forming like combinations.

Thus, the close alliance between liquid honey and cane-sugar, as also between caramel and cane-sugar, having been shown, it follows that the employment of one of these substances in lieu of another, does not involve any new principle of importance. Therefore, we consider that in whatever form sugar may be applied as a preservative, it will only be a modification of Mr. Shadbolt's process.

We have not tried caramel, but should consider it highly probable that intensity could be easily obtained as Mr. Bartholomew states; indeed, we should fear almost too easily. With honey we have never found a tendency for the production of thin negatives, but rather the contrary.

Mr. Bartholomew, in conclusion, says, "Many readers of the PHOTOGRAPHIC NEWS will, I fear, on perusing Mr. Hannaford's "Jottings" dismiss the processs in the summary way he has done, thinking it only worthy to be classed with honey." Now this really was not our purpose, for we consider that the best results can be produced by the honey process and its modifications. The use of honey is open to objections, chiefly in consequence of the reducing power it possesses; it is a very common occurrence in cases of long exposure to find a trace of the picture on taking the plate from the dark slide. This is one of the causes why plates thus preserved will not keep long, especially in warm weather. In using caramel we think it highly probable that these objections would not arise to so great an extent. At all events, so far from wishing to deter the readers of the NEWS from giving this modification a fair trial, we shall be glad to learn that it has been warmly taken up and tested.

We have further remarks, some of a suggestive nature, to make on this class of preservative formulæ, but must leave them for our next "Jotting." MICHAEL HANNAFORD.

## REMARKS UPON SOME OF THE APPARATUS EMPLOYED IN PHOTOGRAPHY.*

BY F. R. WINDOW.

CAMERAS.

Cameras are so naturally divided into two distinct classes, the studio camera, and the field camera, each having its individual requirements, often widely differing from the other, that they must of necessity be treated apart, almost as much as if they were separate instruments. A few remarks may be made that apply equally to both, and also to several other items of the apparatus destined for the use of the photographer.

It should never be forgotten, either by those who make and sell cameras, or by those who buy them, that the chief and pre-eminent type of their construction should be the fitness for producing perfect pictures with the least chance of failure. No consideration should ever be allowed to take precedence of this. It should never *yield* to the questions of expense, portability, size, weight, or other matters which affect the design of an instrument. All these points should, of course, be carefully weighed, but they should always be second to the consideration of efficiency.

I am induced to make these remarks because I think we have hitherto a little neglected this view of the matter, and that we have been rather inclined, in things photographic, to study convenience and cost too exclusively, and to the prejudice of efficiency. If this be so, we have no one to blame but ourselves—the buyers and users of apparatus. It would be unjust in the extreme to lay any blame upon manufacturers and dealers for supplying articles that their customers sought after and approved of. These "remarks" are intended principally to investigate whether or not our apparatus *is* the most suited for taking with certainty perfect pictures, or whether in some cases we have not somewhat sacrificed efficiency to other considerations. I will illustrate my meaning by one or two examples.

I lately purchased of one of our principal firms a portable stereoscopic camera, with four double backs, lens, and all the necessary accompaniments, which packed into an inconceivably small compass, and weighed but a trifle. The material was excellent, the workmanship perfect, the price moderate: but it was not a *cheap* article. I took it with me on a journey to the other side of the globe. Upon arriving at my destination, I found that the damp of the sea voyage had unfastened the glue of all the little slides, (there was not thickness of wood to allow of screws being used), and also some other portions of the instrument, and they were in pieces. The heat had curled some of them up, and rendered repair difficult. I repaired all damage, however, at last, and set to work. The cells for the glass plates were so shallow (to make the double backs as thin as possible) that two out of three of my plates could not go into them. The

* Continued from page 41.

sliding shutters of the backs were so close to the glasses that they often scratched them in the act of uncovering the plate; and everything was so slight and fragile that each day something was strained or otherwise out of order. Now this is a case in which I think we may say efficiency was sacrificed to portability. Had two or even three backs been put in the same space allowed for four, and perhaps an additional pound allowed to the total weight, all the many advantages of this pretty and clever design might have been retained with *perfect efficiency*.

We all of us have seen cheap work. I was asked once to prescribe for a camera (bought in Paris) that the owner found did not work well. It was a double-bodied half-plate camera, intended for portraits. I found that light entered freely at the top, between the inner and outer body, while at the bottom they fitted so tightly that motion could only be obtained with considerable force, and in jerks, which of course rendered focussing very difficult. The ground glass was of the coarsest description, and the back and the sliding shutter of the single plate-holder stuck, and were smeared with varnish. The material was walnut, and the whole was highly varnished, inside and out. I did not enquire the price, but here evidently was a case where efficiency was sacrificed to cheapness. I name this particular case intentionally, because the instrument was manufactured abroad; but do we never meet with similar instances at home?

I feel sure it will not be argued from these observations that I would deny the utility of portable cameras, or that I underrate the great amount of ingenuity and ability that have been displayed in the design of many which are familiar to my readers. I merely wish to point out that our main object being to obtain perfect pictures, nothing that can in any way militate against this should be allowed to affect the design. It is better to bring home two good pictures than eight indifferent ones.

Still less should I wish it to be inferred that I object to cheap apparatus for photography. It is in a great degree to the facility with which slender purses can obtain all that is necessary to take photographic pictures, that the art owes its great popularity, and its present advanced position; for if its practice, from reasons of expense, had been confined to a few, it would certainly not have made the wonderful progress that it has achieved in so few years after its birth. But I argue that cheapness should be attained in the proper way, without any sacrifice to the efficiency of the several instruments. Cheapness should be attained by the humbleness of the material, by the simplicity of types, and by moderation in the number of duplicate parts. If a brass-bound mahogany camera, with four double backs, and all the requisite adjuncts in proportion, of the first style of workmanship and design be beyond our means, it is better to have a pine or other cheap wood camera, of equally good workmanship and design, with *one* double back, than to have an instrument like the first, but cheaper from inferior workmanship and inferior design. Cheap cameras should be of simple nature; and those instruments which, from the complication of design or the multiplicity of parts, and the many uses to which they may be adapted, require much handwork in their construction, should not be produced in a cheap form.

(*To be continued.*)

## PROFESSOR TYNDALL'S LECTURES ON LIGHT.

Lecture i.—Dec. 26, 1861.

[These lectures were delivered at the Royal Institution, and were especially intended for a juvenile auditory. They contain, however, such a lucid enunciation of principles, that we have resolved to lay an abstract of them before our readers, giving especial prominence to those parts more peculiarly interesting to photographers.]

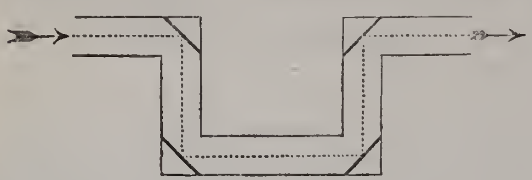
After a few words of introduction, in which it was stated that the present course were really to be juvenile lectures' and that those of mature years who attended them should consider themselves in the light of spectators only, the lecturer commenced by explaining that for the purposes of illustrating the phenomena to be described, it was necessary to have a very intense source of light. This he possessed in the electric lamp, by means of which a light almost as brilliant as the sun itself was able to be produced. This lamp consisted essentially of two pieces of coke, each in communication with the terminal wire of a powerful galvanic battery, and connected with apparatus for keeping the coke points at a proper distance apart. The whole was enclosed in a suitable box, furnished with a circular aperture opposite the coke points. The electric light was produced whenever the two coke poles were allowed to touch, and then separated a short distance. Owing to the atmosphere of the room being rather foggy, the path of the rays of light could be distinctly traced throughout its course.

Attention was drawn to the fact that the beams of light passed through the room in straight lines. The velocity with which light moves is enormous. It runs over a distance of 192,000 miles in a second, or 20 miles in the 1-10,000th part of a second; the time it takes to travel from the sun to the earth is $7\frac{1}{2}$ minutes, whereas it would take a cannon ball 15 years to perform the journey; an express train travelling night and day would also require three weeks to go round the earth, whilst light would perform the same distance in the interval between two puffs of the engine.

The speaker next proceeded to illustrate the manner in which the velocity of light was first measured by observations of the eclipses of Jupiter's satellites. The earth travelling round the sun once in 12 months, and being almost 100 millions of miles from that orb, if at one time of the year it is in that part of its orbit nearest to the planet Jupiter, it follows that six months later, it is the whole diameter of its orbit, or about 200 millions of miles further from Jupiter. Now, the proper time for the occurrence of the eclipses of Jupiter's satellites can be calculated to a fraction of a second, and it was soon observed that when the earth was at that point of its orbit furthest from Jupiter, the eclipses took place *fifteen minutes later* than they did when the earth was at the point of its orbit nearest to Jupiter. This was discovered to be owing to the light from the planet having 200 millions of miles more to travel before it got to the earth in the one case than in the other, and requiring fifteen minutes to perform the journey.

The subject of shadows was next considered. Since light moves in straight lines, it follows that if an object be placed in the path of a ray of light, a shadow of that object would be formed. If the opaque object were a sphere, and the source of light were a point, the shadow would be a sharply defined *divergent* cone; if, however, the source of light were larger than the sphere, the shadow would be a *convergent* cone. In the case also when the source of light was of sensible magnitude, the edge of the shadow would not be sharp, but would be surrounded by a lighter fringe, called a *penumbra*. This is owing to the light having sensible magnitude, so that what is shadow to one part of the light is not shadow to the other, there being only one space in the centre that is really perfect shadow. On account of the great size of the sun, in comparison to the earth or moon, the shadow cast by the latter orbs in space was shown to be a convergent cone, surrounded by a divergent penumbra: these were sometimes seen by astronomers, moving through space during eclipses.

The reflection of light was next treated of. When light strikes an unpolished surface, it is scattered irregularly in all directions; but when the surface is polished, the ray of light is regularly reflected. When the light struck a polished surface perpendicular to it, the ray was shown to be reflected back along the same path; but when it fell upon the polished surface obliquely, the reflected ray formed an equal angle with the perpendicular, to the incident ray. This was expressed by the law that *the angle of incidence is* *equal to the angle of reflection.* It was then shown experimentally that if a mirror furnished with an index perpendicular to its surface, was allowed to rotate horizontally whilst a beam of electric light was allowed to fall on its surface, the ray of reflected light was seen to travel across a graduated arc, with exactly twice the velocity of the perpendicular index. As a practical application of this law, a square wooden tube, with four rectangular elbows was exhibited, and its constructions explained. At the inside, in each elbow, a piece of looking glass was cemented across, in such a manner that the rays of light entering one end of the tube were reflected at right angles four separate times, first downwards, then horizontally, then upwards, and lastly out of the tube in the original direction. By this means, it was shown to



be possible to see objects through the tube, when opaque bodies, such as the hand or a piece of wood were interposed in the apparent course of the rays. This was the principle of the popular toy instrument used by showmen, who professed to enable people to see through their hands. A valuable application of the same law was then described; it consisted of a small tube, with a piece of looking glass placed diagonally across each end, so that riflemen supplied with these could observe anything passing on the other side of a parapet without endangering their lives by putting their heads over. This was said to have been very useful at the time of the Crimean war.

In the next place, attention was drawn to the repetition of the images of an object which was observed when it was placed between two plane mirrors. If the mirrors be parallel to each other, and a lighted candle be placed between them, there is seen a series of luminous images, diminishing in brightness to an indefinite length; but if the mirrors are inclined to one another at an angle, the images of any object placed between them will be seen ranged symmetrically round about in a circle, the centre of which is the point where the mirrors meet. The larger the angle enclosed between the mirrors, the fewer the images; and the smaller the angle, the larger the number of images. The number of images (with the object itself) may always be found by dividing 360°, or the number of degrees in a circle, by the number of degrees in the angle enclosed by the mirrors. This is the principle of the kaleidoscope, and also of the debusscope. The construction of the former instrument was explained, and its action illustrated, by means of the electric light. Respecting plane mirrors, there was one point which was not generally remembered by the public. The image seen in an ordinary looking-glass was shown to be a lateral inversion of the object. "For instance," continued the Professor, holding up a looking-glass before him, "I believe that my hair is really parted on my left hand, but if I look here, I see a person in this looking-glass with his hair parted to the right hand, and thus we are laterally inverted when we look into a looking glass. Photographers often have people complaining when they find themselves represented exactly as they are, because they quite forget that they do not know themselves really as they are; and when a photographer sets the parting of their hair on the proper side—the side on which other people see it, they are sometimes very angry with the photographer. They say he has misrepresented them, forgetting, in fact, that they have been using an instrument all their lives which inverts them in this lateral way."

In conclusion, the lecturer explained the different actions which concave and convex mirrors had upon a ray of light falling on them. Starting from the law of reflection of light from a plane reflector, it was shown that both a concave and a convex mirror might be regarded as a collection of an infinite number of plane reflectors set side by side, so as to form a curved figure; each of these little mirrors would reflect the incident ray of light at an angle equal to that at which it fell on the mirror, and if each of these mirrors were to be set at a certain angle, it would be easy to imagine that they might reflect all the rays of light to one point. This indeed was what took place in the case of a concave mirror; if parallel rays fell on a mirror of this sort, they would be reflected back again, and converged to a single point where they all crossed. This point was called the principal focus of the mirror. The action of a convex mirror on the incident rays of light, was shown to be exactly contrary to that of a concave mirror; convergent rays being rendered less convergent, parallel rays being rendered divergent, and divergent rays more divergent after reflection. These properties of concave and convex mirrors were beautifully illustrated by allowing the rays from the electric light to fall upon their surfaces, the path of the beam before and after reflection being shown in a most perfect manner by the haziness in the atmosphere of the room. By allowing the light to fall upon the mirrors, and then rotating them, it was rendered evident to all that in a concave mirror the principal focus was a real point in front of the mirror, where the reflected rays actually crossed each other: whereas in a convex mirror, the reflected rays did not actually intersect: hence the focus of the convex mirror was called an *imaginary* focus, in opposition to the real focus of the concave mirror.

## ON MEALINESS IN POSITIVE PRINTS.

BY W. J. C. MOENS.*

For some time past I have been convinced that the mealiness complained of in alkaline toning is almost entirely attributable to the way the prints are treated between taking them from the printing frames and immersing them in the gold toning bath. The usual treatment is to put the prints into two or three changes of water, in order to wash out the free nitrate of silver from them. Now, this water nearly always contains inorganic matter, which converts the nitrate into chloride of silver, therefore the free nitrate in the paper is partially removed and partially turned into chloride, and left in the body of the paper immediately under the albumen, which no washing can remove; and, besides this, the first and second waters are saturated with chloride, which settles in the open pores of the paper (this is the reason why a loose porous paper is more prone to the evil than a thin hard one). It is, therefore, evident that after washing in water containing inorganic matter the paper on which the picture is printed has two conditions, being, in fact, mottled with an uneven surface of chloride of silver.

Now, after washing the print, the next step is to immerse it in the gold bath, and what is the effect? Where there is an excess of silver it is speedily toned, but the rest of the print takes a far longer time, so that you have two toning processes at work—the first one is carried on till the latter is completed, thereby you get two results, which constitutes the evil complained of. It, of course, does not show in *full force* till its immersion in the hypo bath.

I will now bring forward a few facts to prove my theory:—

1. Mealiness is never experienced with plain paper, the albumenized surface being the great obstacle to the proper removal of *all* the excess of the silver salts.

2. It is never experienced in the old toning, when the chloride is dissolved before the toning takes place.

3. Or when you wash well with distilled water.

4. Very seldom when you do not wash the prints at all before toning.

5. Wherever there is an accidental excess of albumen, such as a streak running across the paper or the edge of a

* Read at the North London Photographic Association, on Jan. 22, 1862.

sheet where the drainings have accumulated and dried, and therefore there is an excess of chloride. These parts always tone quicker than the rest of the print.

6. It is not so prevalent in thin hard paper, when the the silver salts are removed more easily.

7. It never appears if the print be immersed in hypo, and the silver entirely removed before toning.

8. If the silver is converted into an even film of acetate, it never occurs according to the testimony of many given during the few last weeks.

9. When the silver is entirely reduced by exposure to a strong light it never occurs.

I repeat then it is absolutely necessary in alkaline toning to have an even surface of chloride of silver, or none; in either case you get rid of the complaint; but if you have a mottled and uneven surface of chloride, the print tones accordingly, and the result is useless.

## THE NEW IRON PRINTING PROCESS.

Dear Sir,—In the last number but one of your valuable journal my paper on "A new Iron Process for Photographic Printing" was criticised by Mr. Hannaford. That gentleman does not appear to be pleased at my using the word "new," the unfortunate monosyllable being in his opinion wholly misplaced. I am sure you will agree with me in saying that any process which has not been brought forward before and which possesses any features of novelty and interest, has an undoubted right to be styled "new." The absolute foundation may not be novel, but the method pursued in working out the original observation and applying it to practical purposes has everything to say to making the claim valid or otherwise. I now know that Döbereiner has already observed that light exerts a reducing influence over the peroxalate of iron, but I am wholly ignorant of any regular process for printing photographs, based on this reaction, having been proposed. If it were otherwise do you think it is very likely that I should have wasted my time and labour endeavouring to work out a process which had been proposed before? Although Mr. Hannaford does not say that any other process exists, depending on the reduction of peroxalate of iron to the state of protoxalate, yet he implies that I have adopted the same means for developing the picture as that used by Sir J. Herschel and Mr. Burnett. Now, though Sir J. Herschel and Mr. Burnett used nitrate of silver as a developer, I do not see it stated anywhere that *ammonio nitrate of silver* was used by either of them. The presence of the alkali you will at once perceive makes a very great difference in the final result, as not alone reduction takes place with much greater rapidity, but the oxalate of silver formed is immediately dissolved by the ammonia, the bath playing the double part of developer and fixer. Supposing the paper contains chlorides, the moment it comes in contact with the silver solution, chloride of silver will be formed; but the ammonia which is present in the developer is capable of dissolving a large quantity of chloride of silver, consequently where there is nothing to prevent solution taking place, we have every reason to believe that the chloride of silver will be dissolved. In conclusion I may mention that the whole process originated in a few accidental observations made while conducting some experiments with a far different object in view. Being an *amateur* photographer it occurred to me that the reactions which I had noticed might be made use of in a photographic sense. I immediately followed up the idea, and the result is the process which I have communicated. Such is a simple statement of facts, from which I shall leave your numerous readers to draw their own conclusions, and remain, faithfully yours,

Emerson J. Reynolds.

## PHOTOGRAPHIC EXHIBITION AT EDINBURGH.

[We extract the following notice of the exhibition in connection with the Photographic Society of Scotland from the *Photographic Journal.*]

From the wretched weather with which Scotland, and particularly its western districts, was visited in 1861, we were prepared to anticipate a scanty supply of contributions from that quarter, and to doubt whether these would possess their usual excellence. These anticipations, we are happy to say, have not been realized. Among our resident Scotch photographers the specimens sent equal the best contributions of former years, while Mudd, Dixon Piper, and Vernon Heath from England, and Mr. Maxwell Lyte from the Pyrenees, have filled the walls with specimens of their characteristic styles (for a difference of style among photographers is just as perceptible as a different touch among artists), which leave nothing, we think, to be desired. On the whole, we cannot hesitate to say that the exhibition of this year is at least equal to any of its predecessors. The number of photographs exhibited amounts to 635, many of these (such as the cartes de visite) embracing twelve in a frame. To the old list of exhibitors have been added some new ones of distinguished merit; and some of the productions of amateurs, who have only recently become votaries of this delightful art, maintain their places beside the performances of veterans and professionals.

In an exhibition of this kind the chief point of interest, so far at least as photographers are concerned, is the comparison of different processes and their results. Does wet collodion still maintain its pre-eminence? or are its finest effects emulated by dry collodion, with all its superior conveniences? If so, which of the dry processes appears to most advantage? or do they all appear in skilful hands to produce equally happy effects? Are the paper processes going out entirely? Do specimens of the simple Talbotype, with which in the outset such admirable artistic effects were produced, still fill a niche on the walls? or is that process becoming added to the catalogue *De rebus deperditis?* To some of these questions the Catalogue of the Exhibition of the Photographic Society of Scotland may help to afford an answer.

In point of numbers, wet collodion, it may easily be imagined, stands first. Nearly nineteen out of every twenty specimens are the result of that process; and when the names of Mr. Maxwell Lyte, Mr. Dixon Piper, of Ipswich, and Mr. Vernon Heath are numbered as among the most distinguished representatives of this school, it may be imagined that their productions can hardly be surpassed. But when we place beside them Mr. Mudd's exquisite specimens, produced by the collodio-albumen process, it is impossible to doubt that in all that gives beauty and character to a photograph—softness, aerial perspective extending to the most remote and vanishing distances, distinctness without harsh opposition of light and shadow in the delineation of reflections in water—in all, in short, which tests the merits of any one mode of manipulation, this form of the dry process is capable, at the least, of equalling the effects of wet collodion. Of the Fothergill process we see no specimen but one. Some specimens of the oxymel process are noticed; but plainly that mode of operating is on the decline, Of the tannin processes, there are several specimens, and of a very high order, such as the "Fountain at Holyrood" (469), by Kirkland; the "Last Stoops of Summer" (62), and "Loch Ranza, Arran" (101), by Annan. For fine aerial effect, the latter view can hardly be excelled. From the number of names and performances of considerable merit to which the word "tannin" is added in the catalogue, it is obvious that this process is coming into favour; and although among our own friends we have heard quite as much of failures as of successes, its capabilities in the hands of a skilful manipulator seem indisputable. Another of the dry processes (that of Mr. McNair) —the malt process—appears here to great advantage, though in the hands of an amateur who has only recently adopted it. The Rev. Mr. Drummond exhibits several specimens, some of an architectural character, such as Elgin Cathedral, and Urguhael Castle on Loch Ness, others of Highland scenery, which already leave little to be desired. We wish that our English friends could give a fuller trial to this exquisitely simple and, as these specimens prove, most efficient process, which has as yet been little practised beyond the borders.

In our hasty glance round the room we have not noticed a single calotype; and the wax process retains apparently but few adherents, though the specimens contributed by the secretary, Mr. Adam, and still more those of Mr. Harris, which are more devoted to general landscape, are highly are highly artistic, and show that it possesses great capabilities, along with great conveniences as to transport and manipulation.

The present rage for carte de visite portraits, of which some hundreds over the walls of the exhibition, and many of great beauty and artistic skill in arrangement, has obviously been unfavourable to the larger style of portraiture. Indeed, in Scotland, the demand for anything beyond the album size we understand to be exceedingly small. Much as we admire these charming little specimens, some of which exhibit a taste and beauty of composition, combined with a truth of characteristic portraiture, which will always render them most valuable recollections of friends living and dead, it is yet delightful to see how a great artist in portraiture, like Claudet, can give us portraits on a larger scale, which, with the assurance of likeness, combine the chiaroscuro and middle tint of the finest painting. Three portraits of ladies (58, 313, 331), and one of a gentleman (106), are of first rate excellence. Beside these beautiful portraits may be placed one by H. Hering (103), "Portrait of a Lady," which is perfect, with the exception that the figure does not appear to have sufficient support. If we do not refer to the performances of our own photographers, Moffat, Tunny, Dallas and others, it is not that their contributions are not up to the mark; for they are equal to the best of former years, and one in particular by Moffat, of the eminent Scotch artist, Mr. Harvey, struck us as of peculiar merit. And though the larger portraits of Messrs. McGlachan and Hill are best seen at some distance, their artistic disposition and fine effect of light and shadow are very striking. While on the subject, we may just notice two very fine specimens in this line by an amateur—(484) "the Wanderer," and (519) "Portrait of Mr. C. H. Inglis,"—both skilfully arranged and perfect as to manipulation.

In what may be called composition pictures, beyond mere *pièces de genre*, there is nothing important but Mr. Robinson's "Lady Shalott" (323); but it only proves to us that when a first rate photographic artist, with a strong feeling for art, can produce nothing more interesting, the range of this branch of photography is limited. With all its technical dexterity, it produces no impression.* For rustic and domestic groups, such as the Wood Scene of last year, these got-up scenes and artificial scaffolding may be available; for the higher department of art, we are satisfied they never will. We say this with the utmost respect to Mr. Robinson, for whose talent we have a high admiration.

It is in landscape, as might be expected, that the strength of the exhibition lies: and, as already said, collodion wet or dry, monopolizes the field. But here the difficulty of attempting to enumerate, among so many peculiarly fine and varied specimens of the art, becomes extreme; indeed, consistently with our limits, impossible. As a general feature, subjects of an architectural character are gradually becoming exchanged for rock, wood, water and aerial effect, as the resources of collodion are becoming more understood. Of the purely architectural class the finest specimen, we think, is (327) "Ancient House, Ipswich,"—"King's College Chapel" being less picturesque, and somewhat deformed by the leaning inward of the lines at the extremities. Two landscapes by the same hand (Dixon Piper)—(566) "Stone Bank and Foliage," and (578) "Brignall Bank"—form a charming pair, though in the opinion of some a smaller landscape, (545) "Junction of the Tees and the Greta," marked by a peculiar delicacy of atmospheric effect, is even superior. Mudd's contributions are distinguished by exquisite clearness, softness, and gradation of distance, with a remarkably pleasing tint—a point on which some otherwise very beautiful works by Kirkland are defective, the tone being too deep and too black. Among Mudd's we would particularly direct attention to:—(544) "Yewbarrow Crag," in which the characteristic peculiarities of the Lake Country are admirably rendered; (54) "On the Tay, Dunkeld," which has no defect save the ungraceful form of the hill in the background; (597) "Wood and Water, Perthshire;" (402) "Borrodale;" (324) "Eskdale, from Berker Fell"—a long view consisting of two portions very dexterously joined, where the eye ranges over a whole country, follows up long valleys, and mounts to distant hills, all soft yet well defined as in a bright summer day in nature itself. Of the numerous contributions of Mr. Maxwell Lyte, we are compelled to say that we find them somewhat monotonous in their grandeur; and are more and more led to the belief that the photographer will find better materials among the streams of Derbyshire, or the soft valleys of Devon, than among the passes of the Alps or the gorges of the Pyrenees. A proof of this, we think, will be found in the Alpine and Glacier Scenery of Bisson Frères. The first emotion on looking at them is that of surprise; but after examining a few, the result is weariness and disappointment. To some extent the same remark is applicable to the Pyrenean views of Mr. M. Lyte: they are too ambitious; more would be effected by selecting a more limited range. Yet in their own way they are admirable: for they certainly recall the spirit of the place; and to those who have once explored these valleys, and lakes, and mountain passes, it must be delightful to revive their old recollections by studying these photographs of Mr. Lyte. The two to which we should be disposed to award the palm would be (111) "Vallée d'Argelez de Bigorre" and (97) "Vallée d'Azure."

We scarcely like Mr. Vernon Heath's subjects so well as those of last year. The rich and wooded slopes of Endsleigh please us better than the Perthshire scenes which he has chiefly selected this year. An English cottage, with its overhanging eaves, its windows carried up into the roof, its porch, its little scrap of garden, and rustic gate, is a ready-made picture: not so the flat and almost windowless Scotch cottage, fronting a dirty road, and garnished only by a peat-stack or something worse. Several of Mr. Heath's efforts have this year been wasted on subjects of this kind, incapable, as we think, of photographic treatment.* We congratulate him when he makes his escape from these, or from comparatively formal ploughed fields and flat distances, and gives us two such exquisite specimens as Nos. 354 and 355, both marked "Burn, St. Fillans," or the one (358) entitled "Cottage Porch, Sherwood." What would not a sketcher in Scotland give for a few such cottage porches?

In the few lines that are left to us, we can only indicate at hazard a few pictures that have caught our attention, satisfied at the same time, that we must have overlooked many, perhaps equally deserving of notice, and regretting that neither time nor space enable us to do justice to all.

Among those by Mr. Bedford the finest is (411) "Rocks at Ilfracombe," almost equal to anything in the exhibition; (559) by Mr. Mitchell, jun., amateur, "Scene on the Eye Water;" (360) "St. John's College, Oxford, garden front;" (403) "Roadside on Isle of Wight," R. Gordon; (418) "On the Maclury, Strathallan," J. B. Stewart; (483) "In Hawthorne Grove, Phœnic Park;" (92) "The Dargle, Wicklow," by J. M. Brownrigg, (99) "View on the Don," Lamb (who, by the way, has this year tried the experiment of printing on unglazed paper, and, as we think, with manifest advantage to his prints); "Portrait" (273), H. Hering; (307) "Portrait of Miss M. Wilson," Tunny; (328) "The Bass," D. Campbell; (288) "Fountains Abbey, from the West," A. F. Adam (wax-paper); "Wooden Bridge, St. Fillans," Vernon Heath; (485, 486) "Studies of Trees," A. J. Harris (waxed paper).

Four very remarkable studies of skies are contributed by Mr. Kibble, of Glasgow, who some years since exhibited several specimens which might be fairly called instantaneous, since they bore to have been produced by an exposure of a mere fraction of a second. In three of these, it may be said, nothing is represented but sky; but in the fourth we have a combination of sky with foreground, and with a cart and some figures, which give life to the picture. But it is evident that the exposure, which was just enough for the sky, has been insufficient for the foreground; and we fear we must still submit to the drawback attending

* We cannot reproduce this remark without protesting against the statement. Whatever faults this picture of Mr. Robinson's may possess,—and we have before this alluded to some of them—we can aver that it *does* produce an impression. No picture excited greater interest at the Exhibition at Manchester where it was much admired. We have had opportunity of showing a copy to many persons connected with art as well as photography, and so far from "technical dexterity" being its chief merit, we have found photographers have found more fault with it than artists, many of whom have at first been struck with it as what they deemed a clever copy of a painting! We protest against these remarks, because nothing can be so repressive to the photographer striving to enlarge the range of his art than to be told, he is not successful, and "never will" be.—Ed. Photographic News.

* Those of our readers who visit the forthcoming International Exhibition will doubtless see Mr. Heath's scenes in Perthshire. As to the choice of subjects *chacun a son gout*; but we think some of these the best pictures the artist has exhibited, and a decided advance upon those of last year, perfect as many of them were. We should point to some of Mr. Heath's productions this year as the finest combinations of the most perfect delicacy combined with great brilliancy, which the art has produced.—Ed. Photographic News.

the introduction of skies, that sky and foreground, to be equally effective, must be printed from separate negatives.

We conclude this hasty notice by expressing our strong sense of the fairness and discretion with which the Hanging Committee have performed a delicate and difficult task.

## Proceedings of Societies.

### North London Photographic Association.

The usual monthly meeting of this association was held at Myddelton Hall, on the evening of Wednesday, January 22nd. In the absence of the Vice-President, Mr. C. J. Hughes occupied the chair.

The minutes of the previous meeting having been read and confirmed,

The Chairman called the attention of members to the presentation print for this year, a copy of which was on the table. It is a very fine photograph by Bedford, "A Study of Rocks, at Ilfracombe." The size is 12 in. by 10 in., and is an exquisite specimen of photography—delicate, brilliant, and well defined. Its photographic merit is, however, superior to its pictorial interest.

An ingenious instantaneous shutter, by Messrs. Horne and Thornthwaite, was exhibited. It consists of a frame, having caps to fit on to the hood of the lens; in the frame is a guillotine shutter, which, released by touching a spring, descends rapidly by its own weight. This shutter has an aperture in the middle: in its first position, before the spring is touched, its lower end covers the lens; when it has descended, the upper end covers the lens; the exposure taking place whilst the central aperture is passing over the lens.

Mr. Moens showed some samples of Messrs. Silver and Co.'s photographic vessels of Ebonite, in the manufacture of which, so far as neatness and convenience was concerned, a great improvement had been made. He remarked that it had been stated in a former meeting that ebonite was liable to fracture on falling to the ground. This was manifestly an error; ebonite was not at all liable to break under such circumstances, as the members might ascertain by trying. Probably the gentleman who had mentioned the circumstance was confounding ebonite with the old vulcanite, which resembled it, and might easily be broken.

Mr. G. Wharton Simpson remarked that he had kept seventy ounces of silver solution in an ebonite bath for about three months, without the slightest injurious result. He was satisfied that no injurious action was to be anticipated.

The Chairman then called attention to a letter received by the Secretary, who was addressed as "Sir J. Baruett." The letter was in German, and was accompanied by several photographs. He would read a literal translation which had been made. It was as follows:—

"Duchy Schleswig, Mehlbye in Angeln, 7 January, 1862.

"I take the liberty of forwarding, enclosed, to the Honourable Society of Photography of North London some specimens which are taken without chloride of silver, and without $SO^3$ natron [hyposulphite of soda, $NaO\ S_2O_2+Aq$, is meant, we presume], and which in consequence of their unchangeableness will enter into competition with other photographs.

"These photographs possess the following valuable preferences:—

"1. They remain unchangeable against light, air, dampness, and other matters to which they may be exposed.

"2. They are taken in the most simple manner.

"3. Several impressions may be taken quickly, should no essential re-touch be required, in less than an hour, of one and the same negative.

"4. Any thick satin letter paper may be used.

"The discovery was made by myself without the aid of Poitevin's method, and, I should think, is open to improvement, though based upon the most sure and simple manner of taking.

"My practical knowledge of photography is but of short duration, and, possibly, the representations of the negatives and copies may not satisfy the artists, a practical man would, no doubt, with my means of discovery at his disposal, obtain better results.

"The copies are left, as may be seen, without any artificial additions.

"Against some favourable offer the discovery is at the disposal of any photographical society.

"Begging your pardon for having addressed you in my mother tongue, as I cannot find a proper translator.—I remain, yours obediently, (Signed) "O. Kohnke,
Chemist by trade."

The specimens, which were portraits, were soft and full of gradation, being more pleasing than most of the pictures we have seen produced by the aid of salts of chromium. They have more the colour and appearance of gallate of iron pictures than carbon prints.

After some conversation on the subject it was resolved that the secretary should write to Herr Kohnke, asking for further particulars of the process, and in what way he desired the society to aid him?

Mr. G. Wharton Simpson, at the request of the Chairman, then gave the meeting some detailed information of the final determination regarding photography at the International Exhibition. The particulars appeared in an article on the subject last week.

After some conversation on the subject,

Mr. Moens read a paper "On Mealiness in Positive Prints" (see p. 54).

A desultory conversation on the subject ensued, in which a general opinion was expressed that mealiness rarely occurred where perfect reduction was secured in printing by the use of brilliant negatives.

The Chairman remarked that when, some time ago, he read a paper at that society on printing and toning, he brought some hundreds of specimens, all toned by the alkaline gold bath, and in none of which there was any trace of mealiness. They were all produced from vigorous negatives.

Mr. Hill met with mealiness in his prints, and they were all produced from strong negatives.

Mr. Simpson coincided with many of the remarks in Mr. Moens' paper. The mottled, irregular toning was, doubtless, due to two distinct tonings being in operation at once—one on the chloride of silver, which rapidly assumed a blue black, and the other on the albuminate, which remained more or less of a reddish brown tint. He referred to the practice of one of the first professional portraitists, who, in albumenizing his own paper, used a much less proportion of chloride than was customary; he never was troubled at all with mealiness, but his prints always retained the warm hues in toning.

The Chairman believed mealiness was mainly due to the use of paper with uneven texture and rough surface, which absorbed the albumen solution unequally, so that in minute hillocks all over the surface of the paper albumen was deposited, which hillocks, in toning, obstinately remained red, whilst the remainder was becoming slaty.

Mr. Hill rarely met with it in slightly albumenized paper.

The Chairman suggested that to test the efficiency of the means proposed for remedying this defect, a print should be cut down the middle, and one half treated with the proposed remedy, and the other half in the usual way, the halves when completed and brought side by side, would effectually illustrate the value of the remedy.

Mr. Moens had found it occurred when washing with water containing chlorides, &c., but not when using distilled water.

Mr. Foxlee has tried the use of distilled water, and had not found that it made any difference.

Mr. Shave asked if the same result were observed when printing on albumenized glass.

The Chairman said the operations were different. Albumenized glass was printed by development.

Mr. Simpson said that sun-printing on glass had been proposed, but never carried out, he believed.

Mr. Seeley had a sample of albumenized *Saxe* paper, which at first yielded him perfect results, but after keeping it a few months he could not get good prints from it.

Mr. Blanchard had found the best remedy was careful washing in water containing no salt.

Mr. Moens said the more perfect the washing the better, so long as the water did not contain any salt.

Mr. Foxlee had found slow toning the best remedy.

Mr. Blanchard had never met with it when using the toning bath quite hot. He had found the use of acetate of soda gave him entire freedom from it, but with the same bath his assistants somehow or other contrived to get more mealiness than ever. He used Canson's paper.

Mr. Moens had found no mealiness when the preliminary washing were in sea water.

The Chairman observed that if the formation of chloride of silver was the cause, that was surely the way to get it. He believed many operators immersed the print in the washing water. His plan was to float the print silver side down for about five minutes, when it first came from the pressure frame. The free silver, instead of being formed into an insoluble salt in the pores of the paper, was thus gradually soaked out, and precipitated into the dish.

Mr. Simpson suggested that the use of hot solutions prevented mealiness, and the use of weak solutions and slow toning, although it appeared paradoxical, might really be based on analogous principles. Slow toning was recommended, and was more or less efficient because it kept back the over-readiness of the particles of chloride of silver to tone, whilst the more horny albumen particles were getting permeated with the solution, and thus enabling both to keep pace with each other, preventing the chloride from over-toning until the albuminate could come up with it. A hot solution, on the other hand, rapidly permeated the horny albuminate without accelerating the toning on the chloride in an equal degree, and thus aided the production of a uniform colour.

After some further conversation the discussion terminated.

Some very good stereoscopic slides were exhibited by a member, from negatives taken on the dry plates of Dr. Hill Norris.

The usual votes of thanks terminated the proceedings.

## Correspondence.

### FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

*Paris, 29th January*, 1862.

A method of extracting the silver from old hypo baths is suggested by the Abbé Pujo. He remarks that every positive proof leaves a comparatively large proportion of its silver in the hyposulphite of soda solution. In fact, it may be admitted, in general, the white portions, the half tones, and the sky, from one half, at least, of the total surface of a photograph, from which it may be concluded that one half of its silver is given up to the fixing solution. Besides, even in the most intense blacks, the greater portion of the nitrate and albuminate of silver is not decomposed, and that these salts also pass into the hyposulphite solution. We may safely reckon that out of 1000 grains of silver (contained in 1500 grains of fused nitrate), employed in printing positives, more than 500 grains are left in the fixing solution; and, therefore, if the photographer can extract this unused silver without much trouble and expense, he will realize a saving of at least 50 per cent. in the cost of his positives.

To effect this desirable object, M. Pujo proposes the following simple process and method of treating hyposulphite baths.

Procure a glazed earthen jar capable of containing four or five gallons, in which collect all the old baths of hyposulphite of soda as they become useless. When it is desirable to extract the silver from them, add some hydrosulphate of ammonia, or a solution of sulphide of sodium, and stir the mixture thoroughly. The silver is immediately precipitated in the state of sulphide, and after a few hours of repose it settles at the bottom of the jar. Then put a small quantity of the supernatant liquid into a test tube, and add to it a few drops of the hydrosulphate; if it blackens it shows that a sufficient quantity of the hydrosulphate has not been added to the hypo solution, and a fresh quantity must be added, the mixture stirred again, and left till the precipitate is deposited. Then it must be tested again, and the operations repeated until no precipitate is formed in the supernatant liquid upon the addition of hydrosulphate. When all the sulphide of silver has collected at the bottom of the jar, the liquid is carefully decanted, and the jar filled with water, the precipitate well stirred so as to become washed, and again left to subside; the water is then decanted and added to the first decantation. This washing is then repeated four or five times in the same manner, but the washing-waters are thrown away.

The sulphide of silver collected is heated very strongly in a crucible, to drive off the moisture and the sulphur in excess, which arises from the presence of a polysulphide in the hydrosulphide, or even from decomposition of the hyposulphite.

We then take a quantity of chlorate of potassa equal in weight to the sulphide of silver obtained, and pulverise it finely in a mortar with 5 or 6 times its weight of chalk, and then add it to the sulphide; this intimate mixture of chlorate of potassa, chalk, and sulphide, is strongly heated in a crucible during 15 to 20 minutes. The mass resulting from this calcination is mixed with water. The chalk and sulphate of lime then formed remain in suspension for some time when the liquid has been stirred, while the silver, now in a granulated state, immediately falls to the bottom of the vessel. Then the metallic silver can be separated from all impurities by levigation.

The granulated silver is carefully collected, melted in a crucible and cast into ingots. This silver, which is quite pure, is then ready anew to run the circle of its numerous photographic metamorphoses.

There are one two precautions to be noted in this process, one of which is to carry on the operations away from the photographic laboratory, on account of the sulphurous vapours which arise upon precipitating the silver from the hypo solutions; the other is, that as the mixture of sulphide of silver and chlorate of potassa is explosive, the operator must not neglect to add the proper quantity of chalk, to avoid serious accidents.

### DRY PLATES WITHOUT PRESERVATIVE.

Sir,—In your recent article "On Dry Plates without Preservative," you have inadvertently fallen into an error in stating that I "invariably" use "albumen" as a foundation. My original point was, that pictures could be obtained on simply washed and dried collodion plates, equal, if not superior, to those obtained after the use of any preservative whatever. I stated further that it was difficult to keep the film on the plate without some foundation, and that I preferred albumen for this purpose without at all confining myself to this substance or to any other. Finding it difficult to convince some people that my pictures were due to the collodion, I, in December last, exhibited at the meeting of the North London Association, two plates, one prepared with the albumen foundation and the other without it. No appreciable difference was manifest in the two plates, *even in colour*.

I have to thank your correspondents, Messrs. Ward, Window, and Warner, for their corroboration of my statements, and I trust now that attention is fairly directed to the subject we shall soon be in possession of a collodion which shall adhere firmly and yet give us the required vigour of picture,

I believe that the first suggestion of dry collodion is due to Mr. Barnes, who in 1856 published a pamphlet on the subject. Mr. Barnes, however, used *camphor in his collodion*, one effect of which was to retard the drying, and which I have proved to be unnecessary.

Permit me once more then, sir, to state broadly as the result of my own experiments and practice, confirmed by that of others, that *no "preservative" medium whatever is required for dry collodion plates.*

Further than this, permit me to express the opinion that such preservatives merely modify the tone and intensity of the resulting picture when such picture comes unscathed and perfect out of the unnecessary ordeal.

Starting, therefore, from the simple washed collodion as a base, we have it in our power to modify all the canditions of the case, so as to suit our requirements, by introducing organic matter into the collodion.

If any difficulty is found with the film slipping from the plate, we can firmly fix it by using as a foundation a solution of india-rubber, a *very thin* solution of albumen, or by grinding the surface of the glass plate; but as I have before remarked, I believe it to be possible to obtain a collodion which shall need nothing of the kind.—I am, sir, yours obediently, W. Hislop.

*January 27th*, 1862.

[We understood that it was Mr. Hislop's regular practice to use the albumen coating, and that the specimen, without preliminary coating, shown at the North London meeting, and duly described in our report, was exceptional. It proved, however, as did the pictures of other correspondents forwarded to us, that the albumen was not necessary to the production of a perfect image. We are inclined to believe with Mr. Hislop that the production of a suitable collodion is all that is wanted to secure a simple, certain, and efficient dry collodion process without any preservative whatever.—Ed.]

### CARAMEL AS A PRESERVATIVE.

My Dear Sir,—Would you have the kindness to permit me to apply to Mr. Bartholomew for such details as may be necessary to be observed in order to secure an increased sensibility of Fothergill plates by a final application of caramel solution. It is true that during our experiments in connection with the South London Society, I reported trials made with melted sugar, and sugar converted into caramel.

I did not obtain, however, any satisfactory indications in this direction as to induce me to attach any importance thereto, and I met, moreover, with the oftentimes repeated annoyance of a moveable film, common to this and similar methods of manipulation. The latter difficulty would not, however, apply to the application of the solution to a Fothergill plate, and if, under such circumstances, a solution of caramel acts as "a *powerful accelerator*," the discovery may fairly be regarded as very valuable.

I have applied gallic acid solution to plates prepared according to the albumino-raisin process, but am somewhat doubtful whether the simple raisin extract solution is not to be preferred as a final wash similarly applied. In either instance, I obtain an increased facility and vigour of development, but certainly no material exaltation of sensibility.

As the members of the experimental committee of the South London Photographic Society have their attention still directed to the acceleration of exposure in connection with the practice of dry plate photography, they would be glad of the opportunity of fairly testing the proportionate extent of the action of caramel as an accelerator, provided Mr. Wm. Bartholomew would favour your readers with the necessary data. In the interim, the suggestion will be fairly and impartially tested upon the ordinary Fothergill plates, and the results recorded.

The absolute difference between caramel and honey as regards composition, chemical and general properties, and other characteristics, are too obvious to require more than a parting notice.

*If* your correspondent, Mr. Barthololomew, *can* show that a solution of caramel applied to a Fothergill plate acts as a *powerful accelerator*, he is justly entitled to the merit of having made an independent and valuable discovery.—Your's truly, T. Sebastian Davis.

*January 29th*, 1862.

## Photographic Notes and Queries.

### Intensifying with Iodide of Mercury.

Sir,—I forward for the use of the readers of your valuable pages, a method of intensifying which I have found very efficient, should you think it worth insertion.

I operate as follows:—After fixing, drying, and moistening the plate, I pour over a solution of iod. hydrarg., the strength being one part to seven of water. The film will change colour, first to a slaty grey, and then to a yellowish tint, when it must be well washed and treated with pyrogallic and silver, till the density required is obtained, which will be in a very few seconds. By the use of one part of the solution of iodide of mercury to three or four of water, and prolonging its action on the plate, dense yellow negatives may be obtained without the application of pyro and silver.

I prepare the solution of iod. hydrarg. as follows:—Take one ounce of a saturated solution of bichloride of mercury, and add drop by drop a saturated solution of iodide of potassium, shaking well till all the precipitate is dissolved; then to this add pure iodine in excess, well shaking the mixture, and using one part to seven of water, as stated above.

Should any of your readers try this, I shall be happy to hear the results.—I remain, Sir, yours obediently,

49, *King William Street*. A. L. Henderson.

### Mealy Toning.

Sir,—From experiments I have made I am convinced that mealiness in toning arises from want of sufficient alkali in the gold bath, a want which is proved by the recent recommendations of a preparatory bath of alkali—acetate of soda. The paper being washed after immersion in acetate of soda may contain alkali enough on entrance into the toning, but the quantity cannot be known with accuracy.

If a photograph be put into a simple bath of chloride of gold it will fade very much, and perhaps become mottled with red spots; now to make a good toning bath, the alkali—carbonate of soda for instance, must be added till that disposition to fade is reduced as much as possible, which is not always the case when the bath is neutral to test paper. The right plan to adopt after neutralizing is to place a slip of darkened paper in the bath, and observe the colour; if it become mealy, add carbonate of soda until the bath tones properly. This will be found a perfect remedy in most cases.—I remain, sir, yours respectfully, James Vincent Maginn.

*Manchester, January 27th*, 1862.

[The subject of mealy toning is so important that every suggestion which promises to get rid of it should receive attension. You are in error, however, in some of your surmises, Acetate of soda is not an alkali; although some samples have a slightly alkaline reaction. The action of the bath upon a piece of blackened paper would not always be a test, as mealiness rarely occurs when the reduction by light has been perfect.

### Methylated Spirit.

Dear Sir,—Will you please reply to the following queries in your column for correspondents:—

1st. Can I rectify a small quantity of spirit (alcohol) in a flask over a lamp, by connecting it with a flask in a receiver?

2nd. Do you find methylated spirit and ether answer in collodion as well as the pure kind?

3rd. I have some methylated alcohol that has been standing in a bottle for some time, and has deposited a quantity of fine muddy-looking precipitate. Is this usual with this kind of alcohol? On adding it to developers that had been previously filtered they become quite clouded. The bottle was new for the purpose, so, I suppose, was clean.

Your kind attention to these questions will oblige—Yours truly, An Old Subscriber.

*January*, 1862.

P.S.—Do you think a good ½-plate Lerebour's Lens would take a carte-de-visite portrait? it is about eight inches focus. Have you any idea what length of room such a lens would require for this purpose? I must apologize for asking so many questions at one time.

[1. By agitating alcohol with quick lime, and then distilling as you propose, you can rectify it; but unless you are familiar with such operations the process is not without danger. A simpler plan is to fill a perfectly clean bladder with the spirit, and suspend it in a warm place. The water will evaporate through the bladder, but not the spirit, and you will thus increase its strength.

2. The use of methylated solvents in collodion is a disputed question. We have used it largely without any evil results. If the most highly rectified samples be used, we believe that no difficulty will be experienced.

3. There should not be any such precipitate as you describe. We have never met with it. The turbidity of the developing solution will generally occur on adding methylated spirit, but no evil result will follow.

4. A good lens by the maker named, and of 8 inches focus, will produce good card pictures, but will probably be slower than a lens made expressly for such a purpose by our best English opticians. A lens of 8 inches *equivalent* focus would probably require a room about 20 ft., or from that to 25 ft., for producing card pictures.—Ed.]

## Talk in the Studio.

The Tannin Process.—We had the pleasure of inspecting, a day or two ago, a series of 10 by 8 stereo prints from tannin negatives, produced by Mr. Hurst, an amateur. Many of these were equal in all photographic qualities to anything we have seen produced in dry plate photography by any process. In some of them, containing white houses, dark foliage, and running water, each was rendered with perfect detail and gradation, free alike from monotony and chalkiness. The negatives themselves have just the desirable colour for satisfactory printing; their density is not obtained by piling on silver until opacity is secured, but by the non-actinic character of the deposit; thereby securing delicacy and crispness. Mr. Hurst always gives his glass a preliminary coat of gelatine. His collodion was a mixture of Powell's and Ponting's; the silver bath slightly acid with acetic acid; the washing conducted by changing the plates to three or four successive dishes of rain water; and the general strength of the tannin solution fifteen grains to the ounce. His golden rule is to give sufficient exposure; the stereo negatives having been exposed for various periods, of from three minutes to twenty; and one of the 10 by 8 negatives was exposed towards the decline of day for a full hour, with a lens of fourteen inches and a quarter inch stop.

Photographic Copyright in France.—The correctional tribunal of Paris has just decided that impressions obtained by means of photography are not to be considered works of art, and susceptible of being pirated, as the proofs given by photography are the result of a mere material operation. The tribunal also founded its judgment on the fact that M. Daguerre had formerly sold his process to the state, which intended that the public should enjoy the full benefit of it.

## To Correspondents.

*** The Fifth Volume (for 1861) of the Photographic News is now ready, neatly bound in cloth, price 15s. Covers for binding each of the Volumes, 1s. 6d. each. Reading Covers, to preserve the Numbers clean, 2s. each.

An Aspirant.—Marine glue is the best cement for fastening a ledge of glass to the bottom of a strip of glass for a dipper. 2. Acetic acid is better generally for an iron developer for negatives than citric acid, because a very small portion of citric acid with iron is apt to retard its action very much, and because the colour it gives inclines to blue, and is not sufficiently non-actinic with a thin negative.

John Crabtree.—Probably you make your developing solution with "hard" water, that is, water containing organic matter, which forms insoluble salts of silver. If the water contain chlorides for instance, or carbonate of lime, these on coming in contact with the silver on the plate, will form chloride or carbonate of silver, and cause the curdy appearance of which you speak We will consider your suggestion. It would doubtless be useful; but it is, we fear, impracticable in a commercial point of view.

Acetate.—See articles on Mealiness in the present number, and the discussion at the North London meeting. 1. The best plan is to keep all your prints of one day in a dark, dry place until you are ready to commence toning; then immerse them in the bath of acetate of soda, after which rinse and tone. 2 It is better to wash with cold water. 3. When a solution of ammonia is used previous to toning, the bath of acetate is not to be used, and *vice versa*.

A. Harding.—You will lose too much light by covering all your glass with white lead and turpentine. Blinds to shut out the sun when necessary, will be better, because you can remove them when the sun is not strong. 2. Gum is not a good substance with which to varnish a photograph, because it will readily absorb damp, and aid in injuring the picture. A suitable varnish, or a slight application of wax, will be better.

F. H. W.—Your slides are very interesting; their chief fault is a little under-exposure. Add a little bromide to your collodion, and develop with iron; you will then obtain more detail and softness, which is very desirable in snow scenes.

Sigma.—For most purposes we think the lenses of the two English opticians you name preferable to others, notwithstanding the higher price. In buying cheaper lenses, you may by chance get good ones, but with these makers you have certainty. 2. We prefer the maker you mark as B. 3. The instantaneous stereo lenses will answer your purpose. 4. Choose A or B decidedly in preference to C. 5. This question is not stated explicitly enough; we do not quite understand what you want. 6 The lenses mentioned by Mr. Hardwich in the passages referred to are the "aplanatic." It is a moot point, both amongst opticians and practical photographers, whether any advantage is gained in that form of single lens over the ordinary achromatic meniscus. We have never used them.

Susanna.—Marine glue is a good cement for fixing the glass in the dark slide for paper negatives. Shellac may be used, but it is not quite so good. A cement made of resin, beeswax, and powdered brick is also useful for such purposes. 2. The mottled discolouration in your print is due to imperfect fixation. The hypo has been too weak or too old, or the print has not been in long enough. The dirty yellow mottling is undissolved hyposulphite of silver, which has decomposed.

A Constant Reader.—To colour the hair in glass positives, powder colour of the right tint must be applied to the lights and half tones. If the picture is to be varnished, apply the colour first, using a tint a little more brilliant than the hair. For instance, for auburn hair, apply orange or "horizon" tint to the lights and half tones; then varnish, and the colour will be subdued to the natural tint.

Argent Nitros Pur.—Of the two landscape lenses named, we should prefer Ross's. You are correct, we believe, in supposing the other to be less perfect in definition The quick-acting lenses of the other maker you name, we know to be good; the larger lenses will do all that the stereo will do quite as well, and its own especial work besides. We believe there never was a better field for really able men in photography than there is at the present time. No better test can be found than the salaries of assistants, and, at the present moment, good operators, are commanding rates of remuneration twice or three times as large as was customary a few years ago.

A.—It is not necessary to wash the print before immersing it in the acetate of soda bath; but it is as well to rinse it before placing it in the toning bath.

M. A.—Your glass shall be examined and reported upon. Regarding collodions, No 1 is very good; for iron development the bromo-iodized samples of either No. 2 or 3 will probably be better suited. It is an error to suppose that the addition of a bromide ever makes a collodion slower. A simply iodized collodion will sometimes produce a picture which, although very much under-exposed, may please an uneducated taste, and so pass. The addition of a bromide to the same collodion would not permit a picture to be produced at all passable without sufficient exposure. These remarks refer to pyro development. With iron development the addition of a bromide, always, in our experience, materially accelerates, and produces more perfect results.

R. T.—A silver bath, which has been used for exciting paper, is altogether unsuitable for producing collodion positives; and it is very improbable that any doctoring would make it fit for that purpose. 2. Whenever carbonate of soda is added to a silver solution until precipitation ensues, it of course weakens the solution, seeing that the precipitate is carbonate of silver. It may be re-dissolved by adding minute doses of nitric acid, until it is just taken up.

A. K.—We are not aware that any work on the Fothergill process in tropical climates has been written by Mr. Tawse. An article on that subject, by that gentleman, appeared in the Society's *Journal* for November, and also on p. 566 of our last volume; but we know of nothing else. Probably, from the mode in which that article commenced, you are regarding it as a review of a work: that we think is a mistake.

R. C. R. B. (India).—Messrs. Le Page and Co. have sent out a large stock of the Photographic News Almanac to their British Library, Calcutta; you will be able therefore to procure a copy. 1. Larger pictures can be used in the reflecting stereoscope than can be used in the lenticular or refracting stereoscope: about whole plate is a good size. The same principles apply in taking the pictures for each. 2. In taking stereoscopic pictures with a single lens camera, it is simply necessary to move the camera a little laterally for the second camera, so as to obtain a view from a slightly different point. A few inches movement is generally sufficient. You can produce pictures for the stereoscope by taking two copies of a single picture. 3. For card portraits any good portrait lens, with sufficiently long focus and flat field to define a standing figure properly, will do. 4. To prepare arrow-root paper dissolve 5 drachms of chloride of sodium and 30 grains of citric acid in 15 ounces of distilled water, with this mix carefully 4 drachms of arrow root, and boil in a glass vessel. Whilst hot apply it evenly with a sponge to fine *Saxe* paper, the sheet being fastened on to a board by the corners. Excite and print as usual. 5. Various articles on the construction of glass houses have appeared in our pages, and another will appear shortly. 6. Sir D. Brewster's work on the stereoscope. 7. Crystal varnish is gum dammar dissolved in benzole, about 30 grains to the ounce. 8. You may copy engravings for your own use; but you must not reproduce copyright pictures for sale.

G. P.—Albumen is a very complex organic compound: its solvent is water and a little alkali, and white of egg is an aqueous solution of it. By evaporating white of egg you will obtain albumen in combination with certain salts. By adding acetic acid to white of egg to neutralize the alkali present, and then adding cold water, you will precipitate the albumen in translucent flocculi; this is tolerably pure, but still contains some earthy and alkaline phosphates. This is not soluble in pure water, but is so in weak saline solutions. When you add 12 grains of salt to the white of an egg, you have not salt in the proportion of 1 to 40 of albumen, but to 40 of albumen solution. What is the exact proportion of pure albumen in white of egg we have not data at hand for stating; but the Abbe Pujo, in stating that the proportion of salt to albumen is as 1 to 3 is manifestly referring to pure albumen, and not to albumen solution; to that, in fact, which forms a compound with silver, the same as the chloride does, and not to the water which is driven off in drying. Your error is in confounding white of egg with albumen; the solution with the solid; in mistaking colloquial phraseology for exact scientific phraseology.

W. May.—Your glass being lighter in some parts than others will account for its not entirely keeping out actinic rays. Use two thicknesses of No. 4, and that will probably answer; two thicknesses of No. 2 would not be efficient with a bromo-iodized collodion Plenty of non-actinic light is always desirable in the dark room. We shall be glad to see a description of your tent.

Exhibitor.—Allotments are now made, and we have reason to believe exclusively to those who have complied with the necessary conditions.

Geo. Smith.—We are obliged by the paragraph and for your kind letter. Such assurances of appreciation make our labours pleasant.

Capt. de Langue, J. Hawke, J. F. Taull, No Chemist, Cymao, W. Werner, Borsen, S. P. E., and several other communications will receive attention in our next.

*** Our Correspondents will aid us in our endeavours to solve their difficulties if they will in all cases state details of their operations when failures occur; and when referring to former articles in the News giving the exact reference. Letters intended for the Editor should be addressed expressly to him.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 179.—*February* 7, 1862.

## PROPOSED ADDITIONAL PHOTOGRAPHIC EXHIBITION.

We have pleasure in announcing that it is in contemplation to open a photographic exhibition, independent of, but in no sense in opposition to, that in connection with the International Exhibition. The Committee of the South London Photographic Society have for some time contemplated the propriety of opening an auxiliary exhibition in the course of the coming summer. The circumstance that an amount of space so exceedingly circumscribed has been devoted to photography, at South Kensington, and that there are consequently so many able photographers disappointed in obtaining space, has, however, precipitated this intention, and involved the necessity of immediate action.

Details of arrangement, locality, &c., are at present undecided. For many reasons a central and independent position in the metropolis would have been desirable, and we are able to state that many influential gentlemen have offered to come forward with money, contributions, and effort, to give *eclât* to such an undertaking, and guarantee it from loss. The great difficulty in this respect arises from the fact that every eligible building for such a purpose is already engaged, and it is very doubtful that any suitable room, in a central position, could be obtained. In view of this difficulty, the value of a good position in the Crystal Palace, at Sydenham, has been contemplated, and the committee are already in communication with the authorities of the Crystal Palace Company, endeavouring to make suitable arrangements, and, we believe, with every hope of success.

If the arrangements desired by the committee can be obtained, there can be no doubt of the advantages of a good and distinct position in the Crystal Palace. The number of visitors under ordinary circumstances, when stated in figures, is almost startling, considerably over a million and a half of persons having entered the Palace at Sydenham during last year. In the coming summer it is not improbable but that that number will be doubled or trebled, so that an exhibition of photographs there will secure a publicity far exceeding that of any former exhibition.

The necessity of an auxiliary and independent exhibition is felt on all hands: by persons who have received allotments in the International Exhibition, and by those who have been disappointed. It need not be in any sense regarded as having a hostile spirit to the international undertaking. Every photographer who has prepared photographs for that exhibition, even if he have the opportunity of exhibiting them, will possess duplicates; and those who have been long preparing, and have no opportunity of exhibiting, will find the opening here. This may really be a complete and universal exhibition, for an opportunity can be afforded for hanging in juxta position, admitting of definite comparison, the productions of every nation where the art is practiced throughout the world.

We may add here that some thought had been entertained by gentlemen connected with the parent society of inaugurating a distinct exhibition, seeing that the space at South Kensington was so inadequate to represent the art fairly. When this was mooted, it was intimated on behalf of the South London Society that they would willingly withdraw from their project, if the parent society thought well to carry out an independent undertaking. It was, however, we understand, thought by the council of the latter, that whilst there could be no impropriety in such an auxiliary exhibition, yet it might scarcely be graceful that it should be initiated by them officially. We hope shortly to be able to announce some definite arrangements; as no time should be lost if the exhibition be opened in May next, coincident with the opening of the world's fair at South Kensington.

Whilst on this subject, we may say in answer to a large number of disappointed applicants to Her Majesty's Commissioners, from whom we have received communications, that we understand a further reconsideration of some of the most important application will be made, and any space not occupied, apportioned to those whose requirements have the highest claim to attention. Beyond this there can be no appeal, and those of our correspondents who have sent us letters on the subject, intended for publication, will see the impolicy of occupying space in discussing a question concerning which the decisions cannot be reversed. We remarked in our last that disappointed applicants must await with patience the next chance. We are glad to be able to announce the probability of that chance being so near at hand.

## Notes and Jottings.

### No. 13.

Respecting Preservatives: in Conclusion of Remarks in Jotting No. 12.

Sugar is capable of combining with several bases, thereby generally losing its sweet tase. With chloride of sodium a compound, crystallisable, soluble, and deliquescent, is formed. Cane-sugar here loses one equivalent of water on entering into relationship with the salt, whilst grape-sugar, on the contrary, gains an equivalent. On the latter, however, being heated to about 260°, two equivalents of water are driven off, and the compound then bears the same resemblance to grape, that the first does to cane-sugar.

It will thus be seen that in using sugar and common salt in certain proportions, a distinct chemical substance being formed, it is probable that the effects as a preservative may be different from what we might have expected had we considered the solution in the light of a *mixture* only. We mention this circumstance respecting sugar, not from expectation of the knowledge proving practically of value, but rather because it might be interesting to the reader. Chloride of sodium and sugar, the former in excess, would very likely give much better keeping qualities than sugar alone, but we should be fearful of its crystallizing. Probably the compounds of sugar with baryta, protoxide of lead, &c., would afford subject for interesting experiment.

It may, perhaps, be of service to some of our readers to know that the juice of fruits can be imitated by adding a few drops of lemon juice to a thick boiling solution of common sugar, which immediately becomes limpid, and yields a thick syrup only, on being evaporated. Grape sugar is in fact formed, which, in this state, in presence of an organic acid will not crystallize.

The juices of fruits, and the fermented drinks obtained therefrom, as decoction of malt, malt liquoris, &c., have been, and will doubtless continue to be, brought before us as preservative agents. The principles involved are the same as in the use of honey, although it is evident the presence of other matter, such as organic acids, alcohol, essential oils, mucus, &c., in addition to sugar, have some effect on the results obtained. We do not consider the originally proposed honey by any means the best preservative of this class; and any modification of a distinctive nature will always be welcome. A few numbers back, sherry wine was suggested as containing all the requisites for a preservative. Undoubtedly it does; but we should consider it a waste of good liquor when so many equally effective substitutes are at hand. Besides, it would be likely to get into the head, we fear. Michael Hannaford.

## PHOTOGRAPHIC CHEMICALS:

### Their Manufacture, Adulterations, and Analysis.

*Hyposulphite of Silver.*—In addition to the facts respecting this salt, a few more particulars remain to be mentioned in order to render its description complete. The salt is not easy to prepare, owing to its ready decomposition. It may be obtained in a state of purity by adding a tolerably dilute solution of nitrate of silver to an excess of a strong solution of hyposulphite of soda; a greyish mixture of hyposulphite and sulphide of silver will be precipitated, which must be filtered and well washed with cold water; the mixture is then to be stirred up with dilute ammonia, which dissolves out the hyposulphite of silver and leaves behind the insoluble sulphide. This is to be again filtered, and then the hyposulphite of silver may be precipitated from the ammoniacal solution by exact neutralisation with nitric acid: the precipitate must be rapidly filtered and dried as quickly as possible by pressure between folds of blotting paper. Hyposulphite of silver thus formed is a snow-white powder, slightly soluble in water, and of a very sweet taste; it readily decomposes into sulphuric acid and sulphide or silver:

$$AgOS_2O_2 = AgS + SO_3.$$

When a rather dilute neutral solution of nitrate of silver is gradually poured into dilute hyposulphite of soda, with constant stirring, a white turbidity is at first produced, which, however, disappears immediately. As the nitrate of silver continues to be added, and its quantity in the liquid increases, grey flakes are produced, whilst the supernatant liquid acquires a very sweet taste, owing to the hyposulphite of silver which it has dissolved in it; it is not now precipitable by a chloride, but gives a black precipitate with sulphuretted hydrogen. As the nitrate of silver, which is being added, increases in quantity, the precipitate suddenly turns from grey to brown, and is afterwards converted into black sulphide of silver. At this point the supernatant liquid no longer tastes sweet, and gives a white precipitate with common salt. If the solution of hyposulphite of soda be mixed at once with the exact quantity of nitrate of silver solution necessary to decompose it, the precipitate, which is white at first, soon passes through pale yellow, greenish yellow, yellowish brown, and red brown, into the brown-black colour of sulphide of silver.

Hyposulphite of silver has a great tendency to combine with other hyposulphites forming double salts. They may be formed generally by dissolving in the alkaline hyposulphite, either hyposulphite of silver, oxide of silver, chloride or some oxygen salt of silver. These double salts may then be precipitated from the mixture by means of alcohol, filtered and washed with the latter liquid. As a rule they have a very sweet taste, and are decomposed by a slight elevation of temperature; they must therefore be dried by pressure between blotting paper, and lastly over oil of vitriol in a vacuum. The ammonia salt prepared in this manner has for formula—

$$2(NH_3S_2O_2) + AgOS_2O_2.$$

It crystallizes in six-sided prisms, has a very strong, pure, sweet taste, and is readily soluble in water. Its taste is such as to communicate perceptible sweetness to 32,000 times its own weight of water. When a larger quantity of chloride of silver is added to the aqueous solution of this salt, a white crystalline precipitate is produced, which is quite insoluble in water, and readily decomposed into sulphide of silver. This precipitate contains equal parts of the hyposulphites of silver and ammonia.

The double soda salts are of more importance at present than the ammonia compound. They were briefly referred to in our last article. The following particulars will complete the description. There are two salts of this kind; the most soluble one may be formed by dissolving chloride of silver in hyposulphite of silver until the liquid begins to become turbid by the deposition of the white sparingly soluble salt. Upon filtering and adding alcohol, the double salt is precipitated in the form of a white crystalline powder, which must be quickly filtered and washed till the filtrate contains no chlorine. It must then be dried between blotting-paper and *in vacuo*. The salt has the formula given to it in our last article (two of soda- and one of silver-hyposulphite); it forms silky laminæ united in tufts, which have a very sweet taste. It is not altered by exposure to air or light, but at the boiling point of water it gradually darkens from formation of sulphide of silver; the same change likewise takes place upon continued ebullition of the aqueous solution, the liquid at the same time acquiring an acid reaction from the formation of sulphuric acid. Hydrochloric acid added to the aqueous solution acts slowly on it at the ordinary temperature, forming a black precipitate from which ammonia dissolves chloride of silver. The salt dissolves readily in water and ammonia, and likewise to some extent in warm or dilute alcohol. From its aqueous solution upon evaporation *in vacuo*, crystals are obtained in large plates.

If more chloride of silver be added to the above-mentioned solution of the double hyposulphite, or if the liquid be cooled artificially, the difficultly soluble double salt (equal atoms of soda- and silver-hyposulphite) separates out in small, hard, lustrous crystals. They have a sweet taste, and when heated fuse and turn black, yielding sulphide of silver: when white they are with difficulty soluble in water, but readily so in hyposulphite of soda, forming the soluble salt just described: ammonia likewise dissolves them. After they have commenced to darken by heat or exposure to the air hyposulphite of soda no longer dissolves the crystals. These reactions explain many troublesome phenomena which are noticed during the operation of fixing positives.

*Hyposulphite of Gold and Soda* (*Sel d'or*).—This salt is largely used in the Daguerreotype process as a fixing and gilding agent, and also as a toning salt for positive prints. Its composition is rather curious, as it contains protoxide of gold instead of the ordinary teroxide; its formation is the result of a somewhat complicated reaction, which, however, as it expresses at a glance what would take half a column to describe, we give in chemical symbols:—

$$8(NaOS_2O_2) + AuCl_3 + 4HO = [3(NaOS_2O_2 + AuOS_2O_2 + 4Aq] + 2(NaOS_4O_5) + 3NaCl.$$

The hyposulphite of soda and the chloride of gold must each be dissolved in a very small quantity of water, and the solutions mixed together: upon the addition of alcohol a precipitate is formed consisting of the salt in question, the formula of which is $3(NaOS_2O_2) + AuOS_2O_2 + 4Aq$, whilst tetrathionate of soda and chloride of sodium remain in solution. By redissolving the precipitate in a small quantity of water, and reprecipitating with alcohol, the salt is obtained in a state of purity. It forms colourless needles, having a sweet taste; they are insoluble in strong alcohol, and very easily soluble in water. When quite pure and free from adhering water the crystals contain 37·65 per cent. of metallic gold. When heated in a glass tube the salt first gives off water, then sulphur and sulphurous acid. The water does not go off till the temperature rises to 150°C when the 4 equivalents of water of crystallization are evolved, and the salt is left in the anhydrous state. Upon exposure to the atmosphere for twenty-four hours the dried salt re-absorbs this water, and regains its original composition and properties. When heated suddenly it decomposes, leaving metallic gold and sulphate of soda. Nitric acid attacks it rapidly, forming sulphuric acid: sulphuretted hydrogen, and soluble sulphides precipitate the gold from its solution in the form of a brownish-yellow powder. Tincture of iodine forms no precipitate in a concentrated solution of this salt, but on diluting with a large quantity of water after saturation, pure yellow protiodide of gold is immediately precipitated, iodide of sodium and tetrathronate of soda remaining in the liquid: this proves that all the gold is contained in the salt in the form of protoxide. The presence of gold cannot be detected in the double hyposulphite of gold and soda by any of the ordinary reagents; thus, neither green vitriol, protochloride of tin, nor oxalic acid throw it down. Hydrochloric, dilute sulphuric acid, and vegetable acids added to the solution, neither separate sulphur nor sulphurous acid; nitric acid alone decomposes it at the ordinary temperature. These reactions show that this salt is much more stable than the corresponding silver salts, and not likely to be attended with injurious results, when employed with care, in toning positives, provided other sources of hyposulphite of soda are absent. By the further action of hyposulphite of soda on chloride of gold other products are formed: and amongst the rest, a brown substance soluble in water and insoluble in alcohol. It appears to be richer in gold than the salt above described, and when the chloride of gold is in excess, is resolved into sulphuric acid and metallic gold.

## THE PHOTOGRAPHIC PLANE TABLE OF M. AUGUSTUS CHEVALLIER.

BY LIEUT. PATE.

THE application of photography to topography was pointed out in July, 1839, in the reports made to the Paris Chamber of Deputies, by Arago and Gay Lussac. The merit of inventing a very simple combination which should render this application practicable is due to M. Chevallier, who devoted himself to a task beset with many difficulties, and demanding great sacrifices, with a courage and perseverance sustained by the implicit faith he held to the opinion expressed by the two illustrious academicians.

When, in 1856, M. Chevallier communicated to me his ideas on this subject, he had ascertained—1st, that the photographic image might be very sharp, although taken with a lens in motion; 2nd, that a panorama surrounding an observer may be taken by preserving the azimuth angles. But he wished to obtain his view of the horizon at once, as M. Bardin had long previously done with the ordinary plane-table; to this end, he thought of receiving the image through a very small fixed sector, upon a vertical plate having a rotary motion upon an horizontal axis. M. Chevallier, having constructed his instrument, patented it, the 18th February, 1858, and presented it to the Society for the Encouragement of the Arts, which awarded the inventor its medal.

This apparatus, applicable in the same circumstances as the ordinary camera, resolves, in a new and complete fashion, the problem of the application of photography to topography, by giving at one and the same time the station-point, the azimuths, and the differences of level, so that the picture, without the intervention of any geometric construction, serves at once for the construction of a plan.

When M. Chevallier presented his instrument to the Society, he made known only one mode of operation, that which he termed "the operation with fixed and successive sectors."

*Operation by continuous motion* (*Nadiral.*).—It is not exactly true that the straightened and fixed sector gives a perspective; but let us suppose that the sector straitened indefinitely, the difference between the representation due to the lens, and that which will be due to a perspective upon the same picture, will diminish indefinitely; each of the indefinitely small sectors will be a more and more exact perspective, whatever be the approximation of these sectors to each other.* Therefore, if we gave a continuous horizontal motion to the camera, which imparts to the sensitized plate an identical vertical motion of rotation, the very small sector which replaces the vertical hair of which it has almost the same dimensions, passing before the objects in succession, will give an impression on the plate only successively, so that there will be no fear of superimposed images, as it will reproduce a view of the complete horizon, all the azimuths of which will be equal to those obtained by a thedolite or an exact gonimetric instrument.

*Operation by continuous motion* (*Zenithal.*)—In the preceding operation we have supposed that the centre of the objective corresponded with the inferior radius of the plate; the image is reversed, the sky is carried towards the circumference and the objects near the station towards the centre, so that the latter are excessively diminished in size. A very simple arrangement of the apparatus permits of our avoiding this difficulty; a table with a slide carrying the objective, and in turning it over we place the latter at the height of the middle of the upper radius of the plate, the image still being reversed, the base of an edifice, for example, being uppermost, or towards the circumference, while its summit and the sky will be carried from the side to the centre, all the objects which interest the operator forming, on the plate, a zone surrounding a central circle, which is the picture of the sky; and it is evident that if we have made a complete sweep of the horizon, by a continuous motion, we shall still have a complete representation of the panorama with the conservation of the azimuths.†

*Altitudes.*—By the continuous circular motion of the apparatus, the horizontal point traces a circular image on the plate, which is the curve of the level of all the points situated on the same height as it, and gives a plane of comparison to which we may refer all the other heights.

The height of a signal is known by its distance from the station, and by the tangent of its visual angle. Here the plane constructed gives us the distance, and the relation between the length of the image and the corresponding focal length gives us the tangent, and the calculating rule renders this method very expeditious in practice. Beside, the focal length, invariable for the entire sweep of the horizon, is fixed directly upon the apparatus.‡

Thus it is, in examining the combinations at which M. Chevallier has arrived by a method purely synthetical, that we have been enabled to verify the geometrical accuracy of his results; with the azimuths and the heights above and below a plane of comparison, we obtain the elements of a plan with two sweeps of the horizon taken from the extremities of a base, and when properly oriented, we construct this plan by simple settings off.

*Application and Comparison with the Ordinary Plane Table.*—The first application of this instrument is the same as with the ordinary plane-table when we take sweeps of the horizon from the two extremities of the base, or any number of stations whatever; but in comparing the apparatus of M. Chevallier with the ordinary plane-table, we perceive that it possesses many advantages over the latter.

1st. The errors of aim so frequent when employing the plane-table are no longer to be apprehended, for we obtain every direction around the horizon with complete images of the points situated in these directions.

2nd. With the ordinary plane-table, if we neglect to take an aim in a given direction, the fault cannot be repaired by

* It is scarcely necessary to remark that the distinction will be in the vertical direction.

† We call these two operations *nadiral* and *zenithal*, because the vertical lines *appear* to concur, in the first instance, to the nadir, and in the second, to the zenith of the operator.

‡ Operating by continuous motion destroys the effect of distorted images due to the lenses in the direction of the azimuths, but allows them to remain in the vertical direction. Moreover, the comparison between the image taken in a fixed sector, and the image of the same objects obtained by continuous motion gives an exact and graphic measure of these distortions due to the lens in proportion as they recede from the centres.

This very practical result may be turned to account for measuring the curvature of lenses. When our opticians turn their attention to this question, they will probably obtain marvellous results from it.

returning to the station; here, however, on the contrary, the image gives all the points of the horizon, and we have only to select those which we wish to transfer to the plan.

3rd. A single focus being obtained, the apparatus itself sets up all the bearings, and supplies the data necessary to the calculation of the sides, while with the ordinary plane-table, every point demands two bearings, one of direction, and another of inclination.

4th. If in constructing the design with the bearings there are errors arising from some of them being badly drawn, they are easily remedied by placing the image properly oriented; but with the ordinary plane-table they are irremediable.

5th. We can only have a limited number of bearings on the plane-table without causing confusion; here the image gives distinctly all the bearings of the station possible.

6th. A single negative will furnish as many positive proofs as may be desired; several draughtsmen can prepare the plan at the same time, while the photographer, continuing his operations, will be preparing fresh materials.

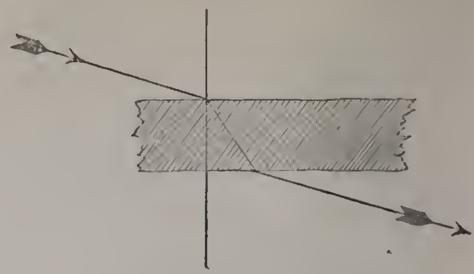
(*To be continued.*)

## PROFESSOR TYNDALL'S LECTURES ON LIGHT.

Lecture ii.—Dec. 28, 1861.

The lecturer commenced by making a few experiments with concave and convex mirrors, in continuation of the subject of the first lecture. An ordinary concave mirror being regarded as a small slice cut from a large hollow sphere, the principal focus was shown to be midway between the centre of the sphere of which the mirror is a portion and the surface of the mirror. If an illuminated object be placed between the principal focus and the surface of the concave mirror, the image formed would be *erect* and *magnified*, and would appear as if it were behind the mirror. If, on the other hand, the object were placed between the principal focus and the centre of the sphere of which the mirror is a part, its image would be formed in front of the mirror, and beyond the centre, appearing *inverted* and *magnified*. In the case of the object being placed beyond the centre of the sphere, its image would appear in front of the mirror between the focus and the centre, and would be *inverted* and *diminished*. This is the case observed on looking at the concave surface of a polished silver spoon. In a convex mirror, on the contrary, the image always appears *upright* and *diminished*, as may be seen by looking at the back of a polished silver spoon. These different effects were beautifully illustrated by means of the electric light, images of medals and of the assistant's face being projected on the screen.

The speaker then introduced the special subject of the day's lecture by asking his hearers to imagine rays of light as particles shot off from a luminous body. When these particles strike against an unpolished surface they act like elastic balls shot against a rough wall. If, however, the rays of light, or the elastic balls strike against a perfectly smooth surface they are reflected. Further—if a stone is dropped into water it falls perpendicularly downwards, but if cast from the hand obliquely, its path would not be straight, but bent, owing to the attraction of the earth pulling it down. The lecturer then proceeded to illustrate the behaviour of particles of light when they fell upon a surface of glass. When a ray of light falls perpendicularly downwards on to the surface of any transparent solid or liquid; it goes *straight* into it, but if the ray strike the surface obliquely, it is bent on entering the solid or liquid, in such a direction as to approach a line passing perpendicularly through the medium. A thick plate of glass with parallel sides was employed to illustrate this, and an intense beam of electric light being taken, it was shown that although the ray of light was bent out of its original course upon entering the surface, yet it was bent back again upon quiting the glass, and thus the original direction of the ray was perfectly restored, although it went forwards, not in the same straight line, but in a line parallel to the incident ray, thus:—



This was well illustrated by allowing a ray of electric light to fall on the screen, where it formed a sharply defined point of light. Its position on the screen being marked, it was seen that the introduction of the plate of glass into the path of the rays made no difference when the surface was exactly at right angles to the beam, but if it was inclined on one side or the other, so as to cut the beam obliquely, the dot of light on the screen instantly shifted its position sideways. By projecting the image of an arrow on the screen, and using a narrow bar of glass for this experiment, the centre part of the arrow was caused to move in either direction out of the straight line. This effect of bending the rays of light was called *refraction*.

Instead, now, of taking a piece of glass with parallel sides, the lecturer took a piece shaped like a wedge—a prism, in fact. In this case the bending produced upon entering the glass was no longer undone upon its emerging from the second surface, but was actually increased; so that the beam of light was permanently deflected, and its direction entirely altered after passing through a prism, the ray of light being seen to be jerked up and down by introducing one of these pieces of glass in its course. Owing to the rays of light being bent upon passing obliquely from one medium into another, the bottom of a quiet pool of water always appears shallower than it really is. Hence, also, if a straight stick be thrust obliquely into water, its immersed end would appear higher than it really was, the stick being apparently bent upwards where it quits the water. These different results were clearly illustrated by experiment, and it was explained that the bending of stick must be carefully distinguished from the bending of the rays; they being in opposite directions.

The path of a ray of light through a prism being well understood, it was at once seen that the section of a convex lens was nothing more than two prisms placed base to base, and that of a concave lens two prisms placed edge to edge; the outlines being in each case curved instead of straight. The former, it was evident, would refract the rays of light inwards,—would squeeze the light together and produce a spot of bright light in the middle of its shadow, whilst the latter would scatter the light outwards, forming a luminous rim round it.

It was next explained that all transparent bodies—gases, liquids, and solids, refract light. The quivering observed over a heated surface is due to the refraction of the heated air, as was seen when a hot iron was placed in front of the electric light so that its shadow fell upon the screen. Tubes of hydrogen and of olefiant gas were also placed in front of the light, and their contents allowed to escape into the air. By the different shadows which these gases formed it was easy to perceive that the refracting power of hydrogen was less, and that of olefiant gas greater, than that of air.

Returning again to the subject of lenses, the Professor exhibited the powerful converging action possessed by a large convex lens on the divergent rays of the electric light. The fine divergent cone of rays to be seen issuing from the coke points was converted into a converging cone after passing through the lens, and after coming to a point called the *focus* it diverged again. This was beautifully seen in the rather hazy atmosphere of the room. A screen was then interposed in the path of the rays, and it was seen upon approaching the focus that an image of the coke points could there be seen; the lens, like a skilful architect, actually building up the particles of light like so many bricks into an edifice of exactly the same kind as that from which they issued. The image was, however, rather blurred and indistinct, and the lecturer proceeded to explain the reason of this. By means of diagrams it was shown that a ray of light from the electric light falling upon the centre of the lens would form an image of the coke points at a certain spot in front of it, but that rays falling from the same coke points upon the edge of the lens would not come to a focus at the same spot as the former, but would cross *nearer* the lens; thus, when one set of rays was in focus the others were out of focus, and hence the indistinctness observed. If, however, the circumferential rays were cut off, and only those passing through the centre of the lens used, a beautifully clear and sharp image of the coke points would be produced upon the screen. In this manner the lecturer exhibited to the audience the curious phenomena attending the production of the electric light. The highly magnified image of the coke points being projected on the screen, it was seen, when they were brought near together, how one appeared to devour the other—to eat it up, the substance of the one being heaped up on the other, so as to form one into a point and the other into a crater.

In conclusion, the formation of images by convex lenses was briefly exhibited; medals, &c., being highly illuminated by means of the electric light, their inverted and magnified images were thrown upon the screen in the same way as with the concave mirror exhibited at the commencement of the lecture.

Professor Tyndall said that at the next lecture he should explain the construction of that most beautiful of all optical instruments—that most wonderful collection of lenses in nature—the human eye.

## WET OR DRY COLLODION.

BY THE ABBE' DESPRATZ.

Various Reactions, &c.—Before concluding what remains to be said upon the developing bath, we shall touch very lightly upon what is undoubtedly the most important part in the photographic art, viz.—*luminous influence.* The action of light, although surrounded with mystery hitherto almost impenetrable, very often nevertheless bends itself to the requirements of the photographer, and in this particular *appreciation* bears no inconsiderable part. When a portrait, or even a view it to be taken, the choice of light ought to be determined at once, according both to theory and experience, and the former should be derived from the latter.

As to what especially concerns portraiture, we shall be a little explicit. Here the photographer must be guided by his own taste, if he has any, and will show himself an *artist*, in the true acceptation of that word: but it may be said of the artist as of the poet, *Nascimur poetæ.* Still, upon the occasion of taking a portrait, we may enter into extremely interesting details.

A visit to the operating room of some of those artists who excel in portraiture, would doubtless be worth more than any detailed description of the arrangement of the light, the accessories, the *pose* of the model, and the means of securing an agreeable expression of the features. We smile at the pompous and flowery description of the *mise en scene* which the photographers on the other side of the Atlantic indulge in, with the view of exciting pleasing emotions in the minds of their sitters; but if we do smile, it ought to be in approbation. The portrait photographer has a double *role*; dry and formal as the science from which he derives his most powerful resources. In the operating room he will be cold and precise; out of it, he will display all the amenities of the artist. We need not, however, dwell upon this point, but proceed to the consideration of the luminous influence in connection with portraiture.

All that we have to say on this subject is almost exclusively related to a fact, the existence of which we have fully proved; and the results of which cannot be neglected in practice with impunity. It is this:—a good portrait can never be taken in the open air, even in diffused light. It will generally be more or less spotty, and the half tones will leave much to be desired. In the open air, even with a northern aspect, the light, however much diffused, is never sufficiently so to compensate for the too vivid action of the direct light; or, to speak more correctly, of the light regularly reflected in its plane of incidence. Hence it follows that the least defect of harmony in the various tints of the model is reproduced very forcibly by contrasts more or less harsh, and always very unpleasing to the eye. But it is not so, when instead of operating in the open air, we work in a glass room. Here we find but little direct light; there is only diffused light, and diffused in the strongest acceptation of the word; for the sides of the room which receive the direct light from without, reflect it more or less in every direction, so that the model inundated with a soft light will give a most harmonious image upon the ground glass, where the lights blend with the shades with a grace that can only be found under similar circumstances.

Thus for a portrait, the more the light is reflected in various directions, the more possible it becomes to approach perfection. In this respect, the glass room presents inappreciable advantages, against which its inconveniences are as nothing. But what are theseinconveniences? Do they really exist? It may be said, that with less light than in the open air, the longer the exposure; and this is the strongest objection that can be urged against the glass room. But is this objection even well founded? We think not, and at the risk of appearing paradoxical, we are disposed to say that there is more *truly efficacious* light under a glass roof than there is in the open air. What strengthens our conviction in this particular is the fact that, if we wish to obtain in the open air shades as transparent and broken as those obtained under a glass roof, we must give an exposure quite as long in the one case as in the other; but then all the lights of the open air picture will be solarized, and the portrait be lost.

If reflected light is so efficacious in a glass room, it cannot be the same in the open air. Frequently the reflections from surrounding objects have a mischievous influence. The green reflection from grass and trees is equally injurious. Again, if in the open air, the model is lighted only by a uniform bluish grey sky, without clouds, as very frequently occurs with a north wind in summer, complete success is scarcely possible; most frequently only a cold, flat image will be produced. Under such ungenial atmospheric influences, the glass room would retain almost all its advantages; the numerous reflections developed in its interior would in some measure imprison the light, and at the same time moderate and soften the tone. If to the action of the glass that of reflectors of linen skilfully arranged near the sitter be added, we may understand that in a glass room a good portrait is always possible, whatever be the state of the sky.

But the photographer does not always require portraits, sometimes he desires views. Even for this class of productions, we must also take the preceding considerations into account. It will not, it is true, be possible any longer to modify the luminous action artificially; but even the efficacy of this action may be foreseen, and employed only with discernment. Thus, we should select not only the season, but also the day and the hour. What we have said above respecting the disastrous influence of a bluish grey sky upon a portrait, applies also to the taking of views. If the numerous reflections produced in a glass room are advantageous, the same advantages attends views when fine clouds are moving towards the zenith, or float immovable at the horizon. It may sometimes happen that by atmospheric refraction, the red rays predominate in the transmitted light, especially at morning and evening. It is well known that these rays are but slightly photogenic; therefore, when they prevail, the photographer must wait, or even postpone his operations, until this malignant influence has passed away.

We shall now treat on clouds, and their influence upon the good lighting of a view, and why we cannot always reproduce the clouds themselves; this enquiry will be doubly profitable, and the second question more so than the first.

It unfortunately happens that clouds can be reproduced only under certain exceptional conditions of light. Some preparations of extraordinary sensitiveness may doubtless be employed very advantageously, but we do not think that they are strictly necessary. We know from experience that the clouds can be obtained in the same time as the earth only with a slow collodion, that is to say, *sensitive only to the action of the most efficacious rays*, but we also know that with a suitable lighting and a collodion sufficiently sensitive not to require an exposure of two or three seconds, a landscape may be produced with very distinct clouds.

The following are the conditions of light which have most frequently given us successful pictures:—

Operate an hour before or an hour after mid-day: this is the time when the light has its greatest efficiency; besides, every object receiving light from above, the shadows are inconsiderable. Thus, the earth, in respect to brilliancy, is in the greatest possible harmony with the clouds above it; all objects will, therefore, produce an equal impression in the camera, and nothing will be solarized.

If it be desired to be placed in circumstances still more favourable for obtaining a good view sumultaneously with the earth and clouds. Then the operator should place himself on the shores of a lake or wide river, so as to have the foreground reflect the light much more abundantly than the sky; if mountains fill up the distant horizon, or if the operator is placed at a sufficient elevation to take in a long succession of planes receding to the horizon, as the light of the distant planes is always more efficacious than that of the foreground, we shall necessarily have a plate equally acted upon throughout the whole extent of its surface.

We can say nothing regarding marine views, as we have not experimented upon this class of subjects; but it seems to us that with so harmonious a lighting, the simultaneous reproduction of clouds and water may be accomplished with great facility. This leads us to think that during winter, when the ground is in great part covered with snow, if the sun shines in one part of the sky—the east, for example, and fine clouds appear in the west, generally the earth and the clouds are reproduced with all the harmony desired.

From what is stated above, this fundamental principle may be derived, that to obtain details both in the sky and in the ground of a landscape, we must operate in such conditions that the light be everywhere of equal intensity, or everywhere equally efficacious. This is entirely an elementary principle. In taking a portrait, we only require that the various articles of clothing be nearly the same in a photogenic point of view. Otherwise, the operator will incur the risk of having a spotty picture. The rules we have laid down, although elementary, are none the less of undoubted value, and for this reason we have thought it useful to give all their importance in detail.

## SUGGESTED NEW PRINTING PROCESS.

Dear Sir,—In my last communication I spoke of a "new" printing process, in which I intended to make use of *water* as a fixing agent.

I daresay you are somewhat incredulous as to the possibility of fixing a silver print by means of water simply; indeed, I have considerable doubt whether my theory will stand the test of practice or not.

You will at once judge from the foregoing that I have not tried the fixing powers of simple water; 'tis true I have not: but when I lay my plan before you, you will, I think, agree that my proposition is not altogether unreasonable.

Acetate of silver, as you are aware, is but very sparingly soluble in cold water, but pretty freely so in hot; now I meant to make use of this property of the acetate, in its employment as a sensitive agent for printing.

A formula something like the following might be made use of in salting the paper.

| | |
|---|---|
| Gelatine ... ... ... | ... 20 grains |
| Acetate of potass ... ... | ... 14 ,, |
| Water ... ... ... | ... 1 ounce. |

The solution had better be used warm, as the gelatine is in sufficient proportion to cause coagulation when cold.

The paper is to be floated on the salting bath in the usual manner of salting, and when dry may be made sensitive as a nitrate bath, as follows:—

*Nitrate Bath.*

| | |
|---|---|
| Nitrate of silver ... ... | ... 25 grains |
| Water ... ... ... | ... 1 ounce |
| Acetate of silver ... ... | ... To saturation. |

Filter.

The paper when dry after salting may be floated on this bath for two or three minutes, then dried, and used as in other printing processes.

After the paper has been exposed to light under a negative, it is to be freely washed in boiling distilled water, and the washings are to be repeated till the drainings from the paper produce no trace of precipitate, with a fresh solution of nitrate of silver.

If the washing water be free from chlorides and other salts, producing insoluble precipitates with nitrate of silver, it need not be distilled, but must in every washing be used nearly boiling.

After the hot washings the print should (if the paper has been suitable, and the washing water pure), require no further fixing.

As a substitute for distilled water common water might be used, if freed from chlorides, &c., in the following manner.

To a large quantity of common water add a solution of nitrate of silver till precipitation ceases. Allow the precipitate to settle, and pour off the clean water, which will now very likely contain a trace of free nitrate of silver. In order to get rid of this throw into the water a piece of brightened zinc, and in a few days the water will be freed from nitrate of silver, and may safely be used as washing water in the above process.

It is some months since I found the plan of this process, but have never got time to put it to the test, and as I see little prospect at present of being able to test it for some months to come, I throw out the suggestion that others may act upon it if inclined.

I shall be glad to have your own opinion on the above process, and if you think it is likely to be of any service please give it a place in your paper.—Yours truly,

T. C.

## BENZOLE—ITS NATURE, PROPERTIES, AND USES.

Robert Nichol, in his beautiful poem "Do not Scorn," has taught us a moral lesson in regard to the wrong of despising the meanest of God's creatures; and a far higher teacher of morals—the Saviour—has rebuked the pride of man by placing "the glory of Solomon," in his kingly robes, beneath that of the flower which blooms in the valley. As it is with moral lessons drawn from natural objects, so is it in regard to useful lessons derived from art and science. Perhaps there is not a more fœtid and offensive substances to be found than coal tar, and yet from it we derive some of the most useful, pleasant and beautiful substances adapted to the wants, the pleasures and tastes of refined and common life.

Who would have imagined that this fœtid substance could be made to yield a product which "the fair and the gay" would use as a perfume for the toilet, but it is even so. And from that dirty, black substance, who could have ever imagined that dyes, rivalling the Tyrian purple, the cochineal crimson, and orchillo lilac could be obtained, and yet it is even so. At the present day rich perfumes and brilliant colours are manufactured very extensively, as profitable branches of the arts, from coal tar. But beside these, there are other useful products obtained from the same source, and none more so than the liquid *benzole*. Many persons have heard of it and have wondered what it was —whether solid, liquid, or gas; or whether it grew upon a tree, or came up out of the caves of the earth like petroleum oil.

Benzole was first discovered by Professor Faraday, many years ago, when experimenting with the condensed vapours of oil; but it derived its name afterwards by having been obtained in distilling benzoic acid with lime. Benzoic acid is a product of the odorous gum-resin obtained from the *styrax benzoin* of Sumatra and Borneo. Benzole is a clear colourless liquid of a peculiar ethereal, agreeable odour; it boils at 168° Fah.; its specific gravity is 0·85, and it freezes at 32° Fah., and becomes a white crystalline mass.

When solely obtained from benzoin it was very expensive, but, in experimenting with coal tar, about the year 1847, C. B. Mansfield, of Manchester, found, among several of the oils obtained at different degrees of temperature in distillation, benzole, as the second of six—all of different specific gravities. This discovery led to its becoming comparatively cheap, and from that day to this its application has been extending. It is now manufactured from the naphtha obtained from coal tar, in large quantities, in London, Manchester, Glasgow, and nearly all the large cities in Great Britain. A few years since its manufacture was introduced from London into this section of our country, and is now conducted in North Second Street, in the Eastern District of Brooklyn. Crude naphtha is distilled in an iron still; at a temperature varying from 176° to 194° Fah., benzole passes over and is condensed. It, however, contains some impurities, which are removed by redistillation and washing with dilute sulphuric acid, water, and weak alkali, in succession. A fluid called "benzole" is obtained as one of the products of petroleum oils.

When atmospheric air, slightly warmed, is passed through benzole, it takes up a portion of it, and becomes a vapour of great illuminating power. In 1836 a patent was taken out in England by M. Beel for forcing common air into a reservoir containing benzole, and burning the vapour thus obtained in the same manner as common coal gas. Since that period several apparatuses have been devised for using it. Were it not that it condenses in cold weather and chokes up the pipes, it would be the most convenient known substance for making gas to illuminate large houses, schools, colleges, &c., in the rural districts.

Benzole dissolves resins and fatty substances, and is used for removing tar, resin, and grease spots from light kid gloves and silks. It has been imported from Europe, and sold in small bottles at extravagant prices for such purposes. Since the war commenced, and turpentine has become so high in price, petroleum benzole has been used to a large extent, as a substitute for mixing with paints, and in the making of varnishes. In England it is used for scouring greasy wool in carpet manufactories. As it is a powerful solvent of india-rubber and gutta-percha, it makes with them a very adhesive cement.

By adding benzole cautiously to strong nitric acid, assisted by a gentle heat, a compound is formed in the form of a yellow oil, which, when the mixture is diluted with water, sinks to the bottom of the vessel. This oil has a sweet taste and the odour of bitter almonds, is used in perfumery, and is sold under the name of the oil of bitter almonds.

By combining nitro-benzole with hydrogen, aniline is formed, which is the basis of the beautiful purple and red colours that have lately been introduced into the arts of dyeing and printing. As heretofore manufactured, such colours have been subject to deterioration by fading when exposed to sunlight; but this defect, we have reason to believe, has been surmounted. Several samples of fabrics coloured with aniline products manufactured in France, have lately been furnished us for trial by exposure to solar light, and thus far the test has been favourable.

Benzole is a carbide of hydrogen. It consists of twelve atoms of carbon and six of hydrogen. As a solvent it is nearly similar to ether and alcohol, and it may be used as a substitute for these fluids. Many of the most beneficial improvements that have been made in recent years have been in reclaiming and applying to useful purposes things which were formerly held to be positively useless. This has been the case pre-eminently with such products as benzole.—*Scientific American.*

## HINTS ON PORTRAITURE.

BY JOHN HAWKE.

[We have repeatedly received from Mr. Hawke some of the most perfect card portaits we have seen for delicacy and brilliancy. At our request he has sent us a brief statement of his method for the benefit of our readers. Whilst we always affirm that as much is due to the man as to the method, it is always interesting to know the exact details of a process giving very fine results, as being suggestive of new ideas, or confirmatory of old ones.—Ed.]

Dear Sir,—As you have been pleased with the results of my humble efforts in photography, and have expressed a wish that the method of producing them should be made generally known. I am much gratified in being able, through your useful journal, to add my mite to the stores of practical photography. I have nothing new to tell, my success being the result of careful working, and not of any new discovery. I have no difficulty in obtaining the results that you are already acquainted with. The method is at the service of your readers, and is as follows:—

*The Silver Bath—Recrystallized.*

| | |
|---|---|
| Nitrate of silver ... ... ... | 40 grains |
| Distilled water ... ... ... | 1 ounce |
| Iodide of potassium ... ... | 2 grains. |

Dissolve the silver in 3 or 4 ounces of water in one measure, and the potassium in another, then filter, and add sufficient water to the quantity of silver dissolved to make the bath of the above strength. Slightly acidify with acetic acid.

*The Developer.*

| | |
|---|---|
| Proto-sulphate of Iron ... ... ... | 2 drachms |
| Water ... ... ... ... ... | 8 ounces |
| Best glacial (acetic acid, solid at 50°)... | 1 drachm. |

The iron is dissolved in boiling water, and enough common spirits of wine added to make the solution flow evenly. When cold filter and add the acetic acid.

*The Intensifying Solution.*

| | |
|---|---|
| Pyro-gallic acid ... ... ... | 2 grains |
| Citric acid ... ... ... ... | 1 grain |
| Water... ... ... ... ... | 1 ounce. |

This is for winter. In summer one quarter less of the above quantities of acid will suffice.

*Fixing.*—With a weak solution of cyanine of potassium.

I have tried all sorts of collodion, but at present I am using Huggon and Briggs' quick acting negative 1 part; and Cook's (Hoxton) positive, 2 parts.

*Toning.*—By the usual alkaline gold process. Fixed as usual with hyposulphite of soda. The paper I use is Sanford's thin paper *Saxe*, and the lens one of Dallmeyer's No. 2 B, which I would advise all who can afford it to purchase.

You will perceive that there is nothing in any method but what is for the greater part already known to most of your readers; the difference in result being mainly to be attributed to manipulation, lighting, pose, &c. In the first place, I am extremely careful in cleaning and coating the plate, to obtain a perfectly even and clean surface; should any inequalities or marks appear, I cast the plate on one side. I again always carefully wipe the back of the plate, and place blotting paper to absorb the drainings. In lighting the figure, I am very careful to prevent any harsh contrasts—the cause of failure in so many; the picture often being a mere mass of black and white, the light appearing to come nearly all from the top, forming great deep masses of shadow under the prominent parts of the face. I am careful also to have my background painted perfectly even in distemper, of a warm grey colour, without gloss, as it would be impossible to produce a good picture with a bad background. The background should also be adapted to the age and character of the sitter; for this, a series of painted profiled backgrounds are necessary. The pose is most important; anything common and stereotyped must be avoided; but this must be left in a great measure to the taste of the operator, and the ease of manner of the sitter. I often take three or four portraits of a sitter before I can get one exactly to my mind, so that I am necessarily slow in a certain sense; but I think if any photographer starts with the idea that he will take a certain number of portraits *per diem*, he had better give up the idea of quality, and be satisfied with quantity; for without entering into the question as to whether a photographer be an artist or not—a question arising, in my opinion, simply from the difference in the definition of the word—it is certain that to be a successful photographer, a man must have a great deal of artistic feeling, and the power of close observation.

If these hasty notes will be of any advantage to your readers, they are at their service.

I may as well add that I expose about twice as long as for a positive, and develop fully; that is, while there is any bit of detail to be brought out; there will be no danger of fogging.

## Proceedings of Societies.

### The London Photographic Society.

The annual meeting of the Photographic Society was held on the evening of Tuesday, the 4th instant, at King's College. Sir F. Pollock, the Chief Baron, in the chair.

The minutes of a former meeting having been read and confirmed, the Chairman called attention to some stereoscopic views in Ireland by Mr. Browning, and a large and interesting collection of slides by Capt. Allen Scott, embracing a variety of Indian subjects in poirtraiture and natural scenery. A pair of coloured miniatures, Her Majesty and the late Prince Consort, being Mayall's album portraits, coloured by Madame Mansion were exhibited. A water-tight bath, invented by Dr. Wright was also handed round for inspection.

Dr. Wright, at the invitation of the Chairman, explained the advantages of the contrivance. It was an ordinary gutta-percha bath, with the water-tight cover in the usual form; its peculiar advantages consisted in the mode in which the cover was fastened. Instead of being held by the ordinary clamping screws, each part of which being loose and separate, involved much trouble and attention in travelling, the screws were attached by a hinge to the shoulder on the bath, and when unfastened, hung attached to the sides of the bath. To fix the top, these screws being brought into a perpendicular position, fit into a notch at each end of the cover, and when screwed tight, hold the top firmly in its place. The top was also arranged so that when the bath was standing, it might be used as the oblique support of the bath.

Votes of thanks were passed respectively to the gentlemen who had exhibited the objects named.

The Secretary then read rule 7th, relating to the election of officers, and stated, that as none but those proposed by the council had been nominated, the gentlemen whose names were announced in December were virtually elected, it was a mere form, therefore, to proceed round with the ballot box.

The Chairman remarked that he did not know of any greater improvement in modern times than the omission it was now customary to make of the practice of going through forms which were found to be useless and unneccessary. Speaking as a lawyer, they had in the practice of the law, both in public courts and private suits, amputated every proceeding of mere useless form, such as all those proclamations which used to take up time, without serving any useful or necessary end. The practical question just raised by the Secretary was that it would be simply useless to go round with the ballot-box, without any names from which selection could be made, and when only one result could arise.

The Secretary read the names of the gentlemen who had been proposed in December as officers of the society. Sir F. Pollock for re-election as President, and Mr. Hamilton as treasurer. Mr. F. Bedford as Vice-President, in place of Professor Bell. The retiring members of the council were Messrs. Crace, Maskelyne, Stokes, Delamotte, Bedford, and Dr. Fane; in place of these, Messrs. Vernon Heath, Glaisher, Joubert, H. P. Robinson, Sedgwick, and Dr. Wright, had been proposed, and were now elected by general consent.

The Chairman said he felt very much honoured by their confidence and re-election. He had not been able to be present so often as he could have wished; but when an occasion had come during the past year when it was necessary to make a determined resistance and energetic protest against what had much of the appearance of an insult to photography, he had endeavoured to place at the disposal of the society his time and powers in reasoning, illustrating, and expressing, he believed, the universal sense of every photographer in the kingdom.

The report, which was read by the Secretary, and afterwards adopted by the meeting, presented in many respects a more favourable aspect than that of the last and preceding years. We hope to have space for it *in extenso* in our next. The balance sheet, which we give below, contrasts favourably with that of last year, inasmuch as it shows a slight excess of income over expenditure, instead of as before a deficit.

*Dr.* Income and Expenditure Account. *Cr.*

| Dec. 31, 1861. | | £ s. d. | Dec. 31, 1161. | £ s. d. |
|---|---|---|---|---|
| To Entrance Fees | £25 4 | | By General Expenditure | 276 16 3 |

| | | 284 2 0 | By Property Account ... | 19 17 0 |
| To Interest Account ... | | 5 15 3 | Capital Acc. per Balance | |
| To Exhibition Account | | 36 14 5 | Excess of Income over | |
| To Photographic Journal | | 7 6 2 | Expenditure ... | 0 1 3 |
| | | £333 17 10 | | £333 17 10 |

*Dr.* General Balance, Dec. 31, 1861. *Cr.*

| | £ s. d. | | | £ s. d. |
|---|---|---|---|---|
| To Sundry Persons for Balance owing to them | 284 11 6 | By Sundry Persons for Balance owing by them | | 185 6 9 |
| To Capital Account for Balance... ... ... ... | 539 12 2 | By Subscriptns. in arrears, say ... .. ... ... ... | | 100 0 0 |
| | | By Cash Acc., Balance at Bank | £70 7 4 | |
| | | By Interest on Consols ... ... | 5 15 3 | |
| | | | | 76 2 7 |
| | | By 3 per cent. Consols ... ... | 192 14 4 | |
| | | By Property Acc. estimated value | 100 0 0 | |
| | | By Stock of Photographic Journal ... ... ... | 170 0 0 | |
| | | | | 462 14 4 |
| | £824 3 8 | | | £824 3 8 |

The Secretary mentioned as a fact interesting to photographers, that Mr. F. Bedford had been appointed to accompany the Prince of Wales on his tour through the East.

## Correspondence.

### FOREIGN SCIENCE.

[From our Special Correspondent.]

*Paris, 5th February*, 1862.

M. Oppenheim sets up a claim for the superiority of positives on paper obtained by the negative process. He admits that there is nothing new in the idea of obtaining pictures in this way, but that the method has never become general because the pictures, obtained by processes exactly similar to those intended for negative proofs—the picture being in the substance of the paper—is always deficient in sharpness and vigour on the surface.

Starting with the idea that a positive picture intended to be viewed by reflected light should be on the surface of the paper, he has invented and successfully applied a process which gives excellent results, which may be briefly described as follows.

Serum of milk is prepared by acidifying warmed milk by tartaric acid. It is then filtered, boiled, and clarified with white of egg, and again filtered. To this clarified serum 5 per cent of iodide of potassium is added. On the other hand, albumen is prepared by beating whites of eggs to a froth, then allowed to settle, and mixed with an equal quantity of iodurated serum. The positive paper is floated for half a minute on this liquid, then drained and hung to dry. The paper not only keeps well, but improves by keeping.

It is sensitized by being floated for a minute on nitrate of silver solution of the strength of 5 per cent., without the addition of acetic acid; the sensitized paper is washed in two successive waters, and either hung to dry or dried between sheets of bibulous paper. This washing is performed by floating the paper during a minute upon a dish of distilled water, and, afterwards, during five minutes upon a second dish of water. The first water must be used for not more than three or four sheets of paper. It serves afterwards for developing. The printing is made in the usual manner, but by diffused light only. The time of exposure is from two to ten seconds. The picture should be little or not at all visible on removal from the printing-frame. Develop the picture with gallic acid with a little aceto-nitrate, and suspend the operation as soon as the desired intensity is attained, for it loses very little in strength in the hyposulphite. It is fixed in a solution of hyposulphite, strength 20 per cent., and washed in plenty of water. The picture is then of a fine sepia colour, and may be toned with chloride of gold in the ordinary manner.

The remarkable experiments of Kirchoff and Bunsen upon the spectra of flames coloured by metals have been fully described in your pages. M. Debray has conceived the happy idea of projecting these spectra upon a screen by means of the Drummond light. The combustion of coal-gas sustained by atmospheric air gives too pale a flame when metallic substances are introduced into it to enable us to see the spectra clearly except with the aid of a telescope; but if we take the exceedingly hot jet of oxyhydrogen blow-pipe, coloured by various metals, the splendour it acquires is so brilliant that it becomes very easy to project the spectrum upon a screen, so as to be seen distinctly by an audience. To this end, the flame is introduced into Duboscq's photogenic apparatus, now so generally employed in optical experiments, and proceed precisely as in obtaining the spectrum from an oil-lamp, or from the voltaic arc. We then obtain upon a screen, suitably adjusted, the series of brilliant and vari-coloured rays which characterise the metal introduced into the flame. These experiments are successful not only with the alkaline and earthy alkaline metals, but also with other metals, such as copper and lead, although these bodies give with a gas flame, and the ordinary apparatus only a very confused phenomenon. As platina melts instantaneously in the flame of the blow-pipe, the metallic substance is introduced by means of the small piece of retort coke, or by a match strongly impregnated with the matter to be experimented upon, which will be preferably selected from the metallic chlorides; with a little practice we can sustain the phenomenon long enough to study all its details at a very great distance.

By employing the Drummond light, we can also project the development of the brilliant ray of sodium, as first observed by M. Foucault, by the aid of the electric light. The Drummond light placed in the photogenic apparatus, gives a continuous spectrum, in which a black ray appears in the place occupied by the brilliant ray of sodium in the spectra of the flames containing this metal, upon placing in front of the slide of the apparatus the flame of a lamp fed with alcohol containing chloride of sodium.

The Academy has elected Mr. Lyell, the distinguished geologist, as correspondent in the section of mineralogy and geology. The first scrutiny showed that he had obtained no less than 49 votes, proclaiming an unanimous election. There were eleven other candidates.

Some very extraordinary results have been arrived at by M. Testud de Beauregard in his experiments upon superheated steam. The details would occupy too much space here, but I may mention among numerous other applications of his *steam gas*, desaturated of water and supersaturated with heat, engendered at a very high temperature, such as the production of steam of every degree of temperature with or without pressure; the suppression in blast furnaces of blowers and their motive power; the superabundant and economic generation of pure and of carburetted hydrogen; the suppression of steam chimneys and of the smoke of furnaces; the easier and quicker reduction of a multitude of minerals, and of oils and fats; the distillation of schists; the heating of glass and porcelain furnaces, brick kilns, &c. Such are the inestimables advantantages to industry offered to the civilized world by M. Testud de Beauregard.

The photographic camera has become an indispensable adjunct of the observatory. At Greenwich and Kew in England, at Paris and Marseilles in France, at Greiffwald and Vienna in Germany, at Pulkowa and Wilna in Russia, at Washington in America, and in Italy at Padua, Modena, Milan, Rome, Florence, Turin, Naples, and Palermo, are observers ready to examine, compare, and verify the various mysterious hidden phenomena of light.

Sig. Zantedeschi, of Padua, in examining the spectrum for Frauenhofer's lines, tested the dogma "that the lines of the solar spectrum have changed neither in number nor position since they were laid down by Frauenhofer." But among the experiments conducted during the months of July, August, and September, Sig. Zantedeschi was never able to obtain an identical system of black and luminous lines, although the experiments amounted to nearly a thousand in number. During serene and quiet days only he observed constant systems at intervals of four or five hours. He appeals to experimentalists to test his observations by means of a camera with fixed elements—constant aperture, invariable distance and position of the flint prism of 60°, and permanent distance from the plane of projection, in order, by taking all these precautions, to make sure that the solar spectrum be absolutely fixed. By proceeding in this manner in his experiments, Sig. Zantedeschi was soon convinced that in Frauenhofer's spectrum, both *fixed* lines and *moving* lines exist. The experiments were made agaiust the comparison of Frauenhofer's spectrum given in fig. 5, table II, *Astronomische Abhandingen, heraus. H. C. Schumacher, Altona*, 1832. It is to this fundamental experiment of confrontation that M. Zantedeschi refers to excite the attention of astronomers and physicists who desire to aid in the progress of science.

The mobility of the lines being established, it was a sure index of the influence of the medium through which the solar light passed, and of the variations to which bodies in combustion are subject; this naturally led him to suspect the modifications which occur, not only in the solar photosphere, but also in the whole universe, and he finally concluded that the spectrum is as excellent a photosphere as possible, that it is the faithful mirror which reflects the most delicate images of the incandescent bodies, and the changes to which our planetary system is constantly submitted. Thus the photographic camera is called upon to solve one of the grandest problems of the age, for it will be evident that photographic images of the spectrum, taken at various stations at the same moment of time, must afford positive means of comparison, which will place the question raised by M. Zantedeschi beyond the possibility of doubt.

M. Civiale has presented to our Photographic Society a large number of positives obtained from negatives on paraffine waxed paper, by a process described to you in one of my recent letters. He prepares the paper with a mixture formed of 1 part of wax to four of paraffine; the manipulation is the same as with wax alone, and is also quite as quickly performed. Forty-five hours suffice to prepare 200 sheets 12×16.

Mr. Ross, the optician, has addressed to the Society the following letter respecting Mr. Sutton's panoramic lens:—

"I have read before the Photographic Society of London a note upon the panoramic lens, which will appear in the forthcoming number of the Society's *Journal*. It will, I hope, reach your Society, for I have not time to write another, my regular business, and the construction of various optical instruments, are so pressing that I cannot at present occupy myself further with this subject, I constantly make the panoramic lens, and am prepared to execute orders for it."

At the conclusion of the reading of this letter, M. Girard remarked that the description of the panoramic lens had already been inserted in the Society's *Bulletin*, and all that was necessary to be added was the dimensions and the price of the apparatus.

M. Antony Thouret addressed some further remarks upon the employment of iodine in the silver bath as recommended by the Abbé Laborde ; he says :—

"Since the remarks offered in my name at the last meeting, upon the introduction of iodine into the silver bath as proposed by the Abbé Laborde, I have further experimented upon the subject. As, in the former, I employed a quantity of iodine comparatively large, this time I took only ½ per cent. of iodine. The acid reaction took place as before, but after a much longer time. Next day, at the bottom of the bottle, I could very clearly perceive scales of iodine covered with iodide of silver. I made another essay with iodine in an alcoholic solution, that is to say, in a very divided state, and, as I had anticipated, the reaction was instantaneous and complete.

From these experiments it appears to me to follow that the transformation of iodine into iodide of silver, at the expense of the nitrate bath, and with the production of nitric acid, takes place in every instance, but that the rapidity of this action is in proportion to the quantity of iodine put in immediate contact with the nitrate of silver. It is clear that by putting very little iodine there will be scarcely any more nitric acid liberated than when we make use of a collodion coloured by traces of free iodine. But in all cases it introduces an unknown quantity of nitric acid into the bath. Now, the addition of this reagent must be made with so much delicacy, that it seems preferable to be able to measure it very accurately by employing a very dilute aqueous solution of known strength, and adding it in drops carefully counted."

M. Frank de Villecholles remarked that daily practice verified the explanations given by MM. Girard and Thouret. Every photographer well knows that a silver bath which causes fogging may be brought to a working condition by the addition of a small quantity of nitric or acetic acid. It is probably to the same cause that must be attributed the good effect of the iodine recommended by the Abbé Laborde. He added, that for some years operating in a warm climate, and not then knowing the effects produced on the bath by the addition of acetic acid, he succeeded in an empirical manner, in correcting the fogging which baffled his operations, by diffusing an abundance of acetic acid in his operating-room.

## PRINTING AND TONING.—NEGATIVE VARNISH.

Sir,—I cannot refrain making a few remarks with regard to printing and toning, &c. ; but some of your readers will think I am very extravagant, but I do not consider beauty is found in cheapness, and moreover say that there is quite as many pictures fading for want of soda, as the latter plays a grand part in toning and permanency, and a strong hypo solution will only dissolve all chloride of silver remaining in the paper ; but if any addition of acid be made to the hypo bath a precipitate of sulphur takes place in the paper, and there is no remedy for such prints. For further permanency it might be tried to wash such prints in a solution of spirits of wine, pure, which will only dissolve the sulphur in the paper.

My mode of manipulation in producing prints which you have praised, is as follows : I sensitize the paper on a silver solution from 60 to 80 grains to the ounce of distilled water. I print very deeply ; the prints are then washed in running water until no more precipitate of silver takes place. I tone as follows : in a pint of water—warm water this season is best—2 ounces of carbonate of soda, to which I add 5 grains of chloride of gold to tone about 50 pictures of various sizes. When toned in this preliminary solution well wash again in running water for ten minutes ; this should be conducted in the dark. Then the prints should be taken, one by one, and thrown in the following solution. Having an old hypo toning bath, containing 5 or 6 grains of gold, and strong in hypo, 14 ounces to the quart, would not be too strong. The prints should change colour as soon as immersed in this bath, if that is not the case, a handful of hypo is added, and a few more grains of gold. The prints should remain in this solution until the tone you wish is attained, and lastly fixed in a strong new hypo solution for 15 or 20 minutes. I then keep blotting-paper ready, and every print is blotted both sides and then washed in running water till next morning, and a last washing in warm water and cold again for a few minutes, dried and mounted, &c.

I hereby give you in addition a receipt for negative varnish, which I make without any trouble.

| | |
|---|---|
| White shellac ... ... ... | 40 grains |
| Gum sandrach ... ... ... | ditto |
| Oil of lavender ... ... ... | ½ ounce |
| Spirits of wine, 50 over proof ... | ½ pint. |

Mix and dissolve by gentle heat. This varnish is very bright, and not brittle, and the more exposed to sunlight the harder it will get. It is to be used by turning the plate before and after varnishing.—I am, your's truly,

111, *High Street, Oxford.* W. Werner.

## CARAMEL AS A PRESERVATIVE.

Sir,—I have much pleasure in sending my formula for the caramel Fothergill plates.

The preparation of them is conducted as for Fothergill plates, up to drying them, prior to which, I coat them with caramel solution, of about the colour of dark brown vinegar, and then dry as usual, develop with pyrogallic acid and water, and intensify with the usual solution. In my estimation the alkaline gelatine process is preferable, as it admits of iron development, is more sensitive. and I infer from the materials, possesses good keeping qualities ; but there is no need of any preservative.

Whilst writing, I must refer to Mr. Hannaford's jotting in last paper. I have not claimed any "important principle" in the use of caramel, and how can the sugars he names be *isomeric* with caramel ? when, to his own showing, they contain water in combination, which caramel does not ; it must be remembered that it is in *chemical* combination and cannot be eliminated at the temperature which usually evaporates water. Mr. Hannaford considers the use of sugar in any form as a preservative to be only a modification of Mr. Shadbolt's honey process ; now caramel is *not* sugar, but sugar subjected to a process which alters its constituents, its taste, its appearance, and its photographic properties, or its reaction when applied on a collodion film ; altogether Mr. Hannaford has lucidly demonstrated that caramel is a very different substance to sugar or honey. Allow me to cite a passage from the October number of the *Quarterly Review*, and I think the observance of the rule there laid down will prove very beneficial. "It is now happily a settled axiom that he alone discovers who proves ; and the principle serves not only to adjust the claims of rival discoverers, but to establish a far sounder philosophy of invention than that which places a random, or even an intelligent surmise, on a par with successful demonstration."—I am, sir, yours respectfully, Wm. Bartholomew.

*Fareham, Hants, February 1st*, 1862.

### THE NEW IRON PROCESS—CARAMEL AS A PRESERVATIVE.

Sir,—Nothing can be more satisfactory or more to the honour of Mr. Emerson J. Reynolds than his letter (p. 55) in the Photographic News. The manner in which persons are treated who modify, improve, or make available, or rediscover and apply in new forms, what others have not been able to use, is much to be condemned. They are, as it were, strangers in the Stock Exchange, jostled, pushed, kicked, turned round, the word "new" chalked on their backs, and their hats jammed down over their eyes. This ought not to be. It is bowie knife treatment. The sincerity and good faith of persons who publish, with their names, what they find to be useful to themselves, and which they believe may be useful to others, ought to be assumed. If they fall on an old track, they are entitled to be treated with courtesy and be accepted as friends; if they make a new and good road with old materials, they ought to be equally cheered and well received.

The letter of T. Sebastian Davis (p. 59) is most courteously written. I think the film of caramel is a preservative, and that its merit is, that it is a very slight film. I cannot think it has an acceleratory effect; but I think, as a film, it would be improved by a small addition of gallic or formic acid, provided the sensitized plate is well washed.

Much is said about the film of plates slipping, and it is an awful disappointment when it occurs. If you gelatinize or albumenize the surface of the glass, you subject yourself to numerous probable defects in a picture if any dust catches the plate. If, however, a thin edge of the albumen is passed along the edge of a plate, it will be found that collodion so adheres to it that you may give a plate any amount of washing without fear of the film slipping in its development; but this is not "new" though it deserves repetition in dealing with large plates. T. F.

[We think our correspondent somewhat exaggerates, or rather misappreciates the intentions of those gentlemen to whom he refers. No one can more strongly deprecate than ourselves discourtesy of language, or the tendency to put down novel suggestions which we have occasionally seen manifested. We have studiously endeavoured to eliminate from the pages of the Photographic News anything which could be repressive or uncourteous. But whilst avoiding this we must also avoid interfering unduly with the freedom of discussion. The great advancement of photography is largely due to the ready and unreserved publication which has generally been liberally made of every new or good idea; but is also largely due to the jealousy with which the landmarks of ascertained theory or fact have been guarded from the more indefinite domain of suggestion or conjecture. The maxim "prove all things; hold fast that which is good," is not less true in science than in theology. "Progression by antagonism" is one of the recognized laws of the universe. We are always glad to receive every communication and suggestion from our correspondents, at the same time we endeavour to exercise a judicious selection as to what should be published, only allowing such matters to come before our readers as we conceive possess sufficient interest. And we would urge upon all correspondents and readers to write and read in a good spirit, never attributing a bad motive when a good one is equally applicable.—Ed.]

### ALKALINE DRY PROCESS.

Dear Sir,—Struck with the suggestion of Mr. William Bartholomew, that in a dry process we require freedom from nitrate of silver, *alkaline reaction, and organic matter*, I prepared a plate with collodion containing 1 grain of gum guaicum to the ounce, and 4 drops of a five-grain alcoholic solution of *glycyrhizine*, sensitized and washed, first with distilled and then with common water. I then placed it in a bath containing 5 grains each of carbonate of soda and chloride of ammonia; washed well, dried and exposed for a very little longer than I should have done for a wet plate, and developed with 2 grains of pyrogallic acid to the ounce of water, without nitrate of silver or any retarding agent; as the image was, of course, very thin and phantom like, I intensified in the usual manner with pyro and silver. The resulting negative was quite long enough exposed, full of detail, and very free from stains, fogging, &c.

You will notice that my formula differs in three essential points from Mr. Bartholomew's; the use of a resin in the collodion, to which the organic matter is added, and washing after the application of the alkali.

In preparing some plates by his method, which he gave in the number for January 3, 1862, I found, after drying, that the lower part of the plate was covered with minute crystals of the carbonate, which produced spots upon the negative. I got rid of this annoyance by applying the alkali, and then washing before coating with gelatine; but this makes the formula rather more troublesome, and more prone to fogging, &c., than the one I have proposed. As we shall, I hope, soon have better light than at present, I shall defer further experiments until I can better test the relative sensitiveness. The results of which I will let you know. As I am sure that experiments in this direction will not prove useless, any of your readers who turn their attention to the new idea of Mr. Bartholomew will not think their time thrown away.

I did not intend to trouble you with so long a letter, but the importance of the subject must be my excuse.—I am, yours respectfully, H. Cooper, Jun.

5, *Aberdeen Park, February* 1, 1862.

## Photographic Notes and Queries.

Composition or Art Photographs.—Backgrounds to Groups or Figures.—Stereograms from Flat Surfaces, &c.

Sir,—I have long thought that the system pursued for the production of art photographs from several negatives (so artistically described by Rejlander, and followed by Robinson and others), was not only imperfect, but troublesome and expensive, as, notwithstanding the care and skill bestowed upon the printing, the joinings in many cases were apparent, and the effect produced upon the eye unpleasant and hard, the figures in many cases appearing to sink into the background, instead of standing out in relief. Not being much addicted to appearing in print, and supposing that the idea must have occurred to many others, I deferred wrinting, expecting it would have been brought forward by an abler pen. The proposition I have to make is, that the artist having made his sketch, and having the idea of the future picture fully in his mind, proceeds as described by Mr. Rejlander to obtain his negatives of the various groups, figures, &c., required, on as large a scale as possible. Perfect prints from these are now taken on paper, toned, and pressed. Each group, &c., is then carefully cut from its background, stiffened at the back so as to stand upright, and the whole arranged on a board or flat surface so as to form the picture required, in the same manner, in fact, as the figures and scenes are arranged in a boy's theatre, all with the proper distances and relief. The copying camera is now brought to bear upon the whole, and the arrangements perfected until the picture seen upon the ground glass is satisfactory to the artist's eye. A negative is then taken of the whole. Accidental lights and shades may be thrown upon the picture; natural skies and other artistic effects produced.

In the same manner, backgrounds to portraits, figures, and groups may be added;—figures introduced into landscapes, and many groups of figures may be formed into one picture.

In the same manner also stereograms from flat surfaces can be taken. A large negative is reproduced from the original picture, a print taken therefrom, the different portions cut out and arranged as before described, and a binocular negative produced. Boisen.

[There would be many objections to your plan. The inferiority of any reproduction, from a variety of causes, would be fatal.—Ed.]

Varnishing Negatives.

Dear Sir,—You have several times explained the necessity of varnishing negatives with spirit varnish, but all the spirit varnishes that I have used not only partially dissolve the film, but wash a part of the silver off tho high lights on to the shadows, giving them the appearanco of ground-glass. As a preservative, I varnish first with positive varnish (I use Whitaker's) and then the spirit varnish. By this process the intensity is not altered, and the shadows preserved as clean as when wet. If you consider this note worthy of insertion you will obligo yours truly, R. H.

## Talk in the Studio.

The Prince of Wales and Photography.—We have much pleasure in announcing tho first public act which illustrates that the heir to England's throne takes as deep an interest in photography as his late royal father. In tho Eastern tour, which he is about to tako in as private a manner as possible, accompanied by a very limited suite, eight gentlemen only accompanying, Mr. Francis Bedford, photographer, forms one of that eight. A complete equipment for photographic operations will be taken so as to secure, under tho best possible conditions, photographic mementoes of a journey through scenes so fraught with historic aud sacred associations. Mr. Bedford has, we believe, received permission to publish the series of photographs, when, after their completion, the requirements of Her Majesty aro supplied. The 13th instant is fixed for the Prince leaviug England.

The Photographic Society.—The Annual Soiréo of the Photographic Society will be held in the Great Hall at King's College, on tho 25th of April next. It has been suggested that it would have been desirable to hold it a month later, to admit of the opportunity of a re-union of Continental and English photographers, as many foreign artists will doubtless be present at the Exhibition. The evening appointed is, however, the only occasion upon which the hall is at liberty. It is not impossiblo that many foreiguers who may be iuterested in being present will be in England a few days before the opening of the International Exhibition.

Bromides in Instantaneous Collodion.—At the recent meeting of the French Photographic Society, Major Webster Gordon, whose instantaneous and other pictures excited so much admiration iu the Paris Exhibition, presented some iustantaneous pictures to the society. In a letter which accompanied the prints he stated that the point of especial interest connected with them, was the unusually large proportion of bromide iu the collodion, which contained equal parts of bromide and iodide of cadmium. The negatives were developed with pyrogallic acid, with which developer somo authorities have regarded bromides as rendering the collodion slow. Major Gordon, however, secures instantaneous pictures by their use.

Egypt in the Stereoscope.—Mr. Bonomi has arranged a hundred stereoscopic views in Egypt, taken by Mr. Frith in 1859 and 1860, into a volume, which Messrs. Smith and Elder have published. Our readers know the very high interest and all but perfect beauty of Mr. Frith's Egyptian views, a great number of which are already familiar in the stereoscopic form to lovers of Oriental scenery and ancient art. Mr. Bonomi has supplied the letter-press, and Mr. Samuel Sharpe added a few notes.—*Athenæum.*

South London Photographic Society.—The usual monthly meeting will be held at Sussex Hall, Leadenhall Street, on Thursday evening next, when Mr. Sebastian Davis will read a paper on the "Mauufacture of Collodiou."

## To Correspondents.

⁂ To Advertisers.—Tho unusual press upon our advertising columns this week compels us to omit mauy advertisements.

Henry Hele, referring to our remarks on toning after fixing, where we remark that in such case "much of the toning is probably due to sulphur," asks where the sulphur is to come from if the hyposulphite have been carefully removed from the print by washing, prior to its immersion in the toning bath. Our remark was founded on the fact that in the majority of the methods proposed for toning after fixation, a mixed bath of hyposulphite of soda and gold is recommended, and that where the simple gold bath is used, the print is often immersed before the hyposulphite of soda is entirely removed from the priut by complete washing. If all traces of hypo be removed, there will not, of course, be any risk of sulphur. The only difficulties then existing will be tardiness in toning and troublesome multiplicity of processes, as the print must be submitted to two thorough washings instead of one. Our meaning in stating that sulphur is not so discriminating in its action as gold, was simply this: toning by gold is regulated carefully by the surface of silver; a particle of reduced albuminate of silver is toned a purple brown, when a particle of reduced chloride by its side would be toned blue black. Whereas in sulphur toning, the effect being produced by the decomposition of hyposulphite of silver throughout the print, the distinction between the organic and inorganic salt of silver does not become apparent in the tone. It is a moot point whether acetic or nitric acid should be added to the silver bath for printing. We prefer a little of the latter, as the paper keeps better without discolouration after sensitizing, and we think the prints are more brilliant.

A Constant Reader.—No. 76 of the Photographic News will not be reprinted at present.

C. A. R.—Marine glue is a better cement for glass than Canada balsam in making a bath. 2. The yellow stains in your print are due to imperfect fixation. It has not remained long enough in the hypo, or the solution has been too weak. A print on *Saxe* paper would fix in a much shorter time, because being of a softer texture it is more easily permeated by the solution *Rive* paper is horny, and requires a longer time to be permeated by the solution.

Clifton.—The quantity of oxide of silver necessary to neutralize a nitrate bath, will depend entirely on the quantity of free acid. There is no danger of adding too much, as any excess will be removed on filtering. The case which you describe of adding a large quantity, which remained in excess whilst the solution turned litmus paper red, arises probably from the fact that the oxide had been made some time and stood in the light. In that case it is much more tardily acted on by the nitric acid. Make a little fresh and use it when made. 2. The pictures called *alabastrine*, when properly produced, we believe to be permanent. We have some before us now, which have been done four or five years, and are unchanged. Much depends on allowing the solution to act upon them for a sufficiently long time. 3. Craping of the film in drying generally proceeds from the presence of too much water. It may be that the collodion is made with too weak solvents. In that case the remedy is a better sample. A very common cause is immersing the plate in the nitrate bath before the film has thoroughly set; care in this respect will often remove the evil.

T. P. E.—The residue which does not dissolve in your solution of gold, is probably silver, which is converted into a chloride by the hydrochloric acid. The quantity of protosulphate of iron is immaterial so long as there is sufficient to precipitate the gold; to ascertain which, after adding what you believe to be sufficient, let the solution stand until it is clear, and then decant the supernatant liquid, and add more iron to it. If all the gold be thrown down there will be no turbidity, but if any gold still be present in the solution it will be thrown down as before. The amount of dilution in the first place, the amount of iron in the second, and the amount of acid in the third, are all comparatively unimportant, so long as they each do their work, after which they are removed. After first dissolving the gold, dilute well: then take care to precipitate it all. Now wash the precipitate to remove any iron; then redissolve and afterwards evaporate the acids. There may be gold in your old hypo bath; but it is doubtful whether it is worth the trouble of recovery. We can only explain the anomaly in the registration of your hydrometer by supposing it is incorrectly graduated.

Exhibitor, G. H., J. T., Solar, F. S., N. C., Apparatus, A Disappointed Applicant, A. C., W. A. H., and other correspondents, are referred to the first article in the present number.

J. Lea.—Consult the recent articles on mealiness, which have appeared in our columns. The specimen sent is a virulent case of that evil. 2. An article on varnishes for prints in our next. 3. We believe both the collodions you name are good, but we cannot say which is best.

R. J. D.—More light on the face would probably be better, but the image is too feeble altogether. Intensifying *does* alter the relative degrees of light. It increases the light, and leaves the deep shadows in their original condition. A collodion giving a little intensity to begin with, would probably be better.

C. J. P.—We have seen very good results produced by the single lenses of both the makers you name; they are each, we should say, equally good.

S. Hill.—There is not, that we are aware of, any book giving instructions for using the photogen. A paper descriptive of the operations is supplied, we believe, with the instrument. The dealer in second-hand apparatus you name is a respectable man. Second-hand articles will be, of course, of all qualities.

Vortex.—If you place the painting in such a position that it gives a perfect image on the ground-glass without false reflections, you ought to be able to produce a picture without fogging. Probably it is a question of exposure. Take care to give long enough, and use a weak iron developer, with plenty of acetic acid. Sometimes inclining the top of the painting a little forward, taking care to keep the camera parallel to it, is useful in avoiding these reflections.

E. E. L., William Clark, W. H. Bolton, John Hollingsworth, Tom Gardner, W. W., J. B. Y., Jacobus, J. F. Ward, A. L. H., James Caldwell, Toby's Ghost, and several other correspondents in our next.

No Chemist.—Crystals of chloride of barium, as sold in the shops, contain Ba Cl × 2 HO = 122. The two equivalents of water may be driven off by heat, when the formula becomes Ba Cl = 104, or *anhydrous* chloride of barium. The chlorides of ammonium, potassium, and sodium, do not contain water of crystallization, their equivalent weights are, therefore, 54, 76, and 60, respectively. Hence in

54 grains of chloride of ammonium,
60 ,, ,, sodium,
76 ,, ,, potassium, or
122 ,, ,, barium, (crystals,)

will be 36 grains of chlorine, which combine with 108 grains of metallic silver, or 170 grains of nitrate of silver, to form 144 grains of chloride of silver. If, therefore, 10 grains of chloride of sodium to the ounce in albumenized paper be taken as a base for comparison, we find that in substituting the other salts, we should have to employ 9 grains of chloride of ammonium, 12⅔ grains of chloride of potassium, or 20⅓ grains of chloride of barium In this calculation, you will perceive that the anhydrous chloride of barium is omitted, as the crystallized salt is that invariably used. Whenever a salt contains water of crystallization, such must of course be taken into account on calculating the equivalent weight.

All Letters, Works for Review, and other Communications for the Editor, should be addressed to the Office, 32, Paternoster Row, London.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 180.—February 14, 1862.

## THE PROJECTED ADDITIONAL PHOTOGRAPHIC EXHIBITION.

The negotiations for holding a photographic exhibition in connection with the South London Photographic Society, to which we referred in our last, are in progress with every probability of a satisfactory and successful termination, under conditions most favourable to photographers. It is hoped that facilities will be secured for the exhibition of new appaiatus and inventions in connection with the art, which will be satisfactory to many houses who have failed to secure allotments at South Kensington. If the arrangements terminate as successfully as we have reason to hope, the causes for regret arising out of the inadequate representation of photography at the International Exhibition during the coming summer will be deprived of very much of its force. We hope shortly to be able to announce full particulars.

## Scientific Gossip.

Preparation of Pure Nitrate of Silver—Properties of the Pure Salt—Not Alkaline, as usually reported, but Neutral—Solution under Pressure.

We have considered it of interest occasionally to lay before our readers in these columns short abstracts of what has lately been done by the Belgian chemist, M. Stas, in his researches on the atomic weight of silver, and its compounds. Perhaps amongst all these facts, the most interesting and important (to us) are those which relate to nitrate of silver; we will therefore follow up our previous articles on the subject by condensing from the voluminous memoir before us a few particulars respecting the formation, purification, composition, and properties of this salt. The most advisable way to prepare nitrate of silver was ascertained by M. Stas to be to dissolve the pure metal in an excess of nitric acid in a Bohemian glass flask, to the neck of which was attached an arrangement of tube, and bulbs containing liquid so as to prevent silver being carried away by the evolved nitrous gas. The silver being dissolved, which requires from twenty-four to forty-eight hours, according to the quantity of the metal employed, (M. Stas worked upon from 100 to 200 grammes of silver at a time,) the flask is inclined, and a receiver attached to the neck. The liquid is then carefully evaporated to dryness; the temperature being raised near, but not quite, to the boiling point; this takes from forty-eight to seventy-two hours. After the evaporation of the liquid, the temperature of the dry nitrate is raised to its fusing point, and kept there until it is of a constant weight. To hasten its drying, and especially to drive away the last traces of nitric acid which the salt retains, there is passed through the vessel a current of air, which has been first deprived of organic matter by being passed through a red hot glass tube containing tarnished copper (which yields its oxygen to the carbon and hydrogen of the organic matter), and then through tubes containing dried chloride of calcium to remove the moisture. These precautions were necessary, since it was found that the air of the laboratory, or even the external air simply filtered through cotton and then dried, slowly but continuously reduces nitrate of silver heated to its fusing point, and still more quickly when fused, with elimination of nitric acid. When it is found that the weight of the dried salt is perfectly constant, the temperature is again increased, so as to fuse it, and it is then kept in fusion in a current of air deprived of organic matter and water until its weight becomes absolutely constant. M. Stas states that in many experiments he has kept nearly 500 grammes of nitrate of silver in a fused state, from eight in the morning till ten at night without in the least diminishing its weight.

Whenever purified air was made use of in any of these experiments, the nitrate of silver obtained was perfectly colourless in the fused state, and after solidification was of a pearly white colour, with a radiating fracture. It was found to be very slightly hygroscopic after fusion; a property which the crystallized salt does not appear to possess, *and was always neutral to test paper.* This is a very important observation, as it is in opposition to statements which have frequently been made by photographic authorities when writing on this subject. Thus, Hardwich in his "Photographic Chemistry" says, that the aqueous solution does not redden blue litmus paper; on the contrary, the pure recrystallized and dried nitrate of silver restores the blue colour of paper previously reddened. This statement has been repeatedly made and copied into other works. It is probable that the slight decomposition which M. Stas mentions as always taking place when nitrate of silver is prepared in contact with air not previously purified, and which consists in the decomposition and removal of nitric acid, and the separation of metallic silver or its oxide as a black powder, may be the cause of this alkaline reaction. It is not yet definitely settled whether the black deposit is silver or oxide of silver, but in either case it might give rise to an alkaline reaction. Supposing it to be the metal, it is known that when finely divided metallic silver is boiled with nitrate of silver in solution, it is dissolved with evolution of nitric oxide forming a light yellow liquid, containing basic nitrite of silver, which has an alkaline reaction. If on the other hand it be the oxide of silver, it is equally certain that this would dissolve in the nitrate of silver solution, and give it an alkaline reaction. In either case then, nitrate of silver made in the way universally adopted, would, even if all the usual precautions were taken, be liable to communicate a blue colour to reddened litmus paper. This, however, after the experience of M. Stas, does not prove that pure nitrate of silver has an alkaline reaction, but merely shows that the specimen, upon the examination of whose property this character has been ascribed to it, was not absolutely pure.

To return to the properties of the pure nitrate. The crystallized salt when dried in a current of air at its fusing point, still loses weight when it is actually fused. The loss is however very trifling. Pure crystallized nitrate of silver kept for six months under a bell-jar in an atmosphere artificially dried with concentrated sulphuric acid, lost in an experiment tried on a tolerably large scale, one four-thousandth of its weight upon fusion. This salt which would be considered by all chemists as anhydrous, loses therefore three times as much water as the salt obtained by direct synthesis and dried at its fusing point. It appears probable, however, that all the loss experienced by the crystallized salt upon fusion should not be attributed to the disengagement of water; it may possibly be that the air, condensed by the surfaces of the small crystalline plates, has something to do with it.

The nitrate of silver was not in every case prepared in the manner described above. It was found that there is a slight loss of silver when the metal is dissolved in nitric acid in the ordinary way. The following modifications were therefore introduced into the mode of operating. The silver was introduced into a white glass flask, with the stopper well ground in with emery, and having very thick sides, so as to enable it to withstand an internal pressure of at least ten atmospheres. On this metal was poured about ten times its weight of pure strong nitric acid. The stopper was put in, and fastened strongly in its place with thick cord. The flask was then closely surrounded with thick wire gauze, and placed in a bath where the temperature could be raised to 45° to 50° C. At the end of twenty-four or thirty-six hours, all the silver is dissolved quietly, like sugar would dissolve in water, without a trace of gas developing itself, and without anything escaping from the flask. Indeed, the binoxide of nitrogen as fast as produced reduces the nitric acid into the state of nitrous or hyponitrous acids, which at this temperature remain perfectly dissolved in the large excess of nitric acid employed. If the temperature of the bath does not exceed 50°, there is really nothing to fear; indeed, M. Stas states that he has made under these conditions, and without any accident taking place, upwards of a hundred solutions of silver in a closed flask, employing from three to fifty grammes of silver at a time. Twice only, the temperature of the bath rising much too high, did two flasks, which were immersed in it, yield to the internal pressure, and produced a rather violent explosion.

It is probable that this process of dissolving silver in nitric acid could be advantageously employed on a large scale in manufacturing the salt for commercial purposes. There is an appreciable quantity of silver carried off by the gas and acid vapours evolved when the metal is dissolved in nitric acid in the ordinary way, and this, when we take into consideration the large scale upon which manufacturing operations are conducted, would in time amount to a considerable quantity. Dissolving the metal in closed vessels would entirely obviate all danger of loss from this cause, and would likewise be of use in another way. Whilst the metal is being dissolved with free exposure to the air, there is always the danger of—nay, the impossibilty of avoiding—the absorption of floating atmospheric organic matter in the acid; but when the solution is effected in a closed vessel, there is a chance of the nitrate being less contaminated, inasmuch as the most critical part of the operation has been performed out of contact with the air.

We have to report upon three samples of illuminating media for the dark room. One is a brown glass of a rather dark colour, sent by M. A. It cuts off all the active rays, except a trace of the upper green and lower blue. In a dark situation, and with an iodised collodion, it would answer very well, but would not be safe to use under all circumstances. M. A. also sends a piece of varnished yellow muslin. This is worthless, the blue rays coming through in quantity.

W. L. likewise sends a piece of calico prepared with four coats of glue and $\frac{2}{3}$-grain of nitrate of silver to the ounce of solution. This is far inferior both in appearance and absorptive properties to those we recently reported on. It allows abundance of active rays to pass through, and an attentive examination with the naked eye shows that it is covered with minute holes admitting white light. It is, therefore, quite unfitted for the purpose for which it is intended.

## REMARKS UPON SOME OF THE APPARATUS EMPLOYED IN PHOTOGRAPHY.*

BY F. R. WINDOW.

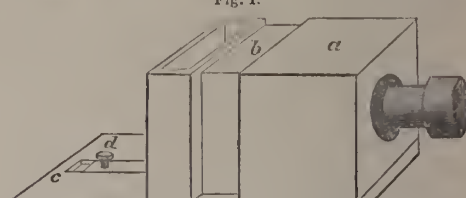
CAMERAS.—*Continued.*

*The Studio Camera.*—The office of a camera is extremely simple. It is to support the lens and the sensitive plate, at a proper distance apart, in such a manner that no ray of light shall shine upon the prepared surface of the latter, excepting those passing *directly* through the former.

The studio camera consists of the body, generally formed in two parts, called the outer and the inner body; the focussing-screen, and the plate-holder or slide.

*The Camera Body.*—It has been remarked above, under the head of *lenses*, that a double-bodied camera is to be preferred for portraiture, the focal distance being adjusted by sliding one body within the other. The ordinary form of camera is not very conveniently arranged for this purpose. The outer body, *a*, (fig. 1) carries the lens, and is fixed on to the table or base. The inner body, *b*, sliding upon this table carries the plate-slide. In the slot *c*, in the table,

Fig. 1.

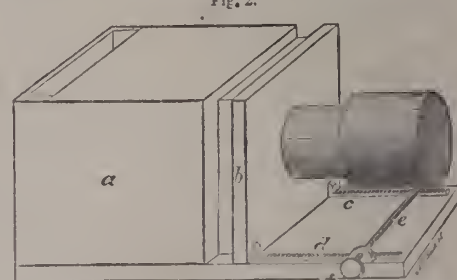


runs a metal rod attached to the inner body, which serves more or less to preserve the parallelism of its motion, and, by means of a screw, *d*, and a nut underneath the table, can be clamped tight, retaining the sliding body in any required position.

Thus, the only means of obtaing a correct focus of an object with this camera is to take hold of the projecting portion of the inner body with both hands, and push it inwards or pull it outwards, as the case may require; and when the desired position is attained clamp it with the screw. This is so inconvenient in practice that it has almost necessitated the use of a lens having a rack and pinion, with which the exact focus is ascertained, after having obtained it approximately by moving the body.

I lately suggested to one of our first opticians a movement for the sliding body, and an arrangement of the parts, which he at once adapted to all his cameras; and I perceive that many houses are already beginning to adopt the same design, which I will describe, as I believe it is a considerable improvement upon the old form, which I have just given.

Fig. 2.



In this camera the body, *a*, (fig. 2) fixed to the table, carries the plate-holder, and the moveable body, *b*, carries the lens. To the bottom of the front of the moveable body, *b*, are screwed two racks, *c* and *d*, one at each side and within half an inch of the edge. These racks, parallel to each other, lie upon the table of the camera, and both work in one pinion, *e*, terminating in a milled head, *f*. By turning the milled head the sliding body is moved backwards and forwards smoothly, and the parallelism of the motion is assured with a certainty which could not well be attained in any other way. This quality is especially valuable for binocular stereoscope cameras, or for carte de visite cameras in which two or more lenses are used simultaneously.

Another advantage possessed by this form of camera is that the plate-holder is in that portion of it which is fixed

* Continued from page 53.

to the table, and, therefore, there is no chance of disturbing the focus by putting it in or taking it out, which, if the body be not well clamped down, sometimes occurs with the ordinary camera.

The addition of the racks and pinion, of course add a little to the expense of the camera, but they replace the guide bar, clamp, and screw of the old system which diminishes this extra cost. In any case this form is not so expensive as the rack and pinion adjustment to one lens, it is more practically efficient, and one camera so fitted will serve for all lenses, which may be mounted in a simple rigid tube. To the purchaser of the complete apparatus consisting of camera and lens, this form would be cheaper than the usual design of camera with a lens having a rack and pinion motion.

The endless screw movement for advancing the inner body, or for any purpose of focussing is open to objection. The movement is too slow, and the eye has great difficulty in appreciating the exact value of the gradually changing image on the screen. The precise point of focus is mostly estimated by *contrast* with positions a little on either side which appear less perfect; but if this contrast is brought about very gradually the power of appreciation is less sensitive. Those who are accustomed to use the microscope well know how difficult it is to get the exact focus with the fine adjustment.

The inside body of the camera is always made to enter flush into the outer body, depending upon the exactness of the fitting to exclude all light, as shown in the section, (fig. 3). This is a fault, for two wooden surfaces cannot well make a light tight joint, unless they are kept by pressure in intimate contact. This is the cause of much inconvenience; of light getting into the camera, or of the bodies not working smoothly one in the other. The former is the more common consequence, but it is the most difficult to detect, and to remedy.

The danger of light entering the camera becomes greater as the inner body is more pulled out, and it is never safe

Fig. 3.

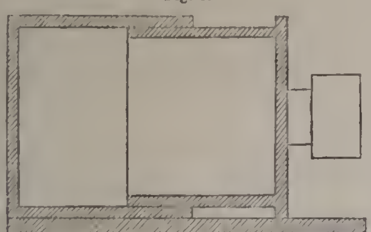


Fig. 4

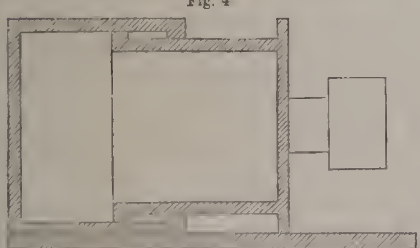


to employ to the utmost the powers of extension. A piece of cloth or velvet is sometimes placed upon one or both of the surfaces to make the joint more light tight, but this produces as great an evil as the one it is intended to correct, the friction soon partially wears these substances, and every movement of the body inward or outward scatters their dust about the inside of the camera.

A proper way to make this joint is to run a strip of wood one-eighth of an inch thick, and a quarter of an inch wide, round the inner edge of the outer body, and also round the outer edge of the inner body, as shown in fig. 4. In this manner light is entirely excluded without the necessity for a very tight fit, or recourse to packing of any description. The frictional surfaces also are reduced to a trifle and the movement is rendered easy and regular. This plan of adjusting the inner to the outer body decreases the dimensions of the former by a quarter of an inch, which if it carries the lens, as it ought, is of no consequence; but if it is made to carry the plate-holder, the difference must be allowed for by increasing the outside body by so much.

The front of the camera which holds the lens should have a vertical movement in order that the image upon the screen may be brought into the required position without altering the level of the camera. This is usually made so that when the lens is in the middle of the instrument, the moveable front is at its lowest point, and allows, therefore, only of an upward motion. For this reason it is called a "rising front." But, as it as frequently happens that the image requires to be lowered, as to be raised, the movement should be contrived so that the lens is in the centre of the instrument, at the middle point of the motion of the front; by this means both an upward and downward movement is at command.

The amount of vertical movement that can be given to the camera front depends upon the nature of its construction, but in all cases it should be as much as possible.

A camera for the studio, where size is of no object, should be considerably larger in all directions than the largest picture it is intended to take; and a diaphragm should be placed about an inch and a half in front of the plate, with an opening just sufficient, and no more, to give passage to the direct rays from the lens on to the plate.

This is seldom found in the cameras ordinarily offered for sale; but it is very important, as it shades the plate from much of the light which would otherwise reach it by reflection from the sides, top, and bottom of the camera. It must be remembered that while a picture is being taken the camera is full of white light, which, coming in through the lens strikes directly upon the surface opposite, that is, the prepared plate, and (if there be no diaphragm) the polished plate-slide; and also, if the camera be narrow in proportion to the angle of the range of the lens, upon the surrounding portions of the top, bottom, and sides. These direct rays are reflected upon other parts of the camera, and ultimately are returned upon the sensitive plate.

These effects will evidently be diminished by the use of such a diaphragm, as I have described. Properly, this diaphragm, which is a fixture, should have fitted to it carriers, or moveable diaphragms adapted to each size plate that the camera is intended to employ.

The fact of the camera being deeper and broader than the glass plate does not necessitate the plate-holder being larger in the same proportion; as, if it is considered advisable, the grooves to hold this latter can be constructed to hold slides of the ordinary dimensions.

It is not necessary to state here that every part of the inside of a camera should be black; but it is as well to remark that a perfectly *dead* black should be employed for this purpose. I have seen a large number varnished brilliantly in the interior with some black spirit varnish. There is an excellent dead-black varnish in the market, which every one can use for himself for this purpose, to which it is well suited.

It has been proposed to line the camera with black velvet. No surface could be more perfect for the purpose, as it is unequalled for its non-reflective properties; but it would be a source of dust and dirt, and for that reason I do not think it is to be recommended.

A shade to protect the lens from all side and top light must be attached, outside, to the front of the camera. This is usually made as if it were a continuation of the four sides of the camera, and projects forward considerably beyond the lens. Care must be taken, however, that it does not project sufficiently far to interfere with the range of the lens, or to offer any inconvenience in taking off and putting on the cap. There is clearly no necessity for the dimensions to be the same as the sides of the camera, provided the lens be well shaded; it is only constructed so usually for the sake of the uniformity of its appearance. The whole of the inside of the shade should be coloured a dead black, or, better still, lined with black velvet, for this being outside the camera there is no reason to fear about dust.

(*To be continued.*)

## PROFESSOR TYNDALL'S LECTURES ON LIGHT.

### Lecture III.—Dec. 31, 1861.

Professor Tyndall commenced this lecture by making a few concluding observations on the refraction and reflection of light. He took a large piece of glass with parallel polished sides, and by means of a bundle of rays from the electric light, showed to the audience that when a beam of light fell upon it a portion of it was reflected, making the angle of incidence equal to the augle of reflection; a portion, however, of the light passed through, and might be found on the other side after having passed through the glass. The light, after having passed through the first surface, and arriving at the lower surface of the glass, did not, however, all escape into the air; some was reflected back again, although the greater portion was refracted through the surface below. The portion of the light reflected upwards from the bottom surface was again split up, on arriving at the top surface, into a refracted ray, which passed out into the air, and into a reflected ray, which went downwards again to the bottom surface. Here, again, the same thing happened, and thus were obtained a series of reflections from the two internal surfaces of the piece of glass. This can readily be observed by any one: take a looking-glass, and, having placed a candle near it, look obliquely at its image in the glass. First of all there is perceived a tolerably bright image, being the one reflected from the silvered surface behind, and then follow a series of images caused by the reflections of the light from side to side becoming gradually fainter and fainter until they are invisible.

Another matter of some importance was then referred to. It was stated, that where there was refraction there was reflection, and where there was no refraction there was no reflection. If any solid or liquid bodies were taken, it was no matter how different they were in substance or in weight, if the solid only bent the rays of light to the same degree as the liquid, it acted upon it just as the liquid itself, and became invisible when immersed in it, owing to the absence of refraction and reflection at the two bounding surfaces. If the eyeball of an ox be plunged into water it vanishes; it appears like the water, although it is a totally different substance. The whiteness of foam and of snow—each consisting really of perfectly transparent bodies—was shown to be due to the repeated reflections of light from particle to particle, occurring so often as to render the mixture perfectly opaque. To illustrate this property of transparent bodies a piece of bibulous paper was taken. This was explained to consist of a multitude of partially transparent fibres, but because they are mixed up with air so much light is reflected at each surface that the paper appears white and opaque. If, however, a substance be introduced into the pores of the paper, which has a somewhat similar refractive power on the light to the fibres themselves, the great reflection and loss of light will be avoided, and the transparency of the paper will be powerfully augmented. Olive oil is such a substance, and the great increase in the transparency of the paper upon touching it with a drop of this liquid was beautifully shown by projecting an image of the paper on the screen by means of the electric light. It was then explained that the terms *dense* and *rare*, applied to a refracting medium, did not refer in any way to the weight of the body. A substance may be *optically denser* than another, though it be the lighter of the two. Thus: spirit of turpentine floats on water, and is therefore lighter, or, in ordinary language, less dense than water; but a ray of light in passing from turpentine to water is bent *from* the perpendicular, and in passing from water to turpentine it is bent *towards* the perpendicular. In optics, therefore, the densest body is that which refracts most.

The important subject of the total reflection of light was then treated of. Supposing a ray of light, passing from a denser medium to a rarer, struck the common surface of both so obliquely, that on quitting the denser medium it was refracted so as just to graze the surface, the angle between that ray and the perpendicular would be called the limiting angle, and for this reason—because no ray that strikes the surface at a larger angle than the limiting angle can get out of the denser medium. All such rays, on striking the surface, are *totally reflected*, according to the law explained in the first lecture. The limiting angle then marks the limits of possible transmission from a denser to a rarer medium. This was explained to be the only case in which the reflection of light was total. It was then shown that a jet of water might be filled with light which could not escape in consequence of the law of total reflection. An electric lamp was placed behind an iron vessel connected with the water pipes of the building, so that water could enter it and issue forth in the form of a jet from a hole in the front, near the top of the vessel. At the back, opposite the hole from which the vein of water issued, was a plate of glass, so that the lecturer was enabled to send a beam of light from the electric lamp through the glass, and straight through the vessel, issuing out of the hole in front in the form of a cone of light. The vessel was then filled with water until it kept running out of the front hole in the form of a jet: upon then turning on the light the beams of light which formerly passed through the hole in the form of a divergent cone, struck obliquely against the interior surface of the vein of water. The consequence was, that they could not get out, and were therefore actually washed down as if the light were a tangible substance, and reflected from side to side; but so obliquely, that they could not quit the liquid. In this way the whole of the jet of water was illuminated from top to bottom by the carrying down of the light which formerly passed straight through. When the Lecturer interposed coloured glasses in front of the lamp, the effect was most gorgeous, the vein of water shone with the most vivid colours, appearing alternately a bright blue, golden yellow, deep purple, and intense fiery crimson. The experiment is one of the most beautiful in the whole range of optics, and elicited universal admiration.

The instrument known as the magic lantern was then described. It was shown to consist simply of two parts, one to illuminate the object, and the other to make a magnified image of that object on the screen. It was was illustrated by placing a glass transparency in front of the electric lamp, and then arranging a single lens in front of this so as to project an image of the picture on the screen. The compound solar microscope was shown to be in effect the same thing as a magic lantern only much more refined. It consists of a little system of lenses, by means of which a very high magnifying power can be brought to bear upon any object placed between two slides and powerfully illuminated by other lenses close to the lamp. By means of an apparatus of this kind the singularly beautiful phenomena of the formation of crystals from a saturated solution of sal-ammoniac was shown on the screen. At first a plain white disc was seen; then the film appeared to move in one corner, and the " atoms marched in time," running together as if they were alive, weaving a crystalline web of such delicate beauty that nothing man ever formed could approach it.

The human eye, that most wonderful optical instrument of all, was then described. This was shown to consist first of all of a substance just in front of the eye like a watch glass, called the cornea; it holds a little fluid called the aqueous humour, and behind that there is a little lump of jelly-like matter called the crystalline lens. Behind is the general mass of the eye ball, filled with what is called the vitreous humour. A large artificial eye was then built up of a glass globe filled with water, having a black paper iris with an an opening in it, for the pupil, in front of this a lens, and at the back a tissue paper retina. Objects were held in front of this large eye, and upon being illuminated by the electric light, they were seen by the audience to be distinctly projected on the tissue paper retina at the back, but in an inverted position. This was explained to be the case with the human eye, the image on the retina of all objects which are looked at being in an inverted position. For distinct vision, it was shown to be necessary that the rays from every point of an object should come to a focus *upon* the retina. Some eyes, however, refract too much and bring the rays to a focus too soon; to remedy this defect a *divergent* lens was shown to be necessary to be placed before the eye; this was explained to be *short* sight. Other eyes, on the contrary, do not refract enough, and to help them, a *convergent* lens is placed before the eye; this is long sight. Different spectacles were then taken and exhibited in the beams of the electric light. The action which they exercised on the rays was clearly visible.

In conclusion a few words were said upon the action of light upon the eye. The effect does not subside the moment the light ceases, but endures about a quarter of a second after the light has ceased to shine. A succession of sparks, therefore, which follow each other at intervals of a quarter of a second would appear as a continuous line, and if the end of a burning stick were taken and moved round in a circle in about the fifth of a second, the circle would appear as a continuous line of light. Instead of a burning stick a beam of light was reflected, by means of a looking glass, to the ceiling, when upon rotating the mirror, the fine luminous index travelled round and gave the appearance of a continuous ring of light, because every revolution was accomplished within the time that the image took to subside.

## ON A NEW PROCESS OF PHOTOGRAPHY WITHOUT SILVER.

BY DR. T. L. PHIPSON, F.C.S.

MEMBER OF THE CHEMICAL SOCIETY OF PARIS, &c., &c.

THIS process, which is founded upon the use of oxalate of iron, was discovered by me about a year ago. I gave a slight sketch of it in the *Moniteur de la Photographie* of Paris, for October 1st 1861, and I did not intend to say anything more about it until I had made further experiments, with a view of testing its value in comparison with the use of salts of silver. But a few weeks ago, to my surprise, I perceived that Mr. Reynolds had brought it before the Dublin Chemical Society as a novelty, and moreover as a discovery of his own. But this author has had recourse to nitrate of silver to finish his proof, whereas in my process, no silver is used at all. It is well known that light has a peculiar action (a reductive action) upon many organic salts of iron, more especially upon the *oxalate of peroxide of iron*, which it reduces to the state of *oxalate of protoxide*. The first of these salts forms beautiful emerald green, prismatic crystals, extremely soluble in water, and decomposable by light; the latter salt is yellow, insoluble in water, and not influenced by light.

The first thing to be done is to prepare a concentrated solution of oxalate of peroxide of iron. For this purpose I take a solution of chloride of iron, and having precipitated the peroxide of iron by ammonia, I collect it upon a filter and wash it with boiling water, after which this acid is dissolved in a warm concentrated solution of oxalic acid. A beautiful emerald green solution is thus obtained, which must be concentrated a little by evaporation, and then set aside in a dark place for use.

If this solution be exposed to the sunlight, microscopic yellow crystals of oxalate of protoxide of iron are deposited, more or less rapidly, until the solution contains no more iron, and has become perfectly colourless. Upon this remarkable decomposition is founded the process of which I speak. The paper destined to receive the photographic image is floated for about ten minutes upon the green solution of oxalate of peroxide in a flat dish or capsule, to which a certain quantity of oxalate of ammonia has been added; the whole of course being kept away from the daylight, and at the expiration of that time, the paper is taken out of the solution and hung up by one of its corners to dry.

Let us suppose, for example, that a positive proof is required; the paper thus prepared is placed behind the negative and exposed to the light for ten or twenty minutes, according to the weather. It is then well washed with distilled water or with rain water (spring water will not answer, on account of the lime it contains which decomposes the image by forming oxalate of lime). All the non-decomposed oxalate of peroxide of iron is thus washed from the proof, and a feeble yellow image of oxalate of protoxide, scarcely visible, is left upon the paper.

The best means I have hitherto discovered of developing the image and obtaining proofs equal in tone, colour, and vigour, to those obtained with salts of silver is as follows:—

The faint yellow proof is plunged for a little while into a solution of permanganate of potash, to which a few drops of ammonia have been added. In this bath the image soon becomes brown and distinctly visible; it is then withdrawn, washed, and plunged into a solution of pyrogallic acid, where it is allowed to remain for half-an-hour, after which it is taken out, washed, and dried.

The image thus developed is a very dark brown, and can be distinguished with difficulty, by inexperienced eyes, from proofs obtained with silver, the tones are peculiarly soft and permanent in the proofs I have made.

This process is, therefore, extremely simple, and as the use of silver is quite excluded, I imagine it will prove economical. A few experiments I have made without a camera seem to indicate that oxalate of iron may be used in the camera for producing negatives, which must be afterwards developed, as above, with permanganate of potash and pyrogallic acid. But I should much like to hear the results this process, or some modification of it, would furnish in the hands of a practised photographer.

## THE PHOTOGRAPHIC PLANE TABLE OF M. AUGUSTUS CHEVALLIER.*

BY LIEUT. PATE.

THESE statements are all the results of operations made by ourselves for the purpose of testing the apparatus. Upon being invited, M. Chevallier did not hesitate to come to Arras to put his instrument to the proof. Neither the officers who took part in the experiments nor myself are expert photographers, so that our sweeps of the horizon are not so sharp as might be obtained with more experience and with better materials; but this question of sharpness of image in the pictures obtained by a continuous rotary motion so successfully solved by MM. Martens, Garella, Baldus, and many others, is a decided progress accomplished in photography and cannot form an objection in this place.

We have operated:—1st. With fixed sectors of 5° each. 2nd. By a continuous motion. The two methods have not only given identical results, but the plan of the front of the citadel of Arras, executed during these operations has furnished a result completely in harmony with the very exact plans deposited with the regimental school of engineers.

We can, therefore, attest the great excellence of this instrument, which Colonel Valdés, in his report to General Zara del Valle, describes in the following terms:—

"The ingenious photographic process devised by M. Chevallier is entirely free from error, very rapid in execution, and requires, in the triangulator, no other special knowledge than that of photography."

Beside its applications to ordinary topography, this instrument is susceptible of a great many others, which are

* Concluded from p. 64.

not without interest. With the photographic plane-table, we can, as pointed out by M. Gay Lussac, reproduce scenes passing simultaneously at different parts of the horizon: for example, we can obtain, without the possibility of error, as pointed out by M. Benoit, in his report, the positions of an army on a field of battle during the principal phases of an engagement. Then, again, in a besieged place, what facilities it affords for surveying from some elevated site, a church tower, for example, the movements of the enemy, and transmitting them to the army of relief to guide its operations.

It does not enter into our plan to speak of the commercial applications of this instrument, of the anamorphic properties of the sweeps of the horizon, of the restoration of the parallels of the verticals by mirrors, either cylindrical or conical, nor of the curious geometrical results which are given by this kind of anamorphosis.

We must be equally silent on its application to the taking the panorama on the external surface of a fixed cylinder or a prism, the reverse of the operation described above.

We can only refer a moment to another application of the photographic plane table, the happiest, which promises in the future the most astonishing results, viz., its utility in the geodosy of an unknown country. And M. Faye himself, when he so warmly praised the geodesic operations of M. d'Abbadie, in Ethiopia, doubtless pleaded the cause of M. Chevallier's ingenious instrument without intending it.

For what took M. d'Abbadie so much difficulty and courage to perform during many long years, the photographic plane-table gives with the greatest facility, so that the traveller takes care to number his proofs successively of the sweeps of the horizon, then he can, after two or three years or more, of travel through an unknown country, construct very exact maps at his leisure; in a word, the new workman presented to us by M. Chevallier is always ready for work, and only asks to make the tour of the world.

The utility of photography in a military point of view has recently been approved by a decree, which proposes that no other instrument should be employed beside the camera obscura; now we have an instrument which, without sacrificing any of the properties of the camera at the same time gives us very correct measurements, it is quite natural therefore, that the photographic plane-table should attract the attention of scientific men, and that it should be proposed as the type of military photographic instruments, and that therein M. Chevallier should find a first recompense for his labours and sacrifices.

The principle of the instrument remains unchanged, although since its first appearance it has undergone many important improvements, has been simplified in its mechanism. and rendered lighter and more portable. We hope on a future occasion to give a detailed description of the instrument, with diagrams, and a plan of the front of the citadel of Arras, made from materials furnished by the plane-table the proofs furnished by fixed sectors, together with special instructions for using the instrument, and on the application of the proofs for producing successively topographic plans, orographic maps and geographic charts.

## Critical Notices.

THE JAPANESE: THEIR MANNERS AND CUSTOMS; with an account of the general characterics of the Country, its manufactures and natural productions. By Thomas Clark Westfield. London; Photographic News Office, Paternoster Row.

The substance of this work was originally delivered as a lecture at the Marylebone Scientific and Literary Institution. It contains a careful resumé of the best information which various explorers have contributed respecting a country and a people, regarding whom so little has been, until recently, known, notwithstanding the great interest attaching to them. The literary portion of the book is characterized by clearness and modesty. The subject has been carefully studied, and is stated with lucidity and brevity. Its especlaim to the attention of photographers is, that besides being written by a photographer, it is illustrated by a series of very choice photographs, consisting of stereoscopic views of the country and people. These have been selected with considerable judgment from the series of Japanese slides published by Negretti and Zambra. As photographs, they are very good: much better than we have frequently seen produced in a tropical climate, being soft, delicate, and full of detail as well as brilliant. The subjects cannot fail to be very interesting, including, as they do, a variety of characteristic scenery and native portraits. A group of "Japanese Ladies," in winter costume, especially please us; one of the faces possesses a placid sweetness, which, despite the Tartar type of features, the costume, &c., we should call beautiful.

The work is very handsomely got up in small quarto: it is well printed and handsomely bound; and the photographs are on tinted mounts with ample margin. Altogether, the volume will adorn worthily the drawing-room table.

THE PRACTICAL ELOCUTIONIST: an extensive Collection of Recitations, selected and arranged expressly for School use; with a few plain Rules for Inflection, Modulation, Gesture, and Action, and Rhetorical Punctuation. The principal positions illustrated from Photographic Studies taken expressly for this Work. By C. H. Pinches, Ph. D., M. A., &c. London: Kent & Co.

The especial claim which this work appears to have on our attention arises from the fact that the illustrations are from photographic studies taken expressly for the purpose. These illustrations, which have been engraved on wood from the original photographs, are very valuable, and will convey to the youthful student a more apt idea of the value and effect of graceful and appropriate position and action than many chapters of mere description. There is something very satisfactory in the photographic truth of drawing in these diagrams, in contradistinction to much of the stiff and conventional which so often characterizes, or used to characterize, similar illustrations.

Having examined the part of the volume which at first glance claims our attention as associated with photography, we find on further examination, that the work is as complete and valuable in every department as it is in illustration. Notwithstanding that we cherish an affectionate remembrance of the "Murray's Reader," the "Enfield Speaker," and the still older "Scott's Elocution" of our school-days, we are constrained to admit that the book before us is a vast improvement on these works, both as regards the simplicity and clearness of the instructions and rules appertaining to elocution as an art, and the choice selection of pieces in prose and poetry for practice. The book will be a treasure to an intelligent schoolboy, and is a valuable work of reference for the library.

STEREOSCOPIC VIEWS OF PARIS. London Stereoscopic Company, Cheapside.

The London Stereoscopic Company have just issued a further series of Mr. England's admirable stereographs of Paris, instantaneous and otherwise. Of the instantaneous street scenes, it is only necsssary to say that they surpass, if possible, in definition and detail, his former pictures. Some of the subjects are somewhat crucial tests of instantaneity; here, for instance, in No. 91 is a regiment of infantry, five abreast, with fixed bayonets, marching towards the camera; every detail in every part is rendered without the slightest confusion. Here also in No. 101, "Halles Centrales," is a busy market-scene, containing a surging crowd of many hundreds of bustling moving people, all perfectly detailed. Many of the subjects are very perfect as pictures, altogether apart from their interest as instantaneous views. Of these we may mention No. 106, a view in the Rue Royale, with natural clouds, which is a most charming composition, and a fine photograph. In this series, Mr. England has produced some very fine interiors. In speaking of them we accord them very high praise when we state that we think some of them are equal to Wilson's interiors. Several views of the interior of the church of St. Etienne du Mont, which we believe presents some considerable difficulties as regards the question of lighting, are exceedingly fine. The magnificently carved pulpit, which, though nearly black and dimly lighted, is here secured with the most perfect definition, detail, and gradation. There are also some fine pictures of scenes in the Bois de Bologne, which are very perfectly executed.

## ON THE MANUFACTURE OF COLLODION.

BY THOMAS SEBASTIAN DAVIS.*

There are few investigations in connection with modern photography that possess greater theoretical, chemical, and practical interest than those associated with the manufacture of collodion. The interest and importance of the subject are not exclusively derived from scientific considerations, but are intimately associated with the greater or less facilities that the compound is capable of affording for the production of artistic effects. It is true that the pictorial merits of a photograph can only partially constitute the standard for a just estimation of the exact value of a collodion or process; yet it is equally undeniable that the conceptions of a cultivated taste may be fairly expected to realize a nearer approximation to its sentiments, when aided by the more appropriate agents. Regarded in this aspect, the manufacture of collodion, and the characteristic results dependent thereupon, constitute a theme of recurrent interest, and one which, from time to time, should be brought under our notice in order to adapt its qualifications to the current requirements of the artistic photographer.

The preparation of collodion embraces the consideration and realization of two especial qualifications; the one the production of a medium that will possess the necessary physical properties of yielding a homogeneous and even film after evaporation from a smooth surface, and the other the power of giving an image possessing the nearest approximation to a true representation of the varied gradations of light and shade as seen in nature. The former requirement directs our primary attention to the constitution of the plain collodion, and the latter to the nature of the salts best adapted for receiving the actinic impression. I purpose, in the present paper, detailing the methods by which the above conditions may be most satisfactorily attained according to the result of my own varied experiments in connection therewith. It may be well here to remark that the special formula which I am about to advocate is the one which I have especially found advantageous to adopt in working the wet collodion process with iron developers, and the washed collodion albumen dry plate processes generally. It is one by which a collodion may be prepared in every respect adapted for yielding the best results with pyrogallic acid development; but under such circumstances the necessary impression of the latent image is received with less rapidity than upon films prepared with one or two commercial collodions particularly distinguished in this respect. It may be judged, therefore, from the latter observation, that I neither advocate or recommend the practical or artistic photographer to make his or their own collodion; but this I would emphatically urge, that no modified form of development, or any description of a dry plate method of preparation should be esteemed of scientific value unless it be capable of being successfully practised in combination with a collodion of known chemical composition.

To turn, in the first instance, to the consideration of the manufacture of the pyroxyline, we may notice that its introduction into photography primarily resulted from the discovery of M. Schonbein, that the elements of nitric acid are capable of combining with certain vegetable fibres, and that the compounds resulting therefore possess new and remarkable properties. The development of the fact led to the knowledge of the practical value of gun-cotton, and consequently to the specification of a patent taken out in our country in the year 1846 by a Mr. John Taylor, of the Adelphi, for the manufacture of explosive compounds. In this specification we have a detailed description of the means by which gun-cotton of the most explosive character may be successfully prepared. I shall venture to make one or two extracts therefrom, inasmuch, as they will contain some practical hints equally applicable to the manufacture of photographic pyroxyline. "The vegetable matter," it states, "which is found best suited for the purpose is cotton, in the state in which it comes to this country, but cleared from any extraneous matter, it being desirable to operate only on the clean fibre of the cotton, which should be dry. The acids which I employ are nitric acid of from 1·45 to 1·50 specific gravity, and sulphuric acid of 1·85 specific gravity. As far as my experience goes the best mode of using them is to mix them in the proportion of one measure of the nitric acid with three measures of the sulphuric acid, in a convenient vessel of glazed earthenware or other material not acted on by acids. By this mixture great heat will be produced. The mixture will be allowed to cool until it reaches a temperature of from sixty to fifty degrees of Fahrenheit. It should be introduced as open as practicable. And in order to ensure the cotton being fully impregnated with the acids, and every part equally and fully subjected to the action thereof, the cotton when in the acids is to be moved or stirred by means of a rod or glass, or other matter not acted on by the acids. The acids are then to be poured or drawn off. * * * The cotton is afterwards to be washed, opened out and dried, which may be conveniently done by spreading it thinly on surfaces in a room heated by steam or otherwise to about 150° Fah., and when dried it is fit for use. I would remark that nitric acid alone produces on cotton an effect similar to that produced on cotton by the mixture of acids above mentioned; but in carrying out the invention with nitric acid alone the cotton should be removed and washed immediately after it has become soaked with the acid, but I believe that so good a result cannot be obtained by the use of nitric acid alone, and the product is more costly." It will be gathered from the above extract that the principle of the manufacture of gun-cotton is not dependent upon the relative proportions of the mixture of the acids, although the preference is given by the patentee to the three to one ratio, as more recently advocated by Mr. Hardwich. The explosive cotton made in acids of the above strengths is unsuited for the manufacture of collodion, inasmuch as the product is insoluble in a mixture of alcohol and ether. If, however, we only dilute the acids to a suitable extent, or, what is analogous thereto, take acids of a less specific gravity, and act upon the cotton therewith, we shall obtain a pyroxyline soluble in an ethereal mixture of alcohol, and distinguishable from the former when saturated with water by a semi-transparent appearance, and a tendency to partial disintegration. Provided we carry the dilution of the acids to too great an extent the texture of the cotton will be entirely destroyed; if to the extreme degree it will be completely dissolved as soon as immersed in the acid mixture. The disintegrating, or solvent power of the dilute acids increases with an elevation of their temperature, so that it happens that an acid mixture, in which the fibre of the cotton would be scarcely altered at a low temperature, might entirely dissolve the whole at a higher one. As it is found that a more fluid collodion can be manufactured from a pyroxyline made at elevated temperatures, it follows that the strength of the acids must be correspondingly less diluted when used at higher temperatures, in order to produce a given action upon the same vegetal fibre. The essential element for consideration, therefore, in the manufacture of pyroxyline adapted to meet the requirements of the photographer, is the proportionate dilution of the acids, that will give the best results when brought into union with the normal cotton at some fixed temperature, ranging between 130° and 150° Fahr. The above rule will equally apply to the case whether the nitric acid be used in its free condition or be liberated from nitrate of potash by the chemical action of the sulphuric acid thereupon. As far as my own experience has led me to a preference between the use of free nitric acid, or the employment of nitrate of potash, I must confess that I consider a slight advantage in respect to uniformity and suitability is gained by the combination of the two. Without, however, dwelling upon this point I must now proceed to the statement of the means by which I manufacture a pyroxyline equally adapted for the production of collodion to be used for the wet and dry plate processes.

*(To be continued.)*

* Read at the South London Photographic Society on the evening of Thursday, February 13th.

## A RAPID PROCESS ON DRY COLLODION WITHOUT PRESERVATIVE.

Dear Sir,—Having been rather successful in experimenting on dry collodion plates, I beg to state how I have operated, for the use of those who, like myself, would be glad to give up their syrups and obtain good negatives with as much certainty and the same rapidity as when wet collodion is used. My silver bath contains 40 grains to the ounce of water, and is slightly acid. The collodion I use is of a powdery character and contains a bromide. I use old collodion to clean my plates.

I coat and sensitize the plates as usual. When coming out of the bath, they are allowed to drain a short time into the bath, washed over with filtered rain water, and finally with pump water, until all trace of greasiness and nitrate of silver is removed.

They are left to dry spontaneously, out of the dust, and when quite dry kept in a plate box. I give the same exposure as for a wet plate, and develop in the following way:—

I have a second vertical bath filled with clean rain water in which I dip my plates to be developed; they are left there for a few minutes, then well drained and removed to the silver bath; a dip or two in this bath will restore to the plates the excess of nitrate of silver removed by the washing. In this state the plates are developed in the same way as a wet plate.

I use an iron developer, which is the following:—

| | |
|---|---|
| Protosulphate of Iron ... ... ... | 15 grains |
| Sulphate of Copper ... ... ... | 10 ,, |
| Glacial Acetic Acid ... ... ... | 15 minims |
| Citric Acid ... ... ... ... | 1 grain |
| Water ... ... ... ... ... | 1 ounce |

The picture I intensify with a saturated neutral solution of bichloride of mercury, and then hyposulphite of soda, in which some nitrate of silver is dissolved, and fix with a fresh solution of hypo.

The result is a fine negative picture, in all respects equal, if not superior, to one obtained of wet collodion. I never have fogging and have not lost a single film.—I am, dear sir, yours respectfully, Capt. de Langue.

N.B. In my hands a dry collodion plate, to which the excess of nitrate of silver is not restored, but added to the developer, requires no more than twice as long exposure as my plates when dipped in the silver bath before development.

## REPORT OF THE COUNCIL OF THE PHOTOGRAPHIC SOCIETY.

In submitting the Ninth Report of the progress and prospects of the Photographic Society, the Council have good reason to look back with satisfaction to the past year's proceedings, and to anticipate an unusual success in the future.

The balance sheet, herewith presented, exhibits a far more satisfactory condition of the finances than has been shown for some years.

In 1858 the deficiency on closing the year's accounts amounted £56. In 1859 it was £88; and in 1860, the large sum of £384. The balance sheet for the past year exhibits a marked improvement, in so far that the receipts of the year are slightly in excess of the expenditure. This result is the more gratifying, as it has been chiefly brought about by means which prove that the art and science of photography is becoming more appreciated by the public, as its capability, its beauty, and advantages become better known and more clearly understood.

In the year 1858 the public exhibition of photographic works, held under the auspices of the Society, left a deficiency of upwards of £100. In 1859 the loss sustained was only trifling, but the exhibition of 1860 showed a serious deficiency of £125.

Now it was highly important that these annual displays should be continued, so the arrangements of the past year's exhibition, and its management, received particular care in order that every possible saving might be effected, and the high character of the exhibition still maintained. The Council have much pleasure in now reporting that a profit of £36 was the result, due to the increasing appreciation by the public of the beautiful works collected together.

The publication of the Journal also shows a small balance on the year's account. Although issued for the convenience and information of members of the Society, it has been accepted as a chief literary authority on photographic subjects, and this position it still maintains, notwithstanding the numerous photographic periodicals which have come into existence since its first establishment.

During the past year a most important matter unexpectedly claimed the attention and compelled the interference of the Council in order to vindicate the position of the members of the Society. It strongly proved how necessary it is that a central representative body, such as the London Photographic Society may rightly claim to be, should watch over and vigilantly guard the interests of the professor, and of the scientific position universally accorded to photography.

In the intended Exhibition about to be opened at Kensington, it was proposed that the results of photography, and the apparatus by which these results were produced, should not be classed with the fine arts, but be included among mechanical contrivances, fitting in between horological instruments and ship's tackle. Against this proposition the Council entered an indignant protest, and their expostulation received the almost unanimous assent of photographers both in this country and on the Continent.

By some confusion of ideas, it appears to have been considered by those who first proposed the objectionable arrangement, that pictures taken by light were merely mechanical results, in so far that they were produced by the agency of the camera, and that, therefore, they should not be classed with pictures and other works of art. It seems to have been overlooked that such a definition must have banished these latter also into the limbo of mechanical products, as they are produced by means of the eye of the artist, and the human eye is simply the most perfect camera known, lens, diaphragm, focussing apparatus, sensitive plate and pictures, which, as Locke writes, "when drawn in our mind are laid in fading colours;" and even high art cannot pretend to accomplish anything without an eye. On any other grounds, as to display of true artistic power, and appreciation of what constitutes a real picture, the proposition of the authorities was still more untenable; and the Council have much pleasure in stating that the impropriety of the proposed arrangement was at length admitted, and that a plan by which photographic works are accorded a position more suitable to their importance has been adopted. And the Council cannot refrain from here mentioning how deeply the Society is indebted to the President for his personal exertions and his invaluable advice and assistance in conducting this important matter to a satisfactory issue. On the settlement of the above difference, the Council willingly agreed to afford every possible assistance in the arrangement of the department, and at the request of the Royal Commissioners, two Members of the Committee, the Earl of Caithness and Mr. Kater, together with Dr. Diamond, were appointed to advise them in their decisions as to the photographic department. The Council have, however, still to express their regret that the position assigned to this department in the building at Kensington is far from satisfactory. Every endeavour has been made to get this disadvantage remedied, but it would appear that no other space is at the disposal of the Commissioners, as they have expressed their wish to do all honour to photography, and promised under the new arrangement to associate it as nearly as possible with the fine art department. The whole space appointed to English exhibitors for the display of photographic pictures is under 3,000 square feet, and that for apparatus and chemicals about 500 feet more.

The applications for space were so numerous that a very much larger extent could be easily filled; indeed, one person alone requested an allotment to six times the whole available amount.

It was hoped and anticipated throughout this country that photographic results of all nations would be exhibited together—and the advantages afforded by such facilities for direct comparison are obvious. The objections to such an arrangement, it is stated, came from the heads of the foreign department: how far this was due to their wish to avoid the objectionable arrangement of their artistic contributions originally contemplated cannot now be known. It may be fairly assumed that photography will form one of the most interesting parts of the new Exhibition, especially as the one great object is to take stock of the progress made since the first gathering together of the results of human skill and industry in 1851.

In alluding to these wonderful structures, there is one honoured name which spontaneously arises in the mind whenever and wherever they are mentioned. It has often been said that the lamented death of the Prince is at this time especially felt as a national affliction, on account of the great work now in progress, which is so identified with his name. Yet, throughout the whole time that the Prince Consort so nobly filled that high position, of which we now recognize the greatness, by sadly noticing how vast is the blank which his loss has left, his efforts were unceasing to advance and assist everything that was good and worthy, so that had that

> "Sweet nature gilded by the gracious gleam
> Of letters, dear to Science, dear to Art,"

been spared to us as yet a little longer, it must still have seemed, whenever the fatal summons came, that then his loss would least of all be borne.

During the past year there have been recorded no great discoveries in photography as a science, and comparatively few improvements in it as an art; but its progress has not been less marked than during former years; for it has now entered on and made great advance in that most important phase in the development of every art, viz., its *application to useful purposes.*

But a few years ago photographs were a scientific curiosity; now it rivals the electric telegraph, or the railway in the multiple interests it subserves. The lawyer receives the photograph of a signature as evidence; the doctor exhibits the result of his skill by photographs of the case before and after treatment; the engineer judges of the progress of his works from daily scraps of paper which the post bring him from the recording camera, and Government so confides in the value of results obtained by photographic aid, that attainment of the art is encouraged, and its practice profitably employed in all departments where exactness in representation and reproduction is required. So great, indeed, is its utility now become, that every improvement in the process, however trifling in itself, acquires importance by its wide application.

To the Royal Society there is yearly apportioned a Government grant of money to be expended in furthering scientific investigations for the benefit of the country.

The Council of the Photographic Society, pointing only to the practical results hitherto attained under unfavourable circumstances, would venture to suggest that assistance should be granted by Government towards improvements in the processes of photography. It would serve to determine many difficulties, and tend to increase the advantages now derived from the various employments of the art in differeut departments of the Government.

A yearly grant, if only a tithe of the money saved by substituting photographs for the mechanical drawings formerly made in all ordnance, naval, and other departments, would stimulate advancement in the art, and assuredly more than repay the expenditure.

The avidity for small full-length photographs has, during the last year, so remarkably increased, that this development of public taste appears almost worthy of historic note. And these little pictures, equally perfect and pleasing, vindicate the correctness of the popular predilection in their favour. They recall, not merely the features, but the attitude and habit of the sitter, and are indeed "the abridgement of all that is pleasant in man."

As now produced, they admirably illustrate how conducive to the pleasures of the many photography may be made, whilst equally valuable to the highest intellectual investigations, or of recording the results of mechanical skill.

During the past year twenty-four new members have been elected, and it is anticipated that a still greater addition will accrue from among those who have hitherto belonged to the societies that have ceased to exist.

The numbers of these have gradually diminished as the advantages of one central and representative body have been recognized throughout the country.

The Council trust that this cofidence, so generally expressed in the Photographic Society of London, as representing the interests of the art and progress of this science, may be always maintained.

---

## PHOTOGRAPHIC DIORAMA.

[The following article from the *North British Daily Mail* will afford our readers some further information on the interesting application to the principle of the diorama to the exhibition of transparent photographs. So far as we can learn, the joint labours of Dr. Taylor and Mr. McNab have been very successful in this matter.—Ed.]

In the present day, the wonders of magic are far more than realised by the plain realities of science. The electric telegraph and photography are perhaps the most marvellous discoveries of an age in which marvels have all but ceased to be wondered at. The art, or rather science, of sun painting has put within the reach of every one scenes and realities that are locally far removed from the observer. That a familiar landscape, or the likeness of some well-known and esteemed friend, can be presented by the photographic and stereoscopic processes by the shadows of the objects being indelibly fixed on durable material, are triumphs of scientific discovery. What further progress these arts may yet make is hidden from our present ken, but that marvellous results may yet be attained is not only probable but most likely. When a landscape is presented on the stereoscope, the defects chiefly noticeable are absence of life, motion, and changing colour. It never can be possible to fix moving objects and show them acting and moving, but discoveries may be arrived at by which the effect, to some extent at least, may be obtained. We were recently shown the result of a discovery made by Dr. Taylor, of the Andersonian University, by which most perfect aerial effects were produced on photographic landscapes. Dr. Taylor is well known for many ingenious experiments with light, and for many ingenious practical applications of scientific discovery. In the matter to which we now refer, it is unnecessary that we should at present describe the mode by which the wonderful effects are produced. Suffice it to be said that the apparatus is simply a box fitted with lenses and other appliances. The pictures we saw operated upon were mostly landscapes taken in the East Indies by Mr. Andrew Williamson, of the firm of Williamson Brothers and Co., Calcutta, the scenes themselves being selected with great skill and taste—also, a few magnificent Highland views, photographed by the Doctor himself in the noble demesne of the Duke of Argyle, at Inverary. The plates are of a large size, and are taken on glass, to which it would seem that this invention is best adapted. The object is to produce the various atmospheric effects which are constantly occurring in the natural landscape, such as the passing of clouds, sunset, sunrise, moonlight, &c., and the success which has been obtained by this ingenious invention is truly as wonderful as the effects are pleasing. For example, we are looking through the glass at an Indian river scene. The glow of a tropical sun is gloaming in the sky and in the waters, the foliage and verdure on the river banks dazzle the eye with the brilliantly reflected light. But as you look a change creeps over the atmosphere; the clouds which seemed to hang in the sultry sky apparently move and assume a dusky hue, the waters looks sombre, and the landscape begins to wear a deeper green, and gradually the light dies away and leaves you to enjoy the cool and quiet of an evening on the banks of the Ganges or the Hoogley. The operator has merely again to say *presto*, and slowly the clouds begin to be lightened up, the sun sends up his red and gold from below the horizon, and as you gaze you have once more a noon-day splendour shining over all. Some very fine Hindoo groups were also operated upon with the most pleasing effect, but perhaps that which struck our admiration most were some avenue scenes from Inverary. The effect is about as superior to painting as are the works of a Claude or a Turner to the sketch of a mere schoolboy, although, in its own walk, there can be no substitute for painting. The invention under notice, of course, requires an apparatus and considerable space to work it, and thus rather takes the place of an exhibition than of a common picture. We are not aware that Dr. Taylor has any wish to do more than make his discovery known, as it deserves to be. All that we need say of the *modus operandi* is that it is extremely simple, and consists of a revolving cylinder, the edge or rim of which is strongly coloured with those hues that are required to produce the dioramic effects. A number of gas jets are so placed as strongly to illuminate the cylinder and reflect its hues upon the photographic plates. The effects produced are really surprising. With such photographic plates and such an apparatus, a person may never leave his own chamber, and yet in reality become acquainted with the peculiarities and beauties of foreign climes, in all their varying hues and shades.

We should add that while the merit of this discovery or invention is due to Dr. Taylor, he has been ably assisted in bringing it to its present state of perfection by Mr. McNab, the well-known photographist, at whose residence we had the pleasure of inspecting the apparatus under the superintendence of the Doctor himself. The plates are the property of Mr. McNab; they have been photographed by him with admirable clearness and force from the original negatives, the size of the plates rendering the process somewhat difficult. The size, however, gives the great advantage over the stereoscopic pictures that nine or ten persons can view them at the same moment; and, indeed, it is in contemplation to get plates so large that a whole roomful of spectators could enjoy the spectacle, which would then become one of the most attractive and beautiful exhibitions.

## Correspondence.

### FOREIGN SCIENCE.

[From our Special Correspondent.]

*Paris, 12th February*, 1862.

M. Derivau has constructed a miniature still for the travelling photographer, which is extremely interesting for the ingenuity displayed in its construction, so that it shall occupy as small a space as possible. The kettle holds over five pints of water, and the whole apparatus, including the furnace, weighs less than 10 pounds, and measures about 18 cubic inches. This economy of space, so important a consideration in photographic baggage, is obtained by calculating the various parts of the still, so that when they are dismounted, they can easily fit into each other. Thus the *worm* fits into the furnace, this latter into the kettle, and the whole into the dome or capital.

In anticipation of the partial eclipse of the sun which took place on the 31st of December last, many of our Parisian photographers made important preparations to obtain views of various phases of this celestial phenomenon. Unfortunately it was a waste of labour, for the sky was overspread with thick clouds during the whole of the day. At Belfont, however, the sky was clear, and M. Vernier was fortunate in being able to obtain some good negatives, and has addressed the following note, respecting the phenomenon, to the Academy of Sciences.

"My proofs, which were taken during a clear sky, are remarkable in this particular, that the last two, numbered 5 and 6, exhibit no trace of the aureola. The image of the sun is traced sharp and clear on a black sky, while the first four proofs are surrounded with an aureola similar to that of the 18th of July, 1860, but still, less visible. This peculiarity cannot be explained by the intensity of the solar light, after the exposure of the negative. In fact, all the proofs were obtained in the fraction of a second; but in proportion as the sun declined towards the horizon, it lost its splendour, or, if I may so express it, its photogenic power. It results from this fact, that if I had prolonged the time of exposure of the negative some thousandth part of a second in the latter proofs, I should have obtained the aureola as well as upon the first.

"From the preceding experience, I conclude that the aureola which surrounds or envelopes the sun belongs exclusively to the terrestial atmosphere; for, notwithstanding the serenity of the sky, which appeared to me favourable for my experiments, the atmosphere at this season of the year is always loaded with moisture which reflects, or produces, a certain splendour, or a radiation of light, more or less extended, around the luminous body which traverses it."

Our Photographic Society has published the following *Notice to Exhibitors* at the Universal Exhibition of 1862:—

"Sir,—I have the honour to remind you, in the name of the Committee, that upon the decision of the Imperial Commission, the admissions to the Exhibition at London will be rendered final, for the section of photography, only after the examination of the photographs intended for this Exhibition.

"You already know that the pictures should have been sent unframed, to the *Palais de l'Industrie* by the 10th inst. at the latest. Each proof must bear the name of the artist, and all by the same person must be sent in a portfolio, which, besides better protecting them, will render confusion less likely to occur.

"I believe it is necessary to urge the inconvenience that would arise from incurring the expense of framing beforehand, since the space, necessarily restrained, accorded to photography, does not allow the Imperial Commission to fix, before the examination of the proofs by the jury, the amount of space which can be awarded to each exhibitor finally admitted.

"I must also remind you, sir, in the name of the Committee, that upon the proposal of the Jury named by the Imperial Commission, the French Photographic Society has accepted the office of General Agent for all the exhibitors of the section of photography who desire to avail themselves of it, whether members or non-members of the Society.

"I think it scarcely necessary, sir, to point out to you the economy and other advantages that must result from this association, which, moreover, not only leaves perfectly intact the right of each exhibitor to the prizes awarded, but will also preserve the individuality of every one connected with it.

"The Imperial Commission will take upon itself the expense of forwarding and returning the pictures to London, but not the expense of fixing them up, and the Royal Commission of London gives the space without any fittings whatever. Now this fixing up the pictures will be much less expensive if undertaken in common. The French Society of Photography cannot possibly be influenced by any speculative motive, but will strictly divide the general expenses among the exhibitors, according to the space occupied by them. The expense of frames and other special items will, of course, be personal.

"The French Society of Photography leaves every one at liberty to act by himself, except, however, in what concerns the stalls, panels, tables, &c., which the Imperial Commission renders obligatory on the whole body of exhibitors, by whomsoever represented, as is absolutely necessary.

"If you accept the proposal of the French Photographic Society, I beg, sir, in the name of the committee, that you will sign the enclosed, put it into an envelope, and return it by post, addressed to the Secretary, Agent of the French Photographic Society, Rue Drouot, No. 11."

The decision of the law courts against copyright in photographs is so contrary to the opinions generally entertained, that it may be interesting to give it in full:—

"Considering that photography is the art of fixing the images of external objects by means of the camera obscura, and various chemical processes, and that it is a purely mechanical operation, requiring skill, no doubt, and much skill, yet it in no respect resembles the work of a draughtsman or painter, who *creates* from the resources of his imagination his subjects and compositions, or represents, with his own feeling, subjects from nature; that in recognizing the service photography has rendered to the fine arts, yet it cannot be ranked with them in the same category; for, in fact, photography neither creates nor invents; it is limited to the obtaining negatives (*clichés*), and afterwards obtaining positives from them, which servilely reproduces the objects placed before the lens; that these works, produced by the aid of mechanical means, cannot, in any case, be assimilated with works of the mind, or confer on the industry that fabricates them a property similar to that of the artist who creates and invents; that jurisprudence has already applied these principles to the operation of modelling, which, like photography, demands only dexterity and practice in their execution; that Daguerre, in selling his secret to the State, gave his invention, as well as all its modifications, improvements, and results, for the public benefit, and it would be contrary to rule, in such a case, to give a privilege, not only to the inventor himself, but to all those who profit, or have profited by his discovery. Seeing, that from these considerations, the reproduction of subjects obtained by photography does not constitute the offence of counterfeit or piracy, provided for and punished by articles 425 and following, of the Penal Code, an action for damages cannot be sustained.

"For these reasons the prisoners are acquitted, the seizure of their photographic copies is void, and the prosecutors are condemned in costs."

This decision may seem hard, and henceforth we must not, I suppose, say much about *artistic photography*.

By a new method of weaving discovered by M. Voisin, he is able to produce shawls in every respect equal to the famous Cashmere, and at about one-eighth of their cost. It would be difficult to explain in what this discovery consists, without going into details of the manufacture of shawls; but, in brief, it may be described as a new method of interlacing the threads, resulting in a very durable product, economy of material, and the employment of any number of colours. This discovery must not be looked upon in the light of an experiment, for no less than 1,650 shawls have been made on the new plan, and worth 350,000 francs, equal in quality and appearance to Cashmere, valued at 1,250.000 francs. We may expect to see in the forthcoming exhibition, not only specimens of these shawls, but of other new fabrics produced by the machine of M. Voisin.

## DRY COLLODION WITHOUT PRESERVATIVE.

Dear Sir,—I am induced once more to address you on the subject of Dry Plates without Preservative, in consequence of the appearance of Mr. Hislop's letter in the News of last week, wherein he says—"you have inadvertently fallen into an error, in stating that I invariably use albumen as a foundation." At which, I must confess, I am somewhat surprised, as I, in common with yourself, and no doubt many of your readers, understood that it was Mr. Hislop's invariable practice to coat his plates first with albumen, and thereby placing the preservative under instead of over the collodion.

By referring to your report of the North London Society's meeting, page 572, vol. v., Mr. Hislop's paper was there read by Mr. Martin, who, in answer to a question from the chairman, said, "That the film had a tendency to leave the glass, and that Mr. Hislop, therefore, always coated the plate with a very dilute solution of albumen, prior to applying the collodion." Mr. Hislop also gives in his paper the formula for the albumen solution, to be used as a foundation for the collodion, and at page 604 of the News, Mr. Hislop, in making some observations at the North London Society's meeting upon the discussion that had previously taken place at the reading of his paper, exhibited his bath solution, to prove that the albumen had no deteriorating effect upon the bath, in which he says, "Some hundreds of plates had been excited, and fully nineteen-twentieths of these had been excited, since it was his *custom* to coat with albumen."

Also, exhibiting pictures from two negatives, he says, "One was upon albumenized glass, *in his usual way*; the other upon unprepared glass."

This is the only instance that I can discover wherein Mr. Hislop makes mention of collodion upon the unprepared glass, and that appears to have been an experimental plate, for the purpose of showing the society the non-chemical effect of the albumen, rather than as a proof that the collodion was in itself sufficient to produce the picture.

I have to acknowledge the thanks which Mr. Hislop in his letter of last week, tenders to myself, in common with others of your correspondents, for our corroborative testimony. Yet I must confess I imagined I was in my process going one step farther towards simplicity of manipulation than Mr. Hislop had then done, which induced me to forward to yourself, sir, the specimens you did me the honour to mention so favourably in your article a few weeks since, and which I flattered myself would be sufficient to show that with a suitable collodion, a preservative either under or over the film was entirely unnecessary.—I remain, dear sir, your's respectfully, J. F. Ward.

*Stratford on Avon.*

## THE EXHIBITION OF THE PHOTOGRAPHIC SOCIETY OF SCOTLAND.

Sir,—Surely those who undertake the duty of publishing opinions for the guidance of others, cannot be too scrupulous and careful. The writer of the article in last week's News,* upon the "Exhibition of the Photographic Society of Scotland," has in his "*hasty notice*," the result of a "*partially made inspection*," not treated me with justice. I do not ask him for praise, but simply for a certain measure of accuracy in his report. He is no doubt entitled "not to like my last season's pictures so well as my Endsleigh series," or, on their merits, to say anything else he pleases. Opinions vary, and it is gratifying to me to find that your own opinion, as expressed in your foot note to the article in question, is in direct opposition to his. This, however, is not my point, though I cannot help saying that the "Scotch Peasant's Cottage" he finds so much fault with, and which I believe *is* a "ready made picture," has received the most unqualified praise, and is ranked as a subject the very reverse of "being incapable of photographic treatment." What I complain of is the inaccuracy of his description of my pictures. Speaking of the subject mentioned above, he says, "It is a flat and almost windowless Scotch cottage, fronting a dirty road, and garnished by only a peat stack or *something worse*." He then says that "several of my efforts have this year been wasted on subjects of this kind, incapable of photographic treatment; and congratulates me upon escaping from these, or from comparatively formal ploughed fields and flat distances." My answer is, that with the definition I aim at, and believe have a right to take credit for, photography is sufficiently capable of delineating texture and form to place beyond question that the "windowless cottage" did not face a dirty road, and that it is not garnished by a peat stack or something worse; the latter remark being an imputation upon my taste I need not, I am sure, notice. Further, so far from "wasting my efforts" upon several such subjects, it is the only one of the kind I have done; and in spite of the writer's condemnation I will add, that I did it not only because I was struck with its picturesque effect, but I conceived it would make a very suitable companion picture to an "English Mansion" I had photographed. As to my "formal ploughed fields," they, along with the dirty road and "something else," are simply in the imagination of the writer, who so described them, not in any one of my photographs.

Your readers will decide whether it is just and fair to publish a "hasty notice" written after an "inspection only partially made." Should the word partially be read in another sense? Vernon Heath.

# Photographic Notes and Queries.

### Iodide of Silver in Collodion.

Sir,—I find the addition of a few drops of solution of iodide of silver will greatly increase the rapidity of the collodion, which seems to get more sensitive the longer it is kept. I prepare the solution of iodide of silver by rubbing down in a mortar a few grains of nitrate of silver, and adding a saturated solution of iodide of potassium drop by drop, till all the precipitate is dissolved.—I remain, sir, yours respectfully, A. L. H.

[The early formulæ for the preparation of collodion generally contained iodide of silver, and many photographers believed that greater sensitiveness was obtained by its aid. If we remember rightly, the original formulæ published by Dr. Diamond, in "Notes and Queries," contained iodide of silver. A gradual conviction appeared to gain ground that it was unnecessary, and it fell into disuse. Possibly, in connection with the other formulæ and manipulation now in use, it may be found advantageous.—Ed.]

* From the Society's *Journal*.

## Talk in the Studio.

The Sculptor and the Photographer. — The Italian correspondent of the *Daily Telegraph*, speaking of the works in progress of Mr. Hiram Powers (better known as Greek Slavo Powers), says:—"This sculptor is singularly fortunate in having a son who is one of the best photographers in Florence. He has made a study of what was once an amusement, and, as is often the case, has surpassed the older hands. His portraits are likenesses as well as pictures. The photographs of his father's works are very beautiful; but what strikes me most are his pictures taken from life, for there his sitters do not look as if they were in the stocks, or gazing vaguely at the heavens—of course void of any '*non-di-meno-gira*' ideas—but simply gentle and genteel 'sitters.'"

Mr. Vernon Heath.—It will interest many of our readers to learn that this gentlemen, known so long in the photographic world as a skilfull artist and as the principal in the firm of Murray and Heath, is about to retire from that firm and devote himself entirely to photography professionally. The freedom from business cares will doubtless afford opportunity for still greater triumphs of manipulatory and artistic skill than those with which all interested in photography are familiar in Mr. Heath's productions. In a letter which is before us, we are informed that Mr. Charles Heisch, Professor of Chemistry at Middlesex Hospital, and well known to photographers by his researches in photographic chemistry, and more especially as one of the earliest and most consistent advocates of the use of bromides in collodion, assumes Mr. Heath's interest in the business in Piccadilly. We hail the accession of such a man into the manufacturing and commercial ranks of photography, as tending to maintain the high position which these departments have acquired in this country, and affording to photographers full reliance on the scientific skill which superintends the manufacture of preparations upon which all their efforts depend.

Apparatus for India.—We omitted to state in our report of the Photographic Society's meeting last week, that Messrs. Murray and Heath exhibited a new double swing back camera, specially adapted for India. By a single mechanical arrangement the swing of the back is effected without any increased size being given to the camera, which is as small as an ordinary portable bellows instrument. The adjustment for focus is effected by means of a screw, which can be thrown in or out of gear by simply touching a spring; and the bellows are made of a material specially suited to resist the effects of a hot climate and the attacks of insects, &c.

## To Correspondents.

⁂ To Advertisers.—The unusual press upon our advertising columns this week compels us to omit many advertisements.

Slate.—We fear that slate is scarcely suitable for a silver bath; but having made one, your best plan will be to coat the inside with some protective varnish. A shellac varnish may be used; or better still, a mixture of rosin, bees-wax, and finely powdered slate, in about equal proportions. This applied hot will give you a fine hard surface when cold.

A Subscriber from the Commencement must have seen that we have repeatedly given formula for the manufacture of collodion. We have not space to give full instructious in this column on such a subject. We may briefly say: take

| | |
|---|---|
| Pyroxyline made at a moderately high temperature | 10 grains |
| Alcohol, 820 sp. gr. ... ... ... ... ... | 1 ounce |
| Ether, 720 sp. gr. ... ... ... ... ... | 1 ounce |
| Iodide of sodium ... ... ... ... ... | 6 grains |
| Ditto cadmium ... ... ... ... ... | 4 grains |
| Bromide ditto ... ... ... ... ... | 1 grain. |

You will find an article giving full details in the Photographic News Almanac.

An Amateur.—It entirely depends on the purposes for which you require the lens. The No. 2B and No. 3 ordinary of the maker you name are altogether different lenses; the first is a very quick-acting lens, covering about 5 by 4, or half plate, and is especially good for card portraits; the other is not so quick acting, and although called a half plate, will cover, we believe, a whole plate. Both are excellent lenses; but your choice will depend on the especial purpose for which you require to use a lens. 2. The keeping of albumenized paper after sensitizing, depends much on circumstances. Some samples rapidly discolour; whilst others in a dry dark place keep a few days without risk It is always better to print, tone, and fix, as soon after sensitizing as possible.

Teesdale.—It is quite manifest that a view lens of 9 inches focus could not be intended for views 9×7. If the lens were sold to you to cover a 9×7 plate, and *guaranteed*, we should imagine that the dealer of whom you had the lens will exchange it. We cannot advise you to attempt to remove the lens from the tube and replace it by another of longer focus yourself, as if you are not familiar with the work, it is probable you could not do it efficiently, and it is very important that the lens should be fixed quite parallel with the sensitive plate. First of all, endeavour to get the dealer to change the lens; and failing in that, sell the one you have got, and buy another. Or else, get the camera body shortened a little, and take smaller pictures for the present with the lens you have.

W. G.—The especial characteristics generally desirable in a collodion for dry plates are, that it should give a powdery adherent film, and possess a bromide. The powdery film may be obtained in two ways: either by making the pyroxyline with weak acid at a high temperature, or by adding an alkali to the collodion after it is made. The addition of a few grains of carbonate of soda to each ounce of collodion, and after agitation filtering, will generally make the film adherent and powdery; but the collodion does not always keep well after it is thus treated. The collodion of which the formula is given in the Photographic News Almanac may be used for dry plates with advantage.

W. H. Bolton.—Shellac is readily soluble in a *hot* solution of borax and water. Have you used sufficient heat? Or try the adoption of a little more borax.

J. B. Y.—On page 248 of our third volume (No. 72), you will find full instructions for making and using a specific gravity bottle, by which the specific gravity of all kinds of solutions may be ascertained.

Tom Gardner.—The silver solution running in greasy lines when the plate is removed from the bath, will occur from a variety of causes. In your case, it is probably from the use of a collodion which gives a horny repellant film. When that is the case, the addition of one or two drops of distilled water to the ounce of collodion will often prove a remedy. Also, move the plate repeatedly in and out of the bath during the time of exciting. 2. The only way in which you can keep size ready for use is to keep it in a very cool cellar. 3. If the water placed on your white lead becomes white and turbid, it shows that there is some adulteration, as carbonate of lead is insoluble in water.

C. F. Booker.—The probable cause of the peculiar cracking of the film you describe, is that some traces of the hypo or cyanide had remained in the film, not having been perfectly washed out after fixing. This has gradually absorbed moisture under the coating of varnish, and then from changes of atmosphere caused the cracks. For those films which are cracked there is no remedy. To prevent others already varnished from going, keep them in as dry a place as possible, and be careful to wash well and dry well in future. Sometimes, however, these cracks will occur after every known precaution has been taken.

Toby's Ghost.—All dry plates must be wet all over before applying the developer. 2. Your question "how to distil the essence from anything not a liquid" is not quite clear. If you refer to essential oil of flowers, &c., they should be bruised well, macerated in a small quantity of water, and then placed in the still, and submitted to as low a temperature as will serve the purpose. If, however, you are not familiar with such operations, you had better see a chemist manipulate before attempting it yourself. 3. In order to avoid injuring the film of wet plates in placing them in a box, use a box with V shaped grooves.

X. Meson.—It is desirable to wash the print carefully for a few minutes between toning and fixing. As a rule, the time required for fixing is about fifteen minutes; but the time will vary with the kind of paper, a soft absorbent paper being quickly fixed, and a hard repellant paper requiring a longer time.

Alphabet.—The price you name is a very low price for a portrait lens. You may by chance get a good one for the money; but not with certainty. You cannot get, as a rule, a standing figure well defined on a quarter plate with a common quarter-plate lens. To ascertain if the visual and actinic foci are coincident, place a pile of books upon a table, each one an inch or two further back than the other; then focus for one in the centre, and if on taking a picture that one is sharp, the visual and actinic foci are coincident; if that one be out of focus in the picture, and some other books in, the two foci vary just in the proportion indicated by the position of the books. In such case your dark slide would require adjusting to the amount of difference. 2. When a collodion dries slightly opaque or opalescent when merely poured on glass it is unfit for producing positives. The only remedy is to change the sample of collodion. 3. The production of instantaneous pictures depends on good light, and good lens, silver bath, collodion, and developer, all being in harmonious relation and in careful manipulation.

Jacobus.—The dealer whose name you mention as No. 1 is a retailer of second-hand apparatus and a respectable man; but it is of course impossible to guarantee second hand goods without trying them. Of the two lenses, regarding which you ask our opinion, we have no means of judging which will suit you best. A rack and pinion is not necessary if you have a ready means of adjusting the camera body. For general landscape purposes we prefer the ordinary view lens of the maker you name to his orthographic.

Cornish Chough.—Your pyroxyline has been made with acids slightly too weak, and has consequently a slight tendency to crape, and also to dry rather opaque. With care in manipulation, it may, however, be made to work very well. The sole cause of your difficulty in the negative sent is under exposure. The plate required at least double the exposure; with full exposure you will get both foreground and distance properly detailed. A little more bromide to the collodion will be an improvement.

W. W.—We do not know any specific house of whom you may get "Judæan asphaltum," but you will probably succeed better in getting it through a respectable drysalter than a chemist. Probably it may be known as "Egyptian asphaltum." Should you still fail we will make some enquiry in London.

Wm. Clark requires a good process of transferring an engraving from paper to glass. He at present varnishes the glass and brings the print into contact with it; then places the whole in water containing a little sulphuric and nitric acid. He is not quite satisfied with the result. Can any of our readers give additional information. We fancy the process he uses is a good one, but probably requires practice to ensure success.

A. B.—It is possible that by proper effort you may succeed. We will see if we can aid you.

Negative Varnish.—In the recipe for negative varnish given in Mr. Warner's letter in our last, for "turning" the plate read "warming" the plate.

E. T., J. H., J. Jones, Economy, E. E. L., and several other correspondents, together with several articles in type, are compelled to stand over until next week.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 181.—*February* 21, 1862.

## VARNISHING AND WAXING PRINTS.

We have received several enquiries recently as to some efficient means of varnishing photographic prints; the objects for which such a process is proposed being two-fold: to give more brilliancy, depth, and transparency to the picture; and protect it from the destructive action of varied atmospheric conditions. From the earliest production of paper proofs, photographers have had a hankering after some means of giving increased depth and transparency to their shadows; or, rather, of giving full effect to all that really existed in the picture. The mode in which photographic prints are obtained has always had a tendency to produce the picture slightly within the texture of the paper, rather than entirely on its surface, and hence a slight loss of detail and transparency in the shadows. The application of a varnish tends to rendeem this defect by making the image "bear out" more perfectly. The use of albumenized paper, which, by keeping the image on the surface, has tended to give more brilliancy and sharpness, came into vogue chiefly on this account, and is, we apprehend, at least for the present, likely to continue in use. To our own taste the use of albumenized paper, although under existing circumstances a necessary evil, is bad enough; but the additional use of varnishes is worse. The use of glazed surfaces for photographic pictures is, we believe, purely a conventional taste, which has arisen rather out of the exigencies of the art, than from any beauty such surfaces possess. We cannot doubt for one moment that, if prints equal in depth and vigour, purity, brilliancy, and detail could be produced on plain paper, albumenized prints would be at once scouted as vulgar and inartistic, and varnished prints not less so.

In the present state of our printing facilities, however, it is clear that all the detail and brilliancy that is in the negative cannot at all times be secured in plain paper, nor even on all samples of albumenized paper. Many photographers will, therefore, prefer the delicacy and sharpness, depth and vigour, to be obtained from a glazed surface, to the chaste and pure, albeit sometimes feeble and dull, simplicity of plain paper. For the benefit of those of our readers interested in the matter, therefore, we have a few suggestions to make on the choice of material, and the mode of using it.

A variety of varnishes and other substances have been recommended and used, to give a highly-glazed surface to photographs. Perhaps the most perfect surface is that obtained by the French method of applying a coating of gelatine. A piece of plate-glass with a very perfect surface is carefully cleaned, then sponged with fresh ox-gall. Before it is quite dry it is coated with a hot solution of fine gelatine, about twenty grains to the ounce. When it is well set and free from tackiness, but not so entirely dessicated but what it would retain the impression of the finger, the picture is laid upon it, face down, and pressed all over; carefully avoiding the enclosure of air bubbles. When firmly in contact, it is left for some hours to harden. When quite hard the edge may be lifted with a penknife, and if the operation has been properly conducted, the picture will leave the glass with a gelatine surface of the most perfect character. This gives a brilliant effect to the photograph; but it is sadly suggestive of the covers of those pretty French boxes which contain *bon bons*. If handled with damp fingers, moreover, the gelatine becomes tacky and dull. To obviate this it has been proposed to first coat the plate with a tough collodion, and pour the gelatine on that, so that the completed picture will have a surface of collodion.

A step beyond the gelatine surface is that obtained by the principle of French polishing. The picture is first coated with gelatine, applied with a large brush. When this is perfectly set, a solution of white shellac in spirits of wine is applied with a piece of cotton wool rolled up in a piece of linen cloth. The method of applying this is, as we have said, analogous to French polishing, a light circular motion being used. It requires some manipular skill, and produces, when well done, a very fine, hard, and brilliant surface; but quite as meretricious and vulgar-looking as the gelatine.

Varnishes of all kinds may be used, from the old-fashioned solution of Canada balsam in turpentine, to Sœhnée varnish. If the print be on plain, or very slightly albumenized paper, it will require sizing or coating with gelatine, to prevent the varnish being absorbed in patches and bearing out with an uneven surface. If the paper be highly albumenized, preparation or sizing is not necessary. On pictures of any size the varnish should be applied with a brush, but in small ones it may be flooded as on glass plates. We have experimented with several kinds of varnish, and found little difficulty with any. The common crystal varnish answers well; as do several spirit varnishes. It is important in order to produce an even, fine surface, that a full-bodied varnish be used—a thin one being apt to sink into the paper, and dry irregular and dull. We have found that advertised as "penetrating varnish"—which on paper prints does not penetrate—work the best. Whatever spirit varnish be used, should be applied near a fire to avoid risk of chilling.

By far the best application, however, giving depth, transparency, and detail to the shadows, without adding offensive gloss, is a coating of wax. This may be applied to plain paper or albumenized paper, and whilst it brings out all that lay hidden in the shadows, it can be used so as to leave no perceptible gloss on the lights of the picture. Just so much may be applied, in fact, as appears to enter sufficiently into the surface of the paper to give it transparency without laying on it to give it gloss.

Regarding the second purpose which these coatings have been intended to serve, we shall not say much. If a photograph have received full justice in the processes of printing, fixing, and washing, we believe it should not fade, without any protective varnish. If it contain within itself the elements of its own destruction, a varnish may delay, but cannot prevent its doom. Some of the substances proposed may even accelerate its destruction. A coating of gelatine may decompose under the influence of moisture, and in its own decomposition hasten that of the print. The same is true of a thin varnish of gum arabic, which has been proposed. Most gums and resins have, moreover, in themselves a tendency to become yellow, and may thus aid in destroying the beauty of the print it was intended to protect.

Regarding wax, it is also slightly liable to discolour, but the very slight amount it is necessary to apply makes this consideration of little moment. The mode in which it is applied and the solvent in combination with it, is of some importance. A correspondent in a contemporary has recently been recommending the application of wax to prints on slightly albumenized paper, as removing the necessity for the use of highly albumenized paper, which he has found difficult to tone satisfactorily. He there recommends the use of turpentine as a solvent of the wax. This is decidedly wrong. The purest white wax should be used, and a solvent which entirely evaporates without leaving any residue. Turpentine leaves a residue, which will not only rapidly turn yellow, but which some chemists have thought might exercise a detrimental effect on the permanency of the print. Mr. Hardwich, speaking on this subject in a paper on the fading of positive prints, some years ago, remarked: "Turpentine, commonly used as the solvent [of wax], is liable to contain a principle possessing oxidyzing properties, as may be shown by agitating commercial oil of turpentine with dilute solution of sulphate of indigo, the blue colour of which it often quickly bleaches." There are, however, various solvents which are innocuous, and evaporate without leaving any residue. Pure benzole, chloroform, or essential oils. The essence of spike, lavender, or rosemary, the cheapest of the essential oils, we have used with complete satisfaction.

There is one class of pictures to which the application of wax will be of the greatest value: we refer to the developed prints produced by the solar camera. The chief defect in these prints arises from their being sunk too much into the texture of the paper, a consequent want of brilliancy resulting. Many continental photographers varnish their enlarged prints, and in pictures of this magnitude the effect is not so offensive as in smaller prints; but we apprehend that wax, whilst answering the same end, would be still more free from objection.

Some time ago we called the attention of our readers to the advantages of Clausel's encaustic paste for this purpose. Our attention had been called to the preparation by Mr. Rejlander, who generally uses it upon his prints. It is prepared by Bailey and Son, of Wolverhampton; and, if we remember rightly, the recipe was imparted to Mr. Rejlander by the late Prince Consort. It consists of white wax, *oglio cotta*, (which is, we believe, an Italian preparation of poppy oil inspissated by heat) and an essential oil. This is easy to use and effective when used. Messrs. Newman, of Soho Square, we believe, manufacture an enamel or encaustic paste of a similar kind.

The best mode of applying the preparation of wax is to rub a thin coating all over the surface with a piece of clean cloth or the fingers; and then with a piece of woollen fabric, which is quite clean, polish well, crossing and recrossing the strokes, until a fine rich surface is obtained, giving richness and depth, but without the offensive glaze of varnish. Touching out of any slight defects should be done first, and after waxing the inequalities of surface will be imperceptible.

## IODIDE AND BROMIDE OF SILVER:

### Researches into their Photogenic Properties according to the Circumstances under which they are obtained.

BY M. E. REYNAUD.

Most of the photographic processes known at the present day, are based upon the property possessed by certain salts of silver being sensitive to the action of light.

Among these salts, chemists have recognized that those most applicable to photography, on account of their greater sensitiveness, are the iodide, the bromide, and the chloride of silver. Photographers have naturally directed their researches upon these salts, and consequently to those salts which they form by double decomposition in the photographic film. We are therefore led to study the various properties of the iodide, bromide, and chloride of silver, according as these salts are obtained by the decomposition of one or the other of the soluble iodides, bromides, or chlorides, and also directly by iodine, bromine, or chlorine.

For the present, I shall limit myself to the study of the salts employed in the wet collodion process, commencing with *iodide of silver*; this salt being the basis of sensitized photographic collodion.

We know that iodide of silver is obtained by the double decomposition of an iodide and of the nitrate of silver forming the sensitizing solution. We have therefore to examine the different qualities of the iodide of silver, according as it is formed under one or the other of the following conditions:—

1st.—According as the collodion contains a solution of iodide of potassium, or of iodide of ammonium, or of cadmium, &c., or of some of these iodides together; or also of an excess of iodine.

2nd.—According whether the sensitizing silver solution be neutral, acid, or alkaline.

Let us suppose for a moment the silver solution to be slightly acid, as is the case usually in practice; and commence our study with the examination of the photogenic properties of *iodide of potassium.*

It is a well-known fact that the iodide of silver resulting from the decomposition of iodide of potassium, receives the luminous impression very slowly. A collodion which contains only this iodide is in fact one of the slowest; but it possesses some special qualities which it is worth while to examine.

First, let us mention its property of giving very dense blacks in the negatives, a quality which renders it so valuable in copying old engravings, the yellow paper of which acts but very feebly upon the sensitive film; and also, generally, for everything requiring great contrasts in the negative, always excluding the representation of animated objects on account of the slowness of photogenic action before spoken of.

Another quality of collodion iodized with iodide of potassium is an extreme delicacy of detail, which is due to the slowness with which the silver reduced on the glass plate during the development of the image, attaches itself to the impressed portions. This second property gives it the preference in obtaining very small negatives, such as are afterwards amplified in the solar camera.

I propose to return to this subject, and examine in detail the molecular state of the silver reduced upon the negatives, according to the products and processes employed. These researches will offer much interest for the solution of the problem of amplifying images.

*Iodide of cadmium*, with regard to rapidity, possesses qualities opposite to those of the preceding iodide; for the iodide of silver formed by it is one of the quickest in receiving the luminous impression; but, on the other hand, it possesses the serious defect of giving fogged pictures: this defect is corrected by the addition of bromide of cadmium; but a surer means of avoiding fogging without altering the sensibility, consists in adding to the collodion a few drops of chloride of iodine, or a very slight proportion (say about 1 or 2 per 100) of chloride of zinc. The use of a very acid silver solution will produce the same result. Without the addition of the bromide, this extremely rapid collodion will have the defect of being nearly insensitive to the green, yellow, and red rays.

I shall now speak of *iodide of ammonium.* This iodide possesses mixed qualities, which admits of its making a very good collodion, employed either alone, or preferably, with a small addition of bromide of ammonium.

Although this collodion is not so sensitive as that with iodide of cadmium, it is preferable to the latter on account of the artistic perfection of the images it yields.*

Let us, however, notice one of its defects, which consists in the great facility with which it forms spots in the sensitive film upon being immersed in the sensitizing silver solution. Certain researches upon this subject have proved to me that this effect is caused by the great facility with which the iodide of ammonium is decomposed into iodide of silver at the time of sensitizing; the liquid veins of the silver bath in motion impress themselves on the film, and it is particularly that part of the film resting on the edge of the bath that is spotted thus, which arises from the veins of the

* I must mention in this place a remarkable coincidence existing between the sensitiveness of the three salts studied above, and their solubility in alcohol. We perceive, in fact, that iodide of potassium, the least sensitive among them, is also the least soluble in this liquid, while the iodide of cadmium, which possesses very great sensitiveness, dissolves in it with remarkable facility.

solution, striking on the glass plate, being broken up on reaching the side of the bath. The result is an inequality of action upon the iodide; the inequalities are reproduced upon the film by reason of the promptitude with which the latter is decomposed under the influence of the nitrate of silver. From this we may readily conceive that this effect may be diminished by the employment of a vertical bath, especially by allowing the plate to descend gradually and gently into the solution: this is verified by experience.

The same kind of spots are produced also when the collodion contains a notable quantity of free iodine.

Lastly, the same accident occurs when the collodion contains too large a proportion of iodides, especially if the sensitizing silver solution is new and strong. Moreover, these various phenomena depend upon the relative quantities of pyroxyline, ether, and alcohol, contained in the collodion.

The three iodides we have examined are nearly all that are employed in the preparation of wet collodion. Sometimes, however, iodide of iron and iodide of zinc are introduced.*

*Iodide of iron* appears to me of no advantage in collodion. Much has been said in praise of its rapidity; as for myself, I have never observed anything remarkable in it in this respect; at least when this salt is produced, as recommended by M. Eugene Sahler, in the collodion itself, my various experiments lead me to suppose that the same result would take place with other iodides in the same condition.

I shall say only a few words upon *iodide of zinc*. Its properties are nearly the same as those of iodide of cadmium. It does not appear to me advantageous when employed alone; but I have obtained a very good collodion in employing it concurrently with other iodides.

Before speaking of the different bromides, it remains to examine the action of *iodine*, when free in the collodion. A well-established fact is the preservative action of iodine against fogged negatives. A pale collodion, that is, one containing no free iodine, sensitized in a neutral silver solution, almost always gives fogged negatives. To make the fogging disappear, the silver solution must be acidified, or what indirectly produces the same result, free iodine must be added to the collodion.

To this end, we may also make use of chloride of iodine, which, at the moment of sensitizing, is transformed into chloride and iodide of silver, and set a certain quantity of nitric acid in the film at liberty.

(*To be continued.*)

* I shall not in this place enter upon the examination of the iodides with organic bases, nor of the iodides of the metals of the first section, recently introduced.

## PHOTOGRAPHIC CHEMICALS:

### Their Manufacture, Adulterations, and Analysis.

*Hydrosulphuric Acid.*—Frequent mention has been made in these articles of hydrosulphuric acid, or sulphuretted hydrogen, as it is just as frequently called, and in most works on photography it is referred to. It is essential, therefore, that the photographer who desires to acquire a knowledge of the chemistry of photography, should be acquainted with the history and properties of this body.

Hydrosulphuric acid is prepared by acting on a metallic sulphide with an acid, in a gas generating apparatus. As this apparatus is of very general use, we think it advisable to give a brief account of the readiest method of constructing one. A large, wide-mouthed bottle, containing about a pint, is fitted with a good cork. Through this is pierced two holes, to admit of moderately stout glass tubing, technically known as "quill tubing." One piece is long enough to reach to the bottom of the bottle, and to project about eight inches above the cork, being surmounted at its upper end by a funnel blown on to it (such "funnel tubes" can be purchased for a few pence at an operative chemist's); through the other hole in the cork a piece of glass tube about six inches long is fitted; this tube is bent at right angles; one arm just passes through the cork, and the other projects horizontally outwards. Another bottle is now selected of a smaller capacity to the former, and fitted in like manner with a cork having two holes in it. Through one hole a glass tube passes, one end of which reaches halfway down the interior of the bottle, and the other end, being bent, at about three inches from its extremity, at right angles, rises up to and just meets the bent tube of the larger bottle. In the second hole of the cork of the smaller bottle another right angled tube is fitted, one end of which just passes through the cork, and the other end of which projects outwards horizontally. Finally, a fifth piece of glass tube is bent at right angles about two inches from one extremity, and the other end cut off to such a length that when the bent end is on a level with the bent tube of the second bottle, the straight end is within an inch of the table. The tubes connecting the two bottles are then joined together by fine vulcanised india-rubber tube; the loose tube is in a similar way connected with the smaller bottle, and the apparatus is complete. The first large bottle is called the generating bottle, and the other the washing bottle. The latter is to be filled with water until it rises to about half an inch above the extremity of the tube, which we have explained is to project half-way into it, and the large bottle is to have about a dozen lumps (about the size of marbles) of fused sulphide of iron placed in it, which are then to be covered with water. The apparatus is then to be tested for leakage in the following manner:—moisten the surface of the corks, the necks of the bottles where the corks fit, and the india-rubber tubes, with plenty of water, then apply the lips to the loose tube hanging down, and blow air in gently; the liquid will be forced up each long tube in the bottles, and, upon stopping the end of the loose tube with the tongue, should remain at the same level quite stationary. If, however, the apparatus leaks, the column of liquid in the tubes will rapidly descend, and the condensed air will escape at the leaky places with a hissing noise, where also it may sometimes be seen bubbling through the water used to wet the corks, &c. If the leakage occurs round the neck of the bottle it may frequently be prevented by giving the cork a tighter squeeze into the neck. If the leakage be at the india-rubber joints, the best plan is to wet them and then bind them round with fine copper wire; but if it be at the holes in the corks, or through flaws in their substance, the remedy will not be so simple. A paste must be made of linseed and almond meal, and, having well wetted the corks, they must be well smeared over with this until all leakage has been found to have ceased upon being tested for; the linseed coating may be smoothed over with the fingers, having wetted them with a little water. As soon as the apparatus is tight it is ready for use. A good stoppered bottle is nearly filled with distilled water, which has been recently boiled and allowed to cool (to deprive it of air), and then placed near the washing bottle, so that the loose glass tube dips into the distilled water and goes nearly to the bottom. Dilute sulphuric acid (one part of oil of vitriol to four of water) is now to be poured into the generating bottle through the funnel tube when the hydrosulphuric acid gas will be immediately seen to rise from the sulphide of iron through the liquid in the form of minute bubbles. The reaction is expressed in the following equation

$$FeS+HO.SO_3=FeO.SO_3+HS.$$

FeS being the sulphide of iron and HS being the hydrosulphuric acid, a compound of equal atoms of hydrogen and sulphur; the other product of the reaction being sulphate of iron $FeO.SO_3$. The gas accumulating in the upper part of the bottle drives the air before it, and bubbles first through the washing bottle, where it is deprived of its impurities, mechanically carried over, and then through the bottle of distilled water, where it is absorbed. It is necessary either to perform this operation in the open air, or under a chimney where there is a good draught, in consequence of the deleterious nature of the gas, and also of its action on metals and the different chemicals, especially silver salts, met with in the photographic laboratory. In fact, so injurious is the presence of this gas to the ordinary photographic processes, that the photographer who has not another room in which to perform such operations as these, except the one in which he prepares his sensitive plates and paper, should on no account attempt to prepare sulphuretted hydrogen, but either purchase its aqueous solution ready made (and even this will require great care in using), or dispense with it altogether.

Hydrosulphuric acid is a colourless gas, of an intensely disagreeable odour of rotten eggs, very poisonous in its undiluted state, and injurious even when dilute, producing fainting and asphyxia, and acting like a narcotic poison. It burns, like hydrogen, with a blue flame, forming water and sulphurous acid, with deposition of sulphur. It is soluble in water when passed through it, and as this aqueous solution is the one most frequently of use to the photographic chemist, we have given above the method of forming it. The bottle should from time to time be removed from the evolution tube, and having inserted the stopper, be well shaken; if, upon removing the stopper, the contents seem to suck inwards, it is a sign that the water is not yet saturated, and it must be submitted to the stream of gas once more, the generation being kept up in the large bottle by adding dilute sulphuric acid from time to time; if however the stopper, upon being removed, appears to be blown out, it is a sign that the water is saturated with gas, when the bottle must be carefully stoppered and placed aside for use. It is advisable, if the stopper be well ground in, to allow the bottle to stand upside down in a corner, its weight resting on the stopper; this prevents the possibility of any air being absorbed by the aqueous solution. In this case the stopper, before being put in, should be well lubricated by being warmed and then rubbed over with solid paraffin.

The amount of sulphuretted hydrogen gas which water will absorb is from two and a half to three times its volume. The solution forms a colourless liquid, having the odour of the gas, which, when exposed to the air, or heated, is entirely evolved. Upon standing, the solution absorbs oxygen from the air, which unites with the hydrogen of the sulphuretted hydrogen, forming water, with precipitation of sulphur, which gives the liquid a milky appearance:—

$$HS+O=HO+S.$$

The chemical reactions of hydrosulphuric acid, and the uses to which it may be applied in the photographic laboratory, must be deferred to our next article.

## PROFESSOR TYNDALL'S LECTURES ON LIGHT.

### Lecture iv.—Jan. 2, 1862.

With regard to the duration of the impression upon the retina, Professor Tyndall commenced by illustrating a very simple and beautiful form of experiment. The illustration was effected by means of the electric light, an image of the effect produced being projected on the screen; but the same thing, the lecturer explained, could be tried by each of his audience in the following manner:—Take a knitting needle, stick a little silvered bead on the top of it by means of marine glue or sealing wax, and having fastened the other end firm in a vice, strike it so as to cause it to vibrate. When the sunlight, or even the light of a lamp or candle is allowed to fall upon the bead upon striking it, the needle vibrates, and the bead goes on describing the most beautiful figures. Generally there is formed a figure of 8, which denotes the vibrations of which the rod is capable; at other times, the spot of light forms the most beautiful circles and ovals, with crimped or serrated edges, and every moment changing into some new form. Several popular toys depend upon this principle of the persistence of vision, amongst others being the chromatrope.

The subject of *irradiation* was then mentioned. This effect is produced when the eye looks at a luminous object; it appears larger than it really is, and the more intense the light, the larger does the object appear. Thus the full moon appears larger when looked at with the naked eye than when looked at through a dark glass. The bright new moon appears also to belong to a larger sphere than the dusky globe which it partially encircles. The lecturer illustrated this by exhibiting two rings of exactly the same size; one being black on a white ground, and the other white on on a black ground. Upon illuminating this with the electric light, the white ring appeared considerably the larger of the two, and even in the ordinary light of the room there appeared a slight difference in size. Another illustration of the same subject was afforded by a fine platinum wire ignited white hot by the battery; it appeared considerably thicker in that state than when it was cold, or when it was looked at through a coloured glass.

The special subject of the day's lecture was then commenced. A slice of white light was first of all projected on to the screen, and then a little glass prism was interposed in its path. The beam was bent very much on one side, and the white light was reduced to its coloured components. This is the grand discovery of the great Newton. The white light of the sun was then explained to be made up of an infinite number of rays of different refrangibilities. Each particular refrangibility corresponds to a particular colour; hence the number of colours involved in solar light is infinite; but for convenience sake, we divide these colours into seven, which are called primary colours. These are Red, Orange, Yellow, Green, Blue, Indigo, and Violet. Of these colours the red is the least refrangible, and the violet the most refrangible; the other colours being intermediate between these two. The spectrum of the electric light was then formed, and it was shown that by placing a lens in front of the prism, the colours could be so blended together again as to reproduce white light. The illustration was carried still further by taking the coloured rays forming the spectrum, and actually building them up again into the form of the very coal points from which they originally issued. Newton's experiment of the blending together of the seven primary colours into white light was then performed by projecting the image of a glass circle, painted with transparent colours, upon the screen. It was caused to rotate rapidly, when the different colours vanished, forming white light.

The spectrum which had hitherto been employed to illustrate these facts was from a glass prism; and attention was drawn to the width which the colours were drawn apart when this material was used. Some substances, it was stated, had the power of drawing the colours more widely apart than others; glass, for example, does this more effectually than water, and bisulphide of carbon more effectually than glass. This drawing asunder of the colours by a prism was called *dispersion:* thus the greater the distance between the red and violet ends of the spectrum, the greater is the dispersion. A hollow glass prism filled with bisulphide of carbon was then employed instead of the glass one to disperse the light, when the colours were seen to be pulled more asunder, and a more richly coloured spectrum was produced. Another bisulphide of carbon prism was then interposed in the course of the rays after they had undergone dispersion by the first prism, when the spectrum was greatly increased in length, stretching entirely across the screen. This was employed to explain the production of colours in nature. A bunch of red artificial flowers with green leaves, was introduced into the red extremity of the spectrum. Instantly the red flowers glowed with increased brilliancy, whilst the green leaves were perfectly black. Upon passing them along, as the bunch approached the green rays, the flowers grew black, and the leaves shone out with their natural colour, and when they left the green, and arrived at the blue rays, the whole bunch appeared jet black. The explanation of this is, that the colouring matter of the red leaves has the power of completely quenching, absorbing, drinking in, and destroying the blue, green, and yellow, whilst the only light which it is capable of reflecting back is the red. The same fact was afterwards illustrated with coloured sealing wax. Mr. Anderson, the assistant, (possessing a tolerably ruddy complexion,) was then requested to pass along the rays of the spectrum from the red upwards. At first his face shone with the bloom of youth; as he passed towards the yellow, one side of his face assumed a very cadaverous aspect, which became perfectly frightful when he entered the blue rays. Upon returning, one side of his whiskers became quite radiant, whilst the other side of his face was corpse-like; until, upon fairly entering the red ray, he shone in the full splendour of boyhood. In fact, the colours of bodies are entirely due to the light which falls upon them. If the white light of the sun were simple instead of compound, we should only have light and shade in the world, but there would be no colour.

The beautiful spectra produced by the combustion of various metals, was afterwards exhibited. A metal heated to whiteness gives a *continuous spectrum* as long as it remains in the solid or liquid condition; but when the metal has been reduced to vapour, and when that vapour is rendered luminous by intense heat, the spectrum of the vapour is usually composed of brilliant bands. Every metal has its own distinct system of bands. These were beautifully exhibited in the case of cadmium, copper, and zinc, by placing the respective metals on the lower carbon pole of the electric lamp, and refracting the light so evolved by means of the usual arrangement of prisms, lens, and slit. The bands produced by copper and zinc having first been exhibited, those of their alloy, brass, were shown, by which it was seen that the bands of each metal are produced in the spectrum of the alloy. Thus, knowing the bands which each separate metal produces, we can determine from the spectrum of an alloy the metals of which it is composed. The bands of metals were also shown to be produced when the salts of the metal are raised to a sufficiently intense temperature.

The light evolved by the ignition of the vapour of the metal sodium was then exhibited. This is intensely yellow, and gives a spectrum consisting of one single yellow band. This was first shown to be the case, and it was then explained that a luminous vapour absorbs those rays, which it can itself emit. Thus the light of incandescent sodium vapour is intensely yellow; but when a beam from the electric lamp is sent through this vapour, the yellow rays of the electric light are intercepted. This was shown by first projecting on the screen the continuous electric spectrum, and then interposing the vapour from a piece of burning sodium in the path of the rays. A broad black band was instantly ploughed out of the spectrum in that part where the yellow soda line formerly fell.

The recent theory of the composition of the sun was finally briefly examined. The sun, according to this, is supposed to be composed of a solid or liquid central portion, which of itself would give a continuous spectrum; but this nucleus is surrounded by a flaming atmosphere, through which the rays from the nucleus have to pass. This solar atmosphere, or *photosphere* as it is often called, intercepts those rays of the nucleus which it can itself emit, and hence the solar spectrum is always furrowed by dark lines (*Fraüenhofer's lines*). From these lines we can determine the metals which produce them; and in this way it has been found that many of the terrestial metals are present in the sun.

## REMARKS UPON SOME OF THE APPARATUS EMPLOYED IN PHOTOGRAPHY.*

BY F. R. WINDOW.

Cameras.—*Continued.*

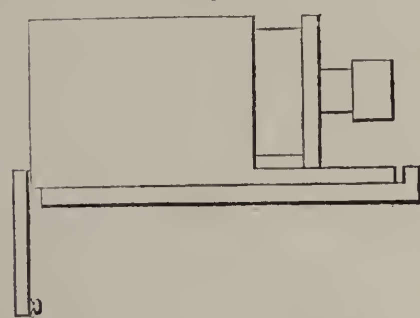
*The Focussing Screen.*—It has always appeared to me a mistake to make the focussing screen a separate piece by itself, instead of attaching it permanently to the camera. It not only has to be put into the instrument and taken out again every time that the focus is examined, but when taken out it has to be laid aside, generally in a hurry, and it runs a great chance of being broken. This applies to all descriptions of cameras, though the remedy cannot in every case be effected in the same manner.

In cameras for the studio it may without any inconvenience be hinged at the bottom, and, opening outwards, it will lie, when not in use, upon the top of the camera stand if this latter is larger than the camera, (fig. 5), or it will hang down parallel with the back if the camera projects beyond the stand, (fig. 6). In either case it will be out of the way of the plate holder, and the arrangement offers no practical objection, while it cannot be denied that it is much more convenient than the usual detached focussing screens.

Fig. 5.

When constructed in this manner, the frame of the screen

Fig. 6.



will not enter the grooves which receive the plate holder, but will lie flush up against them. It is kept up in its working position by means of a spring button on the back of the camera.

There many other ways in which the focussing screen can be constructed to form a permanent part of the camera, but I have described this one in preference, as it is the most generally applicable, and the simplest.

The ground-glass which is now supplied for the best focussing screens is of a very superior description to that which we had to use at first. The grain is fine and even, and the image appears upon it smooth and distinct in the details. Still I am inclined to think that we should find an advantage in using a polished glass, flashed with an extremely thin layer of opaque white glass instead of the granulated surface: for this would be as good or better than the ground-glass for ordinary purposes, and a high magnifying power might be used to focus subjects offering much minute detail, or the negatives of which were intended to be subsequently enlarged with the solar camera.

I am not aware that there is any obstacle to procuring glass flashed in this way; if not, I am inclined to think its use should be recommended, as just now small portraits requiring minute care in focussing are in vogue; and the time is not far off when enlarged pictures from small original negatives will be raised to their proper place in public estimation, and it is essential for these latter, which are to be looked at magnified, that the operator be able to assist the eye with a magnifier while arranging the focus.

## ON THE MANUFACTURE OF COLLODION.

BY THOMAS SEBASTIAN DAVIS.*

To make the pyroxyline, take 3¾ ounces (avoirdupois) of ordinarily dried and pounded nitrate of potash and mix it in an earthenware jar with 10½ fluid drachms of water. Pour upon this 4½ fluid drachms of nitric acid, sp. gr. 1·42 and 8¼ fluid ounces of the strongest commercial sulphuric acid, sp. gr. about 1·845, and intimately mix the whole with a glass rod. As soon as the mixture is at the temperature of 150° to 145° Fah. introduce 100 grains of finely divided cotton, in small quantities at a time, taking speecial care that each quantity is saturated with the acids before the introduction of the next, and allow the whole to remain at rest, standing upon a non-conducting surface, for about ten minutes. After the lapse of this interval, press the cotton with the glass rod against the bottom of the vessel, and pour off as closely as possible, the fluid mixture. The pyroxyline should then be quickly washed in three or four changes of water, and subsequently in several additional ones, with the precaution of pressing as much of the moisture as possible from the cotton between each change; by so doing, the cotton will be quickly and thoroughly freed from the slightest trace of acidity. As a precautionary measure, one or two of the latter washing waters may be rendered slightly alkaline by the addition of a few drops of ammonia: that used for the final cleansing should be neutral and distilled. The cotton may now be allowed partially to dry spontaneously, but the last traces of moisture should be driven off by the aid of a hot-water bath. As the quantity of water in the above formula constitutes the element of success, or otherwise, in the manufacture of the pyroxyline, it may be as well to refer to the extreme ranges and the resulting effects. If we add 12 fluid drachms of water instead of the 10½ recommended, the result would be that the greater portion of the cotton would be dissolved in the acids, and the remainder, if washed and dried, would be found to dissolve but sparingly in ether and alcohol, and yield a powdery, incoherent, and unsuitable film. If, upon the other hand, we were to reduce the quantity of water to 8 fluid ounces we should find that the cotton would be scarcely altered in its appearance when washed and dried, have but little solubility in an etherial mixture, and yield a film possessing a "crapy" texture. It thus follows that all the more characteristic pyroxylines may be produced by a comparatively trifling alteration in the strength of the acids. When, however, the water is added to the extent given in the instructions, the detached particles of cotton will give a milkiness to the first washing waters, it will present, when wet, a semi-transparent appearance when held up to the light, and after subsequent desiccation will dissolve easily and scarcely without leaving a residue, either in glacial acetic acid or an etherial mixture of alcohol. From this pyroxyline the plain collodion is to be made as follows:—

| | | | |
|---|---|---|---|
| Ether, methylated, sp. gr. | ·720 to ·730 | ... | 4½ fluid ounces |
| Alcohol ... | ,, ·837 | ... | 1½ fluid drachms |
| Pyroxyline ... | ... ... | ... | 6½ grains. |

The methylated ether referred to above can be commercially obtained of either the above strengths; the alcohol is the ordinary rectified spirit of 56·60 over proof of the distiller.

The sensitizing solution to be added to the plain collodion is a question of importance second only to the manufacture of the pyroxyline. I deem it exceedingly desirable that care should be taken that the addition of the sensitizing solution to the plain collodion should not be attended with the slightest precipitation; rather that the slight milkiness which the plain collodion may retain even after long standing should immediately disappear upon the addition. In order to ensure this effect, I recommend that a weaker alcohol should invariably be used in the manufacture of the plain collodion, than that which is employed as the solvent for the salts. I am aware that the greater facility with which the salts employed are dissolved by the weaker spirit has led to a practice at variance to the one advocated; but under such circumstances a precipitate generally occurs. The composition of the iodizing solution is to be as follows:—

| | |
|---|---|
| Iodide of potassium ... | ... 6 grains |
| Iodide of cadmium ... | ... 18 grains |
| Bromide of potassium ... | ... 2 grains (in excess) |
| Chloride of ammonium | ... 2 grains (in excess) |
| Alcohol, sp. gr. ·805 ... | .. 1 fluid ounce. |

I give the preference upon chemical and photographic reasons, to the combination of iodide of potassium and iodide of cadmium over the combinations of other iodizing salts, and the stability and solubility of the latter combines conveniently with the instability and sparing solubility of the former. The alkaline iodide is, moreover, eminently qualified to give a great and excessive vigour of intensity, whereas, the metallic salt by itself imparts an image of the opposite character. A combination of the two in the above proportions yields probably the best image that can be realized by the use of iodides alone. The preference may be given to the potassium iodide over the ammonium, inasmuch as the former is less liable to decomposition, and the consequent liberation of free iodine, than the latter. The iodide of sodium is almost identical in its action and properties with iodide of potassium; but as the latter can be obtained with greater facility in a state of purity, convenience suggests its employment. The effect of adding chlorides and bromides to the combination of the above salts is to lessen the exaggerated contrasts which are likely to attend the use of a plain iodized collodion, to give greater immunity from stains and fogging, and what is of considerable moment, permit a longer exposure, where necessary, for the delineation of objects situated in shade, without the prevention of the vigorous rendering of the higher lights. The beneficial effects of the chloride of ammonium will be but trifling as far as regards the use of the collodion for the wet process. It will give however greater sensibility, increased brightness of negative, and general correctness of tone to plates, from which the whole of the free nitrate of silver has been washed away for the purpose of applying a preservative. With respect to the introduction of the potassium bromide in preference to the bromide of ammonium, it may be remarked that although it be less freely soluble in alcohol, yet for negative pictures, in combination with mixed alkaline and metallic iodides, it is sufficiently so to produce the desired effect. By its use we prevent the possibility of double decomposition, which under certain circumstances may otherwise take place. The salts, as described, should be dissolved without heat in about three-fourths of the alcohol, and after having been frequently shaken therein for two or three days, and carefully filtered, the remainder of the spirit may be then added. The iodizing solution is to be mixed with the plain collodion in the proportion of one volume of the latter to three of the former, and it will be found that the resulting compound will meet every possible requirement of the artistic photographer, with the exception of very rapid sensibility. In furtherance of the object of obtaining increased sensibility, I have tried many published and original experiments, but without meeting with any marked success, unaccompanied with some serious inconvenience. The generality of these experiments have been directed to the introduction of such salts into the sensitizing solution as form by double decomposition with nitrate of silver, insoluble compounds more or less effected by actinic power. The salts which can be successfully introduced for the purpose are obviously limited to those which are partially soluble in a mixture of alcohol and ether, and afford insoluble compounds when the electro-negative element enters into combination with the metallic base. In accordance with the above conditions I have selected for my experiments the acetates, malates, citrates, succinates, benzoates, arseniates, arsenites, cinchonates, &c. The only instances in which I have obtained any indications of increased sensibility have been in those in which the salts introduced have possessed an alkaline reaction. Amongst these I may especially mention the arsenite of potassium. As silver salts of a character so formed are prone to reduction under the influence of the ordinary developing agents, their employment is to a greater or less extent attended with a general fogging of picture. In following out some experiments in connection with sensibility, I introduced the terchloride of gold into the sensitizing solution in the place of the less soluble chloride of ammonium. The exaltation of sensibility caused by this addition was both marked and decided, but the known facility of reduction to which this salt is subject, apart from the influence of light, under the action of pyrogallic and protosulphate of iron solutions, defeated the possibility of its successful application. So great is the aptitude of this salt to reduction, that the introduction of a single plate covered with a film containing a mere trace thereof is sufficient to render a large quantity of the nitrate of silver bath solution inapplicable for further photographic purposes. It was therefore with some surprise that I subsequently found that Mr. Barnes, in his excellent and able manual upon the use of collodion upon a thin substratum of albumen as a dry plate process, had not only tried,

* Concluded from p. 79.

but suggested, the use of chloride of gold as an accelerator many months before the date of my experiments. As a general result of my researches in this direction, I am inclined to endorse the opinion heretofore expressed, that at the present moment we must use, even if we are not to rest satisfied with collodions of ordinary sensibility, and that we have not as yet discovered any "accelerator" of unexceptional utility. We may, however, perfect the manufacture of such collodions by a critical study of those minutiæ to which I have endeavoured to direct attention in the present paper.

## PHOTOGRAPHIC PIRACY.

A case of some interest to photographers was tried before the Lord Chief Baron and a special jury, in the Court of Exchequer on Tuesday, the 18th inst. The case as reported in the *Times* stands as follows:—

MAYALL *v.* HIGBY.

Mr. Vaughan Williams and Mr. Blaine were counsel for the plaintiff; Mr. M. Smith, Q.C., and Mr. Aspland for the defendant.

This was an action by Mr. Mayall, the well-known photographer of Regent Street, to recover the original photographic portraits of several distinguished persons, and also damages for the alleged illegal use which the defendant had made of them in copying and selling diminished impressions in the form of *cartes de visite*.

Mr. Mayall was called, and gave the following evidence:—In 1857 Mr. Tallis, the publisher of the *Illustrated News of the World*, called upon me and asked me to lend him a number of my portraits of eminent men, for the purpose of engraving and publishing weekly in his paper. I agreed to lend them on condition only that he would return them as soon as engraved. It was subsequently arranged that I was to have an advertisement inserted in his paper gratis. I handed over to him, from time to time, about 200 photographs for engraving; among them were Lord Brougham, Prince Dhuleep Singh, Mr. Serjeant Shee, the Prince Consort, Lord Campbell, the Rev. J. Bellew, and other distinguished persons. They were all engraved and published in the *Illustrated News of the World* weekly. Some of them were returned after being engraved. I also lent him photographs which, to the best of my belief, have not been engraved. Among them were the Earl of Dartmouth, the Duke of Rutland, Mr. Bernal Osborne, Mr. Tom Taylor, the Rev. Baptist Noel, Prince Joinville, Lord Rosse, and others. The photographs were taken by me by arrangement. Lord Brougham and others came to me for their portraits. I stated to them that the negatives were my property, and I asked their permission to publish them; they gave me their consent. In many cases permission was refused. On all the photographs produced permission was given. I took the portraits at my own expense, and gave a copy to the parties who sat for them.

The portrait of Lord Brougham in an oratorical attitude was produced and handed to the jury.

Witness continued,—Mr. Tallis became a bankrupt in 1860, but his paper continued as before. After his bankruptcy I found that reduced copies of my photographs were being sold. I had not myself published or authorized to be published any copies of them. I found that Mr. Bennett, of Bishopgate Street, was selling them, and I called upon him and ascertained that he was publishing them for Mr. Higby, the defendant. Mr. Higby afterwards called upon me, and offered to sell me the photographs and the negatives he had made from them for £250. I stated I would give him no definite answer till I had consulted my legal adviser. On his calling again I refused to hold another conversation with him.

In cross-examination.—I have sold a few copies of the original of Lord Brougham and a few others to their private friends at £2 2s., with an express understanding that they were not to be copied. I sold no copies of Prince Dhuleep Singh except to himself. No offer that I can recollect was made for Sir John Pakington. (Laughter.) Alderman Carden was returned by Mr. Tallis. As soon as I found that the portraits were being sold I wrote to the assignees of Mr. Tallis, saying they were my property.

The evidence of Mr. Mayall was confirmed by his secretary, and witnesses were called to prove the value of the photographs and of the reduced copies of them sold by the defendant.

On behalf of the defendant, Mr. Smith stated that he should prove that Mr. Higby had bought the portraits from the assignees in bankruptcy of Mr. Tallis under the impression that they had a good title to them, and that he had paid considerable sums for them, and was acting in a perfectly *bonâ fide* manner.

The Chief Baron said that after the evidence that had been given there was no pretence for saying that any property in the photographs passed to the assignees; that the defendant, though acting *bonâ fide*, had no right to them, and must look to the assignees for his remedy.

It was ultimately arranged that a verdict should be entered upon the count in *detenue* for the plaintiff for 40s., upon the understanding that the photographs should be given up to the plaintiff; and, after direction from the Judge, the jury returned a verdict for the plaintiff of £25 upon the count charging the defendant with illegally using the photographs by making and selling reduced copies of the same, the question being reserved for the Court whether any such action would lie in the absence of any law of copyright relating to photographs.

## Proceedings of Societies.

### South London Photographic Society.

The usual monthly meeting of this Society was held at the City of London College (formerly Sussex Hall), Leadenhall Street, on the evening of Thursday, the 13th instant. The Rev. F. F. Statham, M.A., F.G.S., in the chair.

The minutes of a former meeting were read and confirmed, and the following new members were elected:—Messrs. H. P. Robinson, of Leamington, J. J. Cole, C. W. Wood, Harman, Hoskins, and Shooter.

Mr. T. Clark Westfield presented to the Society a copy of his work on Japan, illustrated with photographs, which was noticed in our last

Messrs. Smyth and Blanchard presented to the Society two very fine photographic copies of paintings by Mr. Noel Paton.

Mr. G. Wharton Simpson proposed, after the routine business, that the first act they did in the new premises, which promised to be eligible and convenient in every respect, should be to pass a vote of thanks to their worthy President and the Committee of St. Peter's School Rooms, Walworth Road, for their liberality in so long placing the rooms at the disposal of the Society, The vote was carried at once by acclamation.

Mr. Howard proposed the effects of the Society left in the school-room, consisting of benches and some planks, &c., for the purpose of making long tables, be offered to the Committee of the School Room.

Mr. Simpson seconded the resolution, which was carried, as was also a motion by Mr. S. Davis, thanking Mr. J. Rennel for a liberal offer of an excellent room gratuitously; but which not being sufficiently central had not been accepted.

The Secretary, referring to photography in the International Exhibition, said:—It would undoubtedly be a matter of great and very serious regret if, of all the arts and sciences it is the great business of this year of 1862 to show the world in their most advanced stage of development and promise, photography alone should be represented by a poor, a meagre, or insufficient display. I hear with pleasure that the Committee appointed by Her Majesty's Commissioners for the management of this department of the glorious International Exhibition are most earnestly doing their work, and that they spare neither personal labour nor thought in working out their very important tasks; but the space devoted to photography in the Kensington Exhibition is so very circumscribed, and so unfortunately subdivided, that it seems extremely desirable that an exhibition of photography additional to it, and calculated to convey a more thorough and comprehensive view of the art in its various pictorial and scientific departments, should be organised, and opened at as early a period as possible after the present date. Influenced by such considerations, your committee have for some months past contemplated and discussed the possibility of opening an independent photographic exhibition, which, without opposing, should be additional to the photographic portion of that at South Kensington. Having matured a plan, and put themselves in written communication with the Secretary of the Crystal Palace Company at Sydenham, Mr. G. Wharton Simpson, Mr. Sebastian Davis, and myself, at the request of the Committee, waited upon this gentleman to make some definite arrangements, enter into particulars of detail, &c., and I am enabled to announce that we were met with ready courtesy regarding all our proposals, and that negociations are pending which will, I hope, issue satisfactorily both for this Society and all persons interested in the progress of photography throughout the world. The necessity for an auxiliary exhibition needs no urging: among photographers, we have reason to believe that it is universally felt, and the simple fact that photographs have been prepared for exhibition in all parts of Europe by those who have either received no allotments of space, or have been grievously disappointed in the small portions set apart for them, lead us to hope that a collection may be gathered together, which, for quantity, quality, variety and interest, will probably surpass any exhibition organised under less rare and peculiarly favourable conditions. The opportunity is not likely to be again proferred for many years to come, and your Committee trust that the personal exertions of every individual member will aid them in doing justice both to it and the art we represent. We are anxious to embody all the more recent improvements and discoveries in the art, to illustrate fully the capabilities of different processes, and to show, in various ways, and as completely as possible, all the various applications of photography, to exhibit select specimens of choice or novel apparatus, and, in short, to carry out all suggestions which will tend to raise the art as art in public estimation, and at the same time give the collection a full share of scientific interest, and great educational value.

Mr. Sebastian Davis then read a paper "On the Manufacture of Collodion" (see p. 79).

At the conclusion of the paper Mr. Davis produced various samples of pyroxyline, illustrating the effects of strong acids at a low temperature, and of weak acids at a high temperature. A sample, also, made after the formula recommended by Mr. Davis was shown, and a portion of it added to a mixture of alcohol and ether. It dissolved almost immediately without appreciable residue.

The Chairman, in proposing a vote of thanks to Mr. Davis, referred to the great value of such papers, involving, as they did the careful prosecution and accurate recording of important chemical experiments.

Mr. Simpson, referring to the remarks in Mr. Davis's paper, suggesting the possible accelerating qualities of various organic and other compounds of silver, said, if he remembered rightly, the arsenite of quinine had been used in some of the earliest experiments with collodion. Dr. Diamond had shown him a very early collodion positive, in which there were very distinct traces of five separate tints obtained. The collodion by which it was obtained contained the salt just named.

Mr. C. J. Hughes remarked that, notwithstanding the increased commercial facilities of procuring good working collodion, without the trouble of each photographer preparing it for himself, the subject was as important as ever; and, notwithstanding all the research which had been made, we did not possess that amount of certain and definite information on the subject which we felt we ought to have. The matter appeared simple enough, perhaps, but no one could grasp the whole subject, but those who had had very large experience in every phase of making and using collodion. There were many causes which contributed to render certainty on this subject very difficult to obtain: the intangible chemical composition of some of the elements involved; the trembling state of balance upon which the best conditions depended, and the relation and influence which other things, such as the bath and developer, had in affecting results, all contributed to render the subject a difficult one. Those only who had by experiment realized these difficulties, could properly appreciate the value of a paper like that of Mr. Davis. The subject was wide enough for many evenings' discussions. First, there was the cotton wool and the various substances which had been proposed as substitutes, such as linen, flax, paper, and even silk. Mr. Hardwich had given these substances much attention, and the result of his experiments was, that cotton was out of all proportion the best. True, there were some persons who still preferred paper; but the preference was generally based rather upon experience than any theoretical superiority. Next came the question of acids. We knew that nitric acid alone would produce the desired result; but it was much more manageable and satisfactory to use the mixed acids and water. The use of nitrate of potash used to be very common, but it had now fallen much into disuse, on account of the difficulty of getting rid of the sulphate of potash formed. He had been a little surprised to hear that it entered into Mr. Davis's formula, and should be glad to know the especial ground upon which he used it. Of course, in speaking of nitrate and sulphuric acids, we only meant solutions of the anhydrous acids, and it was convenient in practice to use them of such a strength as admitted the addition of water, which, by generating heat, gave them a suitable temperature. Next came the proportions of acids. Mr. Hardwich had tabulated the results of almost every proportion, from three of nitric acid to one of sulphuric, to three of sulphuric to one of nitric. The maximum of nitric acid gave a film in which there was very little contrast; whilst with excess of sulphuric the pyroxyline gave a film yielding a vigorous intense image. Experience alone could decide upon the desirable medium. The question of temperature came next, that entirely depended upon the quality of pyroxyline desired, and upon the strength of acids used. With strong acids a high temperature was necessary; whereas, if much water were added to the acids, a much lower temperature would produce a similar result. The time of immersion would also be affected by similar causes. He remembered that Mr. Hadow, some years ago, spoke of leaving the cotton in the acids all night; that would, of course, be at a temperature of about 60° Fah. At the temperatures now generally used, about ten minutes seemed to be regarded as sufficient. Mr. Hughes proceeded to refer to the use of nitrous acid and its general abandonment, and to the importance of thorough washing, and the advantages of an alkali wash in neutralizing any remaining acids. The strengths and proportions of the solvents were next passed in review, and the importance of considering them in relation to the quality of the pyroxyline and the size of plates intended to be used. Coming to the question of iodides and bromides, and the undoubted advantage of the latter in conjunction with iron development, he remarked on the singularly large proportion of bromide used in America compared with what could be used with advantage in this country. Regarding the use of chlorides in collodion he had recently been going through a series of experiments in this direction. He had come to the conclusion that the smaller the proportion the better the result, and the entire omission was best of all.

Mr. Simpson said Mr. Hughes had throughout his remarks enunciated a principle of the utmost importance in every branch of photography, namely, the importance of harmonious relation in all the parts of any process. It was almost impossible in photography to speak of the advantage of anything *per se*, as that which was of the utmost value under certain circumstances might be useless under other conditions. Nevertheless it was possible to fix those conditions, and as Mr. Hughes in his able review of the various processes employed in the manufacture of collodion, might perhaps have left an impression on the minds of the uninitiated that its successful manufacture was almost a hopeless task, involving as it did, so many considerations, he thought it might be desirable briefly to state a method in which all the conditions were tolerably well defined, and which, he believed, with ordinary care, would always give satisfactory results. The method of preparing the pyroxyline was an old one, if he remembered rightly, first published in the definite form, in which he should state it, by Mr. Sutton. He took equal parts by measure of sulphuric acid and nitric acid; the latter of a specific gravity of 1420, the former the oil of vitriol of commerce. These were raised to a temperature of about 150° by placing the vessel containing them in another containing hot water. The cotton wool was immersed and kept in about ten minutes, washed well, and dried. Five or six grains of this would dissolve entirely in equal proportions of ether and alcohol, the latter of a specific gravity of ·820. Equal parts of iodides of cadmium and sodium were used in iodizing. He preferred the latter to potassium, as being more soluble. About half-a-grain of bromide of cadmium and two grains of each of the iodides named, gave a collodion very sensitive and very stable, and yielding most excellent results with iron development. For the tyro he knew of no formula so simple; whilst for most purposes he knew none giving finer negatives.

Mr. Hannaford found the formula Mr. Simpson had just described a most efficient one; and by adding different quantities of water to the acids, he obtained pyroxyline of any quality he required, for wet or dry processes. By adding a little water to the acids named, and raising the temperature to about 160°, he obtained a pyroxyline giving great intensity, and by adding sufficient bromide, he could regulate the result. As to the use of a chloride, he thought that might be useful in a collodion for dry purposes, as it was now generally understood that the presence of one or more salts of silver, in addition to the iodide, was of great service in securing sensitiveness in dry plates. Referring to the advantages which many photographers found from mixing different kinds of collodion, he stated that he utilized his waste acids by making a fresh lot of pyroxyline with them, which he mixed with the other, and so obtained some of the advantages of a mixed collodion.

Mr. Wall spoke in high terms of the excellence of the collodion made by Mr. Hannaford.

Mr. Henderson referred to the advantages to be derived from the use of iodide of silver in collodion.

Mr. Davis stated that it was originally used by Dr. Diamond. Mr. Hadow had, however, stated, as the definite results of some experiments, that the iodide of silver formed by double decomposition in the collodion film, was more sensitive, and the addition of iodide of silver fell into disuse.

After some conversation,

Mr Simpson said, in reference to the quantity of bromide which might be used with advantage in this country, he knew that Mr. Hughes, whilst convinced of the advantage of a small amount of bromide, had arrived at conviction, from experiment, that nothing was to be gained by using it largely. He (Mr. Simpson) had used all proportions up to two grains to the ounce with marked increase in sensitiveness, but a slight loss of intensity.

Mr. V. Blanchard had been experimenting recently, and had obtained pictures of equally good quality from one grain of bromide and five of iodide, and from five of bromide and one of iodide. The base was cadmium.

Mr. Harman said he had no difficulty in getting good results with three grains of bromide and three of iodide.

After some further conversation

Mr. Davis stated, in reply to Mr. Hughes, that his object in using some nitrate of potash was to secure a portion of pure nitric acid by its decomposition, and he thought that in its nascent state it was more capable of entering into combination with the cotton.

On the motion of Mr. Blanchard, seconded by Mr. Fry, the discussion was adjourned to the next meeting.

It was announced that at the next meeting Mr. Noel Fitch would read a paper on "The Experiences of an Amateur in Portraiture."

The proceedings were then terminated.

Amateur Photographic Association.

A meeting of the Committee of the Amateur Photographic Association was held on Monday, the 10th inst., at 26, Haymarket, the Right Hon. the Viscount Ranelagh in the chair.

The minutes of the last meeting having been read and confirmed, the Secretary read a letter from the Earl of Caithness, expressing his regret that he could not be in town to attend the meeting.

The Secretary laid before the meeting sample copies from the negatives sent in to the association, the number of which up to the date of the meeting was 1,756, which, together with foreign and colonial ones on their way to this country, will probably amount to about 2,000, and which, even after the process of weeding by the referees, will, it is fully anticipated, show a total of not less than *fifteen hundred good negatives.*

A question respecting the further reception of negatives having been raised, it was decided that the catalogue should not yet be sent to press, but be kept open until the 1st of March, as members residing abroad and in the colonies had scarcely had sufficient time to forward their plates. It also having been suggested that a gold and silver medal is hardly the most useful or acceptable form in which a prize can be given, it was resolved that in each case (at the option of the recipient) a silver tankard, or other piece of plate of equal value, should be substituted.

On considering the propriety and advantage of holding an exhibition and *soirée*, the Chairman kindly offered at any time to place a suitable room at the disposal of the society.

It was decided in reference to the selection and distribution of the prints, that each member shall be requested to select three times as many prints as he may be entitled to for his subscription, arranging the selected numbers in a preferential order in his list, placing those most desired at the commencement, and so on. It is confidently hoped that by this arrangement, although members may not in all cases have *every* print most desired they need, under no circumstances, have awarded to them pictures which they do not value.

The time at which the award of the prizes should take place was next discussed, and it was resolved that it should not, if possible, be deferred later than the 15th of March.

The idea of establishing a "Photographic Art Union," in connection with the Association, was introduced by the Secretary. The subject was considered to be one of considerable interest, but there being many important questions involved, it was deferred for further discussion till next meeting, and the proceedings then terminated.

Photographic Society of Scotland.

The ordinary meeting was held on the 13th inst., H. Ross, Esq., in the chair.

An address of condolence to Her Majesty, on the death of the late Prince Consort, was adopted unanimously.

The decision of the Prize Committee as to award of medals for the best pictures in the exhibition was announced as follows:—The medal for the best portrait has been awarded to Mr. D. O. Hill, R.S.A., for his picture, No. 295, "Dr. John Brown and his cousin Dr. John Taylor Brown;" the medal for the best landscape, to Mr. James Mudd, of Manchester, for his picture, No. 54, "The Tay above Dunkeld; and the medal for the best frame of six cartes de visite, to Mr. H. P. Robinson, of Leamington, for his set, No. 174.

Specimens of zincography, by Sir Henry James, were sent to the meeting by Sir David Brewster. Mr. Taylor also exhibited a few specimens of photolithography, by Mr. Ramage, of Edinburgh, and one by Mr. Osborne, of the Ordnance Survey, Australia. A discussion ensued on the subject of photographic engraving.

Professor Archer exhibited a number of specimens of M. Joubert's process of enamelling photographs on glass.

Sir David Brewster sent for exhibition a few specimens of M. Camarsac's new process of photographic enamelling, which he had received from M. Claudet for that purpose.

A communication was read from Herr Otto Köhnke, Mehlbye, Schleswig, on a new mode of obtaining photographs without the use of chloride of silver or hyposulphite of soda: and specimens of the process were exhibited.*

## Correspondence.

### MEALINESS IN TONING.

Sir,—The articles on "Mealiness in Toning" have interested me very much, although I cannot say I have been so much troubled with this drawback to pleasant and easy printing as some appear to have been; but as the first step towards perfect cure should be to thoroughly comprehend the nature of the disease, I think some further attention should be given to this point. I am not satisfied with the theories at present given. In preparing my own gold bath I have, I believe, generally used an excess of alkali, and perhaps this is one reason why I have been less troubled with this defect. I do not think the question lies so much in the formation of insoluble salts in the paper, but more in the *particular kind of salt*, and in this view of the case, I believe the conversion of the unreduced silver into *any other than the chloride salt* will prevent mealiness. My reason for this idea is, that I believe when the chloride of gold comes in contact with those parts of the print where the action of light has been less energetically felt, and where by consequence, there remains a large amount of unreduced silver, converted by washing into chloride, a new action is set up *between the two metals, setting free the chlorine*, which acting rapidly on those parts where it would in such cases exist in largest quantities, produces those mottled tints, known by the name of mealing. Now I believe the presence of organic matter checks this action more or less according to circumstances, but in the case of the conversion into an organic salt, as in the proposed use of acetate of soda; if this suggested molecular or electric action between the two metals still takes place, there remains no chlorine† in the paper to affect the tint of the proof, but instead the tint is

* See Photographic News, Jan. 31st, p. 57.

† It will be understood that the chlorine in the gold solution is already neutralized.

produced by combination of gold and organic matter, and the toning takes place more equally. I don't know if I have explained my ideas on the subject so that you can understand my meaning, but if I am not quite right in my view I think I have indicated the direction in which the difficulty lies. I think it will also be found that my suggestion explains most of the phenomena attending the efforts to overcome this very serious difficulty.—I am sir, yours respectfully, E. E. L.

The same correspondent writes further as follows :—

I endeavoured in my last note to explain that I understood this defect to arise from a rapid and unequal liberation of chlorine. caused by the action of the silver of the proof in contact with the gold of the toning bath, for it should, I think, be kept in mind that the metals still retain and can be again reduced to their metallic form.

What I wish particularly to correct in my former note is the notion that I there gave that I thought free chlorine unnecessary and injurious in the process of toning. This is not my idea, as I believe it to be the real active agent in the process, and that toning takes place in proportion to the amount of free chlorine present, and also the greater or less rapidity with which it is liberated ; it will, therefore, be understood that it could only be objectionable when existing unequally on the surface of the paper, and producing unequal reduction of the gold. That chlorine is essentially an agent in toning may, I think, be shown in many known facts, as, for instance, the great difficulty in toning proofs that have been previously fixed.

There are, however, some retarding agencies also to be taken into consideration besides the absence, more or less, of chlorine. The most active of these retarding agencies will, I think, be found in organic substances. Judging by my own experience, every organic salt of silver, when present in any quantity, exerts some retarding influence, and to this cause also may, perhaps, be traced the beneficial influence of the acetate of soda, checking the too rapid liberation of chlorine, and allowing more equal distribution of the precipitated gold.

The reason why mealiness does not occur on plain paper proofs, I take to be owing to the absence of organic matter on the surface, as it is well known that the silver salts are more rapidly reduced on this kind of paper, and therefore, when under the influence of the gold bath, the amount of reduced silver being large in proportion to free chloride present, we do not see those rapid and extreme changes of tint so common with albumen paper.

In the *sel d'or* process also, it was formerly recommended to add hydrochloric acid to the bath, and this, however injurious to the permanency, certainly aided rapid toning. I would also call attention to the different action of the newly prepared gold bath, and the same bath when left some time before using. This I take to be owing to the fact, that some of the chlorine being liberated from the gold to form chloride of sodium by the decomposition of soda, effects this new combination very slowly, and it is during this time, and whilst the chlorine is in a nascent state, that it acts most energetically in reducing the gold. It will, therefore, be seen, that according to my view, chloride is essential ; but that being exceedingly energetic, it rapidly frees itself in the presence of the new action taking place between the two metals, and if there be not a *large* amount of *reduced* silver present, the act of substitution soon ceases, and the gold is deposited, not *on the proof*, but *in the dish*, and the hypo afterwards removing the unreduced silver, the slight amount of reduction becomes visible in the pale grey colour of the part not effectually acted on.

In conclusion, my view is, that as free nitrate is necessary to aid reduction of the chloride of silver, so also some free chloride is necessary to aid in the reduction of the gold of the toning bath ; but that the gold is deposited on the reduced silver in proportion to the amount of reduction, and that where the amount of reduction is not in excess of the amount of chloride, irregular toning takes place, and the gold bath is exhausted without aiding the operation.

What I have attempted to describe will also explain, I think, why washing the proof in water containing chlorides is conducive to the production of mealiness, and also that water containing organic matter may check the action of toning. I have already trespassed so far on your patience that I will avoid adding more, otherwise I could mention many known facts in support of the view I have here given of this part of the process.—Yours respectfully,

E. E. L.

P.S.—There is one other matter in connection with mealiness in toning worth observing. I allude to the fact, that this defect is *not* inherent in the process of *alkaline* toning, else it would have occurred when this process first became so common. If, therefore, the cause be unequal reduction of the silver of the proof, whence arises this unequal reduction ? It is, I believe, admitted, that some negatives produce this more than others. Now, my suggestion is, that iron development has brought this upon us. The majority of iron developed plates require redevelopment. I think everyone has felt how very easy it is to produce stains and patches in this latter process. I have often heard operators remark that a stain visible only by reflected light was of no importance. I cannot subscribe to this opinion ; whatever may be the cause of this stain, it differs in colour from the surrounding parts, and if say darker, being composed of the same matter as the light parts, and which matter is used as a retarding agent, it follows that this dark stain may obstruct in a greater degree the reduction of the surface beneath, or if the stain be lighter, may admit an unequal reduction in the opposite direction ; let those who use redeveloped negatives make careful observations on their printing qualities, and I think we shall then learn the origin of mealiness in toning. I have a strong notion that all gold toning processes are perfectly analogous, and with your permission I may another time endeavour to show that the gold of the old hypo toning bath acts just in the same manner on the proof as it does on the alkaline bath, and that the difference is more apparent than real.

---

Sir,—I have of late read much in the Photographic News on the subject of mealiness in toning. Although I always tone by the alkaline chloride of gold process and use albumenized paper I have never met with the above annoyance. For the benefit of others less fortunate, if you think it worth while to give insertion in your Journal to these remarks, I will detail the process I employ. It was communicated to me, in its main features, in the course of last summer by Mr. Bashford, a professional photographer, at Jersey, to whom, therefore, as far as the process itself is concerned, I surrender whatever merit it may possess.

I print a little, but not much, beyond the intensity I wish the finished picture to retain. On removal from the pressure-frame the proof is washed in two or three waters for several hours. When I have the choice, I give preference to soft water for this part of the process, but do not find that hard water exerts any injurious action. My toning bath is prepared as follows :—I take of chloride of gold one grain dissolved in six ounces of water, and this is rendered alkaline by four drachms of a solution of phosphate of soda of the strength of ten grains to the ounce of water. This is sufficient to tone at least eight pictures of the size of nine inches by seven. In cold weather it expedites the operation to raise the temperature to something like blood heat.

The proofs are retained in the toning bath until the shadows by transmitted light appear of a dark chocolate brown ; they are then washed in several changes of water and fixed in a hypo bath of the strength of six ounces to the pint of water, in which they remain from fifteen to twenty minutes, undergoing but little change by transmitted light, though by reflected light the cold violet tint gives place to a warm dark brown. I should add that I use

Marion's "extra albumenized" paper, and that I excite by floating for five minutes on an eighty grain silver bath.

I send you a print from a calotype negative of a street in Dinan, as a fair sample of the results of the above process I am not chemist enough to say whether the absence of mealiness is due to the use of phosphate, instead of carbonate of soda, or whether it should, in more justice, be attributed to the manner in which the albumenized paper is prepared, that I leave for others to determine; but according to your opinion of the merits of the result it rests with you to recommend it or not to your numerous readers.—I am, sir, &c., W. F. Watson.

*Dinan, France, February*, 1862.

[The print received is entirely free from mealiness.—Ed.]

## PORTRAITS IN THE OPEN AIR.

Sir,—With all deference to the opinion of such an authority on photography as the Abbé Despratz, I think he has made a slight mistake in one or two statements, as contained in last week's News. The first is that "a good portrait can never be taken in the open air;" of course I am not in a position to judge what the Abbé might call a good picture. I can only say that my practice has been a good deal in that way, and I never remember being troubled with the "spotty" effect mentioned. I never find any difficulty in getting pictures of fair quality. I enclose a portrait taken nearly two years ago, in which there is plenty of half-tone, and two groups. The negative of the single figure has been scratched somehow, but it will serve to show that at any rate half-tone may be found in pictures taken out of doors. It was taken on a bright day; the sun being at the time obscured by a cloud, and the exposure was, as near as I can remember, two seconds. This brings me to the second point in dispute, viz., the difference of exposure required in the open air in comparison with a glass room. My conclusion is, that under the same circumstances, it would be four or five times as great, that is, about ten seconds! I always find on a bright day, in the shade, that two seconds, and in summer one second, is ample; in fact, I took a picture as nearly instantaneous as could be, by removing and replacing the cap, on a cold dull day last month. It may be well for amateurs and experimental photographers to wait for certain effect of cloud, &c.; but for one like myself who depends upon it for a living, it would hardly pay. I must e'en make the best of my day when out, whether the sun be too bright or the reverse: and if I cannot produce pictures up to the standard referred to, I must be content. I must apologize for occupying so much of your space in this matter, and beg to subscribe myself, yours respectfully, T. Jones.

*Broad Street, Ludlow, Feb.* 12, 1862.

PS.—The one group is scarcely printed enough, and the one figure on the side has spoiled it by moving; that was exposed with a side light ten or twelve seconds.

[We conceive the Abbé is in error. Great skill and judgment are required in open-air portraiture; but it *is* possible, we know, to produce excellent portraits without a glass room. Indeed your specimens prove it.—Ed.]

## THE ALKALINE RAPID PROCESS.

Sir,—As far as my limited opportunities have yet enabled me to test the merits of Mr. Bartholomew's very valuable suggestion, of the use of *soda* in dry plate photography, I can speak most satisfactorily of its results. With a sensitiveness in the camera, almost equal to that of wet collodion, the pictures have a density, detail, and cleanliness, especially in the skies, more uniformly certain, than from any other dry process I have ever tried, although I very much prefer the gelatine one of Dr. H. Norris. I attribute the entire success of this method to the *alkaline*, in opposition to the usual *acid*, reaction of the sensitizing agent, nitrate of silver, for as acids *retard*, may not therefore alkalies excite, or at all events, *not* retard? The presence of organic matter always exists in every photographic process of the present day, whether negative or positive, for without it, no decomposition of nitrate of silver by light alone is effected, the pyroxyline in one case, and the paper and albumen in the other, being always present. No common amount of simple washing will entirely remove all the nitrate of silver from the sensitized collodion film, but for the good keeping qualities of dry plates, it is necessary to reduce the quantity of it to a minimum. Is the fogging evil of wet collodion films, in an alkaline sensitizing bath, owing to their extreme sensitiveness, and if so, might it not be turned to good account in instantaneous photography? Might not an *alkaline* sensitizing bath be always used for dry plates, so that no after use of soda would be necessary, but simply washing them well before gelatinizing and drying, &c.? Is this the secret of Dr. H. Norris's very sensitive dry plates? I have found the best method of applying the soda solution to be *after* the first washing, and *before* the second or last, so as to remove it entirely before pouring on the warm gelatine solution; for if any combination takes place between the soda and the gelatine, certain slight markings, of a cellular or reticular form, fatal to good negatives, are the result. I am very truly yours, &c., E. T.

*Coldstream, N. B., February* 12, 1862.

## THE DRY PROCESS WITHOUT PRESERVATIVE.

Sir,—I do not quite understand the object of Mr. Ward's communication in your last, but if it be to impugn my good faith I must refer him to the article in question, which, from its very title, is descriptive of a dry process "*without* preservative." I there state that "no preservative substances whatever are required; good pictures can be got without them." If the film be excited in the ordinary way, well washed and dried, it will be found as sensitive as the best of any other dry process." I simply stated that I had found it necessary to keep the film on the plate by some means, either by varnishing the edge of the plate, or covering the surface with gelatine or albumen. I preferred albumen chiefly because of its easy preparation, and also because I had been in the habit of using it as a substratum in the wet process.

Having been told that my pictures were all due to the albumen, and further that the albumen would spoil the bath, I produced a picture without the albumen, and showed a sample of the bath, giving also the results of my experience of its use, as I have just stated, namely, as a substratum for wet collodion for a long period of time. The "hundreds" of plates were not stated by me to have been prepared for drying, but they were used while wet.

If you will refer to No. 153 of the *British Journal of Photography*, you will find a letter of mine in relation to the resin process of Mr. Glover, in which I indicate the result at which I was then arriving. My words were, "I strongly suspect that no preservative is required at all." This letter dated October 15th, 1861.

I would simply observe, once for all, that the paper read by Mr. Martin was hurriedly prepared at his request, but if I had imagined that it would have raised so much controversy it is very probable that I might have taken more pains with it.

I find that there are persons who, oddly enough, seem to ignore the facts altogether, as though "vested interests" were disturbed by not using "preservative" substances, but I have to thank you for bringing the subject prominently forward, and if amateurs are enabled to obtain pictures with more care and certainty my object will have been gained without contending who was first in the field, which must really be a matter of perfect indifference to your readers.

I have had several collodions sent me for trial, but I have not yet found one to my mind. The article wanted is a collodion which will not leave the plate during the fixing of the pictures, and will give vigorous results with a moderate exposure. If any of your correspondents can help me in this respect, I shall feel greatly obliged.—I am, yours obediently,

W. Hislop.

[If our readers refer to the last paragraph of Mr. Hislop's paper, read at the North London meeting in November (p. 579, Vol. V, Photographic News), they will find he distinctly states that he claims nothing new. He simply emphasized an old idea which had never received due recognition, and in so doing has initiated or rather revived experiment in the right direction. We believe a suitable collodion is the only thing required. Wo havo not had timo to try Mr. Ward's formula. Will Mr. Hislop do so? Some of our correspondents havo sent us samples of collodion for tho purpose, which we hope shortly to try.—Ed.]

## Photographic Notes and Queries.

### Photographic Exchange Club.

Dear Sir,—If we consider that tho object of tho Exchange Club is not only tho collection of a stock of pictures, but should bo accompanied by an acquisition of knowledge with respect to the working qualities of different processes, and lenses, &c., we must see that the latter part of tho object is not lost sight of, for precious, indeed, is such information that most of our pictures convey.

I think, if wo were to adopt tho uso of such labels as those enclosed, we should, in tho long run, bo not the less satisfied:—

TO BE REVERSED.

| | |
|---|---|
| Subject ... ... ... | The Old House at Homo |
| Process ... ... ... | Fothergill |
| Lens ... .. .. | Ross's 4½ in. focus |
| Stop ... ... ... | ¼ in. |
| Timo ... ... ... | 2½ minutes |
| Light ... ... ... | Bright, without sun. |

NOT TO BE REVERSED.

| | |
|---|---|
| Subject ... ... ... | Valo Crucis Abbey N. Wales |
| Process ... ... ... | Collodio albumen |
| Lens ... ... ... | Aplanatic 4½ in focus |
| Stop ... ... ... | $\frac{5}{16}$ in. |
| Timo ... ... ... | 7 min. |
| Light ... ... ... | Wet, without sun. |

Their use would obviate another evil attending the writing on the back of prints; we should not have the words—*right, left*, staring us in tho faco when we put it in the stereoscope, such being tho caso with some that I havo mounted, the words being as distinct on tho face of the picture as on the back.

I have got a greater number of these labels printed than I shall probably ever want, and if any fellow-member would like to use them, and does not find it convenient to get them printed, by enclosing six stamps to me he may receive 100 by return of post.

*Higher Hurst, Ashton-on-Lyne.* John Hollingworth.

### A Modified Fothergill Process.

Sir,—As I havo seen articles frequently in your Journal on new dry processes and modifications of others, which I supposo may all have their advantages, perhaps you will allow me to say a few words on a method of preparing dry plates, which is a little different to any I have seen described in your paper, and would much like some of your readers to try it.

Being principally engaged in the operating room, but having occasionally done out-door work, and often with dry plates, the method I have adopted in preparing them for about three years past is simple. They are very sensitive, and give good results, and will, I anticipate, have good keeping qualities; but I have never tried them more than a few days.

I first ascertain that my chemicals are in good working order, with fresh plates and pyrogallic development, sensitize a plate as usual, put it into a flat dish containing 40 ounces of water, (this is for a plate 12×10), let it remain until tho water flows freely over the surface; take it out, drain for about a minuto, then pour over it the following solution, which must be kept on from one to two minutes.

| | |
|---|---|
| Albumen ... ... ... ... | 1 ounce |
| Water ... ... ... ... ... | 4 or 5 ounces, |

*Glacial acetic acid*, 20 drops to each ounce of the above, and to bo well shaken in a bottle. This must be free from suspending particles; I prefer it being filtered, or a stock can bo put away to settle, as it will keep any length of timo; at all events, I have used it six months old. The plato may now bo washed, a great amount of washing not being required, as they can bo fully developed without being washed at all, and thereby not being so apt to stain, but still I prefer them being washed.

I havo tried ammonia in the albumen, but never even liked tho idea of putting it to a sensitive plato; I have also tried citric acid, but prefer the acetic.—Yours, &c., T. H—.

*Durham, Feb.* 12, 1862.

P.S.—The albumen will not keep if less acid than I stated is added.

## To Correspondents.

The First Exhibition of the South London Photographic Society.—Specific arrangements for holding a supplemental Exhibition of Photographs at tho Crystal Palaco have now been mado by tho Committee of the South London Photographic Society. Wo hope to bo ablo to publish the conditions in our next.

P. C. Riversdale.—Your suggestion has repeatedly been anticipated in various ways, but without practical success. The mere formation of iodide of silver in the film is not sufficient, excess of nitrate is also desirable. M. Poitevin proposed, about two years ago, to add nitrate of silver, about 5 grains to the ounce of collodion. This was to be immersed in, or coated with. a solution of iodide of potassium. The film of iodide of silver in this state is insensitive to light. To excite the plate for use, a solution of nitrate of silver was to be poured over it. In the various processes suggested during the last year or two by H. Bellini, Captain Dixon, and A. Gaudin, nitrate of silver was added to the iodized collodion.

C. O. E.—If you had acted on our suggestion you would have escaped the difficulty. India-rubber is very tardily soluble in benzole, especially in some samples. We recommended dissolving the india-rubber in chloroform, and, if necessary, diluting with benzole. We can now only recommend you to follow that course. Bi-sulphide of carbon is a ready solvent, but is not a pleasant smelling article to use.

Enquirer.—The lenses quoted in the catalogue you mention are of French manufacture, and we have no doubt but that at the price referred to will be good of its kind. Those of the best English makers are, however, generally much superior in defining power and rapidity, and to those who can afford them, are worth the difference in price. The method of precipitating silver from a nitrate solution with copper may be used if you prefer it; but the use of a chloride is simpler.

C. F. Booker.—The cracking of the collodion film and of varnish film was very fully discussed at a meeting of the Photographic Society a little more than twelve months ago. You will find the matter fully treated at pages 391 and 397 of our fourth volume. A variety of causes were suggested, but a common opinion prevailed that it resulted from traces of the fixing salt remaining in the film Mr. Booker's difficulty consists in the collodion film cracking under the varnish. Can any of our readers suggest further information as to the cause or remedy.

Chirurgicus.—The Kinnear camera is one of the most portable and efficient for landscape work we know. If well made it may be very light without being actually fragile, and will answer perfectly for dry plates. The means of obtaining the same advantage by inclining the lens, as are obtained by a swing back, require, of course, very great care and judgment in use.

Enquirer, No. 2.—The silver obtained by washing prints prior to toning them, should be precipitated in the form of a chloride by the addition of common salt. The chloride thus thrown down should be well washed and dried. It may then be reduced to the metallic state by placing in a crucible with double its weight of a mixture of the carbonates of potash and soda, and submitting to a bright heat.

Economy.—If there be any silver in your waste developing solutions, it will gradually be reduced into metallic silver, which will be found in a grey powder at the bottom of the bottle.

A Novice.—If your folding landscape camera have a sliding body it will answer for portraits as well; if not, the simplest plan will be to buy another for portraits and keep the one you have for its own purpose.

F. G. L.—See articles on "Iron Development and Brilliant Prints" in last volume, also in Photographic News Almanac. A strong iron developer will give more detail, a weak one more contrast.

Anastarchus.—We should prefer to line the cistern with thin gutta percha, as described in the series of articles "Amateur Mechanic," in our second volume.

J. W.—The flame of a candle protected by a yellow shade is not likely to be injurious to an excited collodion plate. 2. We should consider the lens of the English maker you name incomparably better than the French one for card portraits. 3. With a soft negative the *Rive* paper will give you the best prints; with a very vigorous negative the *Saxe*.

T. G. B.—Sunshine is necessary to the efficient use of the solar camera. Without direct sunshine the condenser is useless.

Emily.—The best mode of avoiding stained fingers in photography is to use great care. India-rubber gloves or finger-stalls may be used; but you remember the old adage about a "cat in gloves" You may use horn pincers in lifting sheets of paper from the silver bath; and some of the numerous plate-holders for developing; and by the aid of these, and careful manipulation, you may avoid "getting your hands into *such* a state."

Tom.—Good Scotch or Russian glue may be used for mounting photographs with advantage; and will occasion the least tendency to cockling.

G. G.—We prefer hyposulphite of soda to cyanide for fixing negatives.

Frank Farleigh.—We do not think any especial advantage is obtained in using a bath of greater strength than 40 grains to the ounce, for negatives. The stronger the bath, the greater the proportion of acid necessary to mako it work without stains or fog.

C. F. L.—Wash the inner frames of your dark slides frequently, and tako care to drain the plates well upon a piece of blotting paper. Any accumulation of silver in the slide is apt to cause stains.

X. Y. Z.—All intensifying processes require that the primary image should have an especial character suited to the method to be adopted. Wherever the negative is intensified after fixation, it is desirable that plenty of detail and softness should characterize the image in the first place. Where intensity is gained rather by a change of colour than by piling on additional silver, the greatest delicacy will be secured. It is for this reason that many operators prefer the use of bichloride of mercury and iodide of potassium.

Several correspondents in our next.

All Letters, Works for Review, and other Communications for the Editor, should be addressed to tho Office, 32, Paternoster Row, London.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 182.—*February* 28, 1862.

## EXHIBITION IN CONNECTION WITH THE SOUTH LONDON PHOTOGRAPHIC SOCIETY.

We have already intimated to our readers that it was in contemplation by the South London Photographic Society to hold an exhibition of photographs during the forthcoming summer. That an exhibition affording fuller scope for illustrating the present state of photographic art than can possibly be effected in the space devoted for the purpose in the International Exhibition at South Kensington, is desirable, is universally admitted and emphatically expressed. That such an exhibition should be under the direction of some photographic society need scarcely be affirmed. The parent society having concluded that the initiation of such an additional exhibition on their part was undesirable, and the officers of the South London Society having received intimation of this determination on the part of the parent society, at once resolved to undertake the duty of organising an independant exhibition.

As a *South* London society it was felt that the Crystal Palace at Sydenham possessed a local fitness for an exhibition under their auspices, whilst at the same time it possessed an extent of facilities, and a universality of attraction, which would render it by far the most desirable place in which to hold an exhibition which, if not a substitute for, might at least, be an important auxiliary to, the display of photographs in the building at South Kensington.

We have now the pleasure of announcing that arrangements are completed with the directors of the Crystal Palace Company, which secure to the society a very large and eligible space in the first gallery of the Crystal Palace, immediately overlooking the central trancept. This space will be placed entirely under the management of a committee of the South London Society, and so arranged and screened as to form a complete and separate department. Immediately adjoining this space another portion of the gallery running northward, will be devoted to the exhibition of apparatus &c., in which everything novel and interesting in connection with the material appliances of the art may be exhibited. As regards photographs, arrangements will be made for attendance of a superintendent, who will undertake sales as in other similar exhibitions. This arrangement will not, we apprehend, extend to apparatus.

It is contemplated to open the exhibition about the middle of May. So far as it is possible in the short time now at their disposal, it is the intention of the committee to arrange and classify the pictures sent for exhibition as perfectly as possible, so as to fitly illustrate at a glance every phase of the art. The authorities of the Crystal Palace have, with the liberal courtesy which characterises their management, empowered the committee to offer season tickets to the palace to exhibitors whose contributions possess sufficient excellence for exhibition. When the value of space in this building under ordinary circumstances is remembered, as well as the increased value arising from the enormous influx of visitors who may be fairly anticipated during the ensuing summer, the liberality of the offer cannot be over-estimated, and will require a very strict exercise of supervision on the part of the South London Committee to prevent its abuse.

Among the features which we may with propriety anticipate here, and which, from the limited space, can occupy but a very unimportant position at South Kensington, will be life-size and other enlarged pictures. From English artists large contributions may be expected; and from Continental photographers, many of whom must necessarily be disappointed in obtaining space to exhibit the fine amplified proofs, of which we have heard from time to time such glowing accounts, we may legitimately hope for an extensive and gratifying display of their work.

At the time we write the preliminary arrangements have just been completed. We hope next week to announce the conditions and regulations in full. In the meantime, we make this brief and hasty notification to allow those of our readers who are interested in the matter, to be making any necessary preparation for such a desirable opportunity of contributing to an exhibition which will not, we trust, fall short, in all features of interest and excellence, of any which has been held on any previous occasion.

## Notes and Jottings.

No. 14.

### Mr. Reynolds's New Process: "Summing up."—Dr. Phipson's Iron Printing Process.

The printing process with peroxalate of iron, which Mr. Reynolds recently brought under the notice of the Dublin Chemical Society, has, in consequence of his having put it forward as "new," caused some little discussion, and, on the part of Mr. Reynolds, a misapprehension that he was supposed to have obtained some of his ideas from previous publications on this subject. Having been the first to show that the process had long been known, thereby opening the enquiry, it may not be out of place for us, at this point of the proceedings, to "sum up" the case, which may in fact be considered as practically settled, and to assure Mr. Reynolds that no one ever supposed or intimated, that from beginning to end, he acted otherwise than in perfect good faith.

It may be remembered that the paper "On a New Process for Photographic Printing" was read to the Dublin Chemical Society in November last, and placed before our readers in the first number of the present volume. Mr. Shadbolt next calls attention to the process in a leader in the *British Journal of Photography* of the 15th ult., considering it a subject of "no trifling importance"—and therein he may be right for anything we shall say to the contrary—at the same time describing the idea as a new and original one. That it was original, so far as Mr. Reynolds is concerned, we never doubted, but that it was not *new*, we clearly showed in the News of the 17th ult., at the same time, however, crediting that gentleman for the demonstration of his method of preserving the half tones of the image, which we had not known previously. Mr. Taylor, on the 1st inst., in the *British*, favours us with some "*notes, harmonious and discordant*," on the subject,—"discordant" as regards Mr. Reynolds's claim, but "harmonious" with our remarks thereon. At the same time Mr. Shadbolt, in a second leader confesses to having been caught "napping" with reference to the "so-styled new process;" putting in, however, a good excuse for having given his friends a chance of "waking up the editor," and raising a laugh at his "friend's" expense, demonstrating how little the giant felt the pigmies' kicks. But Mr. Reynolds evidently had not been so accustomed to "'arf bricks" as our stoical friend the editor, and thus we find a letter from that gentleman in the News of the 31st ult., wherein, in reply to our "Jotting," he still stands out for the newness of his discovery, inasmuch as he employed *ammonio*-nitrate of silver, and not plain nitrate of silver as given in our quotations, by which means he preserved half tone, and, in his opinion, disposed of the question we raised respecting the chlorides in the paper, the alkali in excess dissolving the chloride of silver formed. On the latter point we will only stop to express a doubt as to whether Mr. Reynolds can dispose of the chloride so easily; but as regards half tone we gave him full credit for his demonstration. Mr. Taylor's paper had not, at this time, come under the notice of Mr. Reynolds; had it done so he would have seen that ammonio-nitrate of silver had been previously employed by Dr. Halleur for the purpose. Nevertheless, to Mr. Reynolds belongs the credit of showing *why* that salt should be used. Lastly, at present,—for Mr. Shadbolt "may have something to say on this subject in his next number,"—lastly comes a letter in the *British* from the originator of this discussion, to the effect that "no one can be more convinced than he now is that the process is not new," and, as it is ever a comfort to have companions in misfortune, he seizes hold of Mr. Macdonald, who, in a letter to the same Journal, as "the originator of this process more than a year ago," claims "honour to whom honour is due;" this gentleman he pulls with him to the bar of photographic opinion.

The true state of the question then, appears to be that printing with peroxalate of iron and the subsequent application of silver, was introduced by Sir J. Herschel; but that Mr. Reynolds, without any knowledge of the process having been known previously, gave us the results of his rediscovery in good faith. Mr. Shadbolt, overlooking that among the many suggestions for printing without hyposulphite of soda being required as a fixing agent, this particular method had more than once been named, and perhaps being struck by the lucid manner in which Mr. Reynolds gives his information more forcibly than by previous communications; comments thereon, and gives his friends the chance, as he says, of "waking up the editor." Mr. Reynolds being subsequently convinced that the process is not new, frankly states as much, and gives perfectly unnecessary proof that he made his researches quite independently of what had been published before.

In conclusion, we may state that the probable usefulness of the method stands in exactly the same position as it did. It has never been shown that it could practically be employed in photography, and we trust that Mr. Reynolds will not discontinue his experiments because it happens to have turned out the process is not all his own.

---

The discovery of Dr. Phipson given in a recent number of the News cannot be considered the same as the above, as this gentleman states it to be: one is a silver, and the other an iron printing process. As a method of obtaining a positive print in iron it is simply a rediscovery of Mr. Burnett's process which appeared a few years back, simultaneously with one we published. The salt of iron which Mr. Burnett preferred as a sensitizer was the ammonio-oxalate, whilst that employed in our experiments was the ammonio-citrate. Michael Hannaford.

## Scientific Gossip.

Purification of Water-glass for Photographic Purposes—Action of Silicic Acid on Fermentation—Curious Property of Tellurium-Methyl—New Processes for the estimation and detection of Nitric Acid in Solutions.

On many occasions have the peculiar properties of soluble glass been mentioned in these columns, and their adaptation to the wants of the photographer been advocated. As a substitute for collodion, as a varnish, and as a cement, it has repeatedly been the subject of experiments, and it is probable that in one if not all of these characters it would hove found its way into the photographer's laboratory, were it not for the great difficulty of preparing the compound in a pure state. Soluble glass, or *water-glass*, as it is frequently called, is a chemical combination of silica with an excess of an alkali, soda, or potash, usually the former; it dissolves in water with a degree of rapidity proportionate to its richness in alkali. It is prepared by fusing together fine white sand or powdered quartz with soda or one of its readily decomposable salts. For all photographic uses a product should be chosen containing as much silica as possible, so long as it is soluble in water. In no case should there be more than two equivalents of alkali to three equivalents of silica: a glass of this composition will be very slow to dissolve; a more basic salt will have a tendency to deliquesce. Mr. J. M. Ordway has recently devoted some considerable attention to the different kinds of water-glass, and has discovered a very perfect means of purifying the compound from the different saline and earthy contaminations which it is sure to contain when prepared for commercial purposes on the large scale. He finds that by several properly conducted precipitations with alcohol, the impurities may be entirely got rid of. We have therefore in this process a ready means of obtaining a water-glass of the utmost purity, and of almost any required composition. For the preparation of a perfectly pure substance for delicate experiments, it is recommended that a rather dilute solution of a crude silicate be taken, containing not more than ten per cent. of solid matter. To ten parts of the liquid may be added at first one part by weight of strong alcohol, and before filtering the mixture should be allowed to stand several hours, in order to give the reluctant precipitate a chance to get fully aggregated together. Rejecting this first deposit, which contains most of the earthy matters and very little of the alkaline silicate, add to the filtrate twenty parts of alcohol, and the greater part of the water-glass will be thrown down. When the product is rich in silica, it is quite voloминous at first, but gradually contracts and becomes more or less coherent. After a rest of six hours or more, the alcoholic liquid being carefully decanted, the solid silicate may be spread on absorbent paper, and allowed to drain as long as it will remain without adhering to the paper. The mass thus deprived of mother-liquor can then be dissolved in four times its weight of water, and carried through the same round of treatment as before. The result of this second series of operations will in most cases be found almost entirely free from impurities; but if need be a third or even a fourth course of fractionizing may be resorted to. It will be found far easier thus to separate the extraneous substances from a roughly made silicate than to observe the many precautions required in preparing a pure product with pure ingredients; and considering the small quantity of alcohol required, and the means of recovering even this by distillation, the cost appears so moderate that a manufacturer might be warranted in resorting to a single precipitation when a nice water-glass is wanted for use in the arts. In such a case it will do to operate on a tolerably strong solution, say one containing twenty per cent. of solid matter; but it should be observed that weaker liquors allow of a more intimate commingling of the alcohol, and are more likely to retain the foreign salts; therefore for photographic purposes the substance should be prepared from a ten per cent. solution, as above described.

Whilst upon the subject of water-glass, we may mention a very curious and important observation, which has just been made. It has been found that silicic acid precipitated from water-glass produces fermentation in saccharine solutions, particularly after the addition of some tartaric acid, and generates the odour of beer-yeast, afterwards of fruits, and finally of ether; in very dilute solutions the odour of putrid yeast appears. Silicic acid does not lose this property by boiling with water, or by repeated employment for fermenting, and subsequent washing with water. A solution of sugar, containing alcohol and tartaric acid ferments briskly with silicic acid, evolving carbonic acid gas amidst the separation of a yeasty foam. If confirmed, this observation of Leuch's will prove most important to the student of the obscure phenomena of fermentation.

A striking illustration of the powerful action possessed by an almost imperceptibly small portion of matter has lately come under our notice. An experimenter has been occupied for some time upon certain compounds which the element tellurium forms with organic radicles. Amongst others, he prepared some tellurium-methyl. The most remarkable property of the tellurium-methyl compounds is their intolerable and persistent odour. A small quantity of either the body itself or one of its salts allowed to get on to the finger, soon communicates a smell to the whole body, and in a few days is perceptible in the breath. The stench is so lasting that the unfortunate chemist is shut out from society for several months. We mention this because there is a tendency with some experimentalists to introduce the salts of these compound ammonias into photography, and if the fashion be once set, there is no knowing where it would stop. It is not likely that tellurium would be at present introduced into photography, owing to its expense; but this not being due to the rarity of the metal as much as to its want of utilization, may at any moment cease to be a bar to its employment.

It is often of consequence to the photographic chemist to ascertain the exact quantity of nitric acid present in a solution. The ordinary processes for estimating this are tedious in the extreme, and, consequently, recourse is generally had to the volumetric process of analysis proposed by Pelouze. This has lately been modified by Braun in the following way:—Instead of estimating by permanganate of potash the amount of protoxide of iron on which the nitric acid has not acted, he determines the peroxide of iron formed by means of iodide of potassium and hyposulphite of soda. Protochloride of iron is first formed, which is then peroxidised to its fullest extent by the nitric acid whose amount it is wished to ascertain. Iodide of potassium is then added, when the perchloride of iron, as is well known, sets the iodine free, even in the cold, but more completely when the reaction is assisted by a gentle heat. The amount of free iodine present may now be easily estimated by means of a solution of hyposulphite of soda after having added a small quantity of starch paste. The standard solution of hyposulphite of soda may be prepared either by dissolving a known weight of the salt in a similarly known weight of water or by standardizing with a solution of hyposulphite of unknown strength the iodine set at liberty by perchloride of iron prepared from a known weight of metallic iron. An excellent way of detecting the presence of small quantities of nitric acid when the exact amount is not required to be ascertained, has also been given by Schulze. It is founded on the fact that nitric acid in a strongly alkaline solution by the action of finely divided zinc or sodium, or aluminium amalgam becomes transformed into ammonia. When zinc is used only about half the nitrogen is evolved as ammonia, but with sodium amalgam the change is complete. When a solution is to be examined it is to be supersaturated with caustic potash and boiled for some time until the original ammonia is got rid of: the sodium amalgam is then dropped into the residual liquid and the mixture again heated. If the smallest traces of nitric acid are present in the solution it will be rendered evident by the immediate evolution of ammonia, which may be detected by the smell.

## REMARKS UPON SOME OF THE APPARATUS EMPLOYED IN PHOTOGRAPHY.*

BY F. R. WINDOW.

### Cameras.—*Continued.*

*The Plate Holder.*—The plate-holder, or wet slide, is the most important part of the whole camera. On its condition and nature depends materially the condition of the photographic impression. The plate-holder alone comes in actual contact with the delicate sensitive plate, which is entrusted to it during the exposure, and it returns it to the laboratory pure and uncontaminated by this contact, or infected with the germ of stains, spots, rents, and other abominations, accordingly as itself is free or not from imperfection.

Slides for wet collodion plates are, I believe, all made precisely alike, the model dating from the discovery of the process. There is no reason to desire any alteration in the main features, but I think a little attention may be usefully paid to some points of detail.

I mentioned, when speaking of camera bodies, that when, for the purpose of introducing a diaphragm, the camera was made larger than the picture, it did not follow of necessity that the plate-holder should also be larger in the same proportion. There is advantage to be gained, however, in having it made so, as the prepared plate then, instead of resting upon the corners of the plate-holder itself, may be held in an inner chassis, moveable, and more easily cleaned after every plate. Since the cleanliness and consequent worth of the picture depend much upon the plate not being soiled in the slide, no care should be neglected to guard against the possibility of impurity inside this latter, and whatever facilitates the cleaning of it, or that tends to prevent the deposit of hurtful matter in it, increases in the same measure our chances of obtaining a perfect picture.

In the earliest cameras the corners of the plate-holders and of the chassis were fitted with pieces of glass to support the plate, which practically served as a reservoir for a puddle of nitrate of silver, that, draining off the plate settled in these corners between the glass and the wood of the slide or chassis. This nitrate of silver became at once contaminated with organic matter, and if any of it came again in contact with the iodized surface of the plate it was a certain source of stains. When it is considered that the plate and holder had to be carried in this condition from the laboratory to the glass-room and back, and that the plate had to be taken out and its position reversed before development, all which encouraged the impurities to flow over it, it will be understood how difficult it was with such an arrangement to get a plate free from all stain, and, in fact, how rare, in those days, it was to get a plate without at least a mark at the corners and edges, and how often these misfortunes used to obtrude themselves in more important parts of the picture.

This has been remedied to a great extent by substituting silver wires instead of the pieces of glass for the plate to rest upon. By this alteration the formation of a pool at each of the corners is avoided, but it does not entirely get rid of the chance of organic matter being carried on to the plate. The pools of nitrate of silver that have been noticed were only objectionable because they were formed in contact with the wooden frame, and became contaminated with organic matter, and *in this state* would stain the plate. The present chassis fitted with wires, is also made of wood, and when the plate holder is in a vertical position the plate rests upon this wood, and the point of contact receives the draining of nitrate, which—after imbibing impurities from the wood—when the slide is laid horizontally, or when the plate is removed, or even by capillary action only, may flow over the plate and stain it. It is usual to lessen this danger by hollowing out the sides of the chassis, so that the plate can only touch any side at the two extremities. This leaves eight channels by which impurities may be carried on to the plate at one stage of the process alone, and I think many otherwise inexplicable misfortunes might be traced to this source.

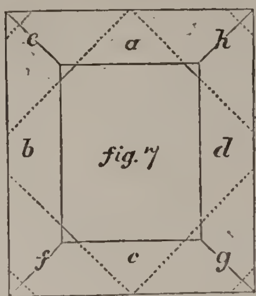
I do not think we can be said to have taken every possible care to produce a perfect picture, so long as we employ wood for any part of our apparatus that is to come into actual contact with a wet collodion plate, or in such very close proximity to it that the silver drainings from the plate can touch the wood, and by any chance get returned to the plate.

It is usual to varnish the inside of the slide, and the

* Continued from page 89.

chassis with spirit varnish, but this is no protection against the action of nitrate of silver. A thoroughly good coating of some resinous combination laid on hot with a brush might be effective for a time; but the proper course is to construct the chassis of some material without action on nitrate of silver. Possibly ebonite may be found the most practical, if its qualities are such as are stated.

I have for some time used chassis of glass, which, while perfectly satisfactory in practice, have the further advantage of being easily made by the photographer himself. Fig. 7



is a representation of one of these chassies. Four pieces of stout glass, (*a*, *b*, *c*, and *d*,) are cut of the required dimensions to form the chassis, the outer dimensions corresponding with the frame of the plate slide, and the inner with the size of the plate. These are laid upon a piece of plate glass, (a sheet of thin paper intervening to prevent sticking), and cemented together at the four corners. Then across each joint is cemented another strip of glass (*e*, *f*, *g*, and *h*), a portion of which overlaps the inside corners of the first pieces, but leaves the inside corners uncovered. This completes the chassis, but it must be left upon the piece of glass until the cement is perfectly set. In use, it rests in the slide upon the outer corners, and the sensitive plate upon the inner corners. This is like the old glass-cornered chassis, only the body of the chassis being in this case of glass, the nitrate of silver remains pure and harmless to the sensitive surface.

After each picture, it is taken out of the slide, held under the tap, and well washed with a brush kept exclusively for that purpose; it is then wiped, and the slide cleaned with a piece of rag, before it is replaced. With these precautions, stains from this source are almost impossible. If photographers who are much troubled with stains in the wet collodion process will make a glass chassis, and will keep it thoroughly clean, they will discover the importance of these observations.

If a diaphragm be used in the body of the camera, it is not necessary for the chassis or inside of the plate holder to be black; but the slide should be coated inwardly with some suitable varnish, to render it as much as possible impervious to nitrate of silver.

A compound of resin and beeswax will be presently described, which is very suited to this purpose.

The sliding shutter mostly in use for portrait cameras is that which opens upwards, and folding forwards, lies, while a picture is being taken, upon the top of the camera. This is a very efficient shutter for in-door work. Care should be taken that it works easily in its groove, and not in jerks or stiffly, so that there may be no danger of lifting the plate holder bodily, and so letting in light upon the partly exposed plate while raising it. A little French polish on the edge of the shutter or in the groove is as often the cause of its sticking as careless workmanship. The remedy for this is a little fine sandpaper applied to the part.

The grooves in which the shutter works should be frequently examined and cleaned from all dust and dirt; as if any is permitted to accumulate there, the friction of raising the shutter is apt to scatter it over the surface of the plate.

Before closing the subject of studio cameras, I must mention that I have purposely abstained from referring to particular instruments of any form, or those exclusively intended for one particular use; altough my observations, being general, mostly apply also to these as well as to the instrument of ordinary construction for general purposes.

(*To be continued.*)

## ON HELIOCHROMY.

BY M. NIEPCE DE SAINT-VICTOR.

Although I still base my researches upon the principle of M. Edmond Becquerel, I believe I have effected an important modification in it, which first admits of my obtaining the most vivid tints upon a light ground; then, after obtaining colours, of fixing them temporarily by a second operation, or rather, of retarding the destructive action of light for a few hours.

The heliochromic colours are obtained upon a film of chloride of silver, formed upon a metallic plate. We can chloridise the silver plate in various ways; at present, I effect this by hypochlorite of potassa. This alkaline bath, although very variable in its composition, generally gives good tints, only the ground of the image remains a little sombre, even after the influence of reheating the plate; moreover, various causes tend to make certain colours predominate.

This chloridizing does not give results identical with those indicated by M. Edmond Becquerel, in his *Mémoire* of the 3rd July, 1854. Nor was it better with regard to sensibility, when I employed it in reproducing the colours of a doll. The bath which I made use of at that date was composed partly of sulphate of copper, and partly of proto- and deuto-chloride of iron, dried, and diluted with one-tenth of water. With this chloridizing, which stood the action of reheating, we can operate, in a quarter of an hour in sunshine, with the camera.

But in my last researches, my aim being rather the fixing the colours than their development, I employed the simplest and most economical means of producing them. It fortunately happened that in my search for the means of fixing the colours, I obtained them more vivid—other things remaining the same.

To obtain the colours on a white ground, it is necessary, before exposing the plate to light, to heat it until the chloride of silver assumes a rosy hue; or rather, replace the action of heat by the action of light under a mixed screen, as pointed out by M. E. Becquerel in his *Mémoire* already referred to. I conceived the idea of extending upon the chloridized plate, before its exposure to light, a film, formed of a saturated solution of chloride of lead, obtained directly from the metal, into which sufficient dextrine is put to form a varnish of a certain consistence. The varnish is left to settle for four-and-twenty hours; when decanted, it will serve for use during several days. Pour this varnish on to the plate, after it has been reheated, and spread it over the entire surface, draining the superfluity off at one corner; then dry it at a spirit-lamp; the plate is now ready to be exposed to the light.

Under the influence of light, the colours are produced in much greater intensity than if the plate were not covered with this varnish, as may be shown by covering only one-half of the plate with varnish. The ground of the portion covered with varnish will be white, because the chloride of lead possesses the property of rendering the chloride of silver white under the influence of light (especially if the chloride of silver has been submitted to the action of heat), and the colours stand out better; besides, and this fact is very extraordinary, the black lines of an engraving are frequently reproduced with very great intensity; the same phenomenon sometimes takes place upon a rose-tinted plate, before exposure to light. After obtaining the colours, the plate is heated over a spirit-lamp, and the temperature raised as gently as possible, without carbonizing the varnish, which sometimes takes place very suddenly upon those parts directly struck by white light, especially if the chloride of lead be too acid or too concentrated. Under the influence of heat we generally find the colours to become more intense, especially if the light has influenced the whole thickness of the film of chloride of silver; in the opposite case, the heat causes the blues of the violet and the blacks to turn red; and this result appears to me very remarkable. It is by this action of heat upon the varnish influenced by light that I obtain the temporary fixing of the heliochromic colours.

If we apply the varnish with the base of chloride of lead after obtaining the colours, they brighten; but they last a much shorter time than when the varnish is applied before the colours are obtained, but still their coming is not delayed.

Generally all the substances applied in the state of varnish upon the film of chloride of silver, either before or after obtaining the colours, blacken the white portions of the images under the action of light, while all the salts of lead, and especially the chloride, whiten them; a too concentrated solution of chloride of lead must also be avoided, else too much white chloride will be produced.

Many substances, as for example, sulphate and nitrate of copper applied with dextrine upon the film of chloride of silver before exposure to light, cause certain colours to predominate and brighten them; but none fix the colours so long as the salts of lead, especially the chloride.

Finally, I hope with this varnish containing chloride of lead, that we may be able almost to entirely suppress the action of re-heating, whenever the plate has been chloridized either by the electric pile or in an acid bath as indicated above; but with the alkaline bath which I employed in my last experiments, it is still necessary to give a semi-heating to the plate before applying the varnish; if the plate be brought entirely to the *rose* hue, the colours are produced more rapidly, the lights are whiter, but the tones are generally less vivid; on the other hand the fixing is more permanent.

In conclusion:—1st. The chloride of lead applied upon the film of chloride of silver before exposure to the light produces in part the effect of re-heating, that is to say, the white light acts in white upon the lights, and admits of all the hues being obtained much brighter than upon a plate brought only to the rose hue by heat. 2nd. The action of heat after that of light produces upon that portion of the chloride of silver covered with varnish a transient fixing of the heliochromic colours. 3rd. White light bleaches chloride of silver in presence of chlorides of lead, instead of making it turn violet, as it would if it were alone. 4th. The destructive action of light is retarded, it acts more slowly, since it requires ten to twelve hours of diffused light to destroy the colours, which usually takes place in a few minutes, besides, there is not always a relative fixity. 5th. Such is the position of heliochromy at the present day, if the problem of fixing is not actually solved, there are at least reasons to hope for a solution.

## PROFESSOR TYNDALL'S LECTURES ON LIGHT.

### Lecture v.—Jan. 4, 1862.

The subject of colour blindness formed the subject with which this lecture was commenced. Supposing the audience before him to represent a pretty fair average of London society, the lecturer said that he was perfectly certain that there were then in the room many who did not see all the colours of the spectrum. He knew numbers of people who could not distinguish between a scarlet geranium flower and the green leaves, and it was known that the celebrated Dr. Dalton, of Manchester, could not distinguish between cherries on a tree and the leaves surrounding them. This peculiarity was, strange to say, more prevalent amongst gentleman than ladies. It is in every one's power to render himself temporarily blind to colour in this way:—take a red wafer on white paper; let it be brightly illuminated by the white light of day; look fixedly at it for minute and then push it suddenly aside. The spot which the wafer formerly occupied will be seen to be green, because the eye being partially deadened to red light, the complimentary colour to the red, present with it in the white light of the paper, makes its appearance.

In another way, however, we are all, to a certain degree, blind. There is a spot in each of our eyes where the optic nerve enters the retina, which is quite blind. This may be found out in the following way:—take two wafers, or make two black spots about two and a half inches apart on

a sheet of white paper. Then close one eye, the right, for instance, and look with the left perpendicularly down upon the right hand wafer. The image of the left wafer will now go into the eye and fall upon the blind spot of the retina, and the consequence will be that it will be invisible. In this way the image of the full moon can be completely quenched.

The subject of *chromatic aberration* was then briefly described. Taking the case of a simple lens, if a beam of white light be sent through it will be converged or refracted; but the violet rays of the beam being more refrangible than the red rays, the former would come to a focus earlier than the latter. The positions of the two foci being different, the distance between the focus of the red and the focus of the violet is called the chromatic aberration. This was illustrated by throwing the rays of the electric light on to a large simple lens. Upon interposing a screen in the path of the rays beyond their focal point there was a disc of light with a blue rim, but upon bringing the screen to a point between the focus and the lens, the disc of light was seen to be surrounded with a red rim, because there the blue cone is surrounded by a red one, the red being least refracted.

A brilliant electric spectrum was then projected on to the screen and attention was drawn to the dark space outside the visible spectrum at the red end. No light was visible, although millions of rays were falling on it. These were the heat rays. At the other end of the spectrum also, beyond the violet there are a perfect shower of rays that are invisible to the eye—that might be called too shrill—for as there are notes of sound too shrill to be heard by the human ear, so there are colours too shrill to be seen by the human eye. These were made visible by taking some solution of sulphate of quinine in tartaric acid and moistening a piece of blotting-paper with it. Upon now introducing the blotting-paper into the dark space beyond the violet end of the visible spectrum the part which had been moistened immediately glowed with a pale blue phosphorescent light. It is this property of sulphate of quinine to render these rays visible that enables these highly refrangible rays which are employed by the photographer, to be seen. This was illustrated in another way. The lecturer interposed a sheet of dark blue glass in the path of the rays, this cutting off the rays of an intensely illuminating power but which have not the property of being rendered visible. Upon then placing the moistened blotting-paper in the blue light, it became quite luminous. The same thing was afterwards performed with the rays from a spark from a powerful induction coil, whereby sulphate of quinine, different kinds of glass, and various powders were rendered *fluorescent*, as this phenomenon is called.

The phenomena of the colour of natural bodies were next considered. That of pure water was shown to be a beautiful green in the following way:—A tin tube, fifteen feet long, with glass ends was arranged horizontally and half filled with water. A sheaf of rays from an electric lamp was then sent through the tube and an image of the end of the tube projected on the screen by means of a lens. The upper half of the bundle of rays of light passed through the air in the tube, whilst the lower half of them passed through the water, and the image on the screen showed a strong contrast between the two media; the air being shown by a bright white semi-disc, whilst the water was shown as a beautiful green fluid. This colour is due to *absorption*. Most of the colours commonly seen are due to absortion; that is to say, they are due to the fact that a portion of the spectrum is absorbed within the body, while a second portion is allowed to pass through the body. To illustrate this a spectrum was formed and various coloured fluids were interposed in the path of the rays forming it. Burgundy wine tested in this way was seen to absorb the blue, indigo, violet, and almost all the green whilst it transmitted the red. Permanganate of potash in solution was in this way shown to chisel out with the utmost distinctness the centre portion of the spectrum whilst it allowed the two ends, red and blue, to pass. Various coloured glasses were afterwards tested in the same way.

Other ways of producing colour were then described. The spectrum itself is an example, its colours being those of refraction; so are the colours of the rainbow, which is, in fact, a solar spectrum. The splendid colours of a thin soap bubble are not colours of absorption, but are due to *interference* (to be subsequently explained). The iridescence on the neck of the dove, the hues of a peacock's tail, the colours of the wings of certain insects are not colours of absorption. Neither are the gorgeous colours which were shown to be produced when colourless spirit of turpentine was poured on to pure water. The gold, straw-colour, or blue of tempered steel is not a colour of absorption. Such colours are produced by a thin transparent film of gas, or liquid, or solid. which itself has no colour. They may, indeed, be produced by an exceedingly thin fissure which is perfectly empty. For example the lecturer stated that he had often produced fissures in the interior of a mass of ice, which showed splendid colours, though no air could possibly reach the fissure. Colours were also shown to be produced by reflection from scratched surfaces. They glisten on the fine threads of the field spider. Thin clouds, especially in Alpine regions, are often flooded with the most splendid iridescences, even when the light which falls upon them is white; these colours are to be distinguished from those of the morning and evening clouds which show simply the colour of the light falling on them. Finally a dust of lycopodium, for instance, whose particles are all of the same size, when shaken in the air or on a glass plate, produces colours when a light is viewed through it.

These colours have received various names in conformity with their modes of production. Some are called the colours of thin plates, others the colours of diffraction. They were all explained to depend on the great principle of *interference*.

This, the lecturer said, was a very difficult point to explain, but he would endeavour to render it intelligible in the next lecture. At present he would break the ground by explaining that, although he had hitherto spoken of light as something darting out of a luminous body, as luminous particles which were reflected like billiard balls, this was not what he believed light to be. All the laws referred to in preceding lectures would follow, if light were supposed to be produced by waves or undulations, in the same way as sound. To show that sound was produced by vibrations of air, and that these vibrations actually did pass from a sounding body through the air on all sides, the lecturer performed a very striking experiment. A small gas flame was arranged, having a long glass tube placed vertically over and round it. Upon now uttering a loud musical note with his voice, the lecturer caused the flame to vibrate, giving out the same sound continuously. This proved in the most perfect manner that some of the vibrations of the air passed from the voice to the flame, and caused it to be started into vibration by hearing it. Professor Tyndall stated that he had stood sometimes at a distance of thirty feet off, and had been able to say to the flame, "Sing," and had then been able to say, "Stop," and in each case it had obeyed him.

## DRY COLLODION: MODIFIED FROM SEVERAL PROCESSES.

BY M. JANE.

The plates prepared as under can be kept more than a year without losing their sensitiveness.

The pyroxyline employed is a French one, which dissolved perfectly. The one made with equal parts of mixed acids at 150° Fah., I find perfectly good.

When the plate is perfectly cleaned coat with collodion:—

| | |
|---|---|
| Ether ... ... ... ... | 67 parts |
| Alcohol ... ... ... ... | 33 ,, |
| Pyroxyline ... ... ... ... | 1 ,, |
| Iodide of cadmium ... ... | 1 ,, |
| Bromide of cadmium ... ... | 0·2 ,, |
| Iodide of cadmium ... ... | 0·2 ,, |
| Pure resin (colophony) ... ... | 0·3 ,, |

Put the pyroxyline, ether, and a part of alcohol in a bottle, and dissolve the iodide and bromide in the remainder of the alcohol, filter and mix them together; then add the resin. After 24 hours it is fit to work.

The collodionized plate is sensitized in a bath of:—

| | |
|---|---|
| Water (distilled) ... ... ... | 1000 parts |
| Nitrate of silver (fused) ... ... | 100 ,, |
| Glacial acetic acid ... ... | 100 ,, |
| Iodide of cadmium ... ... | 0·5 ,, |
| Pure iodine (French) ... ... | 5 ,, |

The plate should remain in this bath about a minute till the greasy appearance of the plate has disappeared, then remove it from the natrate bath and immerse it in a bath of distilled water (this bath of water must be changed at each plate). Coat a second plate, and when it is in the nitrate bath, remove the first plate from the first bath of water, and so on till the first plate has reached a sixth bath made as follows:—

| | |
|---|---|
| Water distilled ... ... ... | 1000 parts |
| Pyrogallic acid ... ... ... | 3 ,, |

Filter very carefully.

After the plate has remained in this sixth bath, whilst another plate is coated with collodion, and to put it in the nitrate bath, take the first plate from this pure bath, let it drain and then cover it with:—

| | |
|---|---|
| Water ... ... ... ... | 100 parts |
| Dextrine ... ... ... | 20 or 25 ,, |
| Camphor ... ... ... ... | 5 ,, |

Filter carefully through a sponge.

This solution is made at a temperature of about 27° centigrade, or about 80° Fah.

Cover twice with this dextrine solution and let the plate dry spontaneously, one corner on a piece of blotting-paper, or on two bars of wood.

These plates must be kept in the same manner as plates by other dry processes.

When they are to be developed—which can be done several days after the exposure—immerse the plate in a bath of distilled water for about 20 seconds, then put it on a level stand and cover it with—

| | |
|---|---|
| Distilled water ... ... ... | 100 parts |
| Pyrogallic acid ... ... ... | ¼ ,, |
| Citric acid ... ... ... ... | ¼ ,, |

Return the solution into the developing glass, and add a few drops of a solution of nitrate of silver at four per cent. (a 20 or 25 grain solution); when intensity is obtained, wash and fix in hyposulphite of soda or cyanide of potassium. The plate can be developed with iron by dipping, but the solution should not be poured on the plate. The iron is made as follows:—

| | |
|---|---|
| Distilled water ... ... ... | 500 parts |
| Protosulphate of iron ... ... | 75 ,, |
| Sulphuric acid ... ... ... | 15 drops |
| Glacial acetic acid ... ... ... | 10 parts. |

Intensify with bichloride of mercury and iodide of potassium as described in former pages of the Photographic News. Varnish as usual.

## IODIDE AND BROMIDE OF SILVER:

### Researches into their Photogenic Properties according to the Circumstances under which they are obtained.*

BY M. E. REYNAUD.

From numerous experiments I have arrived at the conclusion that when we make use of a collodion containing several iodides, the properties of the compound are not in relation to the several properties of each of the iodides when used separately. Thus, iodide of potassium, whose slowness when employed alone we well know, appears to me, on the contrary, to gain in sensitiveness when employed with the iodides of cadmium and ammonium.

I shall now indicate some general rules to serve as a guide in the preparation of iodizing photogenic solution. These rules are derived from the observations stated above, and while leaving the operator free to choose which iodide he shall make predominate, they will serve as a basis of operations, and indicate to him the modifications he must make in his formulæ, according to the circumstances in which he is placed.

1st. The quantity of iodine contained in the collodion (and here I understand not only the *free* iodine, but also that which exists in combination in the iodides employed), will be a mean of 1 gramme for every 100 cubic centimètres of normal collodion (1 per 100 grains, drachms, or ounces).†

2nd. In ordinary cases we shall find the advantage of employing together the iodides of potassium, ammonium, and cadmium.

3rd. When we desire to obtain the maximum of sensitiveness, care must be taken that the collodion contains only a small portion of free iodine.

4th. If the photogenic film becomes spotted during sensitising—although its opaline hue may indicate that it does not contain so much iodide—we may attribute this defect to too great an excess of iodine; but if the colour of the collodion is not deeper than orange, we can only attribute this result to an excessive quantity of iodide of ammonium in proportion to the other iodides.

5th. Lastly, if the collodion film becomes fogged, we must add some iodine or chloride of iodine until it assumes the orange hue. I recommend that an alcoholic solution of iodine be employed, so that the hue arrived at may be at once ascertained by merely shaking the mixture.

I shall now make some remarks upon the action exercised upon the above-described phenomena by the state of the silver bath.

A positively *neutral* silver solution always causes fogging, and in order to cause the fog to disappear, a small quantity of acid must be added to the bath.‡ We may employ acetic or nitric acid; but I prefer nitric to acetic on account of the formation, resulting from employing the acetic, of a certain quantity of acetate of silver, which, by prolonged using, is afterwards precipitated by the iodide of silver, with which the solution becomes more and more saturated. The acetate thereupon remains in suspension in the bath in the state of very minute crystals, and their injurious action in causing the collodion film to become riddled with holes is but too well known to most photographers.

By the use of nitric acid this inconvenience is avoided; but it must be used with great moderation on account of its energy. One drop usually suffices for four ounces of neutral silver solution.

* Concluded from p. 87.

† I say the quantity of *iodine*, and not of *iodide*, for upon examining the equivalents of the latter we perceive that a certain quantity of iodide of ammonium, 5 grammes, for example, contains 4 gr. 38 of iodine, while 5 grammes of iodide of cadmium contains only 3 gr. 45 of this metalloid.

‡ The crystallized nitrate of silver of commerce is almost always sufficiently acid to render the addition of any acetic or nitric superfluous.

There is another acid the action of which upon the silver solution does not appear to have been observed; many experiments, however, have proved to me the advantage that may be derived in certain cases by giving it the preference, I refer to *hyponitric acid*. A nitrate solution into which we put nitric acid charged with nitrous compounds, appears to me to possess the property of giving very dense blacks, and lights free from fog; but what struck me as being very remarkable was, that the sensitiveness, far from being diminished, seemed in this case to become augmented. However, I do not positively assert this as a fact, not having repeated the experiment; but I recommend photographers to verify the fact, and to determine exactly what course to pursue in the use of this substance, especially in its application to instantaneous photography.

I shall not enter upon the means employed to neutralize a bath that is too acid, as they are sufficiently well known; I shall content myself with condemning the employment of ammonia for this purpose, the much too intense neutralizing action of this substance almost always gives rise to accidents resulting from the employment of an alkaline bath. Carbonate of soda or carbonate of lime are substances to which, I think, we ought in this case to give the preference.

It now remains for me to speak of the bromides. We know that bromide of silver, compared with the iodide of that metal, is much more sensitive to the least refrangible colours, such as the red, yellow, &c. It is chiefly on account of this property that we are induced to employ the bromide in collodion.

The *bromides of ammonium* and of *cadmium* are those which appear to me to possess this property in the highest degree.

The *bromide of potassium* communicates to the collodion a sharpness aud delicacy of detail similar to that produced by employing the iodide of that metal, and without diminishing its sensitiveness.

The most suitable proportion of bromide in wet collodion appears to me to be 3 to 4 grammes to 12 of iodide in a litre of plain collodion. Too much bromide causes a superficial fogging, which destroys all vigour in the proof.

I now conclude my observations; there still remains much to be said on these subjects, especially upon the influence of iodide of silver upon the nitrate bath which becomes more and more saturated with it by use; and upon the changes induced in collodion by keeping, &c., &c. Upon these I hope to report on another occasion.—*Bulletin de la Soc. Fr. de Photographie.*

## PHOTOGRAPHIC SECRETS.

BY COLEMAN SELLERS.*

The beginner in photography and the unsuccessful operator alike are always on the look-out for, and most earnestly desire to learn, the "great secrets"—the wonderful instantaneous processes of this or that celebrated artist; and when they are told that these unknown processes are the same as what they have learned from the works of Waldack, Hardwich, &c., they cry out at once, "Oh, no! these men only publish what all the world knows already, and keep back the essential principles of their formulæ;" and the proof of this they hold to be their own failures. This very thing is instanced in the complaints of some inquirers in this Journal.

Some few years ago, being requested by a friend to give him some instruction in photography, I furnished him with a list of chemicals and fixtures needed, and as he was an ingenious man, I watched with interest the admirable arrangement of his dark room. At last he was ready for work, and an evening was spent at his house, directing the mixing of his bath, sensitizing his collodion, and preparing all things for an early trial of his skill. I had furnished him also with the balance of the collodion in the bottle which I had used in showing him how to work. The next day but one he came to me with a sad tale to tell. He had followed my directions to the letter (he was a very precise man), and had "exposed" any number of times in all kinds of light, and no image could he develop. "What

* From *Humphrey's Journal.*

shall I do?" he cried in despair. When anyone says very positively that he has followed my directions, and yet has not arrived at the same conclusion as I should have done, is proof enough to me that he has forgotten something. So, before telling him a reason for his failure, I asked him to recite in detail his course of manipulation, which he did in this manner:—

"I first flowed my plate with collodion, then put it into the bath, and then into holder and exposed; removed from holder in dark room, and *washed*."—"Stop!" I exclaimed, "is that my way of working?" "Oh, certainly; see I have your written directions in my pocket-book." He produced the book, and, lo and behold! he had trusted to his recollection of how I worked, and had done his washing before development, instead of afterwards. He is now a good workman, and laughs at his mistake. This is but one of a great many instances that have occurred within my limited experience. Every schoolboy knows how easy it is to make a mistake in a simple sum of addition. How much easier it is to make mistakes in the routine of a chemical formula.

There are two classes of photographers—the practical operator who makes the art his means of procuring a livelihood, and the amateur who makes pictures for amusement. As far as my observation has enabled me to judge, the best workers in both classes are those who are the most willing to give their knowledge to others; they give freely from their abundant store, confident in their own skill, and expect in return that others should treat them with like courtesy. In the case of the practical operator, it is not to be wondered at that he should want to keep secret the principle of his success—the principles which enable him to work better or cheaper than his rivals in trade. We should value the gratuitous contributions to science from those who are thus helping others to equal or surpass them in what is essential to them in money-making, more than the teaching of amaters, who can only expect fame, and who know that they will gain what they desire by writing.

Now, with regard to the secrets of the art, there are no doubt many changes being made in formulæ and convenience of manipulation. When these changes originate with amateurs, a desire to show their discovery to the world soon prompts them to publish it; but when they originate with the trade, the secret rests a long time with the discoverer; it then slowly finds its way to other establishments, and at the same time is modified by each; amateurs, too, learn it, and under the seal of implicit secrecy they may practice it for a long time before it becomes public property.

Such is the case now with regard to printing on albumen paper. Long after my article on printing had been published in *Humphrey's Journal* I continued to silver my paper on a plain 80-grain solution of silver, acid with citric acid. Yet I heard from all quarters that some of the best work in the country was done with an ammonio-nitrate solution for albumen paper; but not one word on the subject has appeared in the Journals, until at last some English operator, who has worked in this country, goes home and tells the editor of one of the English journals* that in America they silver albumen paper on ammonio-nitrate solution, and that they prevent the tendency to dissolve off the albumen by adding ether.

The editor, commenting on it, says that he rather thinks the strength of the solution has more to do with its success than the addition of ether. Months have passed since this was published, and yet no one has said in print that he used the ammonio-nitrate solution. Now, for my part, I have experimented with various processes of this kind for some time past, and with great success, so that I may now say with safety that it is better and more economical than the old way of silvering. But further experiments may show objections; as, for instance, I do not yet feel sure how to strengthen the bath in the best manner, not yet having had occasion to do so; and now I do not intend to say how I use the ammonio-nitrate solution, but will wait for some one, prompted by what I have just written, to give the world his experience on this subject, and thus ventilate one of the *great secrets* in photography. It is one of the most interesting subjects of scientific inquiry, the more so as the bath, though *slightly* alkaline, does not discolour from use; the prints do not turn red in water, and they tone with great vigour in any of the toning solutions in general use.

The chemistry of the ammonio-nitrate solution is interesting, and I hope that some of those who write for this Journal will anticipate me in making it the theme of future articles.

* See Photographic News, vol. v., p. 480.

## CARTES DE VISITE.

BY A. WYNTER, M.D.*

The commercial value of the human face was never tested to such an extent as it is at the present moment in these handy photographs. No man, or woman either, knows but that some accident may elevate them to the position of the hero of the hour, and send up the value of their counteuances to a degree they never dreamed of. For instance, after the great fight with Heenan, Tom Sayers was beset by photographers, anxious for the honour of paying for a sitting; but his reply was, "It's no good, gentlemen, I've been and sold my mug to Mr. Newbold," that sporting publisher having seen betimes the advantage of securing the copyright of his phiz. Thus a new source of income has been opened to first-rate photographers, besides profit arising from taking portraits. A wholesale trade has sprung up with amazing rapidity, and to obtain a good sitter, and his permission to sell his *carte de visite*, is in itself an annuity to a man. For instance, all our public men are what is termed in the trade "sure cards;" there is a constant demand for them, a much greater one, indeed, than can be supplied. It must be remembered that every picture has to be printed from the original negative, and the success of the printing process depends upon the weather; in foggy, dark days no impressions can be taken from the negative. It is true that negatives can be taken from positives, or from *cartes de visite* already in existence; but the result is a deterioration of the portrait, a plan never resorted to by first-class photographers, such as Silvy, or Lock, or Mayall, although dishonest persons are to be found who will commit piracy in this manner for money. The public are little aware of the enormous sale of the *cartes de visite* of celebrated persons. An order will be given by a wholesale house for 10,000 of one individual, thus £400 will be put into the lucky photographer's pocket who happens to possess the negative. As might have been expected, the chief demand is for the members of the Royal Family. Her Majesty's portraits, which Mr. Mayall alone has taken, sell by the 100,000. No greater tribute to the memory of his late Royal Highness the Prince Consort could have been paid than the fact that within one week from his decease no less than 70,000 of his *cartes de visite* were ordered from the house of Marion & Co., of Regent Street. This house is by far the largest dealer in *cartes de visite* in the country; indeed, they do as much as all the other houses put together. The wholesale department of this establishment, devoted to these portraits, is in itself a sight. To this centre flow all the photographs in the country that "will run." Packed in the drawers and on the shelves are the representatives of thousands of Englishwomen and Englishmen waiting to be shuffled out to all the leading shops in the country. What a collection of British faces! If a box or two of them were to be sealed up and buried deep in the ground, to be dug up two or three centuries hence, what a prize they would be to the fortunate finder! Hitherto we have only known our ancestors through the pencils of certain great artists, and the sitters themselves have all belonged to the highest class. Hence we are apt to attribute certain leading expressions of countenance to our progenitors, which are rather owing to the mannerism of the painters than the sitters. Thus all Reynolds's beauties possess a certain look in common; if we believed his brush without any reserve, we should fancy that the English race of the latter part of the last century were the noblest looking beings that ever trod the earth. No portrait of man or woman ever came from his easel with a mean look. The same may be said of those of Gainsborough and Hoppner, and the result is that all our knowledge of the faces of the last century is purely conventional. But it is far different with the *carte de visite*. Here we have the very lines that Nature has engraven on our faces, and it can be said of them that no two are alike. The price, again, enables all the better middle class to have their portraits; and by the system of exchange, forty of their friends (happy delusion) for two guineas!

Let us imagine, then, a box of such pictures discovered of the time of the Commonwealth, for instance, or a few years later. What would we give to have such pictures of old Pepy's, his wife, and Mistress Nip? Yet treasures such as these we shall be able to hand down to our posterity, for there is little doubt that photographs of the present day will remain perfect, if carefully preserved, for generations. Silvi alone has the negatives of sitters in number equal to the inhabitants of a large country

* Condensed from *Once a Week*.

town, and our great thoroughfares are filled with photographers; there are not less than thirty-five in Regent Street alone, and every suburban road swarms with them; can we doubt therefore that photographic portraits have been taken by the million? Out of these the great wholesale houses, such as Marion & Co., have the pick. Every day brings up scores of offers of portraits, which are accepted or not, according to circumstances. In many cases the sale is wholly local, in others nearly wholly metropolitan. Some have a perpetual sale, others, again, run like wildfire for a day, and then fall a dead letter. Some special circumstance or action scatters these portraits wholesale; for instance, the pluck displayed by the Queen of Naples resulted in a sale of 20,000 of her portraits; and Miss Jolly was only a month ago the rage in Ireland. The sudden death of a great man, as we have before said, is immediately made known to the wholesale *carte de visite* houses by an influx of orders by telegraph. There was a report the other day that Lord Palmerston was dead, and his *carte de visite* was immediately in enormous request; and Lord Herbert to this day sells as well as any living celebrity.

Literary men have a constant sale: Dickens, Thackeray, and Trollope, are bought for every album. Scientific men, again, sell well; but theatrical or operatic celebrities have a run for a short time, owing to some successful performance, and then are not sought for more. The series of Mademoiselle Patti has, however, already circulated to the extent of 20,000 copies. It is a curious fact that the *cartes de visite* have for the present entirely superseded all other sized photographic portraits. This is rather singular, inasmuch as we did not adopt it until it had been popular in Paris for three years. Possibly, however, the rage has its foundation in two causes. In the first place, a *carte de visite* portrait is really a more agreeable looking likeness than larger ones; it it taken with the middle of the lens, where it is truest, hence it is never out in drawing; and then, again, it rather hides than exaggerates any little roughness of the face, which is so apparent in large-sized portraits. Secondly, when a man can get forty portraits for a couple of guineas, his vanity is flattered by being able to distribute his surplus copies among his friends. It enables every one to possess a picture gallery of those he cares about, as well as those he does not, for we are convinced some people collect them for the mere vanity of showing, or pretending, they have a large acquaintance. There is still another advantage: *cartes de visite* are taken two at a time, stereoscopically, that is, a little out of the same line, hence solid portraits can be produced by the aid of the stereoscope. When we remember the old style of portrait we were obliged to be contented with, the horrible limning a lover got of his mistress for five guineas; the old monthly nurses they made of our mothers; and the resplendent maiden aunts, with their gold chains, watches, and frightful turbans; and the race of fathers we keep by us in old drawers, gentlemen built up stiffly, and all alike in blue coats, and brass buttons, with huge towels round their necks by way of cravats; when we remember the art at the command of the middle classes not forty years since, we are deeply thankful for the kindness of Sol in taking up the pencil and giving us a glimpse of nature once more. But even the great Apollo himself has his mannerism, and it is easy enough to detect a Silvy, a Lock, a Mayall, a Herbert Watkins, a Maull and Polyblank, or a Claudet *carte de visite* by the manner in which it is posed, or the arrangement of the light upon it. It is a great mistake to suppose that the art of portrait taking has degenerated into a mere mechanical trade; the difference between a good photographic portrait and a bad one is nearly as great as between a good miniature and a bad one. How difficult it is to pose a sitter well, and how this difficulty is increased where the artist has to work with the sun? Of old, in the course of three or four sittings, the natural attitude and best expression of the sitter was pretty sure to come out, but now the difficulty is greatly increased; when a picture has to be taken, we say, in half a minute, what a natural aptitude the photographic artist ought to possess, to seize the best attitude and position at once. To produce a good photograph it requires a thoroughly artistic hand, and that hand must work, also, with the best tools; consequently, the lenses now in use for first-rate work are exceedingly valuable, and the stock of cameras required by the producers of our best *cartes de visite* costs a little fortune.

Then there is, in addition, all the accessories to make up backgrounds—properties, in fact, some of them of the stale routine style; for instance, the pillar and the curtain does duty as of old, and many a good honest cockney is made to stand in marble halls, who was never in a nobler mansion than a suburban villa in his life. But there are not wanting details in better taste. The French have composed their *cartes de visite* in this respect with great skill and art. The most elaborate carved wood-work, the rarest statuettes, the most carefully painted distances, figure in these backgrounds, and are shifted and combined in endless variety, so as to give every portrait some distinctive character of its own. All these things cost money, and the tendency is to throw the best business into the hands of a few skilled capitalists; and in London half-a-dozen men entirely command the patronage of the fashionable part of the community.

Monsieur Silvy appears to have made the *carte de visite* his special study, and has brought to his task all the resources of an artistic mind. No one knows how much depends upon the photographer until he compares a good with a bad sun portrait. That sense of beauty and instinctive art of catching the best momentary *pose* of the body, is a gift which cannot be picked up as a mechanical trade can be. This gift M. Silvy possesses in an eminent degree. And he not only pursues photography as an art, but also as a manufacture; hence the scale and method of his proceedings. A visit of inspection to his studio in Porchester Terrace is full of interest. In walking through the different rooms, you are puzzled to know whether you are in a studio, or a house of business. His photographic rooms are full of choice works of art in endless number; for it is his aim to give as much variety as possible to the accessories in each picture, in order to accomplish which he is continually changing even his large assortment. Sometimes when a Royal portrait has to be taken, the background is carefully composed beforehand, so as to give a local habitation, as it were, to the figure. The well-informed person, without a knowledge even of the originals, may make a shrewd guess at many of the personages in his book of Royal Portraits by the nature of the accessories about them. Thus, all the surroundings of the Duc de Montpensier's daughter are Spanish, whilst his son's African sojourn is indicated by the tropical scenery. The portraits of members of our own Royal Family are surrounded with fitting accessories which stamp their rank. As M. Silvy takes every negative with his own hand, the humblest as well as the most exalted sitter is sure of the best artistic effect that his establishment can produce. This we feel certain is the great secret of M. Silvy's success, as the skill required in taking a good photograph cannot be deputed to a subordinate. But, as we have said, his house is at the same time a counting-house, a laboratory, and a printing establishment. One room is found to be full of clerks keeping the books, for at the West End credit must be given; in another a score of employeés are printing from the negatives. A large building has been erected for this purpose in the back garden. In a third room are all the chemicals for preparing the plates; and again in another we see a heap of crucibles glittering with silver. All the clippings of the photographs are here reduced by fire, and the silver upon them is thus recovered. One large apartment is appropriated to baths in which the *cartes de visite* are immersed, and a feminine clatter of tongues directs us to the room in which the portraits are finally corded and packed up. Every portrait taken is posted in a book, and numbered consecutively. This portrait index contains upwards of 7,000 *cartes de visite*, and a reference to any one of them gives the clue to the whereabouts of the negative. Packed as these negatives are closely in boxes of fifties, they fill a pretty large room. It is M. Silvy's custom to print fifty of each portrait, forty going to the possessor, and ten remaining in stock, as a supply for friends. Sometimes individuals will have a couple of hundred impressions, the number varying, of course, according to the extent of the circle. The tact and aptitude of M. Silvy for portrait taking may be estimated when we inform our readers that he has taken from forty to fifty a day with his own hand. The printing is, of course, purely mechanical, and is performed by subordinates, who have set afloat in the world 700,000 portraits from this studio alone.

In comparing the Parisian and London *cartes de visite*, it is important to observe the wide difference which exists between the class of portraits that sell. In Paris, actors and singers, and dancers are in demand, to the exclusion of all other kinds of portraits. A majority of these portraits, indeed, are aimed at sensual appetites. Statesmen, members of the legislature, and scientific men, do not sell at all. In England, we know how different it is: we want to know our public men—our great lawyers, painters, literary men, travellers, and priests: in

France, there seems to be no respect or reference for such people —at least people do not care to invest a couple of francs on their *cartes de visite*, and consequently they are not produced. The universality of the *carte de visite* portrait has had the effect of making the public thoroughly acquainted with all its remarkable men. We know their personality long before we see them. Even the *cartes de visite* of comparatively unknown persons so completely picture their appearance, that when we meet the originals we seem to have some acquaintance with them. "I know that face, somehow," is the instinctive cogitation, and then we recall the portrait we have a day or two past seen in the windows. As we all know, the value of the photographic portrait has long been understood by the police, and known thieves have the honour of a picture gallery of their own in Scotland Yard, to which we shall refer in some future paper; but the photograph is also useful for rogues as yet uncaptured and uncondemned. Thus, when Redpath absconded, it was immediately suspected that a negative of him must be lodged at some of our photographers. The inquiry was made, and one of them was found in Mr. Mayall's possession. An order was given for a supply to the detective force, and through its instrumentality the delinquent, though much disguised, was arrested on board a steamer sailing from some port in the north of Europe.

## Proceedings of Societies.

### North London Photographic Association.

The usual monthly meeting of this Association was held in Myddelton Hall on the evening of Wednesday, February 19th, G. Shadbolt, Esq., occupied the chair.

The minutes of a former meeting having been read and confirmed

The Chairman exhibited some stereoscopic portraits of Mr. Coleman Sellers, whose contributions to American photographic journals many English photographers are familiar with.

Mr. G. Wharton Simpson exhibited some exquisite card portraits by Mr. Hawke, of Stonehouse, as illustrative of the value of the preliminary bath of acetate of soda in preventing mealiness in toning. Also some fine prints by Mr. Ward, of Stratford-on-Avon, from negatives on simply washed collodion plates, without preservative or preliminary coating of any kind. (See Photographic News, No. 175, p. 14, Vol. VI.)

Mr. Shadbolt, in the absence of a paper for the evening, having temporarily vacated the chair, read a translation of an article from one of the French journals, by M. Niepce de St. Victor, on "Heliochromy." (Another translation of the same article will be found on p. 100.)

A desultory conversation on the subject of photographing in colours followed, in which various accidental cases of producing a few colours was referred to.

Mr. Shadbolt remarked that he could readily understand various imperfect tints being produced in a collodion positive by the different degrees in which the film permitted a dark ground or backing to be seen. One very remarkable point in M. St. Victor's experiments was the reproduction of black by black on a white ground. The plate being white to begin with, and black being supposed to be inactive, ought to have produced no effect; yet here it was reproduced by black.

Mr. Simpson remarked that Mr. Malone, in his paper on "Ruby Silver," had incidentally mentioned that he had secured a similar result to that described by M. St. Victor.

Some conversation on the practical value of these experiments followed.

Mr. Hughes observed that to him it appeared their chief value consisted in keeping alive the interest and faith in the photographic production of natural colours as a possibility. They showed that the production of colours *was* within the bounds of possibility, and that was a great point gained. What had been done might be done again, and each time some slight advance might be made. We should not, therefore, pooh-pooh such efforts as unpractical, but give every encouragement to those gentlemen who with steady faith pursued this desirable, although far off, result.

Mr. Simpson remarked, in reference to these pictures being single positives on silver plates, that it must not be forgotten that the Daguerreotype on silver plates was the pioneer process of photography, and that possibly these plates on which chloride of silver was formed might possibly be, in like manner, the precursors of a practical process of heliochromy.

A conversation on lenses then arose, in which

Mr. Ross expressed his conviction that for general landscape purposes no lens surpassed the ordinary single view lens. The image yielded had greater vivacity and brilliancy.

Mr. Dawson said Mr. Wilson had abandoned compound lenses for lanscape purposes and returned to the use of a single lens, and was using the old quarter-plate lens for card portraits.

Mr. Hill said that a letter he had recently received from Mr. Wilson was to the contrary effect. It said that he preferred the compound where it was necessary to secure a wide angle.

Mr. Ross said that much misapprehension seemed to prevail amongst photographers as to the extent of angle embraced in pictures. They seemed to overlook the fact that when the picture was measured on the horizontal line, the amount of angle included would vary with the shape of the pictures. It was desirable that the diameter of the circle of definition should be given in speaking of the angle included by any lens. It was an error to suppose that any lens was superior for every purpose, each one had its speciality; the single for landscapes, the orthographic for architecture, and the triple where perfectly straight lines were required.

Mr. Hughes asked if the pincushion-shaped distortion were inherent in the orthographic lens, or only seen in the margins when the lens was strained.

Mr. Ross said it really existed in the image always to just the same extent as the curvature in the single lens in the opposite direction.

The Chairman observed that when the lens was used for the sizes which the lenses were catalogued to cover, the distortion was imperceptible.

A conversation ensued on the various appliances used in the early days of photography, as substitutes for the proper lenses.

Mr. Hughes asked Mr. Dawson if he had properly understood him to say that Mr. Wilson had abandoned compound lenses for landscape purposes?

Mr. Dawson said for stereoscopic purposes, yes; and the other size of pictures he had been taking he was giving up, as he found they did not sell.

After a few further remarks the subject dropped.

The nomination of officers to be elected at the annual meeting in March then took place, after which the proceedings terminated.

## Correspondence.

### FOREIGN SCIENCE.

[From our Special Correspondent.]

*Paris, 26th February, 1862.*

M. Niepce de Saint Victor, in continuing his researches upon heliochromy, has succeeded in giving greater permanence to the colours obtained, chiefly by the employment of a bath of chloride of lead and dextrine. In diffused light, the coloured images obtained will stand ten or twelve hours. This is certainly a step in advance towards the solution of this very interesting problem; and, as M. Niepce remarks, if it be not yet completely solved, it affords encouragement to hope that it may be, ere long.

M. Wothly, of Aix-la-Chapelle, whose process for obtaining positives on paper, without the use of nitrate of silver, was held in doubt, as regards permanence, has addressed a communication to our Photographic Society, in which he states, that by his new process he obtained proofs which, fixed by means of the sulphides of sodium, antimony, and lead, leave no doubt of their permanency.

Photography on wood has received the attention of M.M. Columbat and Couvez, who operate by means of a film of chlorided albumen, which is treated in exactly the same manner as albumenized paper. They claim, for the advantages of this method, great sharpness in the design, and the infinitesmal thickness of the film upon the surface of the wood. Experienced engravers to whom the prepared blocks have been submitted for trial in cutting, state that the ligneous tissue is not attacked by the chemical agents to which it is submitted, and that they could work as well on the photographed block as upon blocks prepared in the ordinary manner.

Designs upon metal plates are obtained by these gentlemen by a different process to that usually employed. It is, well known that certain salts of iron, as the lactate, perchloride, &c. are modified under the influence of light, and become extremely hygrometric: this is the starting point of the new process.

Upon a plate of metal carefully cleansed, they spread a film of gum arabic, which is allowed to drain and dry; when dry, it is impregnated by means of a soft brush with a solution of tartaric acid and of perchloride of iron, and again left to dry during four and twenty hours. It is then exposed in the pressure frame under a positive or a negative, and, after exposure, the length of which will depend upon the intensity of the light, the plate is carried into the dark room. The light has decomposed the perchloride into protochloride, and the design appears as a negative; it is next submitted for a few seconds to the steam of water, which impregnates, in proportion to the degree of solarization, the sensitized portions; with a soft brush charged with resin the whole plate is carefully gone over, the resin adheres to those portions which have absorbed steam in greater or lesser quantity.

Then, without washing, the plate is heated; the resin melts and forms *a grain*, which varies according to its thickness, and thus gives all the tones of black and white correctly. It is afterwards submitted to the usual processes of engraving.

Among the new publications of interest to photographers, we may mention M. Arthur Chevalier's "Treatise on Enlarging Photographs, in a Theoretical and Practical Point of View," and Messrs. Barreswill and Davanne's "Dictionary of Industrial Chemistry."

The editor of *La Lumière*, M. Gaudin, has some remarks in the last number of his journal upon Emerson J. Reynolds's printing process with the salts of iron, and on Mr. Hannaford's criticisms upon the same. He says:—"Mr. Hannaford's remarks are indeed rather severe, and may be better understood when it is remembered that he has himself proposed a printing process with salts of iron. He is perfectly correct when he states that the development of images by nitrate of silver must form chloride of silver in the paper, which a simple washing in water would remove, and which might subsequently alter the lights of a proof. Mr. Reynolds, on the other hand, says, that these chlorides must be removed by the ammonia *in excess*, which exists in the ammoniacal nitrate of silver. This salt has, in fact, always an alkaline reaction to test paper, and it really contains free ammonia: this latter, capable of easily dissolving chloride of silver, also decomposes the oxalate of iron, and produces free oxide of iron, which immediately stains the paper yellow. Does ammoniacal nitrate of silver worthy of the name, that is, prepared with ammonia in excess, and then boiled, dissolve chloride of silver? This case appears to me doubtful; I cannot at present throw any light on the matter; but without reckoning, like Mr. Reynolds, upon the free ammonia which may not exist, I rather believe that the solvent power of ammoniacal nitrate of silver will be strong enough to remove naturally the feeble traces of chloride of silver formed spontaneously in the papers of commerce.

"I have continued making experiments to arrive at producing proofs by this process, without having recourse to nitrate of silver; I have ascertained that the peroxalate of iron is more sensitive with a feeble excess of oxalic acid, and especially, when united with organic matter, such as gelatine; and by this latter addition, I reckoned upon making proofs which will resist washing, by the gelatine being coagulated; but I was mistaken, a single washing in water caused the image to disappear almost entirely, leaving only a general yellow tint, which, with the tincture of galls, formed a reversed image. The printing always proceeds slowly, and I begin to suspect that this process, which was so seductive at first, presents no superiority over other iron printing processes already published."

## Photographic Notes and Queries.

### Transferring Engravings to Glass.

Dear Mr. Editor.—In the days when I was young, transferring engravings on wood and glass was a fashionable amusement, but like poona tinting, and many others of this class, have, I believe, long since ceased to be in request. I remember that the thing to be desired was, that only the ink impression should remain on the glass when finished, and none of the paper. To succeed well, requires a very careful and somewhat tedious manipulation. Procure a tenacious, but quick drying spirit varnish; the engraving must be well soaked for some hours in warm water to take out the size, then dry between sheets of blotting-paper until *surface dry only*, that the varnish may adhere to the fatty substance of the ink, and not sink into the paper; the glass must be evenly coated with varnish quickly, and perfectly free from dust and bubbles. These operations must be performed in a warm room, the glass and engraving being at such a temperature as not to chill the varnish; the engraving must be quickly and firmly pressed down to the glass in every part, and if any bubbles of air should be between the engraving and glass, prick them with a needle. The varnish must be allowed to dry thoroughly, then the glass and engraving should be immersed in acidulated water, as you name, for some time; then, while damp, proceed to rub off the paper by light circular rubs with the finger, dipping the finger new and then into water; when only the impression remains let it dry, then finally varnish with a penetrating varnish.

I have more than once, in out-of-the-way nooks and corners, seen old mezzo-tint engravings transferred to glass, and so finely back-painted as to appear at first sight as old oil paintings by good masters.

I shall be gratified if the above is of service to your correspondent, Mr. Clarke. T. P. E.

### The Alkaline Dry Process.

Sir,—There is so wide a difference betwixt Mr. Bartholomew's mode of preparing his alkaline dry plates, and that suggested by "E. T." in your last impression, that I shall esteem it a favour if you will insert this letter for the purpose of promoting further discussion thereon,

Mr. B. does not anticipate any bad results from a combination of the soda and gelatine, because he says that the alkali may be dissolved in it, whilst "E. T." states that if any combination takes place between the soda and gelatine, certain markings "fatal to good negatives" will result.

Will Mr. B., as the author of this new alkaline process, favour us with his opinion upon "E. T's." observations.—I am, sir, your obedient servant, F. M. Young.

*London, February* 25, 1862.

## Miscellaneous.

### CEMENTS FOR PORCELAIN, MARBLE, ALABASTER, GLASS, &c.

Take of isinglass two drachms, wet it with water, and allow it to stand until softened then add as much proof spirit as will rather more than cover it, and dissolve with a moderate heat. Take of gum mastic one drachm, dissolve it in two or three drachms of rectified spirit. Mix the two solutions and stir in one drachm of gum ammoniacum in a fine powder, and rubbed down with a little water. Keep the cement in a bottle. When required for use place the bottle in warm water, and apply the cement with a stick or small hard brush to the china previously warmed. Compress the pieces firmly together until cold, taking care to make the contact perfect, and using a very thin layer of cement.

The white of eggs thickened with powdered quicklime is also used as a cement for broken china, marble, and glass.

White resin and white beeswax melted and mixed with plaster of Paris make a good cement for mending alabaster and marble ornaments.

A transparent cement for glass is made by dissolving one part of india rubber in chloroform, and adding sixteen parts, by measure, of gum mastic in powder. Digest for two days, and frequently shake the vessel in which these substances are contained. The cement is applied with a fine camel's-hair brush.

The silicate of soda is about the best cement that can be used for mending broken crystal.—*Scientific American.*

## Talk in the Studio.

Singular Photographic Accident.—A somewhat curious, and happily uncommon, accident recently occurred to a well known photographer in Liverpool, and was nearly attended by serious consequences. A stoppered bottle nearly full of crystals of hyposulphite of soda, having stood in a place where it was exposed to a severe frost, the stopper had become consequently somewhat fixed, it was placed near a fire to loosen; after standing a short time, the operator was just grasping it in his hand, when at the first touch it suddenly exploded, the part in his hand inflicting a deep gash across the ball of the thumb. The blood flowed very copiously, and the surgeon on dressing the wound expressed to the friends of the sufferer his certain conviction that lock-jaw must inevitably result. After remaining three weeks in an extremely critical state, and enduring great agony, the patient was declared out of danger, and was happily enabled to resume his duties.

American Photography in the International Exhibition.—The *American Journal of Photography* says:—The differences between the Commissioners of the London World's Fair and the photographers appears to have been satisfactorily compromised, and the photographic department of the exhibition will now be attended to with the good will and support of all concerned. The photography of Continental Europe will no doubt be fully represented, and the photographic exhibition will be extensive and brilliant. But the American department will probably be a vacancy. Congress has just refused to make appropriations for the encouragement of American exhibitors, and our photographers are supposed to be too much engrossed with affairs at home to care anything about what is going on in Europe. Let us console ourselves with the fact that in former competitions we have covered ourselves with glory, and with faith that in the future friendly contests, we shall still retain our strength.

New Photographic Journal.—A monthly journal devoted to photography has recently been issued in Belgium under the title of *Bulletin Belge de la Photographie*. It is edited by M. Leon Delteure, with the aid of Messrs. Monchhoven, Gosselens, Romberg, Ommegauck, and Neyt.

Works of Fine Art.—The Solicitor-General, it was announced, would, on Thursday, in committee of the whole House, move for leave to bring in a bill to amend the law relating to copyright in works of fine art; and Lord Elcho has given notice that he shall on an early day call the attention of the House to the present and future provision for the exhibition of the national collection of pictures, and to the position of the Royal Academy in relation to the fine arts and the National Gallery.

The Late Prince Consort.—It is stated that the photographic portraits of Prince Albert have been rapidly sold in Paris to French as much as English purchasers. In one day a printseller sold 30,000 *cartes de visite* bearing the likeness of the deceased prince.

The Photographic Exchange Club.—The third monthly exchange of this club was recently completed. There was an improvement in the quality of the prints sent for exchange, and in the attention to the rules. There is still, however, room for improvement in both respects. We trust all the members will bear this in mind.

International Exchange Club.—Referring to the recent proposal in our pages to institute an exchange of prints with photographers in America, the editor of the *American Journal of Photography* says:—"A writer in Photographic News, of January 17th, proposes an exchange of photographs between America and England. The suggestion is a wise one, and meets our hearty approbation. Especially at this time, when the silly politicians are doing so much to excite international animosity, it is gratifying to believe that friendship may still continue with those whom we care most about. There is probably nothing in the way of the proposed exchange system, and it may be inaugurated within a few weeks. Perhaps it would be the simplest way to make existing clubs the nucleus of the undertaking. Whether the initiative package is started from England or America, we are sure it will be courteously received, and the favour be reciprocated. The writer in the News suggests that our correspondent, Coleman Sellers, would be a desirable person to superintend the American department. We endorse the recommendation, and hope to be able to give Mr. Sellers' views on the subject in our next issue."

## To Correspondents.

J. F.—The best mode of storing dry plates, so as to be of little bulk, is that adopted by Dr Hill Norris. Strips of cartridge paper are folded alternately each way, making each fold about a quarter of an inch broad. Each strip, when completed, forms a series of crimped grooves. The ends of the plates are placed into these, so that a double edge of paper is compressed between each pair of plates, and a groove of paper round the edge of each plate. Placing tissue paper so as to come in contact with the surface of each plate would be dangerous. 2. We are obliged for your method of intensifying. It is one, however, with which we are perfectly familiar. We have experimented largely on every method of intensifying, by the agency of bichloride of mercury. The simplest, least dangerous, and best, is, we think, that in which, after treating the plate with a hasty wash of bichloride, it is next treated with iodide of potassium, about one grain to the ounce. This gives a negative of a greenish grey, and is very satisfactory in printing. 3. The best mode of changing dry plates is much a matter of taste. We prefer the use of a few double backs to carry a sufficient stock of plates for the day's work without changing. The simplest method of changing is by means of a changing box, as it involves no extra luggage for the purpose. 4. We use a stereoscopic camera, with bellows body and folding tailboard, made by Meagher, which we find light and convenient.

T. P. E.—It is doubtful whether there will be much gold in your old hypo bath If you precipitate both silver and gold by means of zinc, the gold will be left as an insoluble residue on dissolving the silver in nitric acid.

St. Dennis.—After fixing and wasbing the negative, pour over it a solution of bichloride of mercury, about 10 grains to an ounce of water. Allow it to remain a few minutes, until the surface presents a uniform grey. Now wash, and then coat with a one-grain solution of iodide of potassium; pour this off and on until the right intensity is obtained. See article on intensifying in Photographic News Almanac.

W. D.—In printing from several negatives on one sheet of paper to form one picture, or "composition printing" as it is usually called, the prevention of hard lines and distinct edges entirely depends upon manipulation, skill, and practice. Every other part of the sheet but that to be printed at the time is carefully masked. The best modes of doing this have repeatedly been explained in our pages. You will find a simple method explained by Mr. Fry, having special reference to printing separate skies, on page 350 of our third volume. 2. Where "fresh hypo" is spoken of, it simply means that the hypo must not have been used so as to have become exhausted or acid. Your method of keeping the solution neutral, and adding continually fresh crystals, may be used with propriety so long as care and judgment are exercised. 3. Make some fresh toning solution of gold and acetate of soda, and add to the old; this will probably revive it.

A. G. Grant.—Your advertisement is inserted. Regarding the Exchange Club, write to the Secretary. Portraits to be suitable for exchange should possess some especial excellence or interest. Public characters, beautiful faces, or very fine photography, would confer such interest.

G. P. has overlooked our answer. It appeared in the No. for January 31st. Albumen is a very complex organic compound: we have no data at hand for stating its atomic weight. The fact of a chemical combination being formed between albumen and silver is "established," and for convenience the term "albuminate of silver" has been applied to that compound in the absence of a more precise term. How far the term is a correct one, chemically speaking, we do not undertake to determine, not being responsible for the origin of the term. We see no reason for doubting Stockhardt as to the proportion of albumen and water in white of egg.

J. Lomas.—Various forms of view meters may be constructed. A very simple one consists of a tube with a small aperture at one end just sufficient to see through; and at the other an oblong aperture, the usual shape of a picture. The length of this tube must be proportioned to the lens to be used; so that when you look through it just the amount of subject will be seen which your lens includes on the plate it covers. By having different sized oblong apertures you may arrange them so as to give the amount of subject your lens will include on different sized plates; and by making the tube with a sliding body it might be graduated, and marked to suit lenses of different focal lengths.

C. W.—The amount of subject included in the stereo-slide would not be quite so much with the No. 1 B lens as with the compound stereo lenses. For card portraits, however, the former would be best, and would also give excellent results for stereoscopic pictures. 2. Almost any good bromo-iodized collodion will give good results in both wet and dry processes The formula given in the Photographic News Almanac, which we also briefly stated at the South London Meeting, reported in our last, gives excellent negatives for the wet process, and most of the dry processes. 3. In purchasing yellow glass ask particularly for that flashed with silver, and if possible get a sample first. We shall always have pleasure in trying it

J. H. W.—You may purchase agate burnishers at most of the houses dealing in artists' materials. We cannot tell you the price. Your book-binder could give you information, as the burnisher is used in burnishing the edges of books. Rolling presses, which have recently been brought before photographers at much more moderate prices than they used to be, answer the purpose much better than burnishers.

W. W. B. P.—The lenses to which you refer, and regarding the prices of which you institute comparisons, are of entirely different kind and capabilities. Those with the higher price, although intended for the same class of work, are much larger lenses. Their especial peculiarity consists in extreme rapidity, flat field, and perfect defining power. The same maker produces lenses for card portraits at half the price you quote; but, to those who can afford it, those at the higher price are worth the money. An ordinary good half plate lens will answer for card portraits; but will be slow compared with those lenses especially made for the purpose. Your specimen is of average quality; but is disfigured by the row of white balustrades running straight across the picture.

H. V. R.—We generally use kaolin for removing the colour from our exciting bath. A little citric acid or common salt, added so as to cause a slight precipitate of citrate or chloride of silver will also answer the purpose. 2. We cannot recommend you which tent to select. There are several in the market, each of which have some advantages. Their prices range from about 30s. to £6 or £7. A properly made bromo-iodized collodion will keep without deterioration, for months or years after it is iodized. We have some in use at present, made and iodized two years ago: we find it as sensitive now as any collodion in the market.

We are compelled to defer answers to a large number of correspondents until our next.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 183.—*March* 7, 1862.

## SUPPRESSION OF PHOTOGRAPHIC PIRACY.

The growing prevalence of photographic piracy demands some prompt measures for its suppression. The injury to the art is as great as the loss to artists. The metropolis teems with card portraits which are at once a libel on the persons portrayed, a wrong to the original artist in reputation and in purse, and a deep degradation to the art by which they are produced. Even common decency is disregarded by these pirates; photographs of Her Majesty the Queen meet the eye at every turn, in which the original photograph has received certain additions from the pencil of the painter, so that the pirated reduplications represent her in that garb of widowhood which should render the meanest of her subjects sacred from such an impertinence. As might be anticipated, these piracies are rarely undertaken by artists who can make a living by the skilful and honourable practice of the art, and the pictures are what might be expected from the incompetent blunderer. Flat, mealy, fading, and worthless, the prints, as we have said, degrade the art. Apart from the injury to his pocket, this cause alone is almost sufficient to make the photographer who values his reputation forswear publishing altogether. For, it often happens, that when a picture of any value is first published, it generally becomes identified with the name of the artist; and when the town is flooded with vile copies, all their shortcomings are charged by an indiscriminating public upon the luckless artist who was so unfortunate as to issue something tempting enough to become the prey of pirates.

The somewhat complicated state of the law of copyright, as relating to this subject, and the expense of conducting a prosecution against persons from whom, after a case is gained, it is impossible to recover costs, has hitherto prevented decisive steps being taken; and, emboldened by impunity, the offenders seem to challenge consequences. It appears, however, that there is strong ground for coming to the conclusion that the existing law on the subject may, by observing certain conditions, be made to protect the copyright in photographs. We have been favoured by Mr. Mayall with a copy of counsel's opinion on this subject, which as it is not long, and the subject is important, we shall give in its entirety.

### Re Mayall.

(Copy of Counsel's Opinion.)

I have considered the question submitted on behalf of Mr. Mayall, viz., whether the portraits of Her Majesty, and of various members of the Royal Family, produced by him by photography, and intended to be published and sold by Her Majesty's permission, are, or not, protected from piracy by the various Acts of Parliament which have from time to time been made for the regulation of copyright in engravings; and upon the whole, although the question cannot be considered free from doubt, I am of opinion that they are so protected.

The effect of those Acts may be shortly stated:—The first statute, 8 Geo. ii., c. 13 (known as Hogarth's Act), confers the sole right of printing or reprinting any historical, or other print, for the term of 14 years, upon the person who shall invent and design, engrave, etch, or work in mezzotinto, or chiaro-oscuro, or from his own work and invention shall cause to be designed, &c., any such work.

The second statute, 7 Geo. iii., c. 38, in effect, extends the provisions of the first Act to prints generally, made or caused to be made from a person's own design or invention, and also to prints made from any picture, drawing, model, or sculpture, ancient or modern. This Act also enlarges the copyright term to 28 years.

Both of these statutes appear to be limited to engravings in mezzotinto or chiaro-oscuro.

The next statute, 17 Geo. iii., c. 57, however, in effect, extends the provisions of the former Acts to any prints whatsoever which shall be engraved, etched, drawn, or designed.

The following statute, 5 and 6 William iv., c. 59, extends the provisions of the former Acts to Ireland, and gives a right of action to the proprietor of "any engraving or print of any description whatsoever," against any person who shall engrave, etch, or publish any such print without the written consent of the proprietor of any such print.

The last statute upon the subject is the 15th and 16th Vict., c. 12. By the 14th section of this Act, after reciting the former Acts, and that doubts were entertained whether their provisions extended to lithographs *and certain other impressions*, it is declared that the provisions of these Acts were intended to include prints taken by lithography, or any other mechanical process by which prints or impressions of drawings or designs are capable of being multiplied indefinitely.

The question, therefore, appears to be reduced to this, viz., whether the means by which copies of a photograph are produced are a "mechanical process" within the last mentioned Act of Parliament; and I am of opinion that they are. It is certain that they constitute a process by which drawings or designs can be indefinitely multiplied, and they were a process known, and in operation, at the time when that Act was passed, and may well be considered to be included amongst the "other impressions," as to which it is recited that doubts existed, and which it was intended to include in the provisions of the earlier Acts.

I think, however, that to obtain the protection of these Acts, the name of the proprietor of the photograph, and the date of its first publication, must be placed on the photographic plate or negative from which the photograph or positive print is taken, and on all the prints of it (see Newton *v.* Cowie, 4 Bingham, 234; Brookes *v.* Cock, 3 Ad. and Ell., 138). This may be in a similar manner to that usual on engravings; as thus—

"J. E. Mayall, proprietor;" or

"J. E. Mayall, fecit, 1 January, 1861;"

and address; or, the name in one corner, and the date of publication in another corner.

The opinion I have above expressed applies, properly, to positive photographs, or prints produced from negative photographs, and published for sale. The right of the photographer in the original negative, or in a positive, prior to any publication, seems to be the same as that of the painter of any picture to his picture, and depends on ownership, and not on the copyright statutes.

I think also that Mr. Mayall might, perhaps, obtain the protection of the Literary Copyright Act, 5 and 6 Vict., c. 45, for his series of portraits of Her Majesty and the Royal Family collectively, by having them connected together so as to be formed into a book, and adding some short descriptive matter, such as the names, ages, place of birth, &c., of the various persons whose portraits are comprised in the series; and the circumstances under which they were taken. For this purpose, of course, it would be necessary to register the work, and comply in all other respects with the requisitions of that Act (see Bogue *v.* Houlston, 5 Dessex and S. M., 267).

(Signed) Stephen Cracknall,

3, New Square, Lincoln's Inn, 12th March, 1861.

From the extracts of acts above given it appears very clear in the first place that photographs must be included in the term, "print of any description whatever;" and if it be argued that photographs were not in existence at the time that act was passed, it may be answered that the enactment of the 15th and 16th Victoria appears to set aside all possibility of dispute. For the veriest opponent of regarding photography as a mechanical art, will admit that the process of photographic printing is a "mechanical process," by which designs can be "multiplied indefinitely."

The chief difficulty, then, is the cost of putting in operation the law. Each person concerned naturally feels that what is for the benefit of the aggregate body of photographers, or at least those of them who publish their productions ought not to be secured at the expense of a single individual. We have heard it urged that the steps to protect the art ought to be taken by the Photographic Society. It must be obvious, however, that the funds of the society could not with propriety be expended in undertaking such prosecutions, or indeed in interfering in any way with the commercial interests of photographers.

The legitimate mode of effecting the object in question appears to us to be by the formation of an association for the purpose, consisting of those practically interested in the question. We have ascertained that several of the first photographers are favourable to the adoption of such a measure, and our object now is to elicit from any of our readers concerned in the question an expression of opinion on the subject. That will be easy to any association which would be difficult for an individual to achieve. It is very unlikely, however, that more than one or two prosecutions would be necessary, as the mere existence of a body of gentlemen resolved on the protection of the art and their own interests would operate as a terror to evil-doers, and effectually check the abuse which is now uncontrolled by fear of consequences.

It is unnecessary here to enter into any detail of the steps necessary in forming such an association, or to discuss the extent and limitation of its operations. These will be matters for private action. But there is one subject to which it will be important to allude in this connection. A Bill has again been introduced into the House of Commons for amending the law of copyright as relating to works of fine art. In this bill protection is given to photographers as in that which was lost last year. Several of the obnoxious clauses which occasioned the loss of the Bill last session have been removed. The near approach of the International Exhibition renders some legislation on the subject imperative. These considerations give a greater probability to the passing of the Bill than existed last year. But the measure is very far from safe as yet; and every aid should be given to its supporters. To organize such support amongst photographers would be a very proper duty for such an association, as the passing of the Bill into law would at once simplify all future proceedings, and at the same time render them certain and efficient in securing the protection of the art and its votaries.

## PHOTOGRAPHY IN THE LAW COURTS.

Photography has been making acquaintance with the law courts, and is, we fear, but little understood there. In the French courts it was recently denied protection because it "neither creates nor invents, but servilely reproduces what is placed before the lens." In the case recently in the Court of Exchequer, where a clear right of property was involved, Mr. Mayall obtained but half a victory. And on Friday in the Court of Common Pleas, an action was tried, which brought together a number of photographers sufficient to make the court like a photographic meeting, which resulted in a verdict which cannot fail to be unsatisfactory to both parties concerned.

In the case referred to, Mason *v.* Heath, the plaintiff alledged that Mr. Vernon Heath had contracted to produce for him two negatives of His Royal Highness, the late Prince Consort, suitable for a portrait gallery he published, at a fair and reasonable price. The late Prince had been solicited by Mr. Mason to sit for this gallery as early as April 1860. At that time he declined, giving the manifestly sufficient reason, that he could not lend himself to aid the commercial success of any private undertaking. The applications were repeated, and eventually, the work being better established, His Royal Highness consented to sit, somewhat reluctantly we have reason to believe; but there being no absolute reason why he should not sit, with the considerate and princely courtesy which always distinguished him he consented. He was about to sit as president of a congress of the Statistical Society and for other portraits, and had selected Mr. Heath as the artist. Mr. Mason was informed that the Prince would sit to Mr. Heath for him, if he arranged with that gentleman as to terms. This Mr. Mason alleges he did; but that although the Prince sat, and the negatives were taken and approved, he never was able to obtain them; that he was put off on one excuse or other, and finally, that one negative only was offered him, at what he conceived to be an exorbitant price. He brought this action therefore to obtain damages for the loss he had suffered through this alleged breach of contract.

Mr. Heath, on the other hand, entirely denies the existence of any contract of any kind, either absolutely made or implied. He alleges that he was angry and insulted, because Mr. Mason came to him with an untruth, implying that he was bringing the patronage of the Prince to him, with a view to influencing his terms. That so far from making a contract, he informed Mr. Mason that his conduct should be reported at Court. He affirms that he could not make a contract which would bind him to deliver any negative at all, as he had to abide solely by the instructions of the Prince; still less could he contract to deliver *two* negatives, as two only of the size required were taken, one of which was for the Statistical Society absolutely, and the other for Mr. Mason conditionally. When the Prince had decided that one negative was to be given up to Mr. Mason, he was at once prepared to deliver it on receiving fifteen guineas, which he conceived to be a fair and reasonable price. The consideration, on which this question of price was based, was the fact that two days were devoted to the production of four negatives: one day to preparation, so as to secure the highest possible conditions of success, and another day to the sittings and arrangements in connection therewith. Notwithstanding this, however, it appears Mr. Heath had, in a letter, informed Mr. Mason that he would have charged him only five guineas, but for his attempt to impose upon him.

So far as the statements of the plaintiff and defendant are concerned, it becomes simply a question of credibility of evidence. Whatever may be our own personal conviction, it is no part of our duty to express an opinion on this part of the subject here. If Mr. Mason's statement be correct, it is unfortunate for him that he is entirely without evidence to corroborate him as to the existence of a contract at all; whilst, as regards the existence of a contract for two negatives, there is evidence which renders it highly improbable, if not impossible. Mr. Heath is confirmed in many particulars by Mr. Ruland, the Prince Consort's secretary, who states that Mr. Heath reported to him the nature of Mr. Mason's first application to him regarding the portrait. He also confirms Mr. Heath regarding the number of negatives taken, and their destination as decided by the Prince.

As to the value of the negative, we apprehend there was really very little difference of opinion, if the question of contract were set aside. All the evidence of the eminent photographers on both sides tended in one direction so far as that was concerned. Those gentlemen called by the plaintiff gave evidence of the existence of an arrangement whereby they had taken negatives for a guinea each. One of them admitted that the publicity thus involved was a more important element than the guinea. It was also stated that in these cases Mr. Mason always introduced the eminent personages, and in addition to the payment of a guinea, permitted the photographer to obtain a negative for himself. We mention these circumstances, because the general impression which might have resulted from much of the evidence would have been, that one guinea was the regular and understood price amongst photographers for the most valuable negatives. As regards this individual negative, we may state further, that we know that in one case a hundred and fifty guineas, and in another two hundred guineas, have been offered for it, should it be for sale.

The jury, as we have stated, returned an unsatisfactory verdict. Practically for the defendant, but with a recommendation which nullifies it as a decision. The matter will stand over until Easter term, when, on some amendment of the pleas by the judge, the plaintiff may move that the verdict may be entered for himself, for one negative at five guineas, with nominal damages. The defendant's counsel will oppose this on the ground that, if one negative only had been claimed no action could have arisen, as the question of price was entirely a subsidiary one, and would never have been contested; that the action was resisted simply because it was for two negatives, when there was only one to deliver. On this point we can speak, as we remember that several months ago Mr. Heath asked us, personally, if we would act as referee in the matter, and he then stated that it was purely a question of the delivery of one or two negatives, the question of price being to him of minor importance; and we have moreover seen a letter addressed to Sir Charles Phipps in December last, in which Mr. Heath states that had the claim been for one negative he would have been very glad to have been quit of the affair by delivering *the* negative to Mr. Mason "on any terms he chose to offer."

We have made a few remarks on this case, not because, beyond its general interest to photographers, it involves any great principle; but chiefly because we were struck with the inadequacy of a court of law to decide questions of a technical character. The judge was attentive and patient; the counsel on either side were able and watchful; the jury being special were we presume of beyond the average intelligence and respectability. But with all this the verdict is a manifest compromise, an attempt to make it pleasant to all parties. "There is no contract," say the jury, "and so far the defendant is right. Still we should not like the plaintiff, poor fellow, to lose his negative, and we recommend that it be given to him on payment of five guineas." Such a decision decides nothing and pleases nobody.

Surely a couple or half-a-dozen respectable photographers, being familiar with all that legitimately affects such a question, could have arrived at a better decision six months ago, without troubling a jury at all. If Mr. Mason had consented to decide the matter by arbitration, some hundreds of pounds would have been saved in law expenses, and Mr. Mason might have pocketed some thousands by a circulation, the extent of which, under existing circumstances, would have only have been limited by his power of production.

## REMARKS UPON SOME OF THE APPARATUS EMPLOYED IN PHOTOGRAPHY.*

BY F. R. WINDOW.

CAMERAS.—*Continued.*

*Field Cameras.*—As in the preceding article upon the studio camera, it is rather my intention to examine the question of cameras for the field in a general way, than to offer a criticism upon the comparative merits of any individual pattern. This not only would be an invidious task, but it would also be beside my purpose, which is to enquire into the suitability of our apparatus for taking perfect pictures; and not to prescribe the use of one instrument in preference to another when the choice between them lies in a mere question of convenience or taste. Also this question of the superior convenience of one design of camera over another depends much upon the character of work to be executed, and what would be the most suited to one class of operations might be totally unfitted for another.

The forms of camera most generally used in the field are: the rigid box camera, mostly used by wet collodion photographers, and also generally in India and tropical countries; the double body camera, the same as for the studio; the folding camera which folds by hinges in the sides; the folding double bodied camera; and the folding bellows camera. I am not aware of any thing that renders any one of these designs unsuited for producing perfect pictures, so their selection must be decided by the individual opinion of the artist, guided by the nature of the work he wishes to perform with it.

In every form of camera for the field there are certain requirements which must be met, in order to produce the best effects; and it is these which I propose to investigate. I shall assume mostly that the field camera is to be employed for dry plates. The wet collodion photographer has generally so much baggage to carry with the tent and chemicals, that one or more assistants, or a vehicle are necessary to transport it; he has therefore less encouragement to study the portability of his instrument, which to him is only one of many things to be carried, than the dry plate photographer, whose only load is his camera and who generally bears it himself. Therefore the wet plate photographers principally use a double body camera such as I have previously described, or one of rigid construction.

*The body.*—The body of the portable camera is the most most important part, and the greatest attention should be paid not only to its design but to its mode of construction. It has to be carried about from place to place through heat cold, and rain. It has to battle with railway porters who are not a race celebrated for the careful handling of goods committed to their mercies, and to bear the numerous chances and mischances incident upon pedestrian and cross country expeditions. Thus while there is every temptation to *cut down* the material to a minimum, to decrease weight and achieve portability, there is also a necessity for sufficient strength and stamina in the instrument to enable it to bear a good deal of rough treatment without injury to its working parts.

The work which falls short of this sufficiency of strength is to be condemned, as it will probably fail in the hour of need, and at the best will prove to be an unwise economy. Work with more material than is required to give the necessary strength is an evidence of clumsiness in a portable instrument, as it adds useless weight. So we should endeavour to avoid excess either way, and steer a middle course between the flimsy and the ponderous when we select a camera for field work.

All the wood work of the body should be secured by screws as well as glue, and the edges and corners should be rounded off to lessen the danger of injury from blows on those parts. If the price admits of metal bracing, so much the better, and in this case the thickness of the wood may be diminished a little. Flanges and projections generally should be avoided as much as possible, as they are liable to be broken off in ordinary wear and tear; and parts intended to work in each other—such as inner bodies, shutters, doors, &c.—should be made sufficiently free that the ordinary swelling from damp weather will not interfere with their action.

In those cameras having an expanding motion the greatest care should be taken to ensure the parallelism of the movement, and the firmness of the whole when in a working position. The means of doing so, of course are various, and must be adopted according to the kind of camera, but it is very important to avoid all appliances which are in themselves unsteady or tend with a little wear to become rickety.

When a flexible material is used for the body of a camera it should be strained taut when in use, as if it were allowed to bag it would be taken with the least wind, and by its movement create a vibration of the whole instrument. Those cameras of this nature, (such as the bellows camera), which by their form cannot be strained perfectly taut, must be rendered incapable of vibration by some other means.

Much of what I have said in reference to the construction of cameras for the studio applies equally to field cameras, and I need not repeat it in this place: the reader's judgement will readily decide whether the suggestions I have offered have any relation to the requirements of any particular case he may have under consideration.

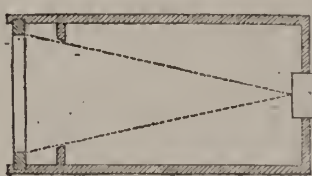
* Continued from page 100.

With respect to the diaphragm that I recommend so strongly for the studio camera, to be placed in front of the plate, at a distance of about an inch and a half from it, this protection is still more necessary in the field camera. While a landscape picture is being taken there is a greater amount of white light inside the camera than when a portrait is being taken in the studio. In the latter instance the aperture used is generally larger, but the principal objects covered by the lens are of a sombre hue; in landscape photography the lens is more stopped down, but about a third of its range mostly includes a bright sky which throws a great volume of white light into the camera.

Several cameras from their form do not admit of such a diaphragm being introduced, as it would interfere with some of their parts. I think that these should only be used for exceptional purposes, and cameras whose construction and design permit ot this protection being added should be preferred for general use in the field.

In most instruments a diaphragm of this nature may be employed, the frame of which exceeds slightly in breadth that of the frame of the plate holder; (see fig. 8, showing a sectional plan). This will be a great protection to the plate, but it would be still better if this diaphragm stood out an inch or an inch and a half from the body of the camera. This could only be effected by making the camera or at least that part of it slightly larger in all directions; and the photographer must decide whether he considers the advantage to be gained by doing so is equivalent to the trifling extra bulk.

Fig. 8.



When an object has to be photographed that is either wholly or in part above or below the range of the lens when the camera is in a horizontal position, so that the instrument has to be "cocked" upwards or downwards to bring the picture into the proper place on the ground-glass, it is necessary to have a camera with a swing back, to avoid the image being distorted, which it will always be when the plane of the object, and of the plate upon which its representation is impressed are not parallel to each other. In representing horizontal lines on different planes this effect produces perspective, and is necessary to the proper delineation of the picture, but all the vertical lines of every view being in reality on parallel planes, must also be represented truthfully parallel to each.

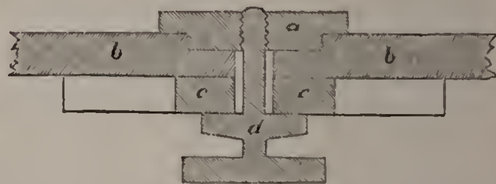
A swing-back is rather an expensive addition to a camera, and, therefore, very few are supplied with it; but whenever the camera has to be "cocked" it is absolutely essential for architectural subjects in which the slightest distortion is so immediately visible and unsightly, and, indeed, without it the truthfulness of the copy is impaired in every subject, although the fact may not be so readily detected in ordinary landscapes without buildings in the first or second plan.

A swing-back consists of a frame into which the plate-slide fits and which is swung at the middle upon two pivots one on either side of the camera. Accuracy of fit is generally depended upon to secure the exclusion of all light at the joints, but it would be safer, I think, to place a beading inside to intercept any stray ray that might filter through, in the same manner that I have described for the studio camera body. A rack and pinion are generally added, by means of which this back carrying the foccussing-screen or plate-slide is brought parallel to the horizon when the camera is "cocked," and a set screw serves to clamp it in position.

As the cases in which the camera requires to be tilted are not of very frequent occurrence this is not a necessary addition to all cameras, but as I have before remarked cameras that are not provided with it must always be placed horizontally to obtain an exact representation of any subject.

The camera is generally attached to the tripod stand by means of a large headed bronze screw passing downward through a hole in the bottom of the camera body, and clamped underneath the triangle by means of a nut. It will be found advisable in all cameras to reverse these parts, and to fix the nut *a* (fig 9) permanently on the inside of the bottom of the camera body *b*, the flanged screw *d*, passing through the boss of the triangle *c*, as usual, works into this nut and clamps the body and triangle together. The advantage of this plan over the uusal loose nut and screw arrangement is that it is more easy to use, and the camera

Fig. 9.



if a folding one, or one that has to be prepared in any way before it is ready for use, can be attached at once to the stand, *before* opening it, and it is thus in a more convenient position to complete the necessary arrangements. Also it reduces by one the number of small loose objects which have to be taken into the field, that run the chance of being lost or left behind, and whose absence is always a source of annoyance, even if it does not bring the day's work to an abrupt end.

(*To be continued.*)

## INSTANTANEOUS PHOTOGRAPHY ON ORDINARY TANNIN PLATES.

BY HENRY DRAPER, M.D., OF NEW YORK.

The process consists essentially in keeping the plate at a high temperature during development, the developer itself being poured on when at the ordinary temperature of the room. I obtained a street view with a lens of 1½-inches aperture, in less than a second, the plate during development being maintained at 200° F.

In a communication to the American Photographic Society at its last meeting (February 10th, 1862), the details of the process were given, and are published in the *American Journal of Photography.* They may be briefly recapitulated as follows:—

A plate is prepared in the manner recommended by Major Russell, except that the film is held at the edges in the way commonly in use in American, that is, by a rim of a solution of albumen one part to water six parts. After exposure in the camera the plate is heated in hot water. The ordinary developer *not* having been warmed, is poured on as soon as it comes out of the water, and worked in the usual manner. If the plate cools sensibly before the picture is developed enough, hot water is to be poured on, and the development then continued.

At a trial before two of the best amateurs of our Society, Messrs. Hull and Cottenes, in my father's (Professor J. W. Draper) laboratory, in the University, by using water only at 130° F., we shortened the exposure to one-twentieth of that which was necessary when another of the same set of plates with the same diaphragm was used, and developed in the ordinary way with water from a tap. The length of time required in the camera depends on the heat of the water into which the plate is put before its development. The shorter the exposure the hotter the water must be. I have been using this process for about six months, having first tried it with marked effect on Dr. Hill Norris's plates, when photographing the sun in my 13-feet reflector of 16-inches aperture. Several of the members of the Society spoke of the great advantages that would accrue from the use of this method for portraits, &c., and said that although they had used hot developers, not noticed any such shortening action as in this instance, where the plate is hot and the developer cold.

Protochloride of palladium, which I introduced as a strengthener some years ago, can be applied with great advantage to negatives produced by this method.

*University of New York, February 13th*, 1862.

## PHOTOGRAPHIC CHEMICALS:

### Their Manufacture, Adulterations, and Analysis.

*Hydrosulphuric acid* (continued).—The reactions of hydrosulphuric acid with the salts of different metals are very important, both to the chemist and photographer. In the chemical laboratory this substance, both in solution and in the gaseous state is of the utmost importance, inasmuch as the very definite nature of the compounds which it forms with metals, and their ready separation by this means into three classes, forms the basis of almost all systems of qualitative analysis. These classes are—1st, those metals which form insoluble sulphides when sulphuretted hydrogen is passed into their *acid* solutions; 2nd, those metals which are not precipitated in the insoluble form when sulphuretted hydrogen is passed into their acid solutions, but which come down as sulphides or oxides in solutions rendered alkaline by ammonia; and 3rd, those metals which are not precipitated by sulphuretted hydrogen either in an acid or alkaline solution. The first group of metals consists of gold, silver, platinum, tin, arsenic, antimony, bismuth, lead, mercury, copper, and cadmium. The second consists of nickel, cobalt, manganese, iron, chromium, alumina, and zinc; while the third contains the alkalies and alkaline earths. It is not necessary for the photographer to enter very minutely into the analytical details, connected with these sulphides, but the broad facts just mentioned should, if possible, be remembered for many reasons, some of which may now be mentioned, whilst others will appear subsequently. Owing to the decided colours and great permanency of several of the sulphides of the first group, they are largely used in painting, whilst on the other hand, several compounds of these metals with other bodies are also used in painting. The above knowledge will enable anyone to know beforehand that a pigment consisting of a member of the first group with sulphur—sulphide of cadmium for instance which is of a beautiful yellow colour—will stand the attacks of sulphuretted hydrogen in the atmosphere, unchanged: whilst another pigment consisting of a member of this group with some other body—chrome yellow (chromate of lead) or white lead, (carbonate and oxide of lead) for instance—will, under the influence of sulphuretted hydrogen lose its own colour and assume that of the sulphide of the metal which is present. Chrome yellow and white lead are therefore not permanent colours, but are liable to *tarnish* in the presence of sulphuretted hydrogen; the proper colour of sulphide of lead being black. The advantage of zinc white over white lead in this respect is also apparent from a knowledge of the chemistryof these sulphides. Sulphide of lead being black whilst that of zinc is white, the latter can stand, undimmed, an atmosphere which would instantly darken white lead. Further details on this subject must be deferred till we speak of the principal metallic sulphides *seriatim*. We cannot warn photographers too strongly against the danger of allowing sulphuretted hydrogen to escape from the bottle into a room where any photographic operation is going on. The metal silver is in the first group above named, and hence it will be understood, that it readily unites with sulphur, forming a sulphide which is unacted upon by the ordinary acids, and which, indeed, is formed in their presence.

We will now pass on to the most important sulphides. *Sulphide of potassium.* These two elements are capable of uniting in various proportions. The only compound which is of interest to the photographer is the one called *liver of sulphide* or *hepar sulphuris.* This consists of tersulphide, pentasulphide, and intermediate sulphides of potassium, mixed with sulphate, and frequently with carbonate of potash, varying according to the proportion of sulphur used in its manufacture. The common receipt is to take two parts of carbonate of potash and one part of sulphur and heat them together in a covered earthen or cast-iron crucible. When the mass is melted, it is allowed to fuse quietly for some time, and afterwards poured out on to an iron or stone slab. As soon as it is cold it must be broken up, and preserved for future use in a well stoppered wide-mouthed bottle. The above proportion of sulphur to carbonate is too small. The smallest quantity that ought to be used is, for 276·8 parts (four atoms) of carbonate of potash 160 parts of sulphur, which forms one atom of sulphate of potash and three atoms of tersulphide of potassium. The largest quantity of sulphur which can be used with 276·8 parts of carbonate of potash is 256 parts of sulphur, which when heated together forms sulphate of potash and pentasulphide of potassium, any excess of sulphur beyond this volatilises without entering into combination. Liver of sulphur forms a dark grey or brown mass, soluble in water, alcohol also dissolves the poly-sulphides of potassium which may be present, and leaves the impurities of sulphur, sulphate, carbonate, and hyposulphite of potash undissolved. When the solid mass is kept in badly closed vessels it gradually oxidises and forms a mixture of hyposulphite of potash and sulphur. When the aqueous solution is added to a liquid, silver, containing gold, platinum, or in fact any of the metals of the first or second group, they are precipitated as sulphides, an excess of sulphur coming down at the same time. On this account, and by reason of its cheapness, liver of sulphur is recommended for precipitating the valuable metals from the photographer's old solutions. This it does in a very perfect manner if care be taken not to employ an excess, but it is liable to the objection of throwing down considerable quantities of sulphur as well unless the operation be conducted by an experienced chemist, who would know exactly when to stop. On this account we do not like liver of sulphur for this purpose so well as sulphide of ammonium, and even this is not so good a means of separating the silver, &c., as the passage of sulphuretted hydrogen through the clear liquids.

*Sulphide of Ammonium* is a very extensively used salt. It is prepared by dividing a quantity of solution of ammonia into two equal parts, and then saturating one with hydrosulphuric acid gas. When no more is absorbed, the other portion of the ammonia is added to the liquid, and the whole shaken together, and preserved in a well stoppered bottle. When freshly prepared, this solution is colourless, and smells strongly of both ingredients; after some time, especially if free access of air can be obtained, it becomes yellow, in consequence of the absorption of oxygen and separation of sulphur, which latter is dissolved by the excess of the sulphide of ammonium. The formula of sulphide of ammonium being $NH_4S$, and that of ammonia $NH_4O$, the reaction expressing this decomposition will be

$$2NH_4S+O=NH_4S_2+NH_4O.$$

This bisulphide of ammonium ($NH_4S_2$) is not injurious when in small quantity, and it is even advantageous in some precipitations. Its presence, therefore, may be disregarded. When sulphide of ammonium is fresh, it will precipitate the pure metallic sulphide from solutions containing silver or gold, without the admixture of any free sulphur. When it has stood for some time, and has acquired a yellow tinge, free sulphur of a white colour is precipitated along with the metallic sulphide. A white precipitate of pure sulphur is obtained when hydrochloric acid is mixed with yellow sulphide of ammonium. As a precipitating agent for silver residues, sulphide of ammonium gives a purer product than poly-sulphide of potassium, but is more expensive. It is also much more convenient in its application than hydrosulphuric acid gas, although for efficiency there is nothing which is equal to this latter.

*Sulphide of Sodium.*—By substituting carbonate of soda for carbonate of potash in the preparation of liver of sulphur, a product is obtained in every respect analogous to the potash compound, which is called *soda-liver of sulphur*. It may be prepared by heating together equal weights of sulphur and dry carbonate of soda. Carbonate of soda being a trifle cheaper than carbonate of potash, it may be advisable in working on the large scale to use it instead of the potash salt. The properties of polysulphide of sodium are identical with those of the potassium compound.

## PROFESSOR TYNDALL'S LECTURES ON LIGHT.

Lecture vi.—Jan. 7, 1862.

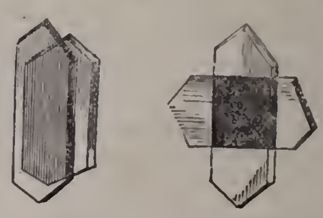
This lecture, the concluding one of the course, was prefaced by a warning that it was going to be a very hard lecture, but the Professor said that his audience had been so attentive during the preceding lectures that he was quite persuaded that he could calculate upon their atteutiou during the concluding hour. The subject was commenced by recalling attention to the phenomena of the reflection of waves on the surfaces of liquids. A boat passing along a canal produces a series of ripples as it proceeds. These ripples or waves strike against the side of the canal, and are then reflected back again, producing a series of waves crossing the original ones, and causing the whole surface of the water to be chased, and reduced to a beautiful mosaic work. Au oval tray was then filled with water, and a reflection from its surface having beeu projected by means of the electric light on to the screen, waves were formed by allowing small drops of water to fall on it from a fine pipette. Owing to the shape of the vessel, the waves were oval, aud by their repeated reflection from the sides of the tray, they coursed backwards and forwards, coiling and encircling one another in the most beautiful manner.

Returning to the phenomena of sound for an illustration of interference, the lecturer asked his audience to suppose two watches—one producing 100 ticks, while the other produced 101. They start together, and the two ticks unite to give an additional impulse to the ear; at the 101st tick they also coincide again, and on each of these two occasions they would have the united ticks of the watches beating agaiust the drum of the ear. But in the intermediate times it was easy to imagine that one tick of a watch was in the act of pushing the drum of the ear in, whilst the other tick was in the act of pulling it out. This action, here illustrated in a very rough way, was shown actnally to be the case when two sounds were produced, the vibrations of which differed in a certain degree. Two organ pipes placed side by side, were then sounded. They were so tuned that at certain times the vibrations of the sounds of the pipes coincided, and produced a loud sound, whilst at others they acted in opposite directions, and produced comparative silence. The alternate beats of sound and silence were very distinctly heard. This was called the interference of sound. It was further showu that if one sound started at a certain time, and then another sound of exactly the same character were to follow the first, but half a wave leugth behind it, they would mutually destroy each other.

Exactly the same phenomena takes place with respect to light. The colours of the soap bubbles and other thin films are produced by interference, thus:—The light falling ou the film is partially reflected at its front surface; but a portion of the light enters the film and is reflected at its back surface. If the film be of suitable thickness these two beams will clash and destroy each other; whilst by a different thickness the two beams may be made to combine and help each other. To cause two red rays to coincide requires a thicker film than that necessary for the coincidence of the blue rays; hence a thickness which destroys one colour developes another: if the thickness of the film be uniform the colour will be uniform; if the thickuess vary the colour will vary. It is owing to the varying thickness of this film that the varying splendours of a soap bubble are due.

The subject of the polarization of light was next touched upon. A ray of light must be supposed as performiug its vibrations in all directions; but when reflected at a certaiu angle ($35\frac{1}{2}°$) from a plate of black glass, all the vibrations are reduced to a common plane. A snake wriggling along on a flat surface was employed as an illustration, all its oscillations or sinuosities being confined to a flat surface. A serpent also wriggling along with vertical folds would represent another beam of this kind. Light, with its vibrations thus circumscribed, is said to be *polarized*; and the rays corresponding to the mode of progression of the snake and serpent are polarized in opposite directions. A beam of electric light was then reflected upwards from a piece of black glass, aud a clearly defined disc of polarized light projected on to the ceiling. Another black glass reflector was then placed at the proper angle in the path of this polarized ray, and its action on it examined. The ray, after it had been polarized, might be likened to a flat ruler, all its oscillations being performed in one plane. It has therefore what may be termed a side and au edge. When the second reflector was held so that the *side* of the polarized ray struck it, the light was reflected off again undiminished in intensity; but when the reflector was turned rouud so that the *edge* of the ray struck it, the light was entirely quenched, not any being reflected.

Polarized light may be obtained in other ways. On passiug through slices of certain crystals called tourmalines, cut parallel to the axis, the light is polarized, all the vibrations which run in the same direction to the axis of the crystal being allowed to pass through, whilst the transverse vibrations are entirely stopped. This beam of polarized light can pass through a second slice of tourmaline, if its axis be parallel to that of the first; but if the axes are crossed at right angles, the beam which passes through the front plate is cut off by the one behind. By projecting the images of these tourmalines on to the screen by means of the electric light, these remarkable effects were beautifully shown. Upon placing them parallel, the light passed readily through them, but upon crossing them they were quite black.



Polarized light can also be obtained by passing common light through a crystal of Iceland spar. The beam is split up into two, one of which is more refracted than the other. This is called double refraction. The images of the coke points were projected on to the screen; by the interposition of a piece of Iceland spar, two images of the points, polarized in opposite directions, were produced. Upon throwing an image of a tourmaliue ou the screen, and dividing it into two in this way, one image was seen to be opaque, and the other transparent.

It was next shown that by the iuterposition of slices and films of crystalline bodies in the path of the polarized ray, and then receiving this ray on a second polarizer, (tourmaline, black glass, or Iceland spar,) some of the phenomena of *interference* would be occasioued, and spleudid colours would be produced. Similar phenomena were shown to be caused when glass in a state of partial tension, by heat and rapid cooling, was interposed in the path of the rays. The two tourmalines of a polarizing apparatus fastened to the electric light were first crossed so as to prevent any light passing through on to the screen, and then slices of crystals, pieces of unannealed glass, &c., were placed between the tourmalines. Films of selenite possessed the power of restoring the light on the disc and giving brilliant colours, varying with the thickness of the film; a wedge of selenite, showing the colours arranged in parallel bars from the thin edge upwards, and a concave lens-shaped piece giving a series of coloured rings. An oblong piece of glass was then taken and placed in the field of the instrument. In its ordinary state it had no power to act upon the light, but upon applying pressure to the middle, so as to bend it slightly, the parts which were in a strain immediately became visible. Another piece of glass was placed in the apparatus, and its particles were thrown in a state of tension by heating one corner with a lamp: it acted in a similar way to the former piece of glass; the particles being thrown into a state of strain by the heat, and assuming temporarily the condition of a crystalline body. A square glass plate was then placed in the apparatus, and its centre touched with the tip of a hot poker; the four arms of a luminous cross were seen gradually to radiate from the part touched by the poker to the edges of the glass.

Professor Tyndall concluded this lecture, the last of the course, in the following impressive words which we heartily recommend to the attention of all our readers, young and old:—"I will say over and over again, that you must not be content—those who pursue the subject must not be content with admiring those beautiful experiments, you must try to get at the law and order and philosophy that underlies them; that is the grand point. There are two classes of people in this world with regard to science. One class—a highly cultivated class—fine fellows, noble men, generous souls, of great knowledge—men of literature; but, unfortunately, they say they have not time at all for science—they are very ignorant of science—they know nothing at all about it. These men I respect; of them there is some hope. But there is another class of men who see in science simply what it produces in the market. These are the men that will shout and yell about the electric telegraph, and about the steam-engine—anything that brings country butter to town is good and great, anything by which you can send messages, anything that you can bring into the market and get money for will be appreciated by these men, and they will stand by science on that account. Boys, that is not science. I cannot point you to a single great discovery in the world, in the history of science made by these men. They are not the men who make discoveries. It is those men who pursue the thing for the love of the thing—whether it be natural philosophy or any other branch of science. It is those men who create these people of the market by thousands. Why, there is Volta of Italy, and Oersted, of Copenhagen, and Mr. Faraday of the Royal Institution; these three men have created ten thousand of your self-styled practical men. All honour to practical men as long as they do not limit to their ends the aims of philosophy. But let us pursue science for its own sake; let us not pursue it merely because it has a certain market value. I trust that when you become men, and become philosophers, you will bear this in mind, and take care to seek to draw all these men of high culture over to our side. The really great practical men sympathise with us, but the market men are incorrigible, we cannot do much with them; but with the other men you can do much. They have high and noble sympathies, and I have no doubt that by-and-bye we shall lay hold of these men, and that they, as well as you, will see that science is a glorious thing, and a noble subject for the human intellect to be engaged upon."

---

## MASON *v.* HEATH.

THIS case, relating to a negative of the late Prince Consort, was heard at the Court of Common Pleas, Guildhall, before Chief Justice Erle and a special jury, on Friday, February 28. Mr. Montague Smith, Q.C., and Mr. Maude were for the plaintiff; and Mr. Hawkins, Q.C., and Mr. Gray for the defendant.

The action was for an alleged breach of contract, the plaintiff stating that the defendant had contracted to supply him with two negatives of the late Prince Consort at a reasonable price. He had since refused to supply more than one negative, for which he demanded fifteen guineas, which the plaintiff was unwilling to pay.

The defendant denied that any contract had been made, and stated that fifteen guineas was a fair and reasonable price for the one negative he was prepared to deliver.

Mr. MONTAGUE SMITH, having stated the case and read a variety of correspondence relating to the subject, called

Mr. MASON, who stated that he was the publisher of a serial work, issued at irregular intervals, entitled the *British Portrait Gallery*. He had made repeated applications to his late Royal Highness the Prince Consort to sit for a portrait to be published in the *Gallery:* His Royal Highness at first refused; but subsequently, when the work was more fully established, agreed to let him have a portrait. In June, 1861, he received a letter from Sir Charles Phipps stating that the late Prince was going to sit to Mr. Heath, and would at the same time sit for a negative for his *Gallery*, and that he was to call on Mr. Heath and make terms with him. He accordingly called and saw Mr. Heath, who said to him, "I suppose you have heard I am about to take a portrait of the Prince, and want to bargain with me for a negative." He (Mr. Mason) denied that this was the case, and produced the letter of Sir Charles Phipps. Mr. Heath then asked him what he was in the habit of paying other artists. He told him a guinea for each negative, and he would require two or more; and added, as Mr. Heath would probably have to go to the Palace, he would not mind a guinea or two extra. Every artist had fixed his own price, and charged one guinea for each negative. Mr. Heath asked him for the names of some of the artists he had employed, and he mentioned Mr. Kilburn. Mr. Heath said he knew him, and would ask him about terms; if he found what he (Mr. Mason) said was correct, he (Mr. Heath) would do as others did. He subsequently called on Mr. Heath, who told him that the Prince had sat, and that he had obtained two negatives, two of which were suitable for his *Portrait Gallery*. He showed him a print, and said, "Of course I have got the duplicate negative to this for you." Mr. Mason then proceeded to say that he had called and sent repeatedly, and had been put off from time to time without the negatives. He had tendered five guineas for the two, and had, after considerable delay, received a letter stating that he could have one negative on payment of fifteen guineas. If he had received the negative according to contract, he could have sold 40,000 copies, his profit upon each of which would have been sixpence.

The witness was cross-examined closely by Mr. Hawkins as to the truth of many of his statements, and as to his omission of facts of importance; but he maintained that the facts were just as he had stated them.

Mr. BARKER stated that he was in the employ of Mr. Mason, and had repeatedly gone to Mr. Heath's for the negatives, and had at one time tendered five guineas, without receiving them.

In cross-examination, this witness confused the singular and plural; at one time stating he went for a negative, and other times for negatives.

Mr. KILBURN stated that he had taken negatives for Mr. Mason's publication for a guinea each, and would have charged a guinea for a negative of the late Prince for the same purpose.

Mr. T. R. WILLIAMS had taken portraits for Mr. Mason's *Gallery*. Mr. Mason told him that other artists charged him a guinea for each negative, and he agreed to do them at the same price.

In cross-examination the witness stated that in the absence of any agreement, he did not consider fifteen guineas an unreasonable price.

Mr. LENTHALL, successor to Mr. Kilburn, had taken negatives for Mr. Mason's *Gallery* at a guinea each.

Mr. CUNDALL gave similar testimony.

Mr. JOHN WATKINS gave evidence to the same effect; but admitted on cross-examination that the extensive publicity obtained by the issue of portraits of eminent persons with his name appended, was an element considered; and that, apart from that, a guinea would be insufficient remuneration.

Mr. Melhuish stated that he had considerable experience in photographic printing. By adopting a process of his own, he could produce from one to two hundred prints in a day from a negative, the exposure necessary with a good light being less than a second.

During the examination of the witnesses, copies of the portraits of the late Prince were shown to several of them, and pronounced very fine.

Mr. Hawkins having stated the case for the defence to the jury, called

Mr. Vernon Heath, who stated that in June of last year he received intimation of the wish of his late Royal Highness the Prince Consort to sit to him for a portrait, intended for the Statistical Society of a recent congress of which, his Royal Highness had been president; he was also informed that a letter had been written to Mr. Mason to the effect that the Prince would sit for a portrait for his *Gallery*, at the same time if he (Mr. Mason) made his arrangements with Mr. Heath. The same day Mr. Mason called upon him and stated that the Prince was about to sit for a portrait, to be published in his *Gallery*, and that he had to submit the names of three photographers to His Royal Highness who would select one of the three, and that he wished to know Mr. Heath's terms in order to mention his name as one of the number. He (Mr. Heath) naturally felt angry that Mr. Mason should come to him with an untruth, inasmuch as he knew that there was no choice in the matter. He told him, therefore, that he would have nothing to do with him until he produced Sir Charles Phipps's letter. This he did, and it proved that no choice was left, as it stated that His Royal Highness was going to sit to him (Mr. Heath) and no one else. Subsequently he told Mr. Mason that he would report this conduct at the palace, and that if His Royal Highness still consented to let Mr. Mason have a portrait, he would leave the price to be decided by any eminent photographer, mentioning Mr. Claudet, Mr. Lake Price, and Mr. Kilburn. He declined entirely to name any price or to enter into any contract at all. The same afternoon he related these circumstances to Mr. Ruland, the Prince's private secretary. A few days afterwards the late Prince sat to him, and he obtained four negatives, two of a size suitable either for the Statistical Society, or for Mr. Mason's publication, and two vignette heads. Before leaving he asked His Royal Highness if one of these negatives was to be for Mr. Mason. The Prince answered "No;" after he had seen prints of the various negatives he would decide. Prints were forwarded to His Royal Highness and met with his entire approval. About a month afterwards he received a letter from Mr. Ruland saying that the Prince had now decided that the plate of the full-faced portrait might be given up to Mr. Mason. He wrote to this effect to Mr. Mason who called upon him and asked him to produce duplicate negatives the same size, and enlarged and reduced. He declined to have anything to do with either of the latter, and advised Mr. Mason to be content with using the negative for the purpose for which it was obtained. He promised to try to duplicate it the same size to increase printing facilities, and charge a guinea for each duplicate negative. After trying, he was not satisfied with the result; and so declined to proceed with the duplicates. He then sent and told Mr. Mason that the negative would be given up to him on payment of fifteen guineas. He then had to leave town and had, personally, no further communication with Mr. Mason, until he received a letter demanding the negatives without further delay. To this he replied, reminding Mr. Mason that he had first come to him with an untruth on his lips, and that his conduct throughout had not been such as to induce him (Mr. Heath) to give up a valuable negative until he received its price. Adding that had Mr. Mason's conduct been straightforward he should have charged only five guineas for the negative. He had never informed Mr. Mason that he had taken five negatives, nor had he on the occasion alleged by Mr. Mason shown him any prints whatever. He had offered to decide this question by reference, and had mentioned the Lord Chief Baron and Sir Charles Phipps, by whose decision he would have been prepared to abide. He had never made any contract at all with Mr. Mason, had never mentioned any price, nor could possibly have agreed to deliver two negatives since His Royal Highness only awarded one.

Mr. Ruland, librarian to his late Royal Highness, confirmed the evidence of Mr. Heath, as related to the arrangements and decisions of the Prince, as to the number of negative taken, and as to Mr. Heath having informed him, on the day named, of Mr. Mason's attempt to bargain with him on the assumption of having to name three photographers.

Mr. Robert Murray said he assisted Mr. Heath when taking the portraits of the late Prince, and prepared the plates: there were not five, only four negatives taken. He described also the visits of Mr. Mason's messenger, first for a negative, and subsequently, for two negatives, offering five guineas.

Mr. G. Wharton Simpson, Editor of the Photographic News, deposed as to the excellence of the negative, and stated his conviction that, under the circumstances detailed, fifteen guineas was a very reasonable price for such a negative.

Mr. C. Jabez Hughes stated that, considering the especial preparation and the anxiety involved in photographing a royal personage, the skill of the artist, and excellence of the result, he thought fifteen guineas was a reasonable price.

Mr. Bishop, manager for Marion's in Regent Street, stated that he had large experience in the publication and sale of photographs, having not less than 50,000 portraits through his hands every month. He considered that fifteen guineas was a very reasonable price.

Mr. Hawkins and Mr. Montague Smith having each ably addressed the jury for their respective clients,

His Lordship summed up very carefully, directing attention to the probabilities of the conflicting evidence, and pointing out that the especial points for their consideration were, firstly, was there a contract to furnish two negatives at a reasonable price? and if so, was the price offered by the plaintiff, five guineas, a reasonable price?

The Jury retired for about half an hour, and then returned with the following verdict:—"We find there was no contract for two negatives, but we think the plaintiff should receive the one negative on payment of five guineas."

The Chief Justice said that was in effect a verdict for the defendant. He would, however, endeavour to give effect to the recommendation of the jury by giving leave to the plaintiff to move to that effect.

Verdict for the defendant, with leave for the plaintiff to move to enter the verdict for him with nominal damages of £20, if the Court could be of opinion that effect could be given upon the pleadings to the recommendation of the jury.

The case occupied the whole day on Friday, the court sitting until nearly eight o'clock. A very large number of photographers were in attendance during the action.

## COPYRIGHT IN WORKS OF ART.

A new copyright bill, of great interest to photographers, was read for the first time on Thursday the 27th ult. in the House of Commons.

The Solicitor-General said that the law on this subject was at present in a very imperfect and anomalous condition. A copyright had been created in books and other subjects. With respect to the fine arts, two series of Acts had been granted, giving a copyright of a limited and special nature. In 1735 an Act was passed giving a copyright in prints and engravings, but awarding no protection to the pictures from which they were taken. In the present reign that protection was extended to lithographs. Another series of Acts gave copyright to sculptures, models, and casts. That was the extent to which works of fine art were protected in this country. It might appear a singular thing that while an engraving enjoyed protection the picture from which it was taken should be divested of any protection at all. Yet that was the present state of the law. This, the principal evil he proposed to remedy, was almost peculiar to England. Foreign countries, by international copyrights, were enabled to give us whatever we gave them. In almost all these countries the principal of copyright extended through the whole range of the fine arts, and especially existed in regard to pictures. The periods for which copyright were given in this country varied rather arbitrarily. He had taken as the period of copyright for pictures, drawings, and photographs, the period of life and seven years beyond. That was one period adopted in Mr. Serjeant Talfourd's Act giving a copyright in books. He believed that this limited protection for life and seven years beyond, would be satisfactory to artists, and this protection would extend to every painting, drawing, and photograph, to be hereafter made and for the first time disposed of. He had not thought it expedient to make the Act retrospective, so as to give a copyright either to the painter or purchaser of pictures, &c., already parted with. The Bill proposed to give the purchaser the copyright as a matter of course, unless the copyright were especially reserved by the author. He did not propose to extend the protection beyond paintings, drawings, and photographs. The Bill would give the ordinary legal remedies and penalties to secure copyright. Another object was to put a stop to a considerable trade which had grown up in spurious pictures, the manufacturers of which, counterfeited the marks and monagrams of artists of eminence, whose reputation suffered by the fraud, while the public were imposed upon. The Bill proposed to make this offence a misdemeanour, and to protect artists against frauds. The Bill somewhat differed from that of last year. It was simplified, and some of the more questionable provisions of the measure of last year were omitted. In the previous Bill there was a provision that, even in cases where there was no subsisting copyright, and where any one was at perfect liberty to engrave a work, the name of the author should not be affixed to the republication. That did not appear to him a reasonable provision, and he had not retained it. In other respects the Bill was much simplified. The penalties would be found to be not so severe as before, some having been omittted and others modified. It was of considerable importance in the present year that such a Bill, if the principle was approved by the House, should be passed with despatch; otherwise foreign artists who had a copyright in their own country in those works which we were most anxious to see in the Great Exhibition, must either withhold their contributions, or expose themselves to the danger of having their rights invaded.—(Hear, hear.) He begged to move for leave to bring in the Bill.

The motion was agreed to, and the bill having been brought in, was read a first time.

## Proceedings of Societies.

### London Photographic Society.

The usual monthly meeting of the Photographic Society of London was held in King's College on the evening of Tuesday, March 4th, James Glaisher, F.R.S., in the chair.

The minutes of a previous meeting having been read and confirmed, Mr. C. F. Bailey, was elected a member of the society.

The Secretary called the attention of the members to some photographs illustrative of the works of Sir Christopher Wren, taken on dry plates by Mr. Cole. Some of the pictures exhibited much softness and delicacy. A letter was read from Herr Kohnke, accompanied by some specimens produced without the use of chloride of silver, or hyposulphite of soda. The purport of the letter was similar to that addressed to the North London Socity, and read at its January meeting (see p. 23). Some conversation on this subject followed. A number of sheets of albumenized paper, prepared by Mr. Watson for Mr. Bourquin, were placed upon the table, and any member was invited to take samples for trial.

Mr. Joubert then read an interesting paper, tracing the history of photography, more especially in its application to ceramic wares. The paper will appear in our next. Some very fine specimens of enamel photographs were laid on the table.

Mr. Shadbolt congratulated Mr. Joubert on the marked improvement in his specimens since he had last seen them. He suggested to him, as a means of avoiding the reversal of the image, the production of direct transmitted positives, by exposing the negative for a few moments to light, just at the commencement of development.

Mr. Joubert was obliged for the hint, and would try it. The specimens to which Mr. Shadbolt referred were reversed; but he now avoided the reversal of the image, by producing his transparency in the camera, placing the negative with the film towards him.

Mr. H. Pollock asked whether, in the specimens containing a variety of colours, the skill of the painter was necessary?

Mr. Joubert stated that the pictures were produced at first in monochrome, and were then tinted by the careful application of ceramic colours.

The Chairman, in proposing a vote of thanks to Mr. Joubert, expressed his great satisfaction with the progress of enamel photography, as illustrated by the specimens before them, which now seemed scarcely to leave room for improvement.

Mr. England then exhibited a very fine series of transparencies from instantaneous and other stereoscopic negatives, consisting chiefly of Paris street scenes and interiors, and of American scenery. The views were projected on a screen about ten feet square, giving an amount of amplification, roughly estimated, of about forty diameters. They were illuminated with the oxyhydrogen light, using the common carburetted hydrogen at hand in the room, instead of pure hydrogen. Notwithstanding the large amount of magnifying power on pictures taken with lenses of very short focus, the effect was highly satisfactory, the distortion in the street scenes of Paris being scarcely perceptible. Some of the latter, in which every detail, even on the shadowed side of crowded streets, was well made out, whilst there were fine natural skies, with light clouds, elicited much applause; as did also the interiors of the church of St. Etienne du Mont, and the scenes in the Bois de Boulogne, and on the Niagara.

In answer to various questions, Mr. England stated that the transparencies were produced on tannin plates. The majority of the negatives were taken by Mr. Dallmeyer's stereoscopic lens of short focus. He developed his negatives with iron. In taking the instantaneous pictures he used a half-inch stop.

After a vote of thanks to Mr. England,

The Chairman said Mr. Claudet had addressed a letter to their Secretary, relative to an exhibition of photographs, independent of that at the International Exhibition. He would read the letter to the meeting. After stating that a general impression existed that another exhibition was desirable, and that it ought to be under the auspices of the Society, the letter proceeded as follows:—

"When we consider that a single building, however great it may be, is to contain the works of art, science, industry, and manufacture of all the world, it could never have been expected that all applicants should have been admitted, and that there should have been space enough for holding all their productions. It is, indeed, to be wondered how the Royal Commissioners have been able to grant 3,000 square feet for the display of photographic pictures. Supposing that the vertical space of hanging photographs should be 5 feet (and it can hardly be so much for a convenient sight), that gives a length of 600 feet, or about 1-9th of a mile of wall in the building. Such a space, certainly, is as much as could ever have been devoted to a single branch of productions. Therefore it would be unjust to complain, and unreasonable to ask more for photography alone. There is no remedy on that score.

"But if, owing to the great number of photographers who are to exhibit, every one has a space in which he cannot display specimens of every kind of photographs, how can he show his capabilities? One of the new features of photography is the enlargement of small photographs by means of the solar camera. Now, suppose that a photographer would have to exhibit only two portraits as large as nature, in suitable frames, one of a lady and one of a gentleman, these two portraits would occupy the entire space allotted to the most favoured.

"Foreign photographers, working in a more favourable climate, where they can operate nearly every week all the year round with the sun, will be able to exhibit those kinds of enlarged pictures, portraits, or landscapes, and if, with immense difficulty under our cloudy sky, we have been able in England to produce such photographs, we shall be prevented by want of space from exhibiting them at all.

"Besides, every photographer who exhibits painted portraits must also exhibit copies of the black photographs which have served to the painters, in order to show the accuracy of the likeness. How can he display the number of pictures exemplifying the various styles of the art? Must he not show how he can treat every subject of portraiture—groups, old and young of both sexes, children, white and dark dresses, uniforms; in fine, all that is constituting the difficulties of photography? The fact is, that photography for the whole United Kingdom cannot be fairly represented at the International Exhibition in 3,000 square feet: it cannot but be incomplete and unsatisfactory.

"I consider that it is the duty of the Protographic Society of London to protect the interest of the art it represents, and to endeavour to prove to the world who is invited to London, that photography in this country has had its share in the wonderful progress made since the Great Exhibition of 1851; that, notwithstanding the absurdities of ignorant and prejudicial writers, the jealousy of incapable *soi-disant* artists, it has attained the highest perfection, and deserves to be ranked among the fine arts.

"The opportunity should not be lost. Let it not be said that those who come to London from all the centres of civilization and knowledge, in order to witness the progress of arts, sciences, and manufactures, the wonderful feats of an era of peace and reason, had no other means of judging the state of photography in England than to see in some parts of the building of the Great Exhibition, not an exhibition of photography, but only, as it were, a catalogue of all those who have worked in the hope of being able to exhibit their productions.

"When it is known that, besides the few specimens of every photographer admitted at the Palace of the International Exhibition, there is somewhere in London a special and complete exhibition of photography, there is no doubt that all those who take an interest in the progress of the art will come and visit this exhibition. There nothing will distract their attention, and they will be able to devote all their mind to study and examine the works of photography, guided by a catalogue full of all the particulars required, and aided by any explanations they may require from competent officers appointed for that purpose.

"The Photographic Exhibition should be in London; and it is supposed that a proper and convenient building may be found in some central part of the town, capable of holding all the numerous and varied works which will be proposed for the exhibition of photography.

"A very simple scheme to secure the success of the undertaking in a financified point of view, would be the entrance fee of 2s. 6d., 1s. to 6d. for specified days and evenings, added to a moderate rent charged to every exhibitor in proportion to the space occupied; this would, it may well be supposed, not only cover the expenditure, but leave a surplus at the credit of the account.

"Before engaging the building and organizing the exhibition, it would be necessary to open a list of guarantors for the success of the Exhibition, in order that the Photographic Society should in no case be exposed to suffer from any excess of expenditure over the receipts. Nothing should be done before having ascertained, by another list, the space demanded by every exhibitor, and having received his engagement to fill up the space occupied, and pay the amount according to the price fixed.

"I propose that the Council of the Society will allow that the question of a separate exhibition under its superintendence should be discussed at the next meeting; and I hope that the reasons I have given for its propriety, and showing its advantages, will induce the Council to have the plan carried out.

"The immense concourse of visitors who will be attracted to London during the time of the International Exhibition of 1862, as it was the case at the time of the Great Exhibition of 1851, will flock to all the minor exhibitions, so that it cannot be doubted that a well managed and complete exhibition of photography will prove to be an excellent commercial speculation, and afford to the Photographic Society the occasion of increasing the fund, which is so essential for the protection and welfare of the art of photography in England.—I am, dear sir, yours very truly, "A. Claudet.

"*February* 21.

"P.S. I see, in this day's number of The Photographic News, that the South London Photographic Society is proposing a Photographic Exhibition at the Crystal Palace at Sydenham. Certainly, such an exhibition would be better than no exhibtion at all, and the proof of it is, that for several years there has been an exhibition of photography there, and that, besides this gratuitous display, several professional photographers think it their interest to pay very high rents to exhibit their specimens in various courts of the Crystal Palace, in order to get customers among its numerous pleasure-seekers. But I am convinced that the Crystal Palace is not the proper place for a serious exhibition of photography. We want an exclusive exhibition in London, under our own management, where people will go for no other purpose than to examine the productions of photography, to judge of its progress, study both its scientific and artistic characters, and compare the various styles of the art. This cannot be done in the midst of singing, concerts, and all the frivolous gaieties of the Crystal Palace."

The Chairman, after reading the letter, stated that it had been determined by the Council to bring the matter before the Society at large, and he would now be glad to hear any suggestions on the subject from members.

Mr. Sebastian Davis said that the South London Photographic Society had been in communication with the Crystal Palace Company with a view to opening an exhibition of photographs, in addition to that to be held at Kensington. He was happy to say the directors of that company had come forward very liberally, and placed at their disposal a large space in the first gallery immediately over the central transept, and had also added some other advantages. The South London Society had acted cautiously in this matter. Not only was the exhibition intended to be in no way opposed to the International Exhibition, but they had waited until they understood that the Photographic Society of London did not intend to hold an exhibition before they took definite steps in the matter; and they would now have pleasure in co-operating with this society in any way in the matter.

Mr. Shadbolt had nothing to say against a suburban or provincial Photographic Society holding an exhibition of its own, but that was quite a different thing to *the* exhibition which ought to be held by *the* Photographic Society of London. He agreed entirely with the arguments of Mr. Claudet's letter, and especially in relation to the Crystal Palace not being suited for the exhibition wanted.

Mr. Durham said the great difficulty was the place. The Council were perfectly willing to have this exhibition if that difficulty were met. He had recently been engaged, with three or four others, in seeking a place for an exhibition, and they spent a whole fortnight without any success. He believed it would be quite impossible to find a place large enough at anything like a reasonable expense.

Mr. Shadbolt did not think expense at such a time should be an object. He thought that a place might be found. There was the German Fair in Regent Street, opposite the Polytechnic, perhaps might be obtained. Perhaps those rooms in the Polytechnic, which were entered from Cavendish Square, might suit; or possibly some of the rooms in St. James's Hall.

The Chairman said, regarding the German Fair referred to by Mr. Shadbolt, he believed they charged very high. The rooms in the Polytechnic referred to were not, he thought, suited to such an exhibition. Perhaps the best plan would be for members interested in the subject to obtain further information as to the rooms and communicate with the secretary.

Mr. Nottage suggested the formation of a sub-committee, say consisting of Mr. Claudet and Mr. Shadbolt, to enquire and report.

After some further conversation on the subject

Mr. Henry Pollock said, the short time seemed to him an insuperable difficulty. Time would be required to get the names of guarantors, and he scarcely knew what gentleman would like to come forward to undertake a possible loss without any chance of gain. Time would be required to get the building, to issue advertisements, to collect photographs; and he thought May would arrive before these things could be done. Regarding the limited space at the Kensington Exhibition, it would be better for visitors to complain of want of quantity than want of quality. He thought the matter would be better left in the hands of the Council, who, he conceived, were fully able to manage the affairs of the society.

Dr. Wright thought Mr. Claudet did not intend that the exhibition should necessarily open on the first of May; but some time during the period in which visitors would be in London.

The Chairman said perhaps it might be desirable that the meeting should know that this subject had been discussed at a former meeting of the Council, and it was then decided that the society would not be justified in taking action in the matter, but that the steps for promoting such an exhibition should be left to those more personally interested in the matter.

Mr. Radcliffe said he was recently one of a committee for holding a large bazaar. The cost of the only room in St. James' Hall, suitable for the purpose, was £90 for three days

It was finally determined that any member obtaining further information on the subject, should communicate with the secretary; who would, if necessary, call a special meeting of the committee. The proceedings then terminated.

## Correspondence.

### FOREIGN SCIENCE.

[From our Special Correspondent.]

*Paris, 5th March*, 1862.

There will be a Photographic Exhibition at Amsterdam in May next. The International Society of Arts is now busy making arrangements for its fourth exhibition of works representing every department of the photographic art. The exhibition will remain open three months from the first of May next. All the specimens, &c., intended for exhibition must be addressed to the Secretary, Dr. J. A. Van Eijk, before the 20th instant, accompanied by a note indicating the number of specimens sent, signed by the exhibitor, with a summary description of the process by which the proof or proofs have been obtained. Any subsequent information as to processes, methods, &c., will be thankfully received. The specimens must be sent in a portfolio, without frame or *passe-partout*. They will be framed and glazed by the Society, at its expense. The Society will also pay the expense of carriage to and fro. Exhibitors who desire to sell their proofs must send the price, under cover, in a note addressed to the Secretary, and no proof can be removed by the exhibitors before the close of the exhibition.

With reference to M. Niepce de Saint Victor's last researches in Heliochromy, M. Chevreul has taken occasion to call the attention of the Academy to two important facts; *the first* is that the image produced by the sun is direct and not reversed, like all the images produced by other processes; *second*, that the light whitens the part it falls upon by a peculiar action of the dextrine varnish containing chloride of lead, while without this varnish it turns the chloride of silver of the Daguerrean plate violet, giving a very remarkable result, as M. Niepce has observed that the black lines of an engraving are reproduced in black on plates prepared with his varnish. The colours of the model are not all produced concurrently; for example, yellow makes its appearance before green, and by the time the latter has come out the yellow is enfeebled, if not effaced. Does it not then follow, he asks, that a means of faithfully reproducing the colours of the model consists in having screens cut out in certain portions, with which to cover those parts of the model where the colours that manifest themselves the soonest exist, so as to give to the colours which require longer to manifest themselves, the time they require. It seems very desirable, he adds, that a skilful and experienced chemist should endeavour to recognise the molecular actions which sensitive materials undergo in ordinary photography and in heliochromy.

At the last meeting of the Academy M. Paul Desains exhibited some photographs which he considered very suitable for facilitating the study of the fascinating science of optics. These consisted of photographic representations of the figures which the luminous ray depicts when projected on a screen, and in its passage through a crystal of one or of two axes, has undergone double refraction. The curves obtained in this manner, and which are intersections of the surface of undulation, circles or ellipses, give, in fact, a very correct idea of the path of light. The projections were given by the well constructed apparatus of M. Jules Duboscq, in which either solar light or electric light may be employed.

Signor Polli, of Milan, has made some very remarkable experiments with a new antidote, which, if verified in practice, will lead to unexpected results in therapeutics. If putrid blood, or the glanders mucus, or pus, be injected into the femoral vein of a dog, general infection very soon manifests itself of a certainty. But if, some days previous to the operation, we administer to the dog some *sulphite of soda* (150 grains in five days), the animal only experiences symptoms of disturbance during the first day; it is dull, and refuses its food; but soon recovers its appetite and liveliness. Whatever may be the theory of this phenomenon, the result is so important as to claim the attention of all hygienists, and cannot receive too much publicity.

The question of copyright in photographs has lately been tested at Milan, in Italy, where Sig. Duroni, who had published a portrait of King Victor Emmanuel, accused one Tuminello, of Milan, of having issued pirated copies of this portrait, and brought him before the Tribunal of Commerce, claiming damages and the destruction of the counterfeits. But the Tribunal declared its incompetence to interfere. Like the Tribunal of Paris, it regards "photography as a purely mechanical process, in which, it is true, the photographer may display more or less skill, but without ever having any right to be classed, as an artist, among those who, true professors of the fine arts, exercise mind and imagination, and sometimes genius based on the principles of art. But the photographer neither draws nor paints, he has only learned to work a machine he may have bought, and put in action certain chemical operations necessary to the obtaining a pictorial result; his mechanical labour cannot, therefore, give birth to products which may justly be ranked among the productions of the human mind."

The plaintiff lost his cause, and was condemned to pay costs.

## COMPOUND LENSES FOR VIEWS.

Sir,—Allow me to offer a few remarks in reference to some statements put forth at the last meeting of the North London Photographic Association (see Photographic News, page 106). A member is there reported as having stated that Mr. Wilson, of Aberdeen, has "abandoned compound lenses for landscape purposes," and returned to the use of single combinations; and again, that he (Mr. W.) "was giving up" the taking of the other size picture (meaning, I suppose, those plates $7\frac{1}{4}\times4\frac{1}{2}$), "as he found they did not sell." Now I beg to say that this is *not* the case, for so far from Mr. Wilson abandoning compound lenses, I need only mention the fact, that amongst other things, I am just about sending him two more lenses of the same kind; and as to the pictures not selling, they have *never* as yet been offered for sale at all; indeed, the numerous enquiries after them have probably induced Mr. Wilson to expedite his bringing them before the public; for I learn from him this day, that the triplet views are to be published by Messrs. Marion on the 1st of May, but he is "anxious to have some stock of them printed before they are announced." The member whom I have quoted must, therefore, have been misinformed.

With regard to some other observations made at the same time, about the angle included in pictures of different forms or shapes. Photographers generally appear to be quite aware of the fact that by measuring the *diagonal* of any given size picture, they have at once the capabilities of the lens; but since the shape of Mr. Wilson's pictures occasions the remark, I may as well state that the No. 1 triple achromatic lens ($7\frac{3}{4}$-in. equivalent focal length), and used for plates $7\frac{1}{4}$ by $4\frac{1}{2}$, covers a plate 7 by 7 also, as can be seen by a picture in my possession. However, Mr. Wilson and others would seem to prefer the oblong form, independent of the convenience attending the use of the same size plate and camera for stereoscopic views. Those interested in the subject of the the respective angles included by the single combination view lens, and the No. 1 triple can readily satisfy themselves by inspecting two prints kindly sent me by Mr. Wilson, taken with both kinds of lenses from the same spot, from which it appears that the picture taken with the triple contains about $\frac{1}{3}$ more of subject or angle (definition being equal), and Mr. Wilson is led to conclude that nothing short of a 10-in. focus view lens would cover the same size plate for which he now uses the No. 1 triple.

In conclusion, permit me to say a word or two about the adaptation of a particular lens, for a particular given purpose. It is now an acknowledged fact that the triple lens is entirely free from distortion, and on that account is not only the most suitable lens for copying, but *especially* also for architecture, or indeed wherever a correct and faithful representation of the original is required. The good quality, moreover, said to be possessed by the orthographic, that when "titled" it reproduces straight marginal lines (otherwise known to be a lens reproducing all straight marginal lines pincushion shaped) is truly a fallacy, for a little consideration will render it obvious, that when thus used, all marginal lines on the lower half of a plate, will be more distorted (leaning inwards) than when taken with any other form of lens, and that it is only in the upper half of the picture where any amelioration takes place.

Apologizing for the intrusion in your space—I remain, Sir, your obedient servant, J. H. Dallmeyer.

19, *Bloomsbury Street, March 5th*, 1862.

## Photographic Notes and Queries.

### The Alkaline Dry Process.

Sir,—In conformity with the wish of Mr. Young, I hope you will grant me a short space for a few remarks about the alkaline dry process.

I do not think that the markings E. T. mentions are caused by any combination between the soda and gelatine, and I am at a loss to account for his success after washing off the soda, in my hands such a proceeding resulted in failure. I believe I am indebted to E. T. for a private communication (from the similarity of the letter in the News), and he there states that he developes with pyrogallic acid, and consequently it is slower than iron development, which I have always adopted, and is, to my idea, much to be preferred; apply the gelatine solution hot, say at least 100°, avoid scratched plates, use rapid iron development, and intensify with pyrogallic acid, and I think the finest results will be obtained.

But I feel sure that others must have tried it, and I hope they will come forward with their experiences, and not prejudice a process, like a gentleman did a few weeks back, in the News, when he stated (with regard to the caramel Fothergill process) that he did not think that caramel could have any accelerating effect on a Fothergill plate, I have tried it over and over again, and I say that it does, have proved it, and recommended him to try it and dispel his doubts. I have another treatment for mealiness to recommend, from personal trial of its merits, viz., make your sensitizing paper bath *alkaline* and tone without the intermediate acetate bath as usual.—I am, sir, yours respectfully, Wm. Bartholomew.

*Fareham, Hants, March 1st*, 1862.

## Talk in the Studio.

Extremes of Comparison.—"They [things altogether unlike] resemble each other no more than do the photographs taken by the leading West-end artists the awful likenesses displayed at the doors of those delusive proprietors who plant bullies on the pavement opposite their premises to worry and torment the passers-by."—*Daily Telegraph.*

Robbery of Specimen Cases.—Mr. Ewin, of the Old Kent Road, writes to us as follows:—"I had a show frame, with 20 carte de visite portraits, stolen from outside of my house on Friday evening. As the Inspector of Police informed me that robberies of this description were very prevalent just now, I thought I would write to you, that you may kindly be induced to give it insertion in next week's News, that it may put photographers on their guard, and probably assist me in discovering the delinquent. Last week, a fellow was taken up on suspicion of stealing a specimen case, in which a scuffle ensued, and the case got broken. The fellow demanded 15s. damages. He was allowed to depart, as there was no proof of his stealing it; he returned in two hours for the amount of the damage; in the interval, the party having lost the case made application to the police respecting it. Of course, when the scamp returned, instead of receiving the 15s., as he expected, he was locked up for stealing the case, which he was proved to have done." Photographers will do well to take the hint, and make their cases secure.

A Hint on Plate Boxes.—M. G. Quincy Thorndike, a correspondent in the United States, sends us the following:—During my travels this past summer I made use of dry collodion plates. As economy of space is a great desideratum when "living in a trunk," it occurred to me that much room was wasted in the present style of plate-box, and that a great improvement could be made thereon. I have adopted the following simple plan, which is successful:—I had a box made similar to an ordinary plate-box, with the exception that, instead of grooves being cut in the wood with the distance of one-eighth of an inch between them (which is the space lost), narrow cuts are made the depth of the box, with a fine saw, of the thickness of an ordinary playing-card, to the depth of one-eighth of an inch. These are made of the thickness of a plate apart—say an eighth of an inch. Into these fine grooves a strip of *glazed* cardboard three-eighths of an inch wide is inserted, with a little gum, which is unnecessary if the cardboard fits tightly, so that a box (old style) of the size necessary to hold *twenty-four* plates can be made to contain *forty-two* plates. Besides the advantage of containing nearly double the amount of plates, there is this superiority over the other method: the plate, when introduced, is not so apt to cut the glazed cardboard partitions, as it invariably does when the sides are of wood, thereby producing dust.

## To Correspondents.

J. M.—Most of the intensifying processes which are used after the picture is fixed may generally be conducted in daylight without risk. In using pyrogallic acid and silver, however, we prefer to avoid white light, as there is some risk of general reduction and fogging.

Wm. Creach, Jun.—The specimen of glass, flashed on one side with ruby, and on the other side with yellow, completely obstructs the passage of all actinic rays; allowing none but the red to pass. Cutting off the luminous, but non-actinic yellow rays, it repels a great deal of light; and it would, we fear, be somewhat trying to the eyes. It may, however, be used with perfect safety with either the iodide or bromide of silver. The yellow flashing only, as tested, where the ruby is ground away, is quite inefficient, allowing all the green rays to pass, and traces of the blue rays.

W. O. W.—If you have read and tried the various suggestions on the subject of mealiness, which have appeared in our pages without success, we fear we cannot help you. Do you take care to have the toning bath mixed at least 24 hours before using it? Try that, if you have not done so. Some recent correspondents tell us that they find keeping the exciting bath quite neutral a remedy. Have you tried the use of distilled water in washing and preparing the gold bath? A change of paper is often the best remedy in desperate cases.

T. H. McAllan.—We can only counsel you to use a cone with the inside blackened attached to the lens to cut off diffused light, and to see that the inside of the lens and camera is well covered with dead black. Read the articles on apparatus at present appearing in our pages. The figure taken in the room does not appear to be sufficiently well lighted. 2. We prefer a twin-lens camera for stereoscopic pictures. The lenses may be about three inches apart. Your lens appears to cover card portraits pretty well.

B. Mew.—The term "correct," as applied to any formula for developing, is scarcely applicable. Either of the formulæ you name, or any modification of them, may be used; but in making modifications, judgment and experience are necessary. Try both the formulæ, and adhere to that which gives you the best results.

Fothergillian.—1. Your selection of a plain paper process will depend much on the kind of results you wish to obtain, and the class of negatives from which to print. If your negatives are weak, the ammonio-nitrate process will give the most vigour and depth. Some of the finest plain paper prints we have seen for some time were on arrowroot paper, according to the formula given in our 4th volume. 2. You must remember that as we do not work out every suggestion given by our correspondents, we cannot always undertake to be the exponents of the exact advantages proposed. We give publicity to such suggestions as appear worthy of attention, and the best mode of ascertaining the worth or relative advantages of any two given processes, is to try them. 3. A hot brick or jug of water is an excellent aid to the drying of Fothergill plates. 4. We cannot recommend the collodion of any especial maker; indeed, different samples from the same makers often vary. The best plan is to have a small stock from the different makers on hand, and mix them in such proportion as a little experience of their qualities may suggest. 5. We cannot tell you why the lenses you use are sold cheap, or whether they are good or bad, as you do not say by whom they are made or sold. If, however, you are satisfied with the quality of the one you have purchased, there can be no reason why you should not buy another like it. 6. The correspondent referred to said he had taken all the precautions you suggest.

J. H. Jones.—We will write to you shortly.

S. J.—Pure silver may be obtained from nitrate of silver by precipitating it with common salt, and then fusing the chloride in a crucible with double its weight of a mixture of carbonate of potash and soda. The silver may be recovered from filtering papers and clippings of prints, by burning them and fusing the ashes, as described above, or with borax and carbonate of soda. The gold may be precipitated from a solution of its chloride by means of protosulphite of iron.

A Constant Subscriber.—It entirely depends on the arrangement the gentleman made with the artist who took the original negative. See our first article in this number. 2. There is no reason why a new bath should serve you as you describe, unless you have failed to saturate it with iodide of silver.

Tyro.—We have not tried the formula, but it strikes us that a large proportion of borax is desirable. We believe some samples of the bleached shellac are considerably adulterated, which may also account for your failure in effecting solution.

J. P.—The difficulty you describe is what is generally known as *mealiness.* Read the various communications in our pages on the subject.

A Young Photo.—You will find full instructions in the calotype process in our first volume. The process there given is substantially the same as that which Dr. Diamond practised, and his calotype negatives are the finest we have seen. We have not tried Mr. Long's formula, but have heard it described as impracticable.

Despair.—The fault is probably in your silver bath. Make a fresh one and try. Or, test the bath to ascertain whether it is acid or alkaline. If the latter, add a trace of nitric acid. If the former, it is probably from an accumulation of nitric acid; in which case neutralize with freshly precipitated oxide of silver or carbonate of soda, and then slightly acidify. Several correspondents have informed us that they have tried the suggestion given some time ago in our pages, of adding a little cyanide solution to cure a foggy bath, with the completest success. If the bath be neutral the addition of a little free iodine to the collodion will often prevent fogging.

W. G. G.—Lime is only soluble in alcohol when it contains water. Oxalic acid, or a soluble oxalate, is the test for lime; a precipitate of oxalate of lime being thrown down from the most dilute solutions.

W. Bartholomew.—We are unable to say, certainly, which of the view lenses you name is the quickest. We should choose either 2 or 3 in preference to 1, as regards defining power; and as No. 2 can be used with the largest aperture perhaps it may be quickest.

N.—Nothing is more easy than to make a collodion which shall produce negatives which do not require intensifying; and in the days when intensity was the *summum bonum* in a negative, such a collodion was in demand. Occasionally delicate and soft pictures were obtained; but not one in ten would compare with those now considered good. The use of bromo-iodized collodion and iron development has brought softness, delicacy, and detail; but it has also rendered intensifying frequently necessary. This, if properly done, *does* increase the scale of the picture, for it adds to the density of the lights; but does not alter the deepest shadows, which should be bare glass. We endeavoured to explain the philosophy of this question in the Photographic News Almanac, in articles on modes of development and intensifying. We shall probably recur to the subject again when we have time. 2. There are three qualities desirable in a dry process; namely, certainty, rapidity, and simplicity. The first, we believe, is best attained in the Taupenot process; the second and third quality are now being anxiously sought by experimentalists. Washed collodion, without preservative, appears by far the simplest process; and it is not improbable may be found to give the greatest sensitiveness; but it has not yet established its certainty. The process to which you refer we have not tried. It may probably be efficient, but it is not particularly simple, as it involves three operations. The plates would not keep; and there would be some liability to stains. We believe all dry plates will keep some hours between exposure and development without deterioration. Dr. Hill Norris believes there is a gradual tendency to return to the normal condition. 3. We do not know of a photographic architect. On p. 73 of our third volume there is some practical information on the construction of glass rooms, and we hope to give some further details shortly. 4. We have not tried the suggestion of S. H., but have generally added ammonia to the albumen solution.

Sigma.—Specimens for the Exchange Club should be sent to the secretary to be submitted to the referees. We should think good prints from your negatives would be accepted. Your queries in our next.

John Hawke.—Your specimens are admirable. The tones of these are very fine; but we like the former ones as well. The balustrade is much better, being lower in tone than it was before. We will write to you shortly.

Rher. Rd.—We are obliged by the specimens. We will examine and report upon them in our next.

R. H. C., An Old Sub, Bolus, P. R. A., R. D., W. Larchin, Tripod, T. Burgoyne, and several other correspondents in our next.

All Letters, Works for Review, and other Communications for the Editor, should be addressed to 32, Paternoster-Row.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 184.—March 14, 1862.

## SUPPLEMENTARY PHOTOGRAPHIC EXHIBITION.

If further argument were necessary to set forth the necessity of an exhibition of photographs, which shall more amply illustrate the present position of the art, than can possibly be effected in the limited space to be devoted to the purpose in the International Exhibition, the able letter of M. Claudet, read at a meeting of the Photographic Society, and published in our last, puts the matter beyond a question. Not a tithe of the pictures of ordinary size which it is desirable should be exhibited, can be accommodated at South Kensington, whilst as regards anything like a fair display of the productions of the solar camera, which undoubtedly constitute a feature of the utmost importance, as illustrating the art as now practised, the case is hopeless. We do not however, so entirely agree with M. Claudet in his view of the unsuitableness of the Crystal Palace for such an exhibition. Many of the qualifications necessary in a place for a large exhibition of photographs the Crystal Palace possesses in a pre-eminent degree. Ample space and hanging convenience, a most perfect light, and the utmost publicity will certainly be secured. And as regards the drawbacks supposed to exist, which will prevent the serious examination and comparison desirable, we must remind M. Claudet, that the "singing, concerts, and frivolous gaieties" to which he refers, are only present certain days, and even then are confined to certain hours of those days, and need never, therefore, act as a barrier to the most thoughtful contemplation which any enthusiastic lover of the art may desire to bestow on its productions. It is with pleasure, therefore, we call attention to the regulations for exhibitors, intending to contribute which we publish on another page of our present issue.

At the same time we see not the slightest objection to the formation of another exhibition, either under the auspices of the parent society, or got up and sustained by private enterprize, if M. Claudet's scheme can be carried out. We must confess we see grave difficulties in the way, both as to time and place, and also as to funds. It is possible indeed as regards the latter that the plan of obtaining a number of guarantors, ready to bear any probable loss, might possibly meet the difficulty. Sometime ago, we had personal applications from several gentlemen, who, when it was understood the society's exhibition would not be held, asked us to aid in initiating such a scheme. One gentleman was willing to put down his name for some hundreds: others, doubtless, would have followed. But then came the difficulty of forming, independent of any society, a working committee. Next came what proved, on inquiry, the still greater difficulty, of obtaining a suitable place. To these would now have to be added another difficulty quite as great: the limited time in which to take all the necessary preliminary steps to make arrangements; for unless such an exhibition were opened some time before the month of May were passed, much of the *préstige* of such an undertaking would, we take it, be lost. The influx of visitors to the metropolis will, doubtless, be great throughout the summer; but it is during the month in which the World's Fair will be inaugurated, that the greatest number of persons from all parts of the world may naturally be anticipated. Nevertheless, if the difficulties can be overcome, and the necessary facilities of all kinds can be provided, by all means let us have another exhibition; and the more central the place, the larger the accommodation, the more numerous and perfect the contributors, and the more complete the arrangements the better. All the aid and publicity we can give it shall be willingly recorded.

As we have before remarked, it was not until the parent society had not only announced that its annual exhibition would not be held this year, but after it had received and considered in council a renewed application to hold an independent exhibition, and had come to a resolution that it was not desirable that it should take any steps in such a matter,—it was not until they were acquainted with all this, we say, that the South London Society began to make any definite arrangements for holding an exhibition at the Crystal Palace. For whilst every society, "suburban or provincial," has doubtless the right to hold an exhibition of its own, it would not have been deemed wise or right by the South London Society to initiate any movement which would have had a tendency to divide the interest, or divert any contributions from any exhibition in connection with the parent society. The arrangements for their exhibition are now presented in a definite form: the committee will, we doubt not, gladly receive co-operation of any kind either from independent photographers, or from members of other societies, as such; their aim being simply a worthy illustration of the art as it now exists, at a time when such an illustration may receive the utmost publicity and recognition.

## HINTS ON ROLLING PRINTS.

The rage for card portraits has introduced into the atelier of the photographer as a necessity, an instrument which at one time few dreamed of indulging in, even as a luxury: we refer to the Rolling Press. In the early days of photography the professional portraitist would have deemed it slovenly in the highest degree to send out a picture without a case or passepartout. Now, however, the simply mounted print, of whatever size, with suitable margin, has become the rule, and some means of calendering without sending out to the hot presser, has become, as we have said, a necessity. Until very recently all the presses of this kind were of French manufacture, and were imported into this country. Since the demand for them has increased, however, English machinists have given their attention to the matter, and presses of first rate quality are to be had of home manufacture.

We have lately been using one of the rolling machines manufactured by Messrs. Bury, Brothers, of Manchester, and can speak in terms of the highest commendation of its simplicity, convenience, and efficiency. It is free from unnecessary complication in structure, but is, withal, easy to work and very powerful. The press we have had in use has two four-inch polished wrought iron cylinders, eighteen inches long; between which the bed travels, on which is a very highly burnished steel plate twenty-four inches long by eighteen inches broad. Others of a smaller size, are. of course, made; and are, we believe, quite as efficient. By means of a fly-wheel of fifteen inches diameter, and what are termed "double gearing" cogwheels, an enormous pressure is obtained with very slight exertion, the amount of force in that we are using being equivalent, we believe, to a pressure of forty hundred weight. The wheels for adjusting the pressure at each end of the cylinder are worked separately. We believe it is a moot point as to whether it is better to adjust each separately, or to have them so connected, as, by the turn of one wheel to adjust both ends at once. Our own experience on this point is insufficient to enable us to form an opinion; but in a recent conversation with a photographer who had been in the habit of using machines with both arrangements, he gave a decided preference to the separate adjustment, on the ground that the slightest derangement of the single adjustment gave an uneven pressure, without the means of regulating it.

The results produced by the machine we have been working are in the highest degree satisfactory; a most perfectly even burnished surface is given to the print, which seems to have a similar effect to the varnishing of a painting or polishing of wood; detail before scarcely seen seems to bear out in a most surprising manner, giving the utmost delicacy and finish to the print. Until the trial is actually made, it is difficult to believe the difference in a print which can be produced by the mere change of surface. Of course, this improvement in appearance results from rolling by any good machine possessing a perfectly burnished plate, and giving very powerful pressure. The especial claim to attention which Messrs. Bury's presses possess consists in the fact that whilst they are very strongly made, very easy to use, and very efficient in result, they are also very cheap. As our readers are aware, we are very cautious at any time of becoming the advocate of cheapness, or rather of lowness of price, if efficiency in the slightest degree have to be sacrificed in its attainment. Cheapness, falsely so called, has been the bane of photography, multiplying difficulties and spoiling results. But where moderation in price can be secured, especially in articles necessarily expensive, without any sacrifice of efficiency, we have pleasure in calling the attention of our readers to the advantage. A short time ago, if we are not mistaken, a rolling press of the smallest size cost £12, now they can be purchased without any sacrifice of quality for less than half that amount; a press of the size we have been trying used to be charged something like £40; now it can be purchased for less than one fourth of that sum.

A few hints as to the mode of using rolling machines may not be uninteresting. Of course they must be kept dry. If kept in a dry place, and in tolerably constant use, there is no danger of injury from rust. It is manifest that the highest efficiency should be the first consideration; if that were not the case, brass might, as has been suggested, take the place of the plate of burnished steel, as being much more easily kept in order; but the superiority of the latter, in point of hardness and polish, will fully repay the extra care required in keeping it in order. Where the machine is only occasionally used, especially if it be not kept in a very dry atmosphere, a thin coat of tallow or wax spread over the polished plate would effectually protect it; and under all circumstances it will be wise to have a green baize cover for the hours when not in use, which will protect it from dust, and in some measure from other injurious influences.

Where it is necessary to use very heavy pressure so as to secure the highest surface, it will be found desirable to pass the mounted picture through the press first with a lighter pressure, and then again with the rollers screwed tighter down. The result will be better, and more easily attained than if the heavier pressure were put on at once. This is especially desirable where the print is cockled or inclined to curl, as in that case there is some danger of a crease being formed, which will leave an indelible mark in the print. In rolling unmounted prints especial care in this respect is necessary, as if a print in the crumpled rough state, common to some samples of albumenized paper, be submitted to a heavy pressure at once, creases, which will mark or cut the print, are inevitably formed.

The best mode of rolling unmounted prints is to place their face to the plate under a piece of card-board, and submit them first to gentle pressure so as to get them flat and smooth, and then roll heavier if necessary. There is less danger of the unmounted print being drawn into creases when a piece of card-board interposes between it and the roller than when it is without such protection. In rolling small pictures, such as cards, it is desirable to place several in the press at once, so as to cover the whole breadth of the plate. This economises time and saves the machines. Where one small picture at a time is rolled, and that always in the middle of the plate, the bed gradually gets sunken, and the roller worn in the centre. This renders necessary the refacing of the roller in the lathe, and the substitution of an entirely new bed.

A short time ago we called attention to the great improvement effected on the appearance of a print by mounting with a small margin of India paper, or a tint to resemble it. Another great improvement, giving a satisfactory appearance of finish, is the plate mark. It is probably a purely conventional taste which is pleased with this plate mark; but still the effect is admired. We recently suggested to Messrs. Bury, Brothers, that a series of copperplates for different sizes of pictures to produce this mark, would be useful; they now supply sets with each size of press; but these are not necessarily included with the press, and must, therefore, be ordered separate by those who require them. We may here suggest, however, a very simple mode of getting the same result, without the copper-plates. It consists in cutting a piece of stout cardboard with a fine surface to the necessary size, and trimming it carefully so as to have a true edge with a slight bevel. The print should be well rolled first; the piece of cardboard must then be placed in the right position on the face of the print which must then be passed through the press again; the print will this time be placed on the plate face upwards with the smoothest surface of the cardboard in contact with it, and between it and the roller: care must be used to prevent the roller displacing the piece of card. This will give the plate mark very well; especially if—as where the India tint is used is commonly the case—plate paper be used instead of cardboard for the mount. The effect is worth the trouble, especially whenever an ample margin is present.

We may add, in conclusion, that the press should always be screwed on to a firm bench or table; or, where it is as large as the one we have spoken of, it should have a strong stand of its own; as it is impossible to work with satisfactory pressure unless the machine is firmly fixed.

## Scientific Gossip.

Photometric Experiments—Value of various kinds of Glass as Transparent Media—Effects of Ground Glass—Bouguer's Experiments on Transparency of Air, Water, and Glass—Draper on the Spectrum of Incandescent Platinum—Examination of Coloured Glass in the Spectroscope.

Some time ago* we gave an account of some experiments on the absorption of light by glass, which had been recently tried by Mr. King. The importance of the subject from a photographic point of view is very great, and we are therefore glad to be enabled to lay before our readers some additional experiments on the same subject, which have more recently come under our notice. The experimentalist is Mr. F. H. Storer, and the trials have been conducted with considerable care. The gas employed was prepared from caking coal expressly for these experiments, and was contained in a special gas-holder. The illuminating power of the gas when consumed from the Parliamentary Argand burner, at the rate of five cubic feet per hour, was equal to 16 candles, consuming 120 grains of spermaceti per hour. Instead of lamp shades, which were used in Mr. King's experiments, flat sheets of glass, six inches wide by eight inches high, were fitted to a rack of blackened wire, which was fastened to the photometer bar (100 inches long) at a distance of three feet from the gas-light. It did not appear that the distance from the source of light at which the glass screen was placed had any appreciable influence upon the amount of light transmitted by it. At all events, no such influence could be detected in a number of experiments made purposely to test this question. The experiments were made in a blackened experimental chamber, with a Bunsen's photometer; every precaution being taken to ensure accu-

* Photographic News, vol. v. p. 18.

racy. We may also mention that none of the measurements (of the distance of the photometer from the standard candle) obtained by actual experiment were calculated—*i. e.*, reduced to their equivalent in candles—until the whole series of experiments was completed, and that no comparison of the results among themselves or with those of Mr. King was made until each result was calculated as given below. Whatever the experiments may be worth, therefore, they have at least the merit of being entirely independent and wholly unbiassed. For convenience of reference, we will arrange the results in a tabular form. The first column gives the description of glass employed. the second column the thickness of the sheet, and the the third column the loss of light in per centages, taking the whole amount of incident rays at 100.

|---|---|---|
| "Single German" window glass | $\frac{1}{16}$ of an inch | 4·27 per cent. |
| Thick English plate | $\frac{1}{3}$ " " | 6·15 " |
| Crystal plate | $\frac{1}{8}$ " " | 8·61 " |
| "Double English" window glass | $\frac{1}{8}$ " " | 9·39 " |
| "Double German" ditto | $\frac{1}{8}$ " " | 13·00 " |
| English crown | $\frac{1}{8}$ " " | 13·08 " |
| Orange coloured window glass | $\frac{1}{16}$ " " | 34·48 " |
| "Berkshire" enamelled, *i.e.*, ground only upon portions of its surface, small figure | $\frac{1}{16}$ " " | 51·23 " |
| "Double German." ground | $\frac{1}{8}$ " " | 62·34 " |
| "Berkshire," ground | $\frac{1}{16}$ " " | 62·74 " |
| "Single German," ground | $\frac{1}{16}$ " " | 65·75 " |
| Green coloured window glass | $\frac{1}{16}$ " " | 81·97 " |
| Purple coloured ditto | $\frac{1}{8}$ " " | 85·11 " |
| Ruby coloured ditto | $\frac{1}{16}$ " " | 89·62 " |
| Porcelain transparency (Tyrolese Hunter) | $\frac{1}{16}$ " " | 97·68 " |

On looking over the above results the reader cannot fail to notice the enormous resistance to the passage of light which is offered by ground-glass. This is certainly worth the attention of photographers and others who are accustomed to employ this medium for glazing their operating-rooms, or, indeed, for any purpose where plenty of light is desirable. The term "loss of light" may be objected to as being scarcely appropriate, for a very considerable portion of the light not transmitted by a glass shade might be reflected against the walls of the apartment in which the lamp is burning, and thus aid in the general illumination of the room. The meaning here attached to the term is, however, perfectly evident, and there can be no doubt that the numbers given above express, as accurately as the circumstances of the case will admit, the actual diminution of the amount of light falling, for example, upon the pages of a book held near to its source, which would be occasioned by the interposition of the shade enumerated in the table.

Referring to these experiments, Mr. B. Silliman, jun., suggests that the great loss of light proved by these experiments may be in part, at least, accounted for by the conversion of a portion of the light into heat, an effect perfectly in harmony with the theory of transverse vibrations as applied to explain the phenomena of the polarization of heat. On this theory heat and light are different effects produced by one and the same cause, and they differ physically only in the rapidity and amplitude of their vibrations. The screen through which the vibrations of light are propagated serves to diminish, first the rapidity of the vibrations requisite to produce the most refrangible rays, and in proportion as the transparency of the screen is diminished by any cause, inherent or superficial, this arrest becomes more and more complete. Hence, the loss of light from polished screens is small compared with that observed in screens of opaline or roughened glass. It would be instructive to examine the spectrum obtained from a pencil of rays under each of the cases given by means of a complete quartz train of prisms and lenses.

The subject of absorption of light by screens has long since been carefully examined by Bouguer. By a photometric method, essentially like Rumford's, Bouguer measured the loss of light in the beam of a candle compared with a flambeau and also with the light of the full moon in passing through 16 thicknesses of common window glass having an united thickness of 0·85 inch. The mean loss of light shown by these trials was as 247 : 1 or over 99 per cent. of the whole quantity. Six plates of the purest mirror plate glass, having an united thickness of 15·128 millimètres diminished the light in the ratio of 10 : 3 occasioning a loss of about 70 per cent. of diffused daylight. A mass of very pure glass about three inches thick diminished the light only about half the latter amount owing to its being in a single mass, and not cut up into many planes. He also measured the absorbing power of sea water for light, and found as the results of experiments made in France, and of observations also in the torrid zone, that at the depth of 311 French feet the light of the sun would be equal only to that of the full moon, and at the depth of 679 feet would wholly disappear. He estimated the transparency of air as 4,575 times greater than that of sea water, and from the properties of a logarithmic curve, whose functions he had determined experimentally, he sought to fix the outer limits of the atmosphere. Bouguer was an expert geometer, and sustains all his conclusions by mathematical demonstrations. His results seem to have received less attention than they merit, the only reference to his researches we have seen being by Daguin, in his excellent "Traité de Physique," vol. iii. p. 300. We should not omit, in connection with this, to refer to the very interesting observations of Draper * on the spectrum, formed by means of a platinum wire heated gradually from dull redness to perfect whiteness by a voltaic current. He observed the red part of the spectrum to appear first, and as the heat and brilliancy of the wire increased the other colours of the spectrum appeared after the violet. This result perfectly harmonises with the views above expressed.

C. W.—A specimen of glass has been forwarded to us for examination in the spectroscope. It is a silver-coloured flashed glass, of the peculiar deep orange colour which experience has shown to be so adiactinic. Examined in the instrument it is seen to cut off all the higher actinic rays in a most perfect manner, but upon attentive scrutiny in a bright light we can detect traces of the higher green rays struggling through. As these are actine on bromide of silver it might theoretically be injudicious to make use of this glass, but the proportion of active rays transmitted is so small, that if the window be not exposed to very bright incident light it might be used with safety. At the same time it should be remembered that any future increase in the sensitiveness of the photographic media would increase the possibility of injury from the use of such a glass.

## GLASS OPERATING ROOMS.

BY M. VOYTOT.

Hitherto, when a photographer has wished to construct an operating room, his first care has been to obtain a northern aspect entirely sheltered from the sun's rays; experience had proved that these rays caused much inconvenience, therefore, it was concluded, they must be entirely avoided.

But of late years photography has taken such an extension, that most available northern aspects have become occupied, and the photographer is now content to acquire any position. no matter what the aspect may be, if otherwise suitable. Fully satisfied that the progress of photography will not be checked by a cause which appears to me quite accidental, I have not hesitated to instal myself in a locality, under conditions which most photographers would have considered impossible. I have constructed, in a full southern aspect, on the sixth storey, an operating room, 30 feet long by 10 feet wide, and 12 feet high. As may be supposed, the light is very strong, and sometimes even unsupportable.

* *American Journal of Science* (2), iv. 388 and v. 1.

I quite understood that to modify this light to suit the requirements of photographic operations, it would be necessary to have coloured glass here, ground glass there, and curtains everywhere. I spared for nothing. But like all my predecessors who had employed the same means, I experienced similar disappointment to theirs.

I had been too long engaged in photography not to have encountered many difficulties, which, at first appearing insurmountable, were gradually overcome by perseverance, and often, too, by suggestions made by members of our society. In the present case, therefore, I would not confess myself baffled. I submitted my difficulties to many friends, who gave me very good advice, but I adopted in preference that afforded by M. Dumonteil, which completely solved my difficulty.

His starting point, elementary as it is, is not to be found, that I am aware of, in any treatise on photography. It may be communicated in a few words; if, like all attempts, it be not perfect, it is, at least, in my opiuion, a great step in the way of improvement.

In an operating room with a southern exposure, where there is nothing to intercept the rays of the sun, it is evident that all the space between the camera and the sitter will be inundated with these rays, which are the more intense when they fall direct.

In this state of things the rays proceeding from the sitter to be reflected in the lens are, comparatively, much weaker than the sun's rays, and therefore they arrive at the lens with much difficulty: they are always weakened by crossing the others, and they are sometimes diverted. To intercept the sun's rays without taking away their light, and make them serve to augment those proceeding from the model to the lens, and thus change what was an obstacle into a means of success, such is the problem to be solved.

To attain this end I employ a series of moveable screens which occupy the whole height of the gallery; these screens' are placed all along the glazed portion, and inclined so as to reflect the light upon the model; they must be arranged so as to overlap each other about 5 or 6 per cent. of their width, which may be about a foot. Under these conditions the diffused light penetrates into the operating room, after being successively reflected by the two surfaces of the screens, which are simply of light blue-grey paper.

With this arrangement made in the unfavourable position for an operating room I have described, I find myself working under as good couditions as if I had a gallery facing the north, and I have at least the advantage of being able to work in all kiuds of weather.

## ON ENAMEL PHOTOGRAPHS.

BY F. JOUBERT.*

Having been invited by our excellent Secretary Dr. Diamond to exhibit, this evening, some specimens of my photographic transfer on glass, in enamel colour burnt-in, so that a novel application of photography might be placed under the notice of the Society, I shall endeavour, briefly, to give some information respecting the process itself, and to poiut out in what direction it might receive great development.

But, previous to entering into the subject immediately before us, I would take this opportunity of casting a retrospective glance at the origin of the discovery of photography, having had the advantage of watching the progress of the invention almost from the very first essays of the inventor.

Although not intimately acquainted with Daguerre, my late and regretted friend, Chevalier Bouton, his partner at the Diorama, first mentioned to me the subject which at that time engrossed Daguerre's thoughts almost exclusively; and one of the first specimens brought under my notice was a portion of a figure, with draperies of such refinement and definition of texture, as to cause a feeling of perfect admiration amongst the few friends to whom Daguerre showed it.

* Read at the Photographic Society, March 4, 1862.

It is well known that before his name became associated with the production of *sun-pictures*, as they were first designated, Daguerre had acquired considerable repute as a landscape-painter, and he had exhibited at various times, amongst other fine works, some interior views of old buildings, which denoted in the artist, besides other great qualities, a complete understanding of the theory of light and shade as applicable to a picture. Daguerre, being ambitious of spreading his works upon a larger scale, conceived the idea of attaining a perfect representation of natural objects, the size of life, lighted as though they were the real scenery, through an arrangement or system of windows much the same as that in use for lighting panoramas, but he painted a picture upon a flat plane instead of a circular one, by means of which he was enabled to introduce side-lights also with great effect.

The success of the diorama in Paris was immense, and many persons may yet remember, among other pictures, one representing the Valley of Unterseen in Switzerland, aud a view of the Royal Chapel at Holyrood, both of which were, I believe, exhibited later in London at the diorama in the Regent's Park.

Daguerre had for many years been in the habit of using both the camera obscura and the camera lucida; the first-named one was particularly serviceable to him in obtaining an accurate representation of the scene he required to paint for his diorama, with all the gradation of light, and he used a camera obscura of very large proportions for the purpose. Many a time in observing upon the white drum in his dark room the beautiful definition of objects outside, which the opening of the room-door caused to disappear immediately, Daguerre had been heard to exclaim, "Ah! that means could be found to fix such an image!" and with his ardent and enterprising mind he had imagined to try the effect of a sensitive paper, without, however, alighting upon the right medium. He tried several agents, and actually by accident obtained, one day, a faint outline of objects upon a sheet of paper, which outline remained some little time, even when exposed to the light, before it passed away. This was assuredly an important step in the right direction; but after trying many experiments, rejecting them, resorting to new ones day after day, and having already, it must be said, far progressed towards the discovery of the object he had in view, a circumstance occurred which was destined to have a great influence in bringing the iuvention to a positive result. Daguerre called one day on a well-known optician of whom he had purchased his instruments, and to whom he had, from time to time, made a confidential communication of the progress of his researches. The optician said to him, "I believe, M. Daguerre, I know a young man who is trying for the same thing that you are trying for; he is extremely clever, and I should much wish you to know him—he might perhaps be of use to you:" this was M. Nièpce.

Daguerre was so struck with the results that Nièpce had arrived at, that he offered to him to combine their efforts, and very soon after the invention was brought before the public by the great astronomer Arago, in a paper read at the Academy of Sciences; and shortly after this, in a series of experiments made by Daguerre himself in a government office, where a vast and select assemblage had been invited, these experiments were perfectly successful. The French Government rewarded Dauguerre nobly for his discovery, and also acknowledged the claims of Nièpce by granting him a pension for life.

Daguerre's invention, ingenious as it is, would scarcely have led to the immense development that we now witness in photography. By a very singular coincidence, about the same time, and perfectly unknown to Daguerre, Mr. Fox Talbot, in this country, after having worked alone with great perseverance and courage, brought out the "Talbotype," which has changed its name, and become better known as "Photography."

It was very natural to expect that many persons, considering the beautiful results of the new discovery on the one hand, and the admitted want of permanency of the photographic prints on the other, should exert themselves to find a mode of giving durability to that which, from its transient nature, was undoubtedly destined to perish sooner or later. The Daguerreotype image being liable to be affected by damp, or by rubbing off, had to be carefully protected by a piece of glass being fastened in front of the image; the Talbotype proofs also were at first frequently found to fade away after a short time if exposed to the bright light.

A better method of fixing the proofs is now generally adopted; but who can tell for certain how much of the best fixed photographic prints will remain on the paper twenty years hence? A mode of preserving the photographic image intact from any atmospheric influence was generally wanted; and soon after the introduction of the method for taking a photograph upon glass by means of the collodion process, many were the attempts at fixing the image by fire, under the notion that the metallic principle of the nitrate of silver would run into the substance of the glass when heated sufficiently, so as to combine with the glass itself, and retain the image when looked at by transmitted light.

This, however, was not the case. 1. Although some portion of the silver was retained in a yellow tint on the glass when taken out of the kiln, the greater portion of the photograph had disappeared; for the organic substance of the collodion was burnt off, and left no trace on the glass in many instances. It was thought that by fixing another piece of glass in front of a photographic image copied in a *positive* by the albumen or other process, a certain degree of permanency could be obtained, and some very interesting results were arrived at by that means. Then the usual mode of printing on ceramic substances was also tried, but failed for want of a medium to apply the pigment required for printing off. In the manufacture of earthenware, as every one knows, the image to be applied to decorate the ceramic wares is first printed from an engraved copper-plate on what is called tissue-paper, or very thin paper, in vitrifiable colour or colours, and applied before the colour has had time to set upon the objects to be decorated; the same process has been in use for decorating glass; but the expenditure of time and money required to obtain first an original plate stood in the way of any great progress being made in that direction.

Having been for many years professionally acquainted with printing in connection with the fine arts, and having observed the immense development the new art of photography has taken, and the large field it has opened for representing all sorts of subjects, of animated, as well as still life, it occurred to me that if a means could be found to print the photographic image on glass, as easily as it is done on paper, and through the agency of some chemical composition which would admit of employing ceramic or vitrifiable colours, and burning them in, a great result would be attained, and a new and considerable branch of industrial art might thereby be opened. Considering the numerous and various attempts which have from time to time been made to introduce a substitute for glass painting in the decoration of houses, I believe it can be said that a want was generally felt for supplying the growing taste for pictorial decoration; for glass painting is an expensive process, and requires also a considerable time to obtain a perfect result.

The invention which occupies us now is resting upon this singular fact, that all saccharine or sticky substances seem to be easily absorbed by light. In consequence, a certain convenient solution being prepared, sensitive to the light in order to obtain the image, photographically, if to this solution there could be added a principle which would combine the property above alluded to with the sensitive property necessary to obtain the fac-simile representation of the object to be copied, then the application of an enamel colour of pigment would become an easy and almost mechanical matter. To render this more easy of comprehension, I shall now read that part of my specification which relates to placing the image on the glass and fixing it by fire:—

"For this purpose, I proceed in the following way:—A piece of glass, which may be crown or flatted glass, being selected as free from defect as possible, is first well cleaned, and held horizontally while a certain liquid is poured on it. This liquid is composed of a saturated solution of bichromate of ammonia in the proportion of five parts, honey and albumen three parts of each, well mixed together, and thinned with from twenty to thirty parts of distilled water, the whole carefully filtered before using it. The preparation of the solution, and the mixing up with other ingredients, should be conducted in a room from which light is partially excluded, or under yellow light, the same as in photographic operating rooms, so that the sensitiveness of the solution may not be diminished or destroyed.

In order to obtain a perfect transfer of the image to be reproduced, the piece of glass coated with the solution, which has been properly dried by means of a gas stove (this will only occupy a few minutes), is placed face downwards on the subject to be copied in an ordinary pressure frame, such as is used for printing photographs.

The subject must be a positive picture on glass, or else on paper rendered transparent by waxing or other mode, and and an exposure to the light will, in a few seconds, according to the state of the weather, show, on removing the coated glass from the pressure frame, a faintly indicated picture in a negative condition. To bring it out, an enamel colour, in a very finely divided powder, is gently rubbed over with a soft brush, until the whole composition or subject appears in a perfect positive form. It is then fixed by alcohol, in which a small quantity of acid, either nitric or acetic, has been mixed, being poured over the whole surface and drained off at one corner.

When the alcohol has completely evaporated, which will generally be the case in a very short time, the glass is quietly immersed horizontally in a large pan of clean water, and left until the chromic solution has dissolved off, and nothing remains besides the enamel colour on the glass; it is then allowed to dry by itself near a heated stove, and when dry is ready to be placed in the kiln for firing."

## PRACTICAL REMARKS ON THE TANNIN PROCESS.

BY E. BORDA.*

Considering the number of new processes which crowd tho photographic papers, and how confusing it is to select amongst tho number; I am inclined to think that what my views and short experience may be worth respecting a process already very popular amongst our amateurs, will be moro welcome than anything new, presenting no decided advantage over processes now in use.

The process I allude to is tho tannin.—I am not prepared to say it is the best, but as far as my experience goes it is decidedly so, and, though able to devote but little time to photography, I have so far attained that confidence in my tannin plates that I can remove the main "objection" of the adversaries of dry processes, viz., the uncertainty of obtaining a satisfactory result. I have had failures of various kinds, but from tho beginning suspected that they could be traced in almost every instance to the development, and I am now convinced of it.—"There's the rub."—If plates are prepared with ordinary care, none of the details apparently trifling, neglected, tho views not too much over, or under exposed, I do not seo why, starting on a trip with a number of tannin plates, the same number of good negatives could not be secured if the development is conducted as it ought to be.

The preparation of the plates is very simple, and if conducted systematically ten of the stereoscopic size can easily be prepared in one hour. The glass should bo thoroughly clean; I clean mine with nitric acid diluted with equal volume of water, leaving them in that solution until wanted, and give the last cleaning with old collodion diluted with alcohol. Tho edges must be ground finely, not only to avoid cutting the fingers, but to allow the collodion to grasp firmly at the sides; a rough grinding is objectionable, creating a multitude of little notches, in which chemicals accumulate during the series of

* Condensed from the *American Journal of Photography.*

operations, very difficult to dislodge thoroughly, and which may be the source of spots during development. A good working bath, working well with wet process will answer, it should not be too weak, and decidedly acid, sufficiently so to prevent fogging, if too much so the sensitiveness will be affected, but it is preferable to lengthen the exposure and have a clear negative to the risk of a foggy one, which is inevitably the case not only with an alkaline bath but even with a neutral one. I have acidified a forty grain silver bath with acetic and with nitric acid, and find either to answer; one drop of nitric acid for ten ounces of fresh silver bath made of crystallised nitrate of silver, such as is sold by the best dealers, is sufficient. I have not yet found a collodion giving good results with the wet process, which did not answer with tannin, and I have used collodions giving inferior results wet, with more success after applying tannin; I may say the same respecting the silver bath, having obtained good tannin negatives with an old bath which I found very deficient in intensity with wet process; this is no doubt owing to the great intensity imparted to the film by the application of tannin.

Some collodions must be better adapted to the tannin process than others, but so many things affect collodion that a formula for a particular one is rarely sufficient to secure the same results, especially if it is kept any length of time. To insure the identity of the two collodions, not only the purity of the chemicals, the preparation of the gun cotton, &c., must be the same, but the temperature itself will effect great changes. Indeed, it is one of the great advantages of the tannin over all other dry processes that the particular structure of the collodion is not of such importance as to prevent good results from being attained with any good negative collodion. I have used old and new, single or mixed, iodides and bromides of ammonium and cadmium, mixed and unmixed, collodions purchased and containing I do not know what, and have been successful with all.

I prefer collodion not too thin, giving a rich creamy film, being a little reddened by age, fine free iodine, and containing a full proportion of bromide, from one-third to two-fifths. The addition of bromide appears essential, great hardness being produced by the use of the iodides alone. I prefer bromide of magnesium or cadmium, readily soluble in alcohol, without addition of water.

From fifteen to twenty grains of tannin to the ounce, is a good proportion, more ought to be used if it contained too much resinous matter, which will not dissolve in water. The stronger the tannin solution, the greater the intensity attained rapidly by development, hence with great contrasts it is desirable not to have it too strong to keep the development under better control; but for copying engravings I should think some advantage may be derived by exceeding thirty grains.

The solution of tannin need not absolutely be new; I have refiltered a solution one week old, already used, and found no difference in the result. I use it in a vertical bath, dipping the plate in it as I do in the nitrate of silver solution, and moving it up and down and sideways. A twelve ounce solution will do me for twenty four to thirty 7 by 4 stereoscopic plates, and may do for more, provided it is not too much weakened by the water introduced in it with every plate as it comes out of the water. The nitrate of silver must be thoroughly washed off, and the plates never handled without previously wiping the fingers perfectly clean. If it is very warm, and the hand prespiring freely, india-rubber tips for the thumb and middle finger ought to be used, or spots, while developing, may extend far enough to spoil a negative, will start from the points held. All dust is of course to be avoided as much as possible, and while preparing plates it is desirable not to "fuss" too much about the laboratory, or disturb anything on the shelves; everything that is needed while the preparation of the plate goes on, ought to be laid in its proper place before beginning.

Some operators consider all these precautions as trifling and useless, but nothing in a dry process is too trifling, if there is a good reason for it, and the common occurrence of persons able to obtain good results with the wet process, and entirely unable to command a dry process, is, I think, mostly owing to this disregard of apparently useless precautions. On taking the plates out of the tannin bath, I wipe the back with a sponge, and stand them on blotting-paper in a box containing one or two hot irons, which I cover, keeping it warm enough to dry a plate in less than from five to six minutes. I have derived much benefit from this drying, and although many, and Mr. Russell amongst them, advise spontaneous drying, I have not been able to obtain as good plates in that way. The atmosphere of some operating rooms may be dry enough, at some seasons of the year, not to require artificial drying, but I find no harm done by it, and much benefit, and therefore would advise it. Plates so dried keep, I believe, somewhat longer. I have been unable to detect any loss of sensitiveness after keeping them one month, merely enclosed in a mahogany box, and in that same room where spontaneous drying did not answer.

The same collodion has more tendency to wrinkle, when the plate is plunged in water, if it is done within two or three days after it is prepared than if kept a little longer. To prevent the water from getting under the film I have used negative varnish, rather thick, applied on the edges after exposure; I find it to answer very well. Any one who has experimented with tannin plates, must know that, although they will stand much washing when the film is well secured, it is almost impossible to save it, owing to its great tenderness when it begins to tear, particularly when the negative is fixed.

The use of citric acid in the developer is important; acetic acid does not sufficiently retard the development unless used in large proportion, and it appears then to make the film more tender. It gives too red a tone, the tannin itself helping that red tint, which is more or less affected by the blue tinge given by the citric acid. A mixture of both acids to develop positives will be found very useful to secure a rich tone. It is also important to have the acid in the silver solution, so that to every drop of nitrate of silver solution added, a sufficient quantity of acid is sure to be added. and no more when it is necessary to push on the development of an under-exposed plate by the addition of pyrogallic acid without silver.

The development must begin with weak pyrogallic solution, and but little silver, to ascertain what further treatment the negative needs to bring out all the details. With proper exposure the relative strength of pyrogallic and silver need not be changed to finish the negative, over-exposure can be remedied by excess of silver, and under-exposure by excess of pyrogallic acid.

The latitude given in the exposure of a tannin plate is one of the peculiarities of this process, and a most valuable one. It is not to say that a good negative can be obtained with a plate much over or under-exposed, but the limits are within the degree of appreciation which practice and judgment can give. For instance, supposing five minutes to be the right time for a particular view, four to six minutes' exposure will give a very good negative of the same view. This I have tried conclusively, and went as far as doubling the time, and all the difference was, that distant hills, miles away, not well defined in either negative, as the day was hazy, were not presorved as distinct in the negative the most exposed, while the rest was perfect in both.

The nature of a view has much to do with the excess to be preferred, for an excess there must be when the landscape is taken, the different parts of which require very different exposure; a sort of compromise must be made, and in every instance it must be left to the taste of the operator; general rules do not apply to such cases. The operator must decide that point of the view which for artistical effect it is most desirable to expose correctly, and weigh the result for the rest, if too much is sacrificed to that one part, the compromise must be made. The strength of the tannin solution will determine whether or not a rapid intensity will be obtained, and the development must be regulated according to that, and to the subject. Success and artistic productions become the result of a harmony at the command of the operator, and the production bears an individuality which sets aside the clamour that photographs are mere mechanical productions. They are certainly nothing else in many cases, and very poor at that, but a large field is open beyond the mechanical part, and it remains for photographers to enlarge it more and more, so as to establish photography as truly a fine art.

A dry process giving as good results as the wet is certainly preferable for field work. The tannin I do not hesitate to say gives better results; the smoothness of the film insures better definition, which is not objectionable in the least, notwithstanding all that has been said against sharpness, and when everything is not sacrificed to it.

To substitute an exposure of five seconds to five minutes for a landscape is no object. Five seconds is entirely too long, and a view which need not be taken in much less time, can just as well be taken in five minutes. Neither exposure will secure moving objects, and if any happen to pass, what will be a blur on the plate exposed five seconds, will leave no impression on the other. It is desired to secure moving objects, or it is not: in the first case, an instantaneous collodion is needed; in the other, nothing is gained by too rapid an exposure, but a risk of failure from the impossibility of giving the exact time, except by mere chance, when a second more or less will materially affect the negative. The breakers of the sea, a street scene, cattle in a field, &c. are natural scenes in which much taste can be displayed, and which must be taken by wet process, until an instantaneous dry process is found, but the introduction of groups in a landscape is, except in a few instances, a matter of very doubtful taste.

I believe that the future of field photography will altogether be confined to small negatives on dry plates, obtained with short focus lenses. But two things are needed to accomplish that end: a very quick dry process, and a good magnifying apparatus.

*Woodside, January*, 1862.

## THE SOUTH LONDON SOCIETY'S EXHIBITION OF BRITISH AND FOREIGN PHOTOGRAPHY.

The Committee of the South London Photographic Society have great pleasure in announcing that they have made arrangements with the Directors of the Crystal Palace Company for holding at Sydenham, during the current year, an exhibition of British and Foreign photography. The Company have placed at the command of the Committee an eligible and well lighted portion of the palace, and they are, therefore, desirous of holding such an exposition of photographic art and science as shall worthily illustrate the present vast development of this great modern discovery. They are inclined to conceive that at the present period photographers are especially interested in exemplifying to the world the high artistic standard to which their works have attained as well as the more freely acknowledged practical character of its results. In the International Exhibition of 1862 the spirit of emulation will be mainly directed to a friendly recognition of the comparative progress made by photographers of different nations, and the limited space at the disposal of the Commissioners will be awarded accordingly. At the Sydenham International Exhibition, upon the other hand, the leading design will be the promotion of the progress of photography itself to be attained by an exposition of its most artistic specimens, a popular illustration of the scientific principles involved in their production, and a display of the varied and highly ingenious philosophical apparatus which have been employed in the attainment.

The Committee of the South London Photographic Society invite, therefore, your hearty co-operation in furtherance of the success of the exhibition, beg to draw your attention to the appended regulations with the least possible delay.

### Rules for Exhibitors.

The South London Society's Exhibition of British and Foreign Photography, to be held at the Crystal Palace, Sydenham, will be opened on or about the 15th of May, 1862, and will continue for a period not exceeding six, or less than three months.

All pictures intended for the exhibition must be framed, glazed, and mounted, with a suitable margin. The names of the subject, process, and artist, must be written legibly at the back of each picture, together with any especial observations, to be inserted in the catalogue.

Photographs for exhibition must be delivered free of charge on or before the 1st of May at the Palace; each package to be addressed as follows:—

*GEO. GROVE, Esq.,*
*South London Photographic Exhibition,*
*Crystal Palace,*
*Sydenham.*
*From (Name)* ______
*(Address)* ______
*Carriage Paid.*

The cost of the return carriage, and all risk of breakage or injury to the pictures or frames, will have to be sustained by the exhibitors; every reasonable care will however be exercised in order to prevent the occurrence of damage.

The Directors of the Crystal Palace Company will present to each exhibitor, upon the recommendation of the Committee, a season ticket available for six months, to be applied for to the Secretary of the South London Photographic Society.

The Committee of the South London Photographic Society, having entered into an arrangement with the Directors of the Crystal Palace Company to exclude all photographs unworthy of public exhibition, reserve to themselves the right of selection.

Coloured photographs will be admissible only when accompanied in the same frame with untouched specimens. This regulation will be strictly adhered to in every instance.

An adjoining, but separate gallery, will be appropriated to the reception of pictures, &c. illustrating the principles or history of photography, and the exhibition of apparatus. Cases for the protection of optical and philosophical instruments will have to be provided by the exhibitors.

The prices of copies of pictures exhibited intended for sale should be forwarded to the Secretary, so that they may be described accordingly in the catalogue kept in the gallery for the purpose; a commission of 20 per cent. will be charged upon all sales effected.

Alfred H. Wall, Hon. Secretary.

## RECOLLECTIONS OF AN AMATEUR PHOTOGRAPHER IN PORTRAITURE.

by NOEL E. FITCH.*

Some few years since I started one morning a full blown photographer with a complete set of apparatus of the value of £3, and, judging from the *number* of gentlemen who have commenced their photographic life with this most wonderful stock of appliances, I presume the originator of the idea of a "complete set" must now be reposing from all earthly toil on a handsome fortune. You all, gentlemen, recollect with what delight you proceeded to take your *first*, your maiden picture, most of you, I doubt not, have it still. *My* first production consisted of a quarter-plate portrait of a most obliging friend, who kindly consented to be taken in the garden of my house; the background is a brick wall, it was raining steadily at the time, and as the experiment was of considerable duration, I am inclined to think the operator had the best of the fun. Failure now followed failure, collodion wasted, baths spoiled, accidents happening, instruction books reading, and so months passed by, until by experience acquiring some dearly bought knowledge, I have arrived at that condition when, if I cannot *take* a good negative, I fancy I can recognise one when I see it, and appreciate the trouble, adjustment, nicety, and balance of each and every thing, from the plate itself to the final washing requisite in its production. However, in due course the poor "complete set" was at length discarded, and after a series of annoyances and disappointments with respect to lenses, having possessed myself of cheap instead of good ones, I equipped myself entirely afresh, built a glass-room and entered heart and hand into the delightful amusement of taking *my* friends and *their* friends portraits.

Individually, I never could see the "fun" of being taken, but my hobby having brought me in contact with a great number of people, I have come to the conclusion that with some the desire to see themselves represented in chloride of silver becomes absolutely a disease. I was once taking the card portrait of a gentleman, and after having taken him thrice was proceeding to wipe my hands as a signal that I had completed the operation, on seeing which he informed me that *he* was not tired and was willing to be taken in a dozen different attitudes. I pleaded lack of time, another opportunity, &c., and thus got out of the difficulty, evidently much to his disappointment, as he was in full uniform, being a member of a rifle corps. He subsequently met me, reminded me of my promise, and I then had to take him thrice again, and was compelled to tell him at last that I could do no more. On another occasion a young lady had the honesty to tell me that to her the operation

* Read at a Meeting of the South London Photographic Society, Feb. 13th.

was a pleasant and agreeable one, and begged me at any time that I might be in want of a sitter, either for experiment or a study, to send for her, and she would be delighted to come. There were, however, certain facial objections to my so doing, and consequently I have not availed myself of her offer.

Another young lady was so determined to have herself taken that although suffering severely from the tooth ache, she first paid a visit to the operating-room of a dentist, and from thence immediately came to mine. This portrait does not represent a happy caste of countenance. In fact, I may assert that out of the very many portraits that I have taken I have never yet met with one sitter who *disliked* the *operation*, and but few who had much consideration for the *operator*, for whether practised as a profession or as an amusement, too much of it becomes irksome, especially with the thermometer showing 90° of heat in the dark-room.

I can scarcely believe that when people are having their portraits taken they give a thought that the operator, when focussing, can see them and their actions most distinctly on the greyed glass, for, if such a consciousness pervaded them, how much amusement we amateurs and professionals would lose. Desiring to get a certain effect of light and shade on the face of a gentleman, I desired him to look and turn his head somewhat to the left, but as he was slightly deaf I had to suit the action to the word by going up to him and with my hand turning his head in the direction I wished it to remain; but I had no sooner enveloped my head in the velvet than curiosity overcame his prudence, and round came his head to look into the lens of the camera. This operation being repeated several times I was at length, of necessity, compelled to take him "full face" and thus spoil the general effect of the portrait. I assure you it amounted at last to the ludicrous to see the old gentleman so persistently gratify his curiosity, although it has since occurred to me that a certain amount of fear might have been mixed up with his feelings on account of the novelty and formidable appearance of the instrument before him.

It is scarcely fair to reveal the secrets of the camera with respect to the fair sex, but as by far the greater number of my young lady sitters repeat their visits only to have their new dress taken one, cannot help taking a very long time in focussing for the purpose of watching how very particular they are in the *set* of it; how that stray piece of trimming is brought forward; how that part arranged or set out; the head daintily felt all over to ascertain that no trace of disorder is there either in the net, hair, or ornament, and then the final effort to compose the entire person and dress for the most pleasing attitude and expression. Then, again, if your sitter is possessed of great personal attractions, you can gaze your full upon the charming picture presented to you on the screen (notwithstanding she is standing on her head), in all the perfections of colour and rotundity, and only regret when the plate has to be inserted which *as yet* fails in copying so beautiful a shadow in all its integrity of life and colour; it is these little episodes in portraiture that give so great a charm to it in the eyes of an amateur.

Our worthy Treasurer, Mr. Howard, in a paper read by him some time since, portrayed with vivid thruthfulness some of the manipulative difficulties of an amateur photographer in portraiture as distinguished from the easy pleasure of those gentlemen who prosecute that part of the art represented by the various dry processes; but while he told you of baths neglected, and glasses to be cleaned, developer to mix, and the sundry and sudden other calls upon the amateur, he omitted to mention to you, on account, I believe, of his limited experience in the matter, a most serious and destructive difficulty applicable, I may almost say exclusively to the practice of an amateur, I mean the familiarity which exists between the amateur operator and his sitter. This may, or may not have occurred to other gentlemen, but, personally, I affirm it is great drawback to my success and tries my temper most dreadfully. It may be taken as an axiom that without patience there can be no successful photographer, for to attempt to take a picture of any sort without a large share of it in your composition, is in my opinion simply folly, and in scarcely any science does the motto that "Patience and perseverence overcometh difficulties" apply so forcibly as to photography. From beginning to end it is the same, success or non-success, the same thing applies; each step we take is one in which we have identically, some time or other, failed before. Now the light is bad; how patiently we try to use what there is or wait with equal calmness for a better; now a dirty plate; now badly exposed, or developed; or the front toned, fixed, or washed imperfectly; still we go on, and the thousand and one difficulties which we *all* experience more or less are usually successfully surmounted simply by patient determination.

But to me the greatest, in fact the insurmountable difficulty, is the friendly sitters who honour an amateur by *being* taken. With gentlemen who practice the art as a profession there *is not* this difficulty to contend with to anything like the same extent. I have observed (for I have the *entrée* to several studios), that the sitters are for the most part placid, quiet, and obedient; the operator does with them what he will, and their dismissal takes place the moment he informs them of his success. Any *pose* that he thinks artistic or elegant, to that will his sitter submit without a murmur, and even if they place themselves in some eccentric or particular position, a little polite and judicious management soon sets things straight, and the artist nearly always has his own way. That occasionally frumpy and disagreeable people do enter glass rooms there can be no doubt, but the quietude that usually reigns there subdues them mostly, and in ninety-nine cases out of every hundred satisfaction, if not felt, is at least expressed. I have seen the case frequently of people who have lost their temper in the waiting room calmly regain it under the mesmeric influence of a Ross or Dallmeyer lens; that momentous second when the cap is removed from the lens, must, I suppose, have something to do with it; for when you come to think it is really a serious question whether you are to be represented with a scowl upon your face or with all the calm benignity of your better tempered self. With amateurs, however, or rather in my individual instance, the case is different. My sitters care naught for me, will not be posed, insist on moving, nay, even speaking during the operation, treat the whole affair as a good joke, imagine that each failure caused by themselves is my amusement, and usually wind up the entertainment by asking for impressions by the dozen. I assure you this is no romance, it is purely the fact, and did I choose I could call upon a gentleman now present to bear me out in the assertion. Curiosity leads some to open the door of the dark room to find out what I am about during that most critical of all periods, development, others remove negatives recently taken, from the rack on which they are placed to dry, and by incautiously touching, spoil them, all complain of the heat, and the last question is "When can they have the copies?" You will have the kindness to remember that I do not exactly complain of this, I am only sometimes a little annoyed that I am not allowed to take my friends my way, instead of being compelled (out of politeness, I must say) to take them their own; for I recently took the card portrait of a gentleman, by profession an artist, engaged on the leading illustrated paper of the day, and whose occupation consists in representing people with elegance of appearance and easiness of pose, who selected for himself the most eccentric, if not the most inelegant position it is possible to imagine, and notwithstanding, I represented this to him in language perhaps more forcible than refined, he insisted on retaining his self chosen attitude, asserting as a reason for so doing, that it was "characteristic of himself." I need scarcely tell you that I had no pleasure in taking the negative, or that an accident happened to it in the printing frame. I console myself somewhat, however, with the knowledge that the obligation is mutual, for if I take any friends "con amore" they supply me with sitters; but still people should remember that amateur photography is not the cheapest hobby a man can amuse himself with, and they should be somewhat moderate in their demands for impressions.

(*To be continued.*)

## THE NEW COPYRIGHT BILL.

We are now enabled to put our readers in possession of the measure which is before the House of Commons on Copyright. It is called "The Copyright (Works of Art) Bill." After reciting that by law as now established the authors of paintings, drawings, and photographs have no copyright in such their works, it is by the first section proposed to enact as follows:—"The author of every painting, drawing, and photograph which shall be made, or for the first time sold or disposed of, either in the British dominions *or elsewhere*, after the commencement of this act, and his assigns, shall have the sole and exclusive right of copying, reproducing and multiplying such painting, drawing, or photograph, *and the design thereof, by any means* and of any size, for the term of the natural life of such author, and seven years after his death: *provided*, that when any painting or drawing shall be for the first time sold or disposed of after the passing of this act, the person so selling or disposing of the same shall not retain the copyright thereof, unless it be expressly reserved to him by agreement in writing, signed at or before the time of such sale or disposition, by the vendee or assignee of such painting or drawing." This section contains the *principles* of the bill; the other sections are mere details for protecting the right thus proposed to be granted. The bill leaves unrepealed and unaltered all the antiquated and inefficient Engravings and Sculpture Copyright Acts. But the most remarkable feature is, that it disregards those three great principles upon which Parliament has legislated with respect to copyright:—1. That it shall commence from the time a work is *first published*. 2. And, during the last twenty years, that no copyright shall be acquired by the author of a work, except upon condition of its being *registered*. 3. Also that the work to be so registered shall be new and *original*. Now, assuming this measure to have become law, let us see how it is intended to be read. As the section stands, it means that when an artist has acquired a copyright by executing a work, that copyright is to cease, unless when he first sells such work his purchaser signs an agreement for the purpose of reserving the copyright to the artist. It follows, that where an artist thus reserves his copyright he will have the exclusive privilege of making as many copies or repetitions of his work as he pleases; but where the purchaser declines to enter into such an agreement, and purchases the work without any such arrangement being made, then that the copyright will *thereupon cease*, and the artist will consequently, as at present, be able to make and sell as many unauthorized copies and repetitions of the work as he pleases; the only difference being, that he will not have the *monopoly* for that purpose. Amongst those who are conversant with this subject, it is well known that the prominent mischiefs which render legislative redress essential are these: the misconduct of a few eminent artists, who have brought disgrace upon a noble profession, by manufacturing and selling unauthorized copies or repetitions of their pictures and drawings, to the serious injury and annoyance of the proprietors of the *original* productions; the fraudulent manufacture and sale of spurious copies of pictures and drawings; and the injury thus inflicted upon artists and the purchasers of works of fine art, which injury also tends to limit and depress an important branch of our national industry. We submit that the present measure is wholly inadequate to remedy these mischiefs; and that, if it should become law, it will tend to increase rather than to diminish the injustice to which all honourable artists and the purchasers of works of fine arts are now exposed. Lastly, we may ask, why is Parliament to be required, in favour only of the authors of paintings, drawings and photographs, to abandon the great principles which it has so long established upon the subject of copyright; and especially when all that is needed to remedy the existing mischiefs may be safely and certainly obtained by adopting the precedent established in granting copyright under the Useful and Ornamental Designs Act, which has now been in operation for upwards of twenty years, and afforded the most efficient protection to the authors and proprietors of new and original designs? and why are sculptors, and the purchasers of their works, to be excluded from the benefit of any amendment of our laws of artistic copyright?—*Athenæum.*

# Photographic Tourist.

## PHOTOGRAPHIC PENCILLINGS OF AN EASTERN TOUR.*

I cannot say I learnt to like the Turks, or found their city improve much with a lengthened acquaintance, although the latter has redeeming features in its splendid cemeteries and the cool shady bazaars. The cemeteries seem from a little distance like path-intersected forests of thickly planted cypress, and afford very charming walks; and the latter are famous lounging places, to which one may escape from the glare and heat of the streets (which in the hot weather is something terrible), and listen to the tinkling, rippling, murmuring, and plashing of delicious fountains: basking in the meanwhile in the rich, deep, softened glow of the modified sunlight. Of these bazaars, I give the preference to that chiefly devoted to the sale of drugs.

Of course my readers are anxious to hear something about the ladies here. We always are curious to know all about things which are so ostentatiously concealed from us. Well, I must confess that the ideas I had previously held about these mysterious fair ones were far from those I shall now express. In the first place, they have both less and more liberty than our European dames. That is to say, while our ladies can gang about and talk to the men at their own sweet will and pleasure during the day, they are never—if at all respectable—supposed to go about alone, heaven only knows where, in the night; whereas the absence of a Moslem spouse from home during a night is no unusual thing, and excites little attention or suspicion. Supposing I am a nice old coffee-sipping Turkish gentleman, with the usual long beard and flowing robes, dozing and smoking away my days in the midst of my wives, young, pretty, and otherwise. One night I find outside the door of my prettiest's chamber her charming little slippers. This is a sign I reverence, intimating that I must go away, and accordingly go away I do. Again, I find this same fair absent from home all night. Well, wasn't she with Mrs. So-and-So, and am I not forbidden to speak to Mrs. So-and-So? while Mr. So-and-So can only tell me that on the evening in question *his* wife's slippers were placed outside *her* door. As the ladies visit each other, you perceive, some such arrangement as this becomes necessary. Intrigues of love, although dangerous, are indeed not so scarce as one might suppose from the scrupulous separation of the sexes. The women are to be seen in the streets and bazaars at all hours, either waddling along under their huge hats, swathed in their capacious drapery, like animated bundles, and looking in their yellow boots comically like ducks out of water, or crowded into vehicles something like infantine lord mayor's chariots.

As a rule, you see little of them beyond their eyes gleaming out at you through the yashmak, or veil; but you may sometimes have the unspeakable gratification of seeing a real female's puffy little nose, and occasionally get glimpses of an entire face and bosom through a yashmak of very thin muslin, and once I saw, without being immediately struck dead, or seeing the lady conveyed kicking and plunging to the water side in a sack—a real naked female face. Wasn't that a delicious event now? A woman in the harem is said to be a very charming object; but what with shawls, voluminous tucked-up skirts, two or three pairs of loose trousers, ungainly ill-fitting yellow boots, long loose cloaks, swollen perhaps by the wind as they walk, huge yellow hats, the white veil, covering from the eyes downwards, and its ends swathed about the neck and shoulders—these ladies of Stamboul are as ungraceful and unattractive-looking abroad as it is possible they could be made.

Next in popularity to the women of Stamboul come its dogs, to which I have already made a passing reference. One day, hearing a prodigious yelping, howling, and barking, I hastened to discover the cause, and found one of these

* Continued from page 45.

wretched animals covered with blood, and howling piteously as he tore along, pursued by a pack of his fierce, vindictive fellows, noisily and cruelly intent upon his punishment. It appeared from what I was then informed, that these animals have divided the place into what one may call parishes, and that the dogs of one parish are at deadly feud with those of the next parish, so that should any rash canine parishioner, tempted by hunger or a roving disposition, pass over the boundary of his own native parish, his breach of dog-law results in such a scene as I witnessed upon this occasion. This struck me as very singular, because it is the best piece of domestic or political economy which the animals could adopt, where they are so numerous, and so purely dependent upon their own efforts as industrious scavengers for support. Unlike the dogs of other countries, these seem to look upon man with a proud indifference, never attempting to enter your house (well knowing how soon they would be beaten forth again), and either allowing you to step over them, or moving reluctantly and lazily out of your way. They are seemingly harmless, fox-coloured curs, very like the sheep-dogs of our own country.

Selecting a bright, clear day, I took out my Turkish servant, with my photographic apparatus, and made my way towards one of the cemetries. Beyond a passing utterance of the word "Ingliz," neither myself nor my apparatus appeared to attract attention, and I was soon among the turban-headed tomb-stones and the tall, crowded cypresses. Many portions of the burial place evidenced no little neglect in their dilapidated condition; but some were as evidently kept and tended with the most scrupulous care. I had just set up my camera, when I espied, coming rapidly towards me, a funeral procession. Here was a piece of luck! my things were in excellent order, and I soon got a plate under weigh. If at no other time, the Turk is always in a hurry to bury his dead, believing that until after burial the soul of the deceased will not know peaceful rest. So quick were the bearers in their progress, that my slide was only ready just as they were preparing to lower the dead, with the usual accompanying pitcher of water, into the grave, and when my picture was developed, mourners and bearers had all gone from the nearly filled-in grave. Speaking of such unexpected luck as this, I may as well here name another similar instance.

I was stopping at the house of a friend, at the village of Therapia, a pretty place of which I got several nice views. It is on the European side of the Bosphorus, about five miles, or perhaps more, up, in a charming tree-sheltered bay, the place has an hotel which I can recommend to any photographer visiting there, and as it is the only one, no mistake can be made. I had pitched my tripod nearly opposite this hotel to get a view down the broad and unusually well kept road, when, just as my preparations were complete, there came riding lazily towards me a fellow followed by a female sitting astride a mule, seemingly a slave being conveyed to or from market. As she passed, attracted by the mysterious apparatus, she turned, and by way of rewarding me for the sight thereof, I suppose, she gave me a full view of one of the most beautiful faces I ever saw, lighted up with the sweetest of amiable smiles. The features were singularly delicate and cast in a mould of purely grecian beauty, *but they were unmistakably black.* Her figure, the costume concealing it less than usual, was evidently such as would be in harmonious keeping with so sweet a face, and as a whole, I should think she more nearly resembled a beautiful grecian statue of Venus, carved in black marble, and then animated, than anything else. Uttering an exclamation of pleasure, intended to attract the attention of my English companion to this lovely vision of novelty and delight, its charming object turned hurriedly away in some confusion, and just at that unfortunate instant, the old rickety-legged mule stumbled and fell, while over rolled our ebony Venus ignobly in the dust; I should have started off to raise her tenderly enough had not my friend restrained me. Not so, however, her undisturbed proprietor who coolly checked his animal and turned slowly round until the "lubly nigger gal" had gathered herself together and remounted her stupid steed.

"What a beautiful black woman!" exclaimed I. "Yes," said my friend, "I dare say she'll sell for as much as ten pounds English."

Before they were out of sight I had their retreating figures safely on a glass plate, with the elegant black face again visible smiling an assurance of being quite unhurt, over her graceful shoulder.

## Correspondence.

### FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

*Paris*, 12*th March*, 1862.

An important improvement in engraving by means of hydrofluoric acid has been made by MM. Jardin and Blancoud. Instead of acting upon the glass with the acid in a gaseous state, they employ it while liquid. They have sought to turn to account the remarkable properties of this acid in engraving hard siliceous stones, and have succeeded in producing, with the greatest facility, some very important artistic results. If a stone upon which it is wished to engrave a design be coated with a varnish of wax dissolved in turpentine, after the drawing is made with a fine point, the hydrofluoric acid is poured on. Immediately a white vapour rises which increases rapidly, and the proportion of which indicates the action of the acid. After a while, the duration of which experience alone can determine, the effect produced may be examined. If the engraving is satisfactory, the varnish may be removed; if the contrary, the action of the acid must be repeated as often and as long as may be necessary. In many instances it may be necessary to complete the action of the acid by the graving tool, in order to secure an artistic result. For ordinary engraving it is indispensable, as in the execution of a line engraving, or an engraving upon lithographic stone, not to prolong the action of the acid more than absolutely necessary, else the siliceous stone will become corroded all over, and so destroy the design. At other times, on the contrary, we can take advantage of this corrosive action to produce certain useful effects, permitting us to realize valuable results in an artistic point of view.

Every natural or artificial substance containing silica, and consequently attackable by hydrofluoric acid, is susceptible of being treated according to the process of MM. Jardin and Blancoud. When the action of the acid is concluded, the lines may be filled with coloured materials, metals, &c., and a kind of damascening obtained which presents a new resource in the ornamental arts. Various kinds of porcelain, transparent or opaline glass, may be treated by this process with very novel and tasteful results.

M. Fizeau, in repeating MM. Bunsen and Kirchoff's experiments on spectrum analysis, met with a very curious result. In burning sodium in the open air he discovered that when the combustion is not very active the spectrum exhibits the brilliant double ray D, which, in the solar spectrum, is replaced by a double black ray; but when the combustion is in full activity, the brilliant double ray D is replaced by the double obscure ray. In attempting to explain this naturally, we may attribute its absence at the commencement of combustion, to the deficiency of an atmosphere of sodium in vapour, which appears subsequently when the combustion is more active.

Among the specimens of photography that will figure at the forthcoming exhibition, I doubt if any will excite more surprise and admiration than those of the Glaciers of Swilzerland, taken by Messrs. Bisson, frères. They fully realize our idea of a perfect photograph, combining all the most desirable qualities, sharpness, brilliancy, tone, and breadth of effect, with a perfect aerial perspective. Instead of the "stopped out" skies which destroyed so many otherwise good pictures in former days, we have a delicately graduated tint which finely relieves the pure white of the snow. The masses of ice, of dazzling brilliancy, taken in full light, when examined under a powerful magnifier, develop a mass of minute details, without exhibiting a single flaw in the proof. In some of the pictures, taken at a moderate elevation, where the foreground consists of valleys filled with trees, it is impossible to imagine the perfection with which the verdure and foliage is rendered, even to the minutest detail, even in the deepest shadows. The atmosphere that pervades these pictures imparts an indescribable charm to them, there is an entire absence of that hardness which strikes the eye so unpleasantly in many views of similar scenes to these. By the union of three proofs, each nearly a yard long, a complete panorama of Alpine scenery is obtained, which is truly surprising.

## MASON *v.* HEATH.

Sir,—Mr. Mason, the plaintiff in this action, has, in letters to some of the daily papers, reiterated what he stated in the witness box, and although the jury, by their verdict, discredited Mr. Mason's account of what had passed between us, these statements may, if uncontradicted, do me serious injury.

Permit me, therefore, to repeat what I said in the witness-box, viz., that it is not true that I received or accepted any kind of order from Mr. Mason, and that it is equally untrue that I ever told him, or implied in any way, that I had two negatives for him. Of this I convinced the jury by other evidence besides my own. Mr. Ruland, librarian and secretary to His Royal Highness, gave evidence that His Royal Highness, who had seen certain photographic portraits taken by me, had himself expressed his intention (without any sort of application from me) to sit to me for some portraits he desired to have taken, before he consented to the application made by Mr. Mason; and that Mr. Mason's application having been renewed at this time, His Royal Highness had arranged that an additional negative should be taken for his publication. Mr. Mason, therefore, received directions to furnish me with the necessary particulars for its execution. I will say nothing here upon that portion of my own evidence which detailed the manner in which Mr. Mason attempted to mislead me as to what his instructions really were. Mr. Ruland proved that the Prince sat to me in my studio on the 2nd of July; that he attended him, and that four distinct negatives were taken. Mr. Ruland also proved that His Royal Highness stated, in reply to an inquiry from me, that he could not then come to any decision as to whether Mr. Mason should have any one of the four negatives, and that Mr. Mason was to be so informed.

A month afterwards His Royal Highness' decision was communicated to me in a letter, which was read in evidence. By this letter, in the clearest and most explicit terms, I was instructed to let Mr. Mason have one of the four negatives. This I communicated my readiness to do, and named a price for its delivery, which I still consider a very reasonable one—one, at all events, which could not be governed by any agreement or bargain he may have previously made with other persons for other portraits.

It was at this juncture, and no doubt in ignorance of the actual circumstances under which the Prince came to me, Mr. Mason set up a claim for two of the four negatives. My instructions were clear; I had but authority to deliver one, and hence the action: *an action which was expressly brought upon an alleged contract on my part, made the 29th of June, to deliver two negatives for a price named.* I was advised, and believed, that the facts herein stated were sufficient for my defence; but as Mr. Mason still thinks the question unsettled, permit me to say, that for the purpose of putting my position beyond doubt, at an early stage of the action, I wrote to Windsor for further instructions, and received the following reply from Mr. Ruland, dated, "*Windsor Castle, Nov. 24th,* 1861.

"As far as the question is concerned as to *what number, or which,* of the negatives taken by you in July last you were to give up to Mr. Mason, I can only refer you to my letter of the 6th of August, in which I distinctly stated and described as plainly as possible THE *particular and only negative* which, in compliance with His Royal Highness the Prince Consort's commands, you were to hand over to Mr. Mason for publication in a certain work, a copy of which had been submitted by Mr. Mason when he first applied for permission to insert a portrait of His Royal Highness into the said publication."

Mr. Mason in his letter to the daily press challenges some juryman to state the actual meaning of the recommendation attached to the verdict. I cannot, therefore, help remarking that I believe the jury would have considered any such recommendation superfluous, had they known that I, and all connected with me, had used our best efforts to prevent this action being tried. You will yourself remember my conversation with you as to my desire to refer it.

The following proposals were actually made. In the first place I stated my readiness to refer it to the President of the Photographic Society: then (after His Royal Highness's death) to Sir Charles Phipps, and then, at the suggestion of Sir Charles Phipps, to another gentleman, and in every instance I offered unconditionally to put my case in the hands of the persons named. It should be stated further, as can be proved by my leters, that I should have been but too glad to let Mr. Mason have *the negative at any time, upon any terms,* had he been willing to content himself with the only one which I had power to give him.

Vernon Heath.

## SOUTH LONDON SOCIETY'S EXHIBITION.

Sir,—I trust that the South London Society will not be prevented continuing their arrangements for an exhibition at the Crystal Palace, by what took place at the meeting of the London Society; it seems to me very unfair that the latter Society, having previously declined to hold an exhibition, should now step in at the last moment and interfere with arrangements made by an energetic "Suburban Society," my impression is, that hundreds would see and enjoy an exhibition at Sydenham, who would not take the trouble to visit one in London.

While on the subject of photography, may I ask what this new process of Mr. Melhuish's is? he stated in his evidence in Heath's case, that by a peculiar process of his own he could print 200 or 300 pictures a day, with one second's exposure to light; a very short time since at a meeting of the Amateur Photographic Association, he said that in consequence of the bad light he could not print much from the negatives sent in, how can I reconcile the two statements? It cannot be development printing, as "cartes" are always on albumenized paper.—I am, obedient servant,

A Photographer.

[You will find in another page the rules for the South London Exhibition. There is no antagonistic feeling to the exhibition on the part of the Executive of the Photographic Society, nor on the part of the society at large. Any such feeling, if it exist, is confined to individuals. Mr. Melhuish referred to printing by development. Of course his evidence could not legitimately apply to the pictures before the court.—Ed.]

## COPYRIGHT IN ENGRAVINGS.

Sir,—In connection with your article on "Photographic Piracy," in the News of Friday last, will you allow me to enquire of you or any of your correspondents how the fact of an engraving being "copyright" or not can be ascertained.

In the regular course of business it frequently happens that the possessor of a choice "proof" engraving wants to have it copied, and probably orders several impressions from the negative. Now as the photographer executing such a commission—assuming the engraving is copyright—obobviously renders himself liable to legal proceedings for infringement, it seems highly desirable there should be some means accessible for discovering whether a particular engraving is made copyright or not, so that one might be in a position to decide whether to accept or decline an order of this nature. There are hundreds of our profession who while they would not knowingly invade the privileges of others, at the same time do not wish to turn away work in cases where there exist "no just cause or impediment" to the contrary.—Obediently,

Copyist.

[The law of copyright in engravings is not by any means clear. We have not at hand the acts in force on the subject; but if we remember rightly the copyright of an engraving extends for twenty-eight years after its publication, the date of which and the name of the artist ought, to entitle it to the protection of the act, to be on each print. Whether the matter will be made clearer by the new act remains to be seen.—Ed.]

## Talk in the Studio.

Astronomy and Photography.—At the recent annual meeting of the Royal Astronomical Society, the gold medal of the society was awarded to Mr. Warren De la Rue for his valuable services in the application of photography to the extension of astronomical observations and their registration.

The Brussells Photographic Exhibition.—We observe that Mr. H. P. Robinson, of Leamington, received honourable mention for his contributions to the exhibition.

## To Correspondents.

Photographic Exchange.—The Secretary of the Photographic Exchange Club has received some views of Indian scenery from Lieut. Impey, but without any advice as to address, postage, &c. Will that gentleman be so good as to send the necessary information.

P. R. A.—Your print has been insufficiently toned. The use of a bath of salt and water before toning frequently causes the gold to deposit slowly. Try simple washing, or the use of the bath of acetate of soda recently recommended in our columns Your negative is manifestly a thin one, which does not allow of sufficient printing to get deep tones. The paper also appears of that quality which tones imperfectly. You will find a Saxe paper tone more easily.

Tripod.—The prices charged for tuition by London photographers vary according to their standing and ability, varying from one to ten guineas for a course of lessons. We believe the terms of Mr. Dawson, of King's College, are five guineas for a private pupil.

J. N.—The discoloration in your prints may arise either from the use of dirty dishes or dirty fingers. Handling the prints before fixing, with fingers which have touched hypo, or after they are fixed and before all the hypo is removed, with fingers which have touched nitrate of silver, will cause such stains to appear in the washing. 2. You will find full instructions for obtaining pure recrystallized nitrate of silver from metallic silver on pages 6 and 20 (Nos. 122 and 124) of our fifth volume.

B. H. C.—You will find all particulars and regulations regarding the Exhibition at the Crystal Palace in connection with the South London Society in another page.

Bolus.—A very low temperature is inimical to intensity. Use a larger proportion of Thomas's collodion in your mixture. The light is a little too evenly diffused around your sitter, a little more light on one side, and a little more shadow on the other, will give your pictures more brilliancy. We prefer a somewhat warmer tone. The picture is in many respects pleasing.

Cassandra.—You have accurately described what takes place on making a bath with impure nitrate of silver. We recently met with a very obstinate case of the same kind. An able practical photographer furnished us with half-a-pint of new silver bath, which had defied all means of making it work without fogging. We proceeded to adopt a course we had generally found successful; *i. e.*, adding oxide of silver, then exposing the solution to light for a few hours, filter, and adding a trace of nitric acid. In this case the treatment was entirely useless; we added a large quantity of nitric acid, hopelessly destroying sensitiveness before we got clean plates. We now added carbonate of soda, a large quantity being required, until a slight precipitate began to be formed; we then filtered, and found the bath neutral, and on trying a plate it gave a clean, rich, brilliant negative at once. The precipitate of carbonate of silver carried down with it some impurity which had been present. We do not charge any fee for advice; but we have not time to write private letters on personal difficulties.

R. D.—The various combinations which you describe might be made with the triple lens; but they would not be perfect, nor is the lens intended for so many purposes. As a copying lens the advantage claimed for it is freedom from distortion, and as a landscape lens, depth of definition. By removing the central negative lens, a portrait lens of short focus is obtained. By using the back lens an ordinary view lens of very long focus is obtained; hut neither of these are, we apprehend, quite so perfect as lenses made for the purpose. The front lens could not conveniently be used as a view lens in its present setting, and it would be too small. The curves of the back and central lenses are not such as render them suitable for forming part of an orthographic.

A. Johnstone proposes a method of exhibiting enlarged photographs with a reflecting steoroscope. The two halves of a stereoscopic transparency are placed in two magic lanterns and projected on to large screens. These screens are placed at the proper angles to be received by the mirrors of a reflecting stereoscope. We fear the result would not equal the trouble. The effect would he coarse unless the pictures and apparatus were all very first rate, and only one person could examine the result at a time.

E. E. L.—Our correspondent is right so far as the formation of chloracetic acid is concerned, but he has omitted a very important fact in the argument, and one of interest in other ways to the photographer, viz.—that the transformation only takes place under the influence of light. To form the compound he has given the formula of—*tri*-chloracetic acid $C_4\left\{\begin{matrix}H\\Cl_3\end{matrix}\right\}O_4$—the acetic acid must be exposed to the action of bright sunshine for some hours in the presence of a considerable excess of chlorine gas. If attempted to be prepared in the way he describes, diffused daylight at least would be required, and then only the mono-chloracetic acid would be formed $C_4\left\{\begin{matrix}H_3\\Cl\end{matrix}\right\}O_4$. Both these acids form soluble silver salts, indeed they are very similar to acetic acid. The supposition that a mixture of normal or partly reduced chloride of silver with acetate of soda would liberate an acid, is an error; and if it did not liberate an acid, it would not decompose the hypo in the way he thinks 2. Experience proves then the organic acid is better both for bath and developer, than the inorganic in all dry processes. Your other letter next week.

T. Burgoyne.—One or two errors or oversights in the paper of Mr. Sebastian Davis on the manufacture of Collodion are calculated to mislead. In the formula for plain collodion, drachms should be substituted for ounces. The formula should stand thus:

| | | | |
|---|---|---|---|
| Ether, methylated, sp. gr. 720 to 730 | ... | $4\frac{1}{2}$ | fluid drachms |
| Alcohol ... ... 837 | ... | $1\frac{1}{2}$ | " |
| Pyroxyline ... ... ... ... | ... | $6\frac{1}{2}$ | grains. |

This, with two drachms of the iodizer made according to formula, will give one ounce of collodion, containing $6\frac{1}{2}$ grains of pyroxyline, 6 grains of mixed iodides, and as much chloride of potassium and chloride of ammonium as it will take up. The phrase in which the proportion of iodizing to be added to the plain collodion is stated, requries the words "latter" and "former" to change places.

A. G. Z.—If you send us specimens of the prints, we shall be better able to help you. It seems probable from your description that your negatives lack intensity. If in toning you get some prints too brown, and some too blue, it would appear that care and experience alone are necessary to hit the medium. The best plan is to break the bottle of chloride of gold, and mix the whole of its contents at once with a definite proportion of water; say 15 ounces to the 15 grains of gold.

Beginner.—It is difficult to state the *best* formula for any process, as different methods succeed in different hands. Transparencies printed by superposition on tannin plates, give excellent results for the magic lantern. It is important to have very soft, well-detailed negatives. Several articles on transparencies appeared in our last volume.

A Subscriber from the Beginning.—There is no danger of your lens having deteriorated, unless you have put it together wrong. If it once worked sharp, it will always work sharp. Your phrase, "indistinct," is too vague to allow us to form an opinion of your difficulty. Indistinctness may arise from fog, movement, want of focus, &c. Send a specimen of the fault, and we will try to help you.

Blunderer.—The mixture of your silver bath with iron-developing solution inevitably spoils it as a bath. The iron will have partly reduced the silver; the only plan now is to complete the reduction and recover the silver originally contained in the bath. Place the solution in a flask, and boil over a spirit lamp until the reduction is complete. This may be ascertained by adding a little common salt, which, if all the silver be reduced, will cause no turbidity or precipitate. If any turbidity be produced add more iron, and continue the application of heat. Remove the precipitate and boil it for a few minutes with dilute hydrochloric acid, and then wash thoroughly. You will now have your silver in the form of a grey metallic powder.

Charles C. Macklay.—Pin holes in the negative arise from a variety of causes. Dust is one of the most fertile sources. The bath or developed requiring filtering, or the bath being super-saturated with iodide of silver will cause them. Where the negative requires the long-continued application of pyro and silver to produce intensity, they will often occur.

R. V.—The collodion which gives an image which entirely loses its brilliancy when dry is altogether unsuited for positives, and cannot be improved. The fault is in the pyroxyline. The collodion which has congealed in the bottle may be diluted by the addition of sufficient of a mixture of ether and alcohol in equal proportions. 2. The solution of bichloride of mercury used for whitening positives is generally saturated, or about 30 grains to the ounce. It is difficult to dissolve this amount in cold water, without the salt be well powdered.

A. You have applied insufficient heat, powder the slag, and proceed to again with the same process, adding a little more of the same flux, or a little borax instead, and use a higher heat this time.

E. F.—The value of your negatives, and the chance of disposing of them will depend largely on the interest of the subjects. Write to some photographic publishing house, such as the Stereoscopic Company.

Stereo.—Your suggestions shall be submitted to the Committee of the Exchange Club.

C. W.—You will find a report on your glass in the usual place. In the formula for the manufacture of pyroxyline given in our Almanack, for six measured *drachms* of mixed acids, read six *ounces*. The proportion of cotton and acids are not of great moment: it is only necessary to add no more cotton than can be immersed with comfort in the acids, so as to be completely submerged. With acids of the strength named no water is be added. Pyroxyline will keep very well keep very well in wide-mouthed bottles or jars, either stoppered or corked. Where more than an equal part of alcohol is added to the ether, a portion of the alcohol must be absolute. Where equal parts are used the alcohol may be of about 820 sp. gr. We prefer the excess of alcohol for all purposes: but mention the other formula because it is sometimes difficult to get absolute alcohol.

G. P.—A very simple method of ascertaining the amount of water in white of egg will will be to evaporate an ounce of it at a low temperature. We cannot help you to the atomic weight of albumen which is, as we before said, a very complex and somewhat variable organic compound. We regret that we cannot supply the information you seem to require, except so far as we have already attempted.

Sigma.—1. Not yet. 2. Yes. 3. Caustic potash will be supplied, under that name, by any chemist. 4. Boiling a nitrate bath will evaporate the ether and alcohol, and also some of the water, and facilitate the reduction of any organic matter present, but we should not boil one ourselves. Unless other causes were in operation, the bath on filtration would work properly afterwards. 5. Albumen being soluble in water could not be used in the same way as collodion without drying. The difference between a moist collodion film and a dry albumen film is very considerable. The former is simply a porous vehicle for holding a loosely compacted layer of iodide of silver, exercising little or no chemical influence on that film; the latter is a horny film forming a chemical compound of a complex character with the iodide of silver. 6. Photographic copies of music should have intense negatives which will bear deep printing: there will then be no difficulty in getting black and white prints. 7. Mr. Heath has not yet contributed his promised formula. We will bear your suggestion in mind.

William Dowler.—We do not know to what you refer as Mr. Sutton's quick-acting lens. Is it his instantaneous camera you mean?

An Old Sub.—The numbers you name are quite out of print.

W.—The use of methylated spirit should not in any way deteriorate a varnish. If it dry dull when sufficient heat is applied, add a little more of the gum. Nos. 6 and 8 of the Photographic News are out of print. The remaining numbers you require are in print. We are obliged by your offer of duplicates of the numbers you name; but of these we have stock.

Answers to a number of Correspondents, as well as the continuation of "Remarks on Apparatus," and a variety of other articles are compelled to stand over until next week.

# THE PHOTOGRAPHIC NEWS.

VOL. VI. No. 185.—*March* 21, 1862.

## INSTANTANEOUS DRY PLATES.

"If to do were as easy as to know what were good to do," exclaims Portia, "chapels had been churches, and poor men's cottages princes' palaces." The Photographic Society of Marseilles know what is desirable to be done, and what is more, are resolved to find out, if possible, the men who can do it. Our French neighbours have great faith in prizes, and if the offer made by the Marseilles Society, the conditions of which we append, have the effect of securing its end, beyond the possibility of a question, we shall be glad, even although we have to wait nearly two years for the accomplishment.

But we really hope the point will be satisfactorily settled long before December 1863. We ought, perhaps, to go further and say that it *is* settled, seeing that during the last few months we have frequently had to announce "Instantaneous Dry Processes" in our pages. Years ago Mr. Kibble produced instantaneous pictures of waves and shipping on collodio-albumen plates. We notice in another page of the present number a series of instantaneous stereographs, taken on Dr. Hill Norris's dry plates; and we have ourselves obtained instantaneous views on plates prepared in the same manner. Last summer we described M. Roman's instantaneous Taupenot process; and one of our correspondents, the Rev. J. Galloway Cowan, assured us of his perfect success in applying that method. Mr. Window recently described in our pages a dry process, in which the only application to the plate, after washing away the free silver, was gallic acid, and by which he obtained excellent instantaneous results. More recently, we received a communication from Dr. Draper of New York, describing his method of producing instantaneous pictures on tannin plates. Mr. Sutton has recently announced that he has discovered a series of modifications by which very rapid or instantaneous dry plates could be prepared. Mr. Bartholomew, and other gentlemen, have also made some contributions to the same end.

It would certainly seem, after this enumeration, that the offer of a prize, for the discovery within the next two years, of an instantaneous dry process, was somewhat late in the field. But although our French brethren are somewhat behind us in instantaneous work generally, and more especially in relation to dry processes, they are perhaps right in coming to the conclusion that something further is to be done. We think the most ardent dry photographer will scarcely say, we think, without *arrière pensée*, that instantaneous dry plates are certainties. We have not yet seen any results by the most rapid dry process which could fairly compare with the instantaneous pictures of Wilson, England, or Blanchard by the wet process. Something still remains to be done; and we have a firm conviction will be done, and that shortly. Long before the decision will be given at Marseilles an instantaneous dry process will, we hope, be amongst the familiar operations of photography.

We proceed, however, to lay before our readers particulars of the Marseilles prize. At the meeting of the society on the 31st of January last, it was decided to institute a general competition for the discovery of an instantaneous dry collodion process; the view of the Boulevard de Strasbourg, taken in full sunshine, with figures in motion, by Messrs. Ferrier and Soulier, being regarded as a standard of comparison. The following are the conditions:—

1. The prize shall be a gold medal value 500 francs; the competition to terminate on the 31st December, 1863.

2. The plates and details of processes intended for this competition should be addressed, free, to M. Leon Vidal, Secretary of the Society, 2, Rue Mazagran, Marseilles, and may be sent between the 1st of June, 1862, and the 15th of August, 1863.

3. The sensitive plates, for stereoscopic pictures, must be packed carefully sealed and light-tight, in a grooved plate-box, containing 12 plates; dimensions of the glass nine centimetres by twenty centimetres. [A centimetre contains 0·39371 of an inch, the plates will therefore be a fraction over $7\frac{7}{8}$ in. by $3\frac{1}{2}$ in.]

4. A communication describing, first, the nature of the process; and second, the method of development, must accompany each package.

5. The above condition as to the process will be required to be rigorously fulfilled only in the case of that which gains the prize. The Society will publish the formula and the process employed, but not in such a way as to deprive the inventor of his exclusive right of property therein; he will, in fact, be able to work his process profitably, and to improve its value in any way he may think proper.

6. The experiments will be made on the sensitive plates all with the same instrument, a quarter-plate combination, full aperture, of four and a-half inches focus, and under the same conditious.

7. One half at least of the members of the jury shall assist in the opening of the boxes and in the experiments, which shall be made with all possible and necessary precautions.

8. To test the keeping qualities of the plates, the development of some of them will be delayed from fifteen days to a month, according to the instructions attached.

9. The keeping qualities both before and after exposure will be carefully recorded, in order to aid the decision of the jury in those cases where they will have to choose between several instantaneous dry collodions possessing the other conditions named.

10. In the event of the jury being unable to award a prize of 500 francs, and cases occur meriting some acknowledgment, a medal of 250 francs value will be given to any one who has or has not taken part in the competition, but has nevertheless contributed by his researches to advance the discovery of a dry collodion possessing uniform and rapid qualities; and the prize of 500 francs will be deferred, with an addition of 300 francs, to the end of December, 1864.

11. All the questions shall be decided by a jury of examiners, composed of fourteen members of the Society. The following are their names:—MM. Gabriel (President of the Society), Leon Vidal (Secretary of the Society), Bremuller (Photographer), A. Guilbault, Hudelot (Cap. d'Etat Major), Joseph Jacquemet, Alexander Lefevre, Ernest Loire, Meynier (Professor of Chemistry), Alphonse de Proux, Arthur Taylor, Charles Teisseire, Thobert (Photographer), and Tissot.

## PHOTOGRAPHING THE ECLIPSE OF DEC. 31st, IN THE WEST INDIES.

BY WILLIAM TUCKER.

Eight or ten days before the 31st December, 1861, Mr. Cruther (the Government botanist) called on me, expressing a desire that I would join several other gentlemen, who were desirous of taking observations of the coming eclipse, and, if possible, photographs, at the Botanical Gardens, St. Ann's. A few days later he again called, stating that the Governor had received a communication from Mr. Hind, desiring, if possible, to have observations on the eclipse. Mr. Hind gave concise and simple instructions how to proceed, stating that the locality best suited for observation would be about Guapo, four or five miles south of the celebrated Pitch Lake, this spot being in a direct line of the central shadow.

By the request of his Excellency the Governor, a committee was appointed, consisting of Messrs. Cruger, Devenish, and Anderson; Lieutenant Le'Messieurer, R.E., and myself. The first four gentlemen to take necessary notes, observations, drawings, &c. &c., and I to btain photographs. Never having before attempted astronomical photography, I was puzzled how to effect the object, the sun depicted in the ordinary camera being too small to be useful.

On the 25th of December, at the Botanical Garden, I tried to fix the body of a $\frac{1}{4}$-plate camera to an ordinary astronomical telescope. In this I was successful, using the telescope in place of the usual lens. The method is best described in an accompanying photograph. This instrument is one of Lerebour and Secretan's, of a focal length of sixty-one centimetres. Object glass sixty-one milimetres. The field-glass had a magnifying power of 45. No eye glass was used. Having everything ready on this day, I got but a momentary peep of the sun, not sufficient for a trial. Next day the same. On Friday I had the instrument brought to my house in town. On Saturday I fortunately got one chance, and succeeded in obtaining an image. This was satisfactory, so far, and a proof that something might be done. On Sunday, the 29th, at 5 p.m., we started from Port of Spain, in the Customs' four-oared boat, which was much too small for the purpose, having to take with us provisions for three days, tents, &c. and changes of clothing. After an eight hours very painful and cramped journey of twenty-eight miles, we called in at Sanfernando (the only other town of importance) to pick up Mr. Hamilton Warner, whose astronomical knowledge we were wishful of pressing into our service. Him we roused from bed, when, unfortunately, he told us he had already made arrangements to take observations on the Sanfernando Hill, at the back of the town. Consequently we had not the pleasure of his company. We then determined to take two or three hours' rest at the only hotel in the town. At five o'clock on the morning of the 30th we resumed our voyage, at eight rounded Point La Brea, and at nine landed on the beach at Guapo, thirty miles south of Port of Spain, in a direct line, or forty by our route. Opposite the landing is the entrance to the Perseverance estate, where, leaving Mr. Cruger to superintend the disembarkation of luggage, &c. &c., we walked through a heavy, muddy road, to the manager's house, about a mile inland. Most fortunately we met that person then in the act of starting for the village of La Brea. His trip was put off, and. on learning our mission, he kindly offered the use of his dwelling, and immediately obtained eight or ten negroes and coolies to bring up the baggage, it being impossible at that season of the year to use a cart. By noon everything had safely arrived, and whilst breakfast was preparing, instruments were unpacked and adjusted, preparatory to a preliminary trial we were wishful of making. I was particularly anxious to test my instrument, chemicals, &c. to ensure the successful working on the morrow. This, like the preceding days, was dull and cloudy, having obtained but a glimpse of the sun just before he dipped below the Gulf of Persia. Our hopes for the coming day were below zero, and a successful issue very doubtful, particularly with myself. I got up several times during the night, which was fine. Mr. Cruger aroused us soon after four o'clock. Every person was now at work—some rolling puncheons for stands, others carying their instruments to the spot chosen as the observatory. By day-break all was arranged and coffee taken. On our earliest observations to eastward there was seen a dense bank of black clouds. This remained after day broke, and fears were entertained that it was the forerunner of a cloudy day. We anxiously waited the appearance of the Sun, which at 6h. 47′ rose above the cloud. It was hailed with applause. I immediatety got my instrument adjusted. and was highly gratified in obtaining a sharp image on the focussing glass. There appeared now nothing to mar our attempt, except the ominons looking clouds under the sun. Mr. Anderson, and Mr. Gardis (the manager) were appointed to assist me—Anderson to keep the sun in the centre of the field and note time, and Gardis to expose. According to Mr. Hind the first contact was to have taken place at 8h. 26′. Until the first contact I kept the sun's image in the field, and at 7h. 14′ 30″ fortunately observed the first appearance of the moon in contact. I sang out immediately on perceiving it, and in a few seconds every one was fully engaged.

Having coated and prepared a plate, at 7h. 19′ took photograph No. 1.—giving as quick an exposure as it was possible with the hand.

No. 2, taken at 7h. 28′. In this *negative* three spots appear on the face of the sun.

No. 3, taken at 7h. 36′ 20″.

No. 4, taken at 7h. 41′ 20″, immediately on the moon's contact with the two upper spots. A slight shadow is here perceptible on the lower limb of the sun.

No. 5, taken at 7h. 51′ 5″. The shadow is here considerably deeper.

No. 6, taken at 8h. 2′. In this the shadow is much sharpened, and still more perceptible.

No. 7, taken at 8h. 10′ 45″, the last taken before totality.

I now prepared a plate for taking the principal object, viz.: the total obscuration. This occurred at 8h. 26′ 25″. The scene now was appalling and grand. It appeared as if the sun was a ball of fire suddenly crushed, throwing out at different parts jets or rather rays of a bright orange colour. All nature was under its influence; the birds which but a moment before sang and chirruped around suddenly ceased. Domestic fowls had been gathering around the negro dwellings for some time before. A negress sung out from a neighbouring hut that the fowls were "going to bed." A cold chilly wind blew. The light produced resembled that of a dark room illuminated by placing a candle behind a sheet. I could see to work in my tent, it having a yellow glass window of about 6 inches aperture. These were my impressions from a momentary glance at the eclipse, around at the landscape and at the image on the focussing glass. Quickly inserting the dark slide Mr. Gardis gave the usual exposure (momentary), on applying the developing solution no image appeared, when it immediately occurred to me that from my forgetfulness it was insufficiently exposed, and, unfortunately, no time left for a second trial. A little forethought would have prevented this failure, had I taken the precautions to instruct Mr. Gardis that a longer exposure were required. The totality ended at 8h. 27′ 20″.

No. 8, taken at 8h. 34′, first after totality.

No. 9, taken at 8h. 39′ 40″. The double outline in this was caused by an accidental vibration of the camera.

No. 10, 8h. 46′ 20″, taken through the clouds which now began to obscure the sun.

No 11, 8h. 53′ 10″, taken through a cloud. In this the instrument had been moved, throwing a part of the image out of the field.

The bank of clouds which had been lying low in the horizon now moved rapidly upwards and obscured the sun, bringing with it a heavy tropical shower. I succeeded, however, during the first pioneer drops, in taking a view of our observatory, No. 11, and a group of the committee, No. 12.

During the time of observation the sun was slightly obscured by misty transparent clouds (see photographs).

Altogether we could not but be gratified at the so far successful issue of our journey. This was observable by the lively manner in which we enjoyed our *dejéuner*, Our trials were not, however, at an end. In returning to Sanfernando we were met with one of the heaviest torrents of rain that had fallen during the season. A few minutes drenched everything, and in less than twenty minutes filled the boat above our ancles with rain-water.

Fortunately we arrived in time to take advantage of the steamer, and reached Port of Spain at 10 P.M., on Tuesday, December 31, 1861.

The collodion used on this occasion had been iodized upwards of six months, using equal parts of iodide and bromide; developer—iron, acetic acid, and water.

[Mr. Tucker has kindly forwarded a complete series of the interesting photographs here described, showing the various phases of the eclipse. We shall have pleasure in exhibiting them at the next meeting of the Photographic Society.—ED.]

## REMARKS UPON SOME OF THE APPARATUS EMPLOYED IN PHOTOGRAPHY.*

BY F. R. WINDOW.

### FIELD CAMERAS.

*The Focussing Screen.*—It must depend entirely upon the particular design of a field camera, whether it is possible to make the focussing screen a part of the instrument, permanently attached to it, or whether it must be of necessity a separate piece. I think it is very desirable to have the focussing screen a fixture in field cameras; indeed more so than for the studio, as the loose screen when taken out of the instrument in the field has no recognised place in which it may always be laid out of danger, as may be the custom in the glass room, but it must be laid down, often on the ground, sometimes half hidden in high grass, in places where its presence may be temporarily forgotten, and it runs a continual chance of injury from a thoughtless movement of the photographer or any bystander.

As the perfection of the photographic picture does not in any way depend upon this question, I do not think that a camera which, in other respects, may be unexceptionable in design, should be rejected because the focussing screen belonging to it must of necessity be a loose piece, but it will be found a matter of convenience to adopt the plan I have named in all cases in which it is possible.

The focussing screen of a field camera must not be hinged to the instrument, as recommended for a studio camera, in such a way that it hangs down loose while a picture is being taken, (fig. 6.) as it would be caught by the wind. It must be contrived to fold in such a manner as not to be affected in any way by the wind. There are many ways in which this can be done, which need not be described.

*The plate-slide.*—It is usual to make the plate-slides intended for dry plates to hold two plates each, and they are, from this circumstance, called double backs. This type, I believe, is universal. It has often puzzled me to explain the cause of this uniformity in one particular detail of an instrument which in every other item of its construction has shown itself a very Proteus; and in which so many patterns and devices have been introduced, sometimes with a greater claim to novelty than to improvement. I confess that up to the present I have been unable to decide the question in a manner satisfactory to myself.

A double back, in a photographic point of view, has no superiority over two single plate slides.

Two single plate slides properly made need not occupy more space than one double back. The former need not be more costly, for the most expensive part, the sliding shutter, is supplied to each half of the double back, and each half should also have its separate back shutter. The single backs would fit into a groove one half the width of that required by a double back, and, consequently, the focussing screen would be that much narrower, and the whole apparatus be so much smaller. The number of single backs would be doubled for the same quantity of plates, but they would fit into the same space. If you drop a double back you break two glasses instead of one if the same misfortune happens with a single one.

These seem to be the chief arguments *pro* and *con*, and they appear to me so nicely balanced that I am surprised one form should have been so universally adopted to the complete exclusion of the other; that at least a few cases have not occurred where, if only for novelty, which has its attraction for some, the single back was used for dry plates.

After my remark, that there was, in a photographic point of view, no superiority in one kind of back over the other, it will not be supposed that I in any way intend by these observations to recommend the single slide in preference to the double back now in universal use for dry plates. I merely note the fact I have alluded to as curious.

The two most usual forms of double back are those which are fitted into the camera from the top, in which the sliding shutter opens upwards; and those which slide in from the side in which the shutter opens sideways. The former have a flange running round the upper end; the last are without any flange.

For many reasons a flange upon the plate-holder is open to objection. All projections are liable to fracture; also, they interfere with the facility of packing the parts together in a small compass. Their use should, therefore, be dispensed with as much as possible. Even the strips of wood at the bottom of the shutter, which serve as stops to limit its movement, are for the same reasons objectionable in field cameras, and it would be better to effect their purpose in some other way. For all mechanical purposes the best outward form for a plate-holder would be a parallelopiped, having all its surfaces perfectly plane and without asperities. I think we should give our preference to those which in practice approach the nearest to this type.

The double back should consist of two similar parts, each perfect in itself. It is very much the custom to make them with a single partition between the glasses, which is buttoned down upon one cell only. I think this is very objectionable. The sensitive glass plate in the cell, which is unprotected by any cover of its own, is unnecessarily exposed to the damp and other effects of the atmosphere, which can reach it by filtering through the joints of the two halves of the slide. Also when the slide is opened, the plate which is not retained in position by any mechanical means is very likely to fall out and get broken or scratched.

Considering the very trifling addition to the thickness of the slide which is occasioned by making each half alike and properly covered in, I think it is an error to omit this precaution. Also it will be found in practice more convenient, especially when only one plate is put into a double back.

In the early days of dry plates some double backs were made without any fixed partition at all between the two plates, which were simply separated by a piece of black paper. I have four slides made in this manner belonging to my first camera, but I do not believe that any are constructed so now. It is a dangerous system and should not be employed.

Care should be taken that the cells for the plates are of very full dimensions for the glasses they are intended to hold. It should be borne in mind that it is next to impossible to cut the plates exactly to the required size; some will be a trifle larger, some a trifle smaller. To allow for this an extra $\frac{1}{16}$th of an inch should be added each way, and at least $\frac{1}{8}$th of an inch should be allowed for the thickness.

## ON THE CHEMICAL EFFECTS OF LIGHT.

BY M. H. POITEVIN.

BEFORE employing the salts of uranium as reducing agents. I had, in March, 1857, experimented upon the action of light upon the lactate of uranium, which the *Annuaire de Chemie*, of Millon and Reiset, for 1848 (p. 281), pointed out as being very sensitive, and reduced to the state of oxide from the peroxide by light. I also knew that all the yellow salts of uranium are converted into green salts by the action of light, which reduces the salts of silver and gold; but I did not then know the application that had been made in England of the nitrate of uranium to replace nitrate of iron, in the chrysotype process of Sir John Herschell.

I prepared some paper with a solution of lactate of uranium, and I exposed it to the light under a negative—a very distinct image was formed; it was of a brown colour, which disappeared upon washing it in distilled water. I employed it with the view of fixing several re-agents: it was in vain, only nitrate of silver would fix it, by blackening it; this appeared to me very curious, and also very useful for printing positives. I did not continue my experiments, being too much engrossed in photographic printing, which I was gradually improving to bring it to practical use.

Some time subsequent to this M. Niepce de Saint Victor commenced his photographic researches upon nitrate of uranium. He communicated the results to the Academy of Sciences, but I know of his labours only through what has appeared in the photographic journals, in August, 1858, and May, 1859.

M. Niepce's labours were not undertaken from a chemical point of view, as is proved by his explaining the reduction of the salts of silver and gold by the uranium salt submitted to the action of light, as produced by a storing-up of the light; thus confounding the effect with the cause.

I did not resume my experiments upon the salts of uranium until the first months of 1859. I then perfectly explained the reaction I had observed in 1857. I proved anew that the salts of the peroxide of uranium, applied upon paper, were brought by light to the state of salts of the peroxide, upon which gold and silver solutions formed a deposit of metal; and, moreover, that the ferro-cyanide of potassium formed very beautiful red positives upon paper imbued with nitrate of uranium, printed through a negative. I fixed them by a simple wash with water, pure or slightly acidulated. I also changed this red colour into violet black, by treating the proof with a weak solution of perchloride of iron, which changes one portion of the ferro-cyanide of uranium, which is red, into ferro-cyanide of iron (Prussian blue); the mixture of these two colours produces violet more or less deep. By prolonging the action of the perchloride of iron upon the proof, I finally obtained a proof in blue, which I could change at pleasure into black ink (gallate of iron), as stated above.

The operations of nitrate of uranium alone upon paper are numerous and well known, and I have nothing new to add upon the subject. I shall, therefore, speak here only of the use I have made of this salt mixed with other maximum salts, with the view of accelerating their reduction by light.

*Nitrate of Uranium and Bichromate of Potassa.*

When a solution of bichromate of potassa is added to a solution of nitrate of uranium, a pale yellow precipitate of chromate of uranium is formed, which redissolves in excess of the same nitrate. Paper coated with this mixture is yellow. It bleaches in the light at first; then it turns rose red. If printed under a screen, by afterwards treating the paper with a solution of nitrate of silver, chromate of silver is formed upon all the parts that have been influenced by light. It is the same reaction as that produced when employing alloxantine and bichromate of potassa, and the same use can be made of it; only, it must be observed that here the nitrate of uranium does not exist in the state of protoxide salt in the solarized parts, for it reduces the nitrate of silver, but only after having been decomposed by light, it returns the oxygen to the bichromate of potassa.

A solution of ferro-cyanide of potassium colours the exposed portions of the proof brown-red; but upon afterwards treating the paper with a solution of perchloride of iron, prussian blue is formed on the impressed portions.

A solution of tannin produces no apparent effect; but upon afterwards treating the paper with a solution of per chloride of iron, ink (tannate of iron) is formed only on the influenced portions.

*Nitrate of Uranium and Bichloride of Mercury.*

Paper prepared with this mixture is very sensitive to light, which reduces the bichloride into protochloride of mercury; this is blackened by solution of hyposulphite of soda or by solution of ammonia.

*Nitrate of Uranium and Perchloride of Iron.*

This mixture, applied upon paper, very quickly loses its colour in the light, it changes from yellow to white; some nitrate of protoxide of uranium is at first produced upon the solarized portions and reacts upon the perchloride, which it changes into proto-chloride. The solutions of gold and silver are reduced by the proto-chloride of iron.

Ferro-cyanide of potassium colours the non-impressed portions brown, where it forms a mixture of ferro-cyanide of iron and uranium,

The ferro-cyanide of potassium forms prussian blue on the printed portions of the proof. This reaction is very marked, and may perhaps be turned to account, for we can easily, as I have stated, convert this blue into gallate or tannate of iron.

Solutions of tannin, gallic acid, pyrogallic acid, &c., produce ink on the portions which have not received the action of light, that is, where the perchloride of iron is not reduced. This reaction is also very distinct, and the one which I have particularly endeavoured to turn to account, and upon which I have based the method of photographic printing, which I published on the 29th of May, and which is inserted in the *Bulletin de la Société Francaise de Photographie*, June, 1859.

I shall continue my experiments upon the reduction of various maximum salts of iron, in view of their application to this kind of printing, almost all of them may be employed, even the sesquioxide itself, mixed with a reducing agent; but it is the nitrate that is the most easily reduced, next to the perchloride. I shall also search for less expensive reducing agents than alloxantine and nitrate, or lactate of uranium; and I have ascertained that glycerine, oxalate of ammonia, and especially tartaric acid, can well fulfil the same purpose. I always make use of tartaric acid now. On the 28th of May, 1860, I communicated a second process of printing with gallate of iron and prussian blue, with specimens on paper and textile fabrics.

*Positives.*

The proofs obtained in this manner, by making use of a positive to print from, are always deficient in stability on the surface of the paper, which the colour even penetrates, so that the proofs look much better when viewed as transparencies; this is specially due to the quality of the paper employed. If very sharp proofs are required, collodioned paper must be employed. It is prepared as follows:—

Upon a well-cleaned glass plate pour a film of plain collodion, immerse it under water, and when the greasy aspect has disappeared, withdraw it, and pour on the surface, several times, some acidulated water; then apply the gelatined side of a sheet of paper previously moistened with perchloride of iron and tartaric acid (10 of perchloride and 3 of tartaric acid to 100 of water); when complete contact is secured, the collodion adhering to the gelatined paper is removed. This paper is very sensitive to light, and yields very clear and vigorous proofs. It was during my last experiments that I discovered the impermeability communicated to paper by the mixture of perchloride and tartaric acid: light subsequently destroys this impermeability. I immediately thought of turning this observation to account for printing either with fatty inks, or with carbon in powder, &c.; but it was especially in seeking to substitute glass for paper that I remarked the new and curious fact of hygroscopy imparted to this preparation by light—a fact which has led me to, and forms the basis of, my second method of printing in carbon and inert powders, which process I communicated on the 26th of October last.—*Bulletin de la Société de la Photographie.*

## RECOLLECTIONS OF AN AMATEUR PHOTOGRAPHER IN PORTRAITURE.

BY NOEL E. FITCH.*

A friend of mine having a relation an officer in a cavalry regiment, asked me if I would kindly take his portrait; of course I consented to do so, and took a very successful one.

* Concluded from p. 129.

The sitter was a very good one—quiet and still, with a face even in repose thoughtful and expressive; and altogether it being a very good day, the picture was liked most immensely. Fifteen impressions from this half-plate did I give, and then was asked for more. This I playfully declined to do, but forwarded the negative to my friend, with instructions as to where any number of copies could be obtained by the very simple process of paying for them. I could give you numerous instances of this sort of thing, this want of consideration towards amateurs generally, not only in photography, but in water colour drawing, and in fact in anything which may be either an amusement to some, or a source of profit to others. I once, I assure you, had a friend bring me beside himself, his wife, and three children, of the respective ages of 6, 4, and 2 years, to have their portraits taken, without asking me if *I would* take them, and specifying as regards the children, that they should be taken like the sleeping child, which I shall have the pleasure of handing round to you this evening, and which they appeared to admire very much. I declined to make the attempt absolutely, and he departed in peace with a portrait of himself and wife only.

And this reminds me, gentlemen, that if I were to give you all my recollections of children offered and declined, I should possibly detain you here longer than you would wish. How my neighbours even who can see my glass house and guess at its use, and who possess (which of course it is) the prettiest little child in the world, will politely send the muslin'd and mottled-legged little thing, with a polite request that I will be kind enough to take its portrait. How also each little one is warranted to stand or sit like a lay figure; and the black looks we have to put up with from mamma, when we politely but firmly decline to make the attempt, unless her "lively beauty" be converted into a "sleeping" one, when of course there is not much difficulty in the matter; in fact, I think every fond parent desiring to possess photographs of their children should provide themselves with one of those extraordinary little instruments with that most extraordinary name, invented by Mr. Skaife, or else patiently wait until their little ones arrive at a really "taking" age. Strangely enough too, it happens that photographers who have children of their own very seldom indeed have photographs of them; no one likes the work, and it is put off from day to day with the usual result of such a proceeding.

The absolute hard work amateurs do, and call it amusement, is readily wonderful. Not for them is the handy youth to clean glasses, clear up the room-filter baths, wash bottles, or do the numberless little offices connected with photography—not for them is an assistant to sensitize paper, print, tone, fix, and wash—no, the whole work falls single-handed on the poor amateur, who simply consents to do all of it, and bear the expense of it too, for his love of the art, and all he asks in return is some reasonablenesses and consideration at the hands of his friends, and some encouragement for his efforts. To an amateur the most tedious part of photography is the printing and toning; and I firmly believe that visitors generally imagine that having obtained "the glass," as they call it, there is nothing more to be done. I have, however, lately found the printing so tedious, that I have given the negatives to their several owners, who have them printed by a professional printer, of course very much better than I could myself do for them.

Next, as to the satisfaction usually given by us amateurs to our sitters, I don't think we have much to complain of on that account; I find most of mine, at least, easily pleased; but the part that frequently surprises me is this. It happens with me, as also with several friends of mine, that having taken one negative, there is some *very* slight defect in it which induces me to take a second, which may be, turns out infinitely superior as an artistic picture: the two negatives are printed, and a proof of each submitted for selection; almost invariably the better one is rejected, whether it is as your secretary may inform you, that the second picture is too sharp, or from an absolute incapability of appreciating that which is better, I must leave to wiser heads than mine to determine. Recently, a professional photographer, with whom I am intimately acquainted, showed me some card pictures, with which he acknowledged he was very much dissatisfied—they were certainly not up to the standard of his productions, but after hesitating for some little time, he finally sent them home, expecting of course to hear complaints of them; but, much to his surprise, received in a day or two a very good order for impressions from the same negatives.

Usually people admire the *best* and *most artistic* portraits of *their friends*; but, strange to say, are not so critical with portraits of *themselves*; in fact, they sometimes, like Narcissus, fall in love with their own reflection, and with the usual blindness of that condition, fail to see most patent defects in the picture.

Some short time since, I was spending an evening with a friend, and photography forming the subject of conversation, a gentleman present said—"he certainly admired photography; but out of the great number of portraits he had seen, he had rarely met with one representing the face with a pleasing expression. Some appeared staring, others in pain, and but very few absolutely truthful;" and in furtherance of this (although to my mind a perfect refutation) he pointed out some really beautiful productions on the walls of the room.

One portrait, however, he admitted to have seen, nay to possess, which comprised all that *he* wished, which was indeed all a photographic portrait should be, viz., truthful to nature, pleasing in expression, and graceful and easy in pose; in fact, he said he happened to have it in his pocket. I naturally asked permission to see so great a gem, to admire and imitate, to beg, borrow, or steal it, so that I might call it mine, and thus have for my model this wonderful type of all that was perfect. He consented, and as in the schoolboy tale of the "Chamelion," he produced the card, and lo! it was himself; badly taken, and as badly printed, and as to truthfulness of expression, the man had hair of that colour which cannot be represented by photography, and carried on his face a most decided smirk. I could not restrain a smile, and coldly telling him I did not think much of it, he replaced it in his pocket, and did not speak to me again the remainder of the evening. Fortunately photography stands in no need of begging admiration; it has grown from a very small seed, is growing, and will, I feel sure, continue to do so while the world lasts, more especially while it receives the august patronage it has hitherto secured.

Gentlemen, I submit for your inspection a few photographs, the best that I can do: be merciful while you strike; remember, if you please, that I am only an amateur, compelled to work at odd times, and those frequently at some distance apart. The main object I had, however, in bringing them this evening was to show you the results produced by my old faithful friend Pyro, as a developer. It is said that this is the "iron" age, and that, I suppose, has something indirectly to do with the use of that metal as a reducing agent; but, irrespective of the double process necessary in its use, I have always found that I could do everything I desired with pyrogallic acid. The whole of the portraits now before you were taken in a glass-room, with the sitter facing due south, the slides being totally opaque, and the front admitting scarcely any light at all; and, without wishing to "bore" you, I will shortly tell you my mode of taking them. The lenses are Ross's, the bath 40 grs. to 1 oz., without any addition whatever. The collodion, Ponting's negative, and the developer $1\frac{1}{2}$ grs. Pyro to the oz.; the smallest quantity of glacial acetic acid, with which to ensure a clean picture, and a little alcohol to make it flow easily. Fix by pouring saturated solution of hypo on the plate, not by immersion. From this I seldom vary, save for experiment; and as I never intensify by adding silver to the developer, but produce my negatives by one (albeit prolonged) development, I do not think I shall resort to other means. Results surpassingly beautiful have been, and are produced, with iron, but the tendency with many manipulators is to produce hard negatives with violent contrasts. I find my way simple, and to me tolerably certain, and although it may be old fashioned, it answers my purpose in all that I wish. Too much light I find a decided objection with pyrogallic acid, and it is a matter of surprise with gentlemen who have visited me to find all my light received through the top only, and even that for the most part through stippled glass. I like to see the light fall on the sitter, so as to give a gloss to the hair—it looks to me natural and familiar, for in these days of Maccassar and pomades it is always visible, either by day or artificial light. I suppose, however, it is simply a question of taste, or, perhaps, with me, a very "questionable" taste. Although the aspect of my room is certainly not the best, on account of the sun, I am almost of opinion that it produces greater roundness of feature than any other, and should certainly choose the same aspect on building another.

Before I conclude I should like to draw the attention of photographers to the great advantage of the automatic washing system; many friends who have seen my arrangement have immediately constructed one with success, and have found on testing that, with the occasional use of a sponge, the prints have been perfectly washed. The contrivance is very simple and may be made by any gentleman at the expense of a few shillings, it will last for years and is not at all likely to get out of order. I have a diagram here which will perhaps explain to you its construction;

it is simply, as you will observe, an oval wooden tub with an orifice made some two inches from the top, through this is inserted a leaden pipe of about $\frac{3}{4}$-inch bore, which is then brought to the bottom of the tub through a false and perforated bottom of zinc, the portion of the pipe immediately in connection with the outside of the orifice is then bent into two elbows, taking care that the second is slightly below the first, it is then continued any length you please. Immediately the water rises above the first and higher elbow the syphon begins to work, and rapidly empties the tub from the bottom. The false bottom is only to prevent the prints being sucked up the pipe. I am aware there is nothing new in this, but it may have escaped the notice of many gentlemen, and I wish to bear my testimony to its advantages, as all that is necessary is to place it below the tap of a cistern, in such a manner that the influx may give a rotatory motion to the prints, with the projecting limb over a drain, and regulate the supply so that it shall emty itself, say three times in the hour.

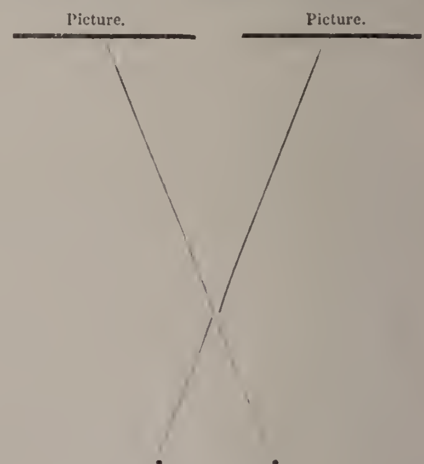
One word with respect to varnish, about which we have lately read so much. I have for a very long time used varnish prepared after a receipt of a very practical friend of mine. I can vouch for its usefulness, cheapness, and capability of standing any amount of sun-heat. Obtain from any colourman some best white hard carriage varnish, and dilute the same down with methylated alcohol. Warmth is necessary for its application, and the right proportions are soon ascertained after a few trials. Should it become cloudy on adding the alcohol, in a few days it will become absolutely limpid and may then be decanted, immediate filtration, however, having the same effect. Gentlemen, I thank you for your attention.

## ON THE STEREOSCOPIC PICTURE EXECUTED IN THE SIXTEENTH CENTURY BY JACOPO CHIMENTI.

BY SIR DAVID BREWSTER, K.H., F.R.S.

In 1859, when Dr. John Brown and his brother Dr. Alexander Crum Brown were visiting the Museum of Wica at Lille, their attention was called to two pictures of a man sitting upon a low stool, and holding in his left hand a pair of compasses, and in his right hand a line reaching the ground. These two pictures appeared to be exactly the same, as if the one had been copied from the other. They were each about *twelve* inches high and *eight and a half* broad, and were placed close to one another like the pictures in a stereoscopic slide. Dr. A. Crum Brown, on his return to England, sent me, through Principal Forbes, the following account of these two pictures, which I think was read in his presence at a former meeting of this Society.

"These two drawings," he says, "are by Jacopo Chimenti da Empoli, a painter of the Florentine school, who was born in 1554, and who died in 1640. They are drawings of the the same person from points of view slightly different. That on the right hand is from a point of view slightly to the left of that on the left hand. They are so exactly on the same scale, that by converging the optic axes I succeeded in uniting the two so as to produce *an image in relief*. They united so easily and completely, that I could not help



thinking that they had been drawn for the purpose of being looked at in that way. So far as I could judge, the difference between the pictures was greater than would be produced by a change of the position of a spectator equal to the distance between the two eyes; so that *the stereoscopic effect was somewhat exaggerated*. I think, if we had a photograph of the pictures it would be much easier to prove their stereoscopic character than merely by referring to them; and if the photographs were of such a size that they could be *transposed* and put in the stereoscope, any one could see it."

I had no sooner received this very interesting communication from Dr. Crum Brown, than I took measures for obtaining a photograph of this stereoscopic picture. I wrote to M. Delezenne, a corresponding Member of the Academy of Sciences, requesting him to have such a photograph executed at my expense. In reply to my letter, he told me that photographs were not permitted to be taken of the objects in the Museum, but that Mr. Bingham was engaged in taking photographs of them for the Prince Consort, who alone had received this privelege from the trustees of the Museum.

Upon receiving this information, I applied to the Prince Consort, through Sir Charles Phipps, for a copy of the photograph of the stereoscopic picture, and explaining the high interest which attached to it as a great fact in the history of binocular vision and the stereoscope. In answer to this application, I learned that though the Prince had not the slightest wish to confine these photographs to himself, yet His Royal Highness did not think that he had any power to give permission for additional copies to be taken, though he certainly had no objection to this being done.

When I received this letter, I was writing the article "Stereoscope" for the *Encyclopædia Britannica*, and I inserted in it the remarkable discovery made by Dr. Crum Brown. I had previously shown, in my "Treatise on the Stereoscope," that Galen had, 1500 years ago, proved that in looking at solid bodies the pictures given by each eye were dissimilar, and that with both eyes we saw these two pictures combined. In illustrating these views of Galen, Baptista Porta gives a figure, in which we not only see the principle of the stereoscope, but a virtual representation of the binocular slide by three circles, two of them indicating the right- and left-eye pictures, and the middle one the other two united by the eyes and producing the figure in relief which we actually see.

The work of Baptista Porta, containing this diagram, was published in 1593, and Jacopo Chimenti lived 47 years after its publication. It was therefore probable, as I stated, that in executing the stereoscopic picture Chimenti was illustrating the binocular diagram of the Neapolitan philosopher, and was the true inventor of the ocular stereoscope, that is, of the method of obtaining a solid representation of any object by uniting right- and left-eye pictures of it by converging the optic axes to a point nearer the observer than the pictures.

This was founded on the supposition that Chimenti's figures were truly stereoscopic; and as I knew that Dr. Crum Brown was thoroughly acquainted with the subject of binocular vision and the theory of the stereoscope, I had no doubt that he had seen a figure in perfect relief by uniting the two plane pictures of it.

Having failed in procuring a copy of these pictures, I had no means of testing the accuracy of Dr. Brown's experiment; but it appears that in June 1860, Mr. Wheatstone applied applied to Prof. Kuhlman, of Lille, and obtained from him a photograph of Chimenti's drawings. In the letter which accompanied it Prof. Kuhlmann states "that the copy has been taken of such a size as to be suitable for examination *in the stereoscope*," and he adds "that, at the first sight of it, and without the aid of any instrument, it would be seen that the two pictures were *not stereoscopic*."

The photograph, thus described, was accordingly placed in the stereoscope by Mr. Wheatstone and his friends in London, and they all found it *not to be stereoscopic*.

(*To be continued.*)

## Critical Notices.

TRAITE' POPULAIRE DE PHOTOGRAPHIE SUR COLLODION; contenant le procéde négatif et positif, le collodion sec, le stéréoscope, les epreuves positives sur papier, &c., Par D. Van Monckhoven. Paris: Leiber.

This is one of the best elementary works on photography which has yet reached our hands; popular, explicit, and complete; and above all illustrated with a series of engravings, numbering upwards of a hundred, which make clear to the uninitiated better than any amount of letterpress description, the exact character of the various manipulations to be effected.

We have delayed our notice of this excellent little work, which we received at the beginning the year, because at one time we contemplated translating and editing it for English readers, the author having kindly some months ago made application to us for that purpose. Although our own time did not permit us to undertake that duty, we have pleasure in informing our readers that it will shortly appear in an English dress, with the same copious illustrations. Messrs Horne and Thornthwaite will, we believe, publish it. We defer therefore a detailed notice for the English edition. We may add here that some original articles from M. Van Monckhoven's pen will appear in our pages shortly.

INSTANTANEOUS STEREOSCOPIC VIEWS, taken on Dr. Hill Norris's Dry Plates, by H. Sampson, Southport.

However much faith we may have in a process, we like to see tangible results. Descriptions may be very accurate, but they are always the results of other peoples' impressions. In relation to instantaneous pictures, this is especially true: when no further guide can be obtained than is supplied by a narrator's impressions, an instantaneous exposure may mean anything from a tenth of a second to one or more seconds, whilst the result which may be called a picture, is possibly nothing beyond a silhouette without detail. With results before us, there need be no mistake on the latter point, whilst as regards the former, some data is generally supplied by the amount of definition or blurring in moving figures.

We have before us something like a couple of dozen stereoscopic slides of marine views, with shipping and steamers at full speed, and street scenes, with moving figures. As the results of dry plates, they are truly marvellous, and we may state at the outset, without any derogation from their excellence, that whilst they are not equal to the best of Wilson's, England's, or Blanchard's pictures by the wet process, the majority of them equal and surpass much that is called instantaneous photography. The subjects chosen are very daring, and involve great contrasts: here a stormy sea, with shipping in the distance, with a boat landing through the surf in the immediate foreground. Here a view of the new iron pier at Southport, with a gay assemblage of not less than a hundred persons; and another "On the Shore" at Southport, with a motley crew of many scores of persons. It is somewhat singular that these views are best in which we should most readily have expected failure. The pier just referred to is one of the best exposed and best defined pictures in the series; clouds, water, figures, foreground, all being good. The scene on the shore is also very good, as are various street scenes in Liverpool. Most of the pictures have natural clouds. In some of the marine views there is under-exposure, and in some a want of instantaneity; but there is enough in all to prove that more may be done. We have no particulars as to the lens or aperture; but we are disposed to believe that something better might be effected. In the printing also, Mr. Sampson has scarcely done himself justice; the tones being too black and heavy for the subjects, a warmer tone would have relieved the appearance of under-exposure, which some of the pictures possess. On the whole, we are highly gratified by the series, as giving high promise of what may be done with instantaneous dry plates. We congratulate Dr. Hill Norris on the result, for whilst we have ourselves produced instantaneous pictures on his plates, and heard of others doing so, this is the first commercial series which we have seen issued.

## Proceedings of Societies.

### South London Photographic Society.

The usual monthly meeting was held in the City of London College, Leadenhall Street, on the evening of Thursday, March 13th. Mr. G. Wharton Simpson in the chair.

The minutes of the previous meeting having been read, the following gentlemen were elected members of the society:—Messrs. C. T. Newcombe, T. Lloyd, T. Mills, S. Cawston, E. Buck, and F. Fitch.

The Secretary then read the address and regulations for exhibitors at the Crystal Palace, which appeared in our last.

Mr. Noel E. Fitch read a paper entitled "The Experiences of an Amateur in Portraiture," (see p. 127.) Mr. Fitch exhibited an exceedingly fine selection of his productions as an amateur in portraiture, the whole of which were distinguished by great softness and delicacy, and were much admired.

After some conversation on the specimens,

The Chairman called attention to the fact that notwithstanding the absence of all side-light in Mr. Fitch's room, which was only illuminated from the top, these pictures were full of half-tone, and free from heavy shadows under projecting features.

Mr. Sebastian Davis presumed that the sitter was effectually screened from direct vertical light by having the part immediately overhead darkened.

Mr. Fitch explained that he had two feet six inches dark at one end of the room; but that the sitter was placed flush with the front edge of the darkened part. A portion of the glass adjoining the darkened part was stippled. His usual exposure in a pretty good light, with a quarter plate lens, was about twenty seconds, using Ponting's collodion and pyrogallic acid development.

Mr. Davis remarked that he believed when Ponting's collodion was used, nothing was gained by iron development and intensifying.

Mr. Fitch said he occasionally used iron in dull weather, and he thought with advantage.

Mr. Howard wished to bear testimony to the excellence of the varnish Mr. Fitch had described. He had now used it for twelve months. He found it very easy to make and use, very hard, and free from tackiness, even in strong sunshine. It was a much better protective than any of the varnishes he had ever used without heat.

Mr. Wall said he had tried three different samples of varnish sold for protecting negatives, and found none of them good. He had recently tried that recommended by Mr. Fitch, and had found it perfectly satisfactory.

The Chairman said that the varnish mentioned by Mr. Fitch, known as white hard varnish, was a spirit varnish, made, he believed, with lac, copal, and sandarach. As a general principle, spirit varnishes requiring the aid of heat in application, afforded a better protection to the negative than any varnish which could be applied without heat. The latter class was apt to turn tacky in the heat of the sun; and the gums were generally more friable, so that the varnish was easily scratched and abraded.

Mr. Martin asked if Mr. Fitch used the same formula for the exquisite reproductions which were laid on the table.

Mr. Fitch used everything just the same, but he always placed the picture to be copied in full sunlight.

Mr. Cole asked Mr. Fitch with what the glass in his studio was stippled.

Mr. Fitch: With white lead and turpentine.

Mr. Cole asked if this had any advantage over ground glass.

Mr. Fitch said only that it was cheaper. It was apt to turn yellow, and also to scale off in winter. He had it done afresh, therefore, each spring.

Mr. Davis said that having a south aspect, he presumed all Mr. Fitch's practice was in the early part of the day.

Mr. Fitch said except in winter, when the sun was very low, the stippling shut out the light from that part of his room where he placed his sitter.

Mr. Howard remarked that whilst Mr. Fitch was an amateur he had all the appliances of a professional photographer. He also avoided the false economy of using bad materials, either in chemicals or apparatus. He thought it was wise in amateurs to take a lesson from professional photographers in this respect, who always found the best the cheapest.

Mr. Harman said in reference to the use of pyrogallic acid development, it was always better to avoid the addition of silver. He thought the length of exposure was longer with pyro than iron; and in portraiture that was a question of considerable importance in securing agreeable expressions.

The Chairman remarked that Mr. Fitch had stated that he used iron occasionally in dull weather; by which, of course, he implied that a less amount of exposure was necessary. There could be no doubt about the possibility of producing the softness and detail which characterised Mr. Fitch's pictures by means of pyrogallic development, provided sufficiently long exposure were given. The cause of pyrogallic acid negatives often having harsh contrasts arose simply from the practice of under-exposure. The great advantage of iron development consisted in the fact that it gave a softness and detail with a very much less exposure than was necessary with pyro development.

Mr. Fitch expressed a conviction that one cause why longer exposure was necessary with pyro development, was the custom of adding excess of acid. He did not adhere to any specific quantity; but always added as little as possible, just sufficient to prevent fogging.

Mr. Davis remarked that Mr. Fitch in giving a somewhat longer exposure than many professional photographers, used at the same time a much more subdued light, by which means it was comparatively easy to sit the longer time without discomfort. He had observed, moreover, that where pyrogallic acid development was used, a subdued light gave much softer pictures than a glaring light.

Mr. Fitch, in answer to a question, stated that he toned with gold prior to fixing. He first neutralized any free acid in the gold by adding carbonate of soda, and then adding a little acetate of soda, he was not particular as to the amount. He wished especially to call attention to the automatic washing trough which he used, and which he found very efficient. He gave his prints 24 hours' washing, during which time they were sponged three times, and finished with boiling water. The prints were generally washed two hours before toning, during which time they had four or five changes of water.

Mr. Harman was in the habit of washing prints before toning in three waters, for five, ten, and twenty minutes respectively. If the last water showed no milkiness, he thought that was sufficient.

Mr. Howard thought no matter what little troubles might have been found in the alkaline gold toning process, it had established its reputation for permanency. It had been in use upwards of three years, and it was an uncommon thing to see yellow fading proofs which had been subjected to its treatment.

After some further conversation, the subject dropped.

The Chairman then said in the absence of either Mr. Blanchard or Mr. Fry, the mover and seconder of the adjournment of the discussion on Mr. Davis's paper, he would call on Mr. Lane to open the question.

Mr. Farringdon Lane said he had but little to say on the subject. In his experience as an engineer, he had been struck with the fact that the manufacture of gun cotton for explosive purposes, was attended with as much or more uncertainty as its manufacture for photographic purposes. Two charges labelled as having each the same power would have entirely different effects. One would tear a rock to fragments, whilst the other would scarcely produce any result at all. One of the largest and most careful manufacturers had at the present time some hundreds of pounds of it sunk in the river, afraid to take it out of the water. If it were not for this uncertainty, it would be of immense service in tunnelling, as it gave off no sulphurous fumes as gunpowder did, which caused much loss of time, in preventing men from resuming work at once.

Mr. Harman asked if proper care were used in making the gun cotton.

Mr. Lane said he believed the greatest care was used. The firm had paid a very high price for the sole right to use it in this country.

The Chairman said he believed that it would be impossible to manufacture gun cotton, commercially, for blasting purposes, with the care which was necessary in producing it for photographic purposes. It could not for the latter purposes be made in large quantities with any success. From half an ounce to an ounce was the largest quantity which should be made at a time, if uniformity and excellence were desired.

Mr. Davis would not recommend amateurs to make more than the quantity he had recommended at one time. If a quantity were required, two lots might be going on together, but the greatest uniformity was obtained by operating on small quantities. If a large quantity were attempted, a minute or two might elapse between putting in the latter part of the cotton and the first, and a difference in character must be the result.

Some further conversation on the subject followed, in the course of which Mr. Davis explained that from a clerical error in his paper, the proportions had been mis-stated. He really used 4½ drachms of ether, and 3½ drachms of alcohol in each ounce of collodion, and in these he dissolved about 6½ grains of cotton, which was rather more than the proportion commonly used. He also showed some samples of collodion, one with the tough character made with strong acids, and another with the powdery character made with excess of water in the acids.

The Chairman pointed out a characteristic in the latter, which he stated would generally be found to be accompanied by intensity; he referred to the milky appearance. He had noticed that wherever the plain collodion was characterized by an opalescent or milky appearance, it indicated the presence of that tendency to form an organic compound with the silver, and give great intensity.

Mr. DAVIS had noticed the same characteristic, and probably the Chairman would remember that at the time Mr. Hardwich recommended his formula to the society, he (Mr. Davis) had stated that less water was desirable, both to prevent decomposition during manufacture, and for the quality of the results. Regarding the use of bromides, he thought that the quantity should be regulated by the quality of the pyroxyline. With the pyroxyline he recommended, about half a grain to the ounce was sufficient. With a pyroxyline giving greater intensity, more might be used, up perhaps to one grain.

Mr. HARMAN thought more bromide might be used with advantage where iron development was used, than with pyrogallic acid development.

Some consideration on the use of bromides alone followed, in which it was generally agreed that bromides alone gave much less sensitiveness than either iodide alone or a mixture of iodides and bromides.

Some conversation on the cause of streaks in the direction of the dip followed, in which Mr. Fitch remarked that it often occurred to him with pyrogallic acid development, but never with iron.

The usual votes of thanks terminated the proceedings.

---

CHORLTON PHOTOGRAPHIC SOCIETY.*

THE ordinary meeting of this Society was held on the 13th ult., —Mr. W. Griffiths, Vice-President, in the chair.

The minutes of the previous meeting received confirmation, and a few items of the Society's private business were disposed of.

The CHAIRMAN in opening the discussion on dry collodion processes, detailed some experiments on simply washed and dried collodion plates, and said he thought that coating the sensitive film with albumen or any other substance was a step in the wrong direction, as such substances always had the effect of diminishing sensitiveness, independently of the extra amount of labour entailed in their preparation. His opinion was that their experiments ought to be directed to the addition of substances to the collodion itself: something had already been done in that way, and with sufficiently encouraging results. The perfection of a collodion film was that in which iodide of silver was intimately associated with another salt of silver, such as the nitrate, acetate, bromide, chloride, &c. It was a mistake to suppose that an organic substance *per se* increased the sensibility of iodide of silver. The effect produced by resin in collodion was simply mechanical. On dipping in the nitrate bath the resin (insoluble in water) became precipitated throughout the substance of the film in the state of a fine powder; and, in the act of that precipitation, each particle carried down with it a portion of nitrate of silver, which was retained with too much force to allow of its entire removal by the ordinary subsequent washing. Some kinds of collodion (without the addition of resin), simply washed and dried, would produce very good results, and in those cases it would be found upon investigation that a small portion of the pyroxyline composing them had, from the temperature or strength of the acids employed in its manufacture, been converted into a resinous substance, as proved by the later researches of Mr. Hardwich. These were the collodions generally preferred for dry processes, and to which the term "powdery" had been applied. Collodion of the opposite or horny character was believed by competent authorities to be without action on nitrate of silver. If *chemical action* was understood that was no doubt true; but the fact was patent to all that such a collodion simply washed and dried would produce pictures, though not always successful ones. In that case also its action must be referred to as mechanical only, retaining, though with less force, a small quantity of free nitrate of silver in its pores. Some might object to that as not possible after the thorough washing usually given to the plates; but any one might prove for himself the correctness of the statement, by stripping off the film from a glass, putting it into a test tube, with a little distilled water, and, after well boiling, filter, then test the clear liquid with a chloride, and distinct evidence would be obtained of the presence of silver. In fact he believed it to be more difficult to wash out every trace of free nitrate from a film of collodion *whilst attached to the glass*, than to remove it entirely from paper that had been dipped in it, and that would be found a matter of no small difficulty if simple washing in distilled water were resorted to. Assuming what he believed to be the fact, that iodide of silver was totally incapable of change under actinic influence without the presence, in immediate contact, of some other salt of silver, an explanation was at once afforded of many of the strange anomalies met with in working the various dry processes. Referring to iodide of silver, he said it was susceptible of change under light or not according to the manner of its formation. If it were produced by precipitation from a solution of the nitrate or other soluble salt of silver, and with excess of the silver salt, it would be darkened by light, but not so if the *precipitant* were in excess: and yet the two iodides were identically the same in their chemical constitution. The difference in their properties he accounted for in this way:—Every particle of iodide of silver precipitated from a solution in which nitrate of silver was in excess carried down with it a portion of the latter (for which it had, like most precipitates so formed, a kind of mechanical affinity); and however much it might be washed it would still retain sufficient to make it susceptible to actinic influence. The same thing occurred when iodide of potassium or other precipitant was in excess: a portion of *it* was in like manner carried down in mechanical combination, and from which it was almost impossible by washing to entirely free it. But iodide of potassium, not being a salt, like nitrate of silver, susceptible of change when exposed to light, the iodide of silver formed in that way did not darken on exposure; for it could not be expected that two stable iodides, whose affinities were both satisfied, should react on or decompose each other. The latter or insensitive iodide could be converted into the former or sensitive iodide by adding to it the smallest trace of nitrate of silver.

Mr. WARDLEY said it was generally understood that a powdery film was best adapted for dry work; nevertheless his experience led him to prefer a collodion that gave a slightly horny film. He could not say he had found powdery collodions more sensitive than such as he was in the habit of using, nor could he say the powdery kind had in his hands produced greater density of image.

Mr. HOOPER objected to the conclusions arrived at by Mr. Wardley. He had a firm preference for the so-called powdery film, and had long considered it quicker in the camera, or otherwise more sensitive to the developer, than the horny sort of film. He had never experienced any difficulty in obtaining a sufficient degree of density. The addition of resin to most collodions gave such a film as he had a partiality for in dry collodion work.

After some further discussion, the proceedings terminated.

---

MANCHESTER PHOTOGRAPHIC SOCIETY.

AN ordinary monthly meeting of this society was held on Wednesday, the 5th inst., Mr. PARRY, Vice-President, in the chair.

Mr. KERSHAW presented six photographs for the society's portfolio. One of these was a copy of an engraving taken by Mr. Dallmeyer's triplet lens, and was nearly the size of the original. The margin was perfectly straight and square, and the definition in all parts was beautifully rendered.

The CHAIRMAN said that Mr. Sidebotham, who was unavoidably absent, had requested him to present a copy of the title-page of THE PHOTOGRAPHIC NEWS, very nearly the size of the original, and taken with one of Mr. Dallmeyer's triplet lenses by Mr. Wardley. This, as in the case of Mr. Kershaw's photographs, exhibited qualities rarely met with in full-sized copies.

The SECRETARY remarked that he could appreciate the difficulties of obtaining such copies as these, he having had some experience in that direction. Copies were easy enough, so long as a considerably reduced result was desired; but, when it was sought to obtain a negative approaching the original in size, then no lens but one of very superior capabilities would answer.

The CHAIRMAN said he had also been requested by Mr. Sidebotham to lay before the meeting a print he had received from Mr. Woodbury, of Batavia. The negative was taken in a stereoscopic camera with two lenses, and at two operations, so as to obtain a panoramic effect. It was quite impossible for the unassisted eye to detect the junction of the two exposures. So complete, indeed, was the union that it was considered there must be some error in the description, and that the whole had

* Our notices of the proceedings of provincial societies, when not received direct, are condensed from their official organ.

been exposed together. By the aid, however, of a powerful lens a faint line was discovered which showed there had been two exposures. He (the Chairman) had himself tried a similar thing, but with one lens. He first of all focussed for one part of the picture, then for the next after turning the camera upon its centre, making a mark to denote the point to which it was to return, after the first exposure, and he thus obtained a panoramic picture; but he had not taken the precaution to use a spirit level, and he therefore had one part of the picture higher than the other. His experiment, however, was sufficient to show that the thing could be done if the camera were arranged perfectly level.

Mr. Petschler suggested that the picture might be produced by causing the camera to turn upon a point coincident with the stop, if a single lens was used, or with a point midway between, if double lenses were employed. This he illustrated by a diagram upon the black board.

From information subsequent to the meeting, it appears that Mr. Woodbury used an ordinary binocular camera without any special arrangement. One-half of the picture was taken with one of these lenses, the other being closed, and then the other half with the second lens, the camera having been turned to a point previously registered. In focussing for the two exposures it is necessary to make the one picture slightly overlap the other, but this does not cause a line of demarcation, the light gradually softening from one image to the other.

[We may remark in connection with this subject, that some months ago Mr. Penny, of Cheltenham, sent us one of the finest prints we have ever seen from a tannin negative, which consisted of a panoramic picture produced at two operations with one stereoscopic lens, the camera being wheeled round so as to produce the right junction. It was only on the most minute examination that any appearance of a division or junction could be discovered, and the effect in the particular subject chosen was very good. It must not be forgotten, however, that the perspective is inevitably false, as the pictures must have two points of sight.—Ed. Photographic News.]

## Correspondence.

### FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

*Paris*, 19*th March*, 1862.

An instantaneous dry collodion is a so much coveted desideratum that the Marseilles Photographic Society, with a view of stimulating its production, have undertaken to offer a prize of 500 francs to whoever may succeed in producing it.

The satisfactory results that have already attended many efforts in this direction, induce the hope that the photographic art may be yet further enriched with improved agents and formulæ. The future of photography will be influenced in nothing more fertile in resources than by an instantaneous dry collodion.

Hitherto one of the indispensable conditions of the rapidity designated as *instantaneous* is the employment of a wet collodion. But how great the improvement, how important the advantages, if results as satisfactory and as sure can be obtained by the employment of dry collodion.

Desirous of contributing as much as possible within the sphere of its labours to the progress of the Art it endeavours to cultivate, the Photographic Society of Marseilles, at its meeting on the 31st January last, resolved to offer a prize, open to general competition, for the discovery of an instantaneous dry collodion; that is, of a collodion which, employed in the dry state, will admit of the operator obtaining a view during sunshine, of a street as full of motion as the Boulevard de Strasbourg, taken by MM. Ferrier and Soulier, which is to be taken as the standard of comparison.

The Abbé Laborde offers to the attention of chemists his proposed new chemical notation, the aim of which is to place the reactions they represent more clearly before the eye. He is fully aware of the great reserve that must be employed in attempting to modify a system now so generally adopted, but the changes he suggests are so trifling in appearance that they cannot disturb the operations of chemists, while they possess the advantage of imparting greater clearness to a great number of formulæ.

The alteration consists in writing the oxy-salts with both terms, not one after the other, but one over the other—the base below, the acid above. The following examples will show how many advantages this simple change offers.

1st. Suppose it be desired to express the mutual decomposition of two salts—sulphate of potassa and nitrate of barytes; according to the old method it will stand thus:—

$$KO, SO^3 + BaO, NO^5 = BaO, SO^3 + KO, NO^5.$$

In the new method it would stand as follows:—

$$\genfrac{}{}{0pt}{}{SO^3}{KO} + \genfrac{}{}{0pt}{}{NO^5}{BaO} = \genfrac{}{}{0pt}{}{SO^3}{BaO} + \genfrac{}{}{0pt}{}{NO^5.}{KO.}$$

a much more condensed formula, in which the eye, in following a diagonal, encounters more readily the acids and the bases which must unite together. It can also be guided by an arrow placed in the first member of the equation, and always directed from the acid to the base which will form the insoluble body, thus:—

$$\genfrac{}{}{0pt}{}{SO^3}{KO} \searrow \genfrac{}{}{0pt}{}{NO^5}{BaO}$$

From this example it will be seen that it is scarcely necessary to add the second member of the equation.

2nd. This way of representing the salts will render them easily recognizable in a formula at the first glance, and, moreover, will often permit of our adopting an arrangement which will place the nature of the binary compounds clearly before the eyes. Suppose it is desired to represent, first, the action of sulphuric acid upon carbonate of potassa; in putting the acid in the line of acids we shall have:—

$$\genfrac{}{}{0pt}{}{SO^3 + CO^2}{KO} = \genfrac{}{}{0pt}{}{SO^3 + CO^2.}{KO}$$

Second. The action of baryta upon sulphate of soda, by putting the baryta in the line of bases, we shall have:—

$$\genfrac{}{}{0pt}{}{SO^3}{BaO + NaO} = \genfrac{}{}{0pt}{}{SO^3}{BaO + NaO.}$$

The acids and the bases will occupy this place only in proportion as they are in presence of a salt and in the same member of the equation; besides, we put them on the mean line like all the compounds expressed by the ordinary notation; for example, sulphate of lead and sulphite of lead, heated together:—

$$\genfrac{}{}{0pt}{}{SO^3}{PbO} + PbS = QSO^2 + QPb.$$

Chemists are not agreed as to the manner of grouping the atoms in haloid salts; they will, therefore, be retained in the ordinary notation. As to the saline oxides, they will be represented like the oxy-salts:—

$$\genfrac{}{}{0pt}{}{Mn^2 O^3}{Mn} \quad \genfrac{}{}{0pt}{}{Fe^2 O^3}{Fe \ \ O} \ \&c.$$

Between the written expression $FeO, SO^3$, where we place the electro-negative body second, and the spoken expression, sulphate of iron, there is really a sort of contradiction, which disappears upon placing the two terms one above the other, for then there is neither first nor second.

The part water plays is not clearly indicated in the formulæ adopted, $KO + HO$, $SO^3 + HO$, to express hydrate of potassa, or hydrated sulphuric acid. As it is now recognized that water plays the part of an acid with potassa, and that of a base with sulphuric acid, the new formulæ, $\genfrac{}{}{0pt}{}{HO,}{KO} \genfrac{}{}{0pt}{}{SO^3,}{HO}$ will express it clearly.

3. A last example will exhibit many other advantages. Purposely selecting a very complex formula, that representing the action of bibasic phosphate of soda upon nitrate of silver:—

$$(NaO + HO)\ PhO^5 + 2\ (AgO, NO^5) =$$
$$= 2AgO, PhO^5 + NaO, NO^5 + HO, NO^5.$$

By the new formula we have:—

$$\genfrac{}{}{0pt}{}{PhO^5}{NaO, HO} + \genfrac{}{}{0pt}{}{NO^5}{AgO} = \genfrac{}{}{0pt}{}{PhO^5}{2AgO} + \genfrac{}{}{0pt}{}{NO^5}{NaO} + \genfrac{}{}{0pt}{}{NO^5.}{HO.}$$

The parentheses and the sign + are suppressed for the bibasic phosphate of soda, the formula of which is, nevertheless, much clearer and easier to read. The parentheses are also suppressed for the nitrate of silver, because the position of the figure 2 on the mean line allows it to be clearly seen that it multiplies both acid and base.

As to the phosphate of silver which comes afterwards, the 2 placed before AgO addresses itself evidently to the base, and without other artifice we perceive that it is not at the same time the co-efficient of the acid $PhO^5$.

These examples will suffice to show that many real advantages would be gained by adopting the change proposed, without at the same time incurring any inconvenience.

## MEALINESS IN TONING.

Sir,—If you will not think me troublesome, I would offer a few further remarks on the causes of mealiness in toning positive proofs. I believe I am correct in considering this disease of comparatively modern date; and amongst the various causes that have been stated as giving rise to it, I do not think any of your correspondents have suggested that it arises from a too free rise of *nitric acid* in the *sensitizing bath*. Recent experience brought this under my observation.

If chloride paper is floated on a bath containing excess of nitric acid, and exposed in diffused light, the action of the oxygen seems to be considerably retarded by the large amount of free acid present; and I believe similar results occur in a relative degree when a smaller amount is present. With acetic acid in this bath, it appears, according to my experience, that a larger amount of free acid present does not materially hinder reduction; and a moderate quantity, I consider, materially aids reduction, probably by the same means suggested in my last note on the action of acetate of soda—by parting with its hydrogen to the chlorine of the silver, and so acting as a reducing agent. Another proof within the general experience of photographers on the retarding influence of nitric acid, is the superior keeping qualities this acid imparts to prepared paper, which I take to be owing to the indisposition of the nitrogen to combine with further proportions of oxygen, so that the latter element acts but very slowly in its presence, unless an organic salt be also present. My conclusions are, that if acetic acid be used in the sensitizing bath, mealiness will not occur, and there will be no necessity for the use of acetate of soda in the after process; but I do not recommend a recurrence to the acetic acid, but rather the adoption of some other means to avoid the evil.—I am, sir, yours respectfully, E. E. L.

P.S.—I may add, that a strong silver bath acidified with acetic acid produces the same violet tints in the proof as when acetate of soda is used. I have some proofs, given me about three years back, in which very beautiful violet tones existed. They have all deteriorated, although kept in a portfolio, and the lights have become yellow. They were evidently toned with an alkaline bath, as the lights were very perfect when I first received them. Probably the best remedy will be to adopt the ammonia nitrate for use with albumen paper. I have tried it years back with little success; but as it appears that it can be used, I shall renew my efforts in that direction.

## ORGANIC SALTS IN COLLODION.

Dear Sir,—The introduction of a salt with an organic base into the collodion, for example, the acetate of morphine, increases the sensitiveness 6 or 8 times, I have instantaneous stereo negatives taken a month ago, possessing excellent detail; it produces the natural clouds *without instantaneous* exposure. I have taken negatives six weeks ago with 10 seconds exposure, including full detail in foreground combined with the natural clouds. thus landscapes of large dimensions can be obtained on calm days, possessing truly magnificent effects.

The muriate of morphine in the collodion, or nitrate of morphine in the bath, confers on the excited and washed plate, the property of retaining unimpaired its sensitiveness and complete negative developing qualities, and the bath is uninjured. My advertisements some weeks ago in the News, were for the application of this property, and I confess that I was disappointed in enquiries for my new bath, for I only got one application for it, and that gentleman has sent me an unqualified testimonial in its favour. As I see in the *British Journal of Photography*, that M. Jacquemet is on the road to my discovery (to my great loss), I have made my secrets known to show with certainty my prior claim to the above discoveries, I am, dear sir, yours respectfully,

Wm. Bartholomew.

(I have enclosed some experimental prints.)

[The prints enclosed satisfactorily illustrate our correspondents statements. We rather fancy, however, that some of our photographic *quidnunes* will tell him that salts with organic bases have been added to the collodion and bath before. Dr. Diamond has, for instance, added the arsenite of quinine. We are not aware, however, that these salts have ever been tried in connection with the dry processes. We are not by any means sure whether the re-examination of old experiments in the light of our present knowledge may not turn out one of the most valuable directions of research which can be undertaken.—Ed.]

## ACETATES IN TONING.

Dear Sir,—I have been experimenting lately with different acetates as a preliminary bath to toning. I give the preference to that of lead, placing the print from the frame in a bath of

| | |
|---|---|
| Plumbi acetatis ... ... ... | 2 drms. |
| Aqua distil. ... ... ... | 6 oz. |

for ten minutes; slightly rinse, and tone as usual, after which, replace in lead bath for a few minutes. This will cause all the gold on the print to precipitate, and greatly improve the tone. I may also say that this bath does not bleach much, nor does the print redden so much in the fixing. Should you think this worth place in your columns, you may insert it.—I remain, yours respectfully,

A. L. Henderson.

P.S.—An equal quantity of acetate of soda and lead may be used with equal success.

# Photographic Notes and Queries.

### Washed Collodion Plates.

Sir,—In consequence of your soliciting communications on plain dry collodion, I beg to forward you the enclosed for your inspection and comments. They were all done last summer, and are on plain glass.

No. 1, is by the tannin process unwashed; No. 2, by tannin process washed; No. 3, washed with water, and afterwards with solution of pyrogallic acid; No. 4, on washed collodion only. They were all prepared the same evening, exposed exactly the same time, one after the other, in the middle of the day, under a strong negative, by the wet process, and all developed in the same manner during the afternoon.

The stereoscopic slide is on washed collodion and on plain glass, and was printed by superposition on negative on washed collodion. The negative was almost my first experiment, and was not developed so strongly as it might have been. One picture you will perceive is better than the other, which was always the case with my lenses.

The collodion was made by myself, and worked well either by the wet or dry process.

Is there no photographer who can reproduce the cartoons of Raffaelle the original size as transparencies, back them with the necessary colours, and exhibit them in the forthcoming Exhibition, to show their adaptability for introduction into churches, &c., and give the art a lift in the estimation of the public at the same time?—Yours truly, Rheb Rd.

N.B.—The washed-collodion plates were exposed in the camera for one minute for open view; close dark subjects would require from one to three minutes: but these exposures would, of course, depend upon lenses, stops, &c.

[The specimens which accompanied this letter are highly satisfactory. No. 1, the tannin process proper has produced a rich brown, slightly foxy, just the tint given by burnt sienna. No. 2, the tannin process washed, possesses the pleasantest tone for a transparency, being of a deep chocolate tint. No. 3, washed with water and then with pyrogallic, is not a bad tone, being somewhat of a smoke colour. No. 4, simply-washed collodion, is rather cold and grey. We fear your suggestion regarding the cartoons could not be well carried out.—Ed.]

TRANSPARENT SPOTS IN DRY PLATES.

DEAR SIR,—I have been experimenting during the last two or three months on dry collodion, without preservative, with variable success; I have simply washed the plate and dried, at other times washed and chlorided, and sometimes covered with a solution of gallic acid; but through all these modifications and changes there has been one evil common, and that has been the occurrence of spots of *transparency*, or *insensitiveness*, sometimes being totally transparent, other times partly so, and in size from ½-inch diameter to a pin hole. I have used two different samples of collodion, and washed both under the tap and in trays with like results. Three weeks ago I prepared six plates, two I exposed on the fourth day, which were entirely free from this and all other faults; No. 3 I exposed on the sixteenth day after preparation, 4, 5, 6 on the seventeenth day, and all of the last four contained them more or less, these plates were washed in three changes of water in trays, and then steeped in a bath of common salt, and then washed again under the tap. I have had them in plates exposed shortly after preparation.

If you or any of the correspondents of the NEWS could suggest a cure or remedy for this evil, it would greatly oblige,

M. P. E. C.

[Can any of our readers suggest the cause and remedy of this trouble ?—Ed.]

## Talk in the Studio.

MR. BEDFORD AT THE PYRAMIDS.—We notice that Mr. Bedford is attempting instantaneous effects in his eastern tour with the Prince of Wales. The *Times* correspondent describing the visit of the royal party to the Pyramids states that the cavalcade was successfully photographed by Mr. Bedford before its return to Cairo.

STEALING NITRATE OF SILVER &c.—A plate cleaner named Williams employed by the London Stereoscopic Company was recently charged before the Lord Mayor with robbing his employers. The prosecutor, Mr. George S. Nottage, managing partner of the Company said: the prisoner had been in their service since September last. A few days ago, from information they received, they were led to believe he had been robbing them. He was called from his work and questioned on the subject, when he confessed to have stolen 13 ounces of nitrate of silver, or, he added, it might be more, belonging to them. The value of it was about 2*l*, 12s., at the ordinary retail price of 4s. an ounce. He also admitted he had robbed them of four valuable lenses, pledging them afterwards at so many different places, and giving at each a false name and address. They were worth from 12s. to 21s. apiece, but he had pawned them for a few shillings scarcely a tithe of their value. He likewise confessed to several minor thefts of chemicals used in photography. Mr. Nottage said, in reply to the Lord Mayor, their business was of a character requiring from them a certain amount of confidence in the persons about them who were always intrusted with considerable quantities of valuable chemicals. They had received a character for honesty and good conduct with the prisoner from a photographer at Woolwich, in whose service he had been, and who had since admitted he gave it with the knowledge that the prisoner had robbed him on one occasion.

MEALY PRINTS.—A correspondent says that until recently he did not know what a mealy print was; when one day, finding his exciting bath neutral, he added a few drops of acetic acid, and the next batch of prints were all mealy.

## To Correspondents.

OMEGA.—The "dirty deposit" thrown down by iron from your alkaline gold toning bath is metallic gold in fine powder. Add nitro-muriatic acid, and make it into chloride of gold in the usual way.

J. C. L.—Albumenized paper will gradually deteriorate with keeping, especially if kept in a damp place. 2. The toning bath of acetate of soda and gold may be kept a few days, and should always be kept 24 hours before using. 3. A back ground for full length standing figures, such as *cartes de visite*, should be about 6 ft. wide, and, if possible, 8 ft. high.

EGRORG YEVRAH.—Thanks for your note, which shall be inserted. The tones of the enclosed prints are both good; the warm tone is perhaps the richest, but the other would be best for general purposes.

A BEGINNER.—We cannot recommend the lenses of any especial maker in this column. The maker you name does not stand high. See our advertising columns, and if you can afford it, try a lens from one of the best English makers. Those which you describe appear to be very slow. 2. A bromo-iodized collodion may be bought ready iodized with advantage.

M. A. O., (Helensburgh.)—The Stereoscopic Exchange Club was merged some months ago into the Photographic Exchange Club, with new rules and regulations. The rules are printed in the PHOTOGRAPHIC NEWS for Oct. 18, 1861 (p. 492, vol. v.), and in the PHOTOGRAPHIC NEWS ALMANAC for this year. Your specimens would doubtless be accepted by the Committee; the figures are very good indeed. Ladies are admitted with pleasure to the privileges of the Exchange. 2 The formula for arrowroot paper was given in the PHOTOGRAPHIC NEWS, No. 105, and in the PHOTOGRAPHIC NEWS ALMANAC for 1861. 3. The iodizing solution which has become yellow may be used without disadvantage.

MC. ALLAN.—You will probably find it difficult to obtain another quarter plate lens of exactly the same focus, unless it is by an English maker. For street scenes a portrait combination would probably be better than the single lenses. When we recommended three inches as the distance between the lenses, we meant from centre to centre; not that amount between the inside edges of each lens. We cannot give you the recipe of the marine glue. It is generally sold at tool shops. Equal parts of resin, bees-wax, and pounded tiles, make a good cement for glass. The cause you mention may possibly produce mealiness.

J. M. S.—There is a slight tendency to mealiness in the print forwarded; but its chief fault, and the cause of the "dirtiness" of which you speak is want of brilliancy in the negative. The effect is suggestive of the negative having been produced in a very dull diffused light. The advantage of yellow glass over yellow paper or yellow calico arises from the tendency of the latter to fade; and although they may be cheaply renewed, that does not quite meet the difficulty. The fading is a gradual process, and long before the colour may be sufficiently gone to arouse attention to the necessity of a renewal, sufficient white light may get into the dark room to render it difficult to produce brilliant negatives with iron development.

T. FISHER.—To recover the gold remaining in alkaline toning baths, add protosulphate of iron until the whole is precipitated in a dark powder, which is metallic gold. See answer to OMEGA.

T. M. B.—The address of Mr Hawke is 53N, Union Street, Stonehouse, Devon.

WM. VAUGHAN.—Mealiness consists in a very fine irregular mottling, of reddish brown and slate coloured spots. Your print is brilliant and entirely free from it. The defect is more common with these portrait negatives than with more brilliant landscape negatives. An even expanse of middle tint, like a plain back-ground, generally shows it most.

TYRO.—We do not conceive that there can be any objection to the name of subject and photographer being placed neatly on the front of each specimen for the South London Exhibition. That at the back is for the guidance of the committee in cataloguing.

JOHN HAWKE wishes to inform a photographer at Knaresborough, who wrote to him, that he has mislaid his letter, and desires him to write again.

AN AMATEUR.—There need be no danger of fogging in using a shifting front with portrait lens on your binocular camera. Be careful that the division between the two halves of the camera is properly light tight.

R. J. E.—We do not remember that any researches have been undertaken in the direction you name. We shall be glad to hear more from you on the subject.

J. D. SANDERS VAN LOO.—We shall have pleasure in inserting your letter in our next.

S. W.—An article on enlarging appears in the PHOTOGRAPHIC NEWS ALMANAC for 1862. We will endeavour to write to you soon.

WM. TUCKER.—We are much obliged by your communication and interesting photographs. We shall have pleasure in receiving the MSS. you name, and to hear from you at all times.

E. H.—Your card pictures are not well lighted, and are deficient in half tones. That of the pony held by a groom is very good. Some of your pictures might be passed by the referees of the Exchange Club, but they are scarcely sufficiently good for the Exhibition at the Crystal Palace.

A. B. B.—It is very difficult to give any trustworthy advice as to the arrangement of any especial glass house, from merely a written description of the position and circumstances. The exercise of judgment on the spot is much more valuable. In the case you describe, so far as we can see, it will be wise to have glass on each side of the roof, and one side as far below the roof as you conveniently can.

BANDON.—See remarks above. In your case, so far as we can see, it will be wise to glaze the whole of the roof, except four or five feet immediately over the head of the sitter. Your plan seems good. You can stop out the western sun towards evening by means of blinds. White sheet glass admits the most actinic light, but is apt to sweat unless very good. We hope shortly to have some articles on glass rooms; but we can then only deal with general principles, not individual cases.

ENQUIRER.—The statement was an error, arising out of some kind of misunderstanding. Mr. Wilson has not given up the use of the triple lens for landscapes, as he states that he cannot get any single view lens to include nearly so much subject as the triple. His instantaneous and other views, including wide angle, are 7 in. by 4½ in., and are taken in the same camera he uses for stereoscopic work.

MASON v. HEATH.—We have received a long letter on this case from Mr. Mason, too late for insertion this week. We think the public interest in the subject is fully satisfied; but on the principle *audi alterem partem*, we shall insert it next week. Before doing so we shall, however, reduce it to reasonable bounds, by making some elisions of mere epithet, and giving simply statements.

W. LARCHIN, W. NURSE, B. JONES, A. MELHUISH, A NOVICE, GOLD, FOCUS, A. B., and several other correspondents, together with several articles in type, are compelled to stand over until our next.

THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 186.—March 28, 1862.

## COPYRIGHT IN PHOTOGRAPHS.

From a report givcu on another page of the proceedings in the House of Commons on Thursday evening week, it will be seen that the Bill for Amendment of the Law of Copyright in works of Fine Art is progressing much more rapidly than it did last session, aud will iu all prabability soou pass into law. This Bill, as our readers know, affords full protection to photographs, classing them in the same category as paintings and drawings, and will, if it pass in its present form, at once set at rest the question of piracy. All probability of evading the enactments of the Bill, or of involving protracted litigation are carefully provided for, as any person who shall without the consent of the owner "repeat, copy, colourably imitate, or otherwise multiply for sale, hire, exhibition or distribution," or shall cause this to be done, or shall import any such imitation or copy, or shall offer such copies for sale, shall forfeit to the proprietors of the copy £10 for each offence, and "all such repetitious, copies, and imitations, and all negatives of photographs, and other things which shall be exclusively applicable for obtaiuing such copies, shall be forfeited to the proprietor of the copyright, who shall forthwith destroy the same." The penalties are to be recoverable by summary proceedings before two justices of the peace.

Perhaps it was only to be expected—when the determined opposition on the part of art authorities to the recognition of photography as a fine art is remembered—that some hostility to the protection of photographs in such a Bill, should be manifested. Accordingly, we find Mr. Harvey Lewis objectiug that it would be "dangerous" to include photographs in the Bill. "Photography was not a fine art; but a mechanical process," he observes, but he thinks it might be "expedient" to give protection to photographs at some future period. Whether this objection be one which the honourable gentleman himself honestly entertains, or whether he has been "coached" by some narrow section of the artistic fraternity, we cannot congratulate him on the felicity with which he puts the case. In what sense it can be "dangerous" to protect photographs at present, or what is the danger apprehended, we cannot conceive; nor is it at all clear why it should be "expedient" to give protection to photographs at some future period, instead of both just and expedient to do so at once.

The Solicitor General very wisely waived the discussion of the question as to whether photographs were works of art in a technical sense, but insisted on their claim to protection on the ground that time, ability, and money, were expended in their production. This is a position we have always maintained. Whilst in no sense surrendering the claim of photography as a fine art, we do not in any sense grouud its sole claim to protection upon its art character. As a mere work of industry, it surely possesses a right to protection. All paintings or drawings are not works of art; but this fact does not in any way militate against their right to protection. The claim to protection against piracy in either books, paintings, or photographs is based upou the fact that skill and capital of some kind are necessary to produce them. The exact nature of the skill employed, it is altogether unnecessary, for the purpose in question, to determine. It may be creative power, or manipulative skill. The author of a guide book is not deprived of the copyright in his work because it is not a volume of poetry; nor should it be necessary to establish the position of photography as high art, in order to obtain for it the protection due to skill and enterprize.

The suggestion of Mr. Pope Hennessey that photographic portraits should be excluded from the Bill is based upon such an inconsequent reason, that we can only conclude that the honourable gentlemau did not know of what he was speaking. Because a less amount of capital and enterprize, it is implied, than is necessary for the production of some kind of photographs, is requisite here, therefore the amount of skill and capital that are necessary, should not be protected at all; and the more so, because it would be hard to prevent the public from obtaining copies of portraits. Mr. Hennessey surely cannot need to be told that the existence of a copyright would uot prevent the public from obtaining portraits of public men; but would simply secure to each photographer the right to supply the public with his own works; and secure to the public, photographs of reasonably good quality, in the place of the flat, fading, mealy abominations which are now pirated aud foisted on the public as originals.

We believe it is impossible to urge one tenable argument upon which the propriety of excluding photographs from the Bill can be justified; but we are by no means sure, uuless those interested in the question see that proper evidence is laid before the Committee, and that some effort is made to give strength to the promoters of the Bill, that the efforts to exclude photographs from the protection to be enacted may not be successful.

## CHIMENTI'S PICTURES.

We have been favoured by the courtesy of Dr. Carpenter, Registrar of the University of London, with an opportunity of inspecting the photographs taken from Chimenti's pictures in the Museum at Lille, which form the subject of Sir David Brewster's recent communication to the Photographic Society of Scotland. We have no wish whatever, personally, to enter into the coutroversy which that communication renews; but as with the majority of photographers the point upon which the whole question rests—the stereoscopic character of the said drawings—must depend upon the value of testimony, we feel bound to lay the results of our own examination before our readers. Sir David Brewster states that the evidence of Professor Wheatstone and his friends is of little value, because they are interested parties. As Sir David's evidence must unquestionably stand in the same category as that of Professor Wheatstone and his friends, and for like reasons possess like value, independent testimony is of more importance.

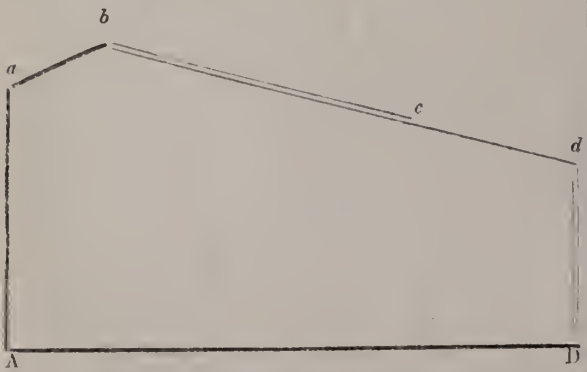
We have the facility of combining stereoscopic pictures without the stereoscope, and we have examined these pictures carefully with the aid of that instrument and without it. We have examined them in their original position by converging the optic axes so as to see the left picture with the right eye and *vice versâ*; and we have examiued them transposed, in the same manner. In the stereoscope we have inspected them both transposed and otherwise. The result of each method of examination is to lead us to the unhesitating conviction that on the one hand they were not drawn with any knowledge of stereoscopic principles, or any view to stereoscopic effect, or ou the other hand they are a complete failure. In no case is anything like an approximation to perfect stereoscopic relief produced; but in every mode of combining the pictures certain parts possess some amount of relief, whilst other parts remain flat or are pseudoscopic, presenting a generally confused effect. The result is just what might be anticipated by placing side by side any picture and a carefully drawn duplicate; the slight differences which must inevitably occur would give rise to a similarly confused effect of relief and intaglio. The action of the figure is such as would have been favourable for the production of marked stereoscopic effect; but the relief under the most favourable conditions is far inferior to that of some very simple geometrical diagrams, with which, as being drawn by hand and affording legitimate means of comparison, we have contrasted them. In truth the monoscopic relief of each single picture appears little, if any, inferior to the effect of both when combined in the stereoscope.

The pictures are in most respect facsimiles; but a closer inspection at once leads us to the conviction that one is an artist's drawing and the other a clever copy by a somewhat mechanical hand. In the drawing the first there is freedom, ease, expression, and general character, which indicate the hand of the artist; whilst in the other there is faithful copying, but a loss of character and expression; the dimensions of the copy are, moreover, slightly greater every way than those of the original.

We confine our observations strictly to the effect of the pictures before us, and do not enter into other evidence against their stereoscopic character, such as that afforded by the relation to each other of the originals, which, it is stated, require the convergence of the optic axes in a manner which, to nine persons out of ten, is impossible. We hope shortly to lay before our readers some extracts bearing, on the subject, from Dr. Carpenter's recent lecture on the stereoscope at the London Institution.

## GLASS ROOMS WITH TOP LIGHT.

Every photographer is familiar with the heavy opaque shadows under the eye-brows, nose, lips, and chin, which are produced when the sitter is illuminated with vertical light only. Yet it not unfrequently happens, especially in large towns, that a skylight is the only available means of lighting the studio, which is often so blocked in on every hand that a side light is impossible. Such persons will read with considerable interest the report of the last meeting of the South London Photographic Society, at which Mr. Fitch, an amateur of considerable ability, exhibited a series of very exquisite portraits produced in a room lighted wholly from the top, without any side light whatever. The pictures were free from any trace of the evils usually attendant upon vertical lighting: there were no black, heavy shadows under projecting features, no dirty-looking neck, nor any prematurely grey hair; all was delicate, soft, and natural. On further inquiry, it was found, however, that whilst the light was only admitted through the roof, no vertical light was permitted to fall on the sitter. The top light was cut off, the only direct light reaching the model falling at considerable angle, and producing a most satisfactory effect. In order to make the matter clearer than the report of the meeting may possibly render it, we subjoin a diagram of the room, as described by Mr. Fitch.



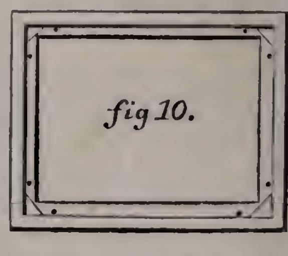
In order that the amount of light may be understood at a glance, we may remark again, that there is no side light at all, and that in the diagram the black lines represent entire absence of glass, the double thin lines represent stippled glass, and the simple thin line clear glass. The length of the room from A to D is twenty-two feet; the height at *b* twelve feet, and at *d* seven feet. From *a* to *b* is three feet, which is quite opaque; from *b* to *d* is all glass; but two-thirds of this, from *b* to *c*, are rendered semi-opaque by stippling with white lead and turpentine. The end D *d* is also rendered semi-opaque in the same manner. The only direct light which obtains admission is through about seven or eight feet of clear glass, *c* to *d*. As the aspect is direct south this will generally be very powerful. The background occupying the end of the room A *a*, the sitter being placed underneath *b*, is illuminated with a soft diffused light over head, and by a direct light at a considerable angle passing through the clear glass at *c d*. It will readily be seen that under such circumstances the direct light is nearly equivalent to a side light, and that the lower the end of the room, and more slanting the roof, the more the light will partake of this character.

Although we cannot quite go so far as Mr. Fitch, and say that with the choice of position we should build a room of this character, ignoring side light proper, there can be no doubt about its answering the purpose exceedingly well; and we may add, that it is very nearly in principle the form of the glass room used by one of our first, if not *the* first, metropolitan professional portraitist.

## REMARKS UPON SOME OF THE APPARATUS EMPLOYED IN PHOTOGRAPHY.*

BY F. R. WINDOW.

Field Cameras.—*The plate-slide* (continued).—As dry plates do not run the same risk of fouling themselves by contact with wood as wet plates, which are covered with liquid nitrate of silver, some of the precautions recommended for the interior of the wet slide may be dispensed with. The interior of the cell should be thoroughly well varnished with a good dead black to exclude moisture, and also to keep the vapours of the essential oils in the wood from the plate. I find it is advantageous to prevent the plate from actually touching the cell, because in doing so it is apt to grind off little particles of the varnish, which, flying about the interior, settle upon the sensitive surface, and cause spots and pinholes. For this purpose, the inside corners of the slide should be furnished with wires, the same as in the wet slide, and two metal pins should be driven into each side at the edge of the cell for the glass to rest against (fig. 10).



By this means the plate is held perfectly insulated from the wood, both in front and at the sides, and the back also is only in contact with the metal spring which secures it in the proper position. Electro-plated copper wire is suitable for this purpose.

Dry plates of necessity undergo much handling in the course of preparation, and, notwithstanding the greatest care, the edges are liable to become contaminated with organic matter or other impurities, either from the fingers, or from their own drainings upon the filtering paper while drying; or from other causes. It is prudent, therefore, to let the front

* Continued from page 135.

of the slide project slightly over the plate to protect the edges from the light (fig. 10), as without the aid of light these slight impurities seldom produce stains under the action of the developer. I strongly recommend the adoption of this precaution as an important protection against stains upon dry plates. Many plate-slides are made in this manner, but the generality, I think, expose the whole plate to light. For a small camera, $\frac{1}{8}$th of an inch all round is sufficient, but for large plates which are more handled, and drain in larger quantities, I should advise $\frac{1}{4}$ inch all round.

The sliding shutter by which the plate is uncovered is a very important part of the plateholder, especially for out-of-door photography; and I do not think we have yet hit upon any form that, when applied to the field cameras, is quite satisfactory in all respects. The principal considerations that should affect its design are—its capability of excluding all light from the plate, excepting from the front, when it is raised; and the action of the wind upon it while a picture is being taken. The forms of shutter mostly used are those which open upwards, and lie upon the top of the camera; those which open downwards, and remain at right angles to the axis of the camera; those which open sideways, and remain stretched out at right angles to the axis of the camera; and finally, those which open sideways and folding forwards lie parallel to and against the side of the camera. I believe the first of these, which is the one most commonly used, is the best, though I am inclined to hope that we shall ultimately attain one which more completely fulfils the necessary conditions.

I do not think there is any danger of light getting improperly on to the plate with any one of the forms of shutter I have named, if carefully made; but they all of them offer the inconvenience of being considerably affected, when open, by a very small amount of wind. Those which fold down and lie against the instrument, of course, less than the others. Still, from their thinness, which gives them a certain amount of spring, even these catch every little breeze, and create a vibration which is communicated to the whole camera, and tends to destroy the sharpness of the image. My practice, to avoid this as much as possible, is, when I have raised the slide, and before I uncover the lens, to put a stone or other weight upon the shutter to keep it steady; but I should be glad if we had a shutter with which such a contrivance was unnecessary. Those shutters which do not fold down, but stand out stiff, of course are yet more easily caught by the wind, and as they are generally slight, and flexible to a certain degree, they chatter and vibrate considerably, and often very detrimentally. I speak on this point from experience, having had a camera, the slide of which opened in this manner, and I had to contrive a stay to keep it steady whenever there was the least movement in the air.

In some of the early Daguerreotype cameras, the shutters opened inwards by means of a spring or other contrivance. This method was abandoned in the idea, I believe, that the opening in this manner raised a dust in the interior, and for a long time none have been so made. I am inclined to think the plan was too lightly abandoned without a sufficient trial. If dust was the only objection, the remedy lay in the photographer's own power; he had only to keep his camera clean. A shutter opening inwards would of course be perfectly light tight, and would not in any way be affected by the wind. Such a shutter could not be adapted to many of the present designs of camera, which pack up into a small compass.

Every double back should be numbered in plain figures, one corresponding to each plate; and it will be found a convenience if a small ivory plate be let into each shutter, or some other part upon which the photographer can make in pencil a memorandum of the view taken upon the plate, recording the time of exposure, &c., which he may copy into his diary at home.

Before closing these "remarks" upon the subject of cameras, at the risk of repeating myself, I would strongly advise photographers, when they select an instrument for general field work, to let their choice be biassed less by the price, the size, the weight, or prettiness of any particular form than by its efficiency to produce good pictures with as few openings for failure as possible. Let portability and convenience be attained by ingenuity and mechanical skill, but never by the sacrifice of any necessary quality. If the price has to be studied, let cheapness be gained by moderating the ambition to a simple form, without any complication of details beyond what is strictly necessary, and to a limited number of duplicate parts.

*(To be continued.)*

## PHOTOGRAPHIC CHEMICALS:

### Their Manufacture, Adulterations, and Analysis.

*Sulphides of Arsenic.*—Passing over several metallic sulphides which possess no interest to the photographer we come to those compounds, which, owing to their colour, are used in painting. Arsenic forms several compounds with sulphur, the most important being the bi-sulphide, the ter-sulphide, and the penta-sulphide of arsenic, composed respectively of one atom of arsenic with two, three, and five atoms of sulphur.

*Bi-sulphide of Arsenic*, known also by the names of *red sulphide of arsenic, realgar, sandarach*, and *ruby arsenic*, is of frequent occurrence in nature; it is also prepared artificially by fusing arsenic with a higher sulphide. It is of an aurora-red colour inclining to brown, when in mass, and yields an orange yellow powder, which becomes red-brown whenever it is heated. It fuses easily, and is not decomposed when heated out of contact with air, volatilizing unchanged at a temperature much below a red heat. Heated in the air it burns with a blue flame, forming sulphurous and arsenious acid. Heated with nitre it deflagrates with production of a vivid light. Several brilliant pyrotechnic mixtures employed in night photography are based upon this property. The *Indian white-fire* is produced by the combustion of a mixture of 24 parts of nitre, with 7 of sulphur, and 2 of realgar. The signal light employed by the English Government is very similar to this, with the exception that a higher sulphide of arsenic is used. It is prepared by mixing nitre 7 lbs., sulphur 1 lb. 12 ozs., orpiment 8 ozs. This is said to be the best white fire known. It must be carefully borne in mind whilst experimenting with these compositions in which a poisonous metal plays so important a part, that the products of the combustion must on no account be allowed to escape into a room, but must pass to a chimney having a good draught.

*Tersulphide of Arsenic*, known also by the names of *yellow sulphide of arsenic*, and *orpiment*, is also found native. It may be prepared articially by precipitating an acid solution of arsenious acid with sulphuretted hydrogen, and also by fusing the red sulphide of arsenic with sulphur. There is a so-called orpiment prepared on the large scale by subliming arsenious acid with a small quantity of suphur. According to Guibourt this is a mixture of 6 per cent. sulphide of arsenic with 94 of arsenious acid; the latter may be extracted with boiling water. This preparation is much more poisonous than the true tersulphide, although the latter is a dangerous poison. The colour of powdered orpiment in the native state is lemon yellow; that of the artificial variety has an orange yellow colour, and turns brown whenever it is heated. It fuses easily and volatilises unchanged if access of air be prevented. The use of orpiment in the preparation of white fire has been already alluded to.

*Pentasulphide of Arsenic* is formed by decomposing arsenic acid by sulpuretted hydrogen. It is a lemon yellow powder lighter than orpiment, and without any tinge of red. It fuses less easily than sulphur, and after fusion appears darker and somewhat reddish.

Besides these definite compounds of sulphur and arsenic there are others which need not be particularly referred to here, as they are of no special interest to the photographer.

One fact connected with these bodies may, however, be worth remembering, and that is that most of the sulphur of commerce contains arsenic, in the form of per-sulphide. Arsenious acid may be fused with any excess whatever of sulphur; sulphurous acid is evolved, and a brownish yellow sulphide of arsenic formed, which, on cooling after fusion, remains soft for a long time; its powder is yellow, the brightness of the colour increasing with the quantity of arsenic. On distilling a compound of this nature, sulphur passes over, accompanied by a continually increasing quantity of arsenic, much of the ordinary sulphur of commerce is really a compound of this nature.

The sulphides of arsenic are of considerable value as pigments, owing to the brilliancy of their colour and their inalterability under unfavourable atmospheric agencies; being already saturated with sulphur, sulphuretted hydrogen can have no further action on them.

*Sulphides of Antimony.*—Like arsenic, antimony forms several compounds with sulphur, the principal being the ter- and the penta-sulphide. The *ter-sulphide of antimony* exists in two distinct modifications, the crystallized, and amorphous condition. The first is of a leaden grey colour and is the common ore antimony, it possesses but little special interest. We may, however, mention that it is used in some photogenic compositions to replace sulphide of arsenic; a good white fire may thus be made by mixing together 7 parts of nitre, 2 parts of sulphur, 1 part of the native grey sulphide of antimony, and 1 part of red lead.

*Amorphous Tersulphide of Antimony*, known also by the name of *mineral kermes*, is prepared on the large scale from the grey sulphide by a tedious process of solution in caustic or carbonated alkali, and precipitation. It is of a red colour, and is used in medicine, and also as a pigment.

*Penta-sulphide of Antimony.*—This is of a bright yellow colour, and is prepared on the large scale in several ways: either by precipitating antimonic acid in solution by sulphuretted hydrogen, or by boiling the grey sulphide with caustic alkali, and sulphur, and then precipitating by an acid.

Antimony also forms compounds with both sulphur and oxygen, called oxy-sulphides. These are of yellow or orange colours, and are sometimes, but rarely, used as pigments. Further allusions to them is unnecessary.

*Sulphide of Zinc* is produced by acting on a soluble compound of zinc with a weak acid, by sulphuretted hydrogen; a white powder is precipitated, which is the sulphide of zinc. When heated it loses combined water, and becomes of a pale yellowish colour. This compound is formed when zinc-white is exposed to an atmosphere which is contaminated with sulphuretted hydrogen. Being of the same colour as the original pigment this gas has no apparent effect on it; hence the advantage of using zinc-white, instead of white lead in painting: the latter body, as is but too well known, readily tarnishing in a sulphuretted atmosphere to a brown surface, owing to the dark colour of its sulphide. Sulphide of zinc is found native in transparent pale yellow crystals. It then goes by the name of *blende*.

*Sulphide of Cadmium.*—This is one of the most important of the metallic sulphides. It is formed by igniting oxide of cadmium with sulphur, or by precipitating a solution of a cadmium salt with sulphuretted hydrogen, or an alkaline sulphide. It is also found native. The native sulphide is of a honey yellow colour, semi-transparent when in mass, and yields an orange yellow or brick red powder, which becomes carmine red when it is heated. The artificial sulphide in the precipitated state is an orange yellow powder, which when heated to redness becomes first brownish, and then carmine red. As a pigment this sulphide is of considerable value, owing to its brilliant yellow colour, and its entire permanency in an impure atmosphere. It is usually prepared by precipitation, and its colour may be slightly varied by alterations of temperature, and employing solutions of different strengths, as well as by certain subsequent treatment which the sulphide undergoes. These details are mostly trade secrets, each manufacturer employing a slightly different process which experience has taught him to be best.

*Bisulphide of Tin.*—The only compound of tin and sulphur which is of interest to the photographer is the bisulphide of tin, known also under the name of *aurum musivum*, or *mosaic gold*. It is prepared in several ways, one of the most successful being to mix together 5 parts of protosulphide of tin, and 8 parts of corrosive sublimate. The mixture being placed in a loosely closed flask, and heated in a sand bath. A gentle heat is applied for some hours, and afterwards the heat is raised, but not quite to redness. The greater part of the mosaic gold is found at the bottom of the vessel; the smaller but purer and finer portion sublimes to the upper part of the flask. It forms gold coloured, translucent, delicate scales, or six-sided laminæ, unctuous to the touch. It is largely used in the fine arts: it does not tarnish in the air.

## APPLICATION OF PHOTOGRAPHY.

### DOVE'S NEW PHOTOMETRIC PROCESS.

A new photometric process is proposed by Professor Dove. It is extremely sensitive, and may be applied to objects which are strongly or feebly luminous, uniformly or unequally coloured, transparent or opaque. It enables the experimentalist to measure the luminous power of optical instruments, and moreover it possesses the advantage of requiring the use only of a microscope, an instrument in the possession of every physicist and naturalist.

It is well known that there are certain objects, such for instance as the *epidermis* of the *ephemera*, which viewed in the microscope appear dark upon a light ground when they are lighted from beneath, but are, on the contrary, light on a dark ground when we cover up the mirror. This is especially the case with micro-photographs. Upon lighting them from below, they show black lines upon a white ground: when the mirror is covered they appear in white lines upon a dark ground. From this it is evident, that the lines will disappear when the light falling from above, and that coming from below, are both of the same degree of intensity, or rather, have a certain determinate relation of intensity to each other when they fell under different angles. If a Nichols' polarizing prism be fixed upon the object bearer, and if the ordinary eye-piece be replaced by a Nichols' analysing prism, on turning the lathe properly, we shall again see the lines disappear. Starting from this position, the least rotary movement of the eye-piece causes the outlines which had appeared before as black, to reappear in white, which is a proof of the sensitiveness of the experiment. We also recognise that, if everything being in the position where the figures disappear, we interpose in the path of the light coming from below, a plate of glass slightly ground on the surface, the figures immediately appear light upon a dark ground, while the contrary takes place if the plate of glass is placed in the path of the light coming from above.

To compare the lights, it is evident that if the methods employed which necessitate a weakening of the more intense lights to give it an equality with the feeblest, contain an exact means of measuring the degree of weakening, we shall be able to arrive at the relation of intensities under the same conditions.

In new microscopes, the illuminating mirror can be made to move laterally by a double angular movement, and besides, the instrument can be made to pass from the vertical position through every degree of inclination to the horizontal.

To weaken the light we can employ the following means.

1st. Diminish the aperture of the object bearer. To this end we take a small rule, a slide pierced with circular holes the diameter of which diminishes as they proceed from the object bearer, and these diameters must be accurately measured.

2nd. Remove the luminous source from the object bearer. We measure the distance by means of a scale the zero of which, in the horizontal position, is the centre of the photographic image fixed upon the object bearer.

3rd. The increase of the acting luminous surface, on being inclined more and more in relation to the aperture which represents the vertical projection, the microscope being horizontal: and for the photographic image to receive parallel rays only, we must adapt a tube blackened internally to the aperture.

To measure the extent of the luminous surface, it will be sufficient to know its inclination in regard to the axis of the microscope either by placing the surface in the centre of the horizontal circle or by fixing a mirror on this surface, and examining a distant scale by means of a lens in this mirror. The same process may be applied to measure the angle of incidence if we study the intensity of the reflected light under various degrees of incidence.

If the source of light be too feeble, it may be strengthened. To this end in the vertical position of the microscope we replace the illuminating mirror by a concave mirror, and in the horizontal by a lens, if the parallelism of the incident rays be necessary, we must place the source in the focus of the lens.

M. Dove has applied his method in numerous researches. First, to the absorbing power of coloured glasses according to their thickness; we lighten the photographic proof above, by diffused daylight below, by the light reflected from the mirror, then we place the coloured glasses upon the object-bearer, modifying their thickness until there is compensation. To modify the thickness we take glasses cut with elongated corners. To study how the transmission diminishes when the thickness augments, we establish the compensation upon the greatest thickness, then by means of a shutter, modify the aperture of the object bearer for the least thickness. We can apply this method also to liquids by placing them in tubes.

We can compare diffused light by opaque bodies. In placing under the object-bearer of the horizontal microscope a sheet of white paper lighted by diffused daylight, we can regulate the upper lighting so as to produce a black image upon a white ground; by inclining the paper, the ground will become more and more brilliant. By replacing the white paper by a black sheet, or by a surface covered with lamp-black, the images appear white upon a dark ground under every inclination. It is just the reverse with coloured surfaces: in the horizontal position the images are luminous upon a dark ground; they disappear under a certain inclination, and the latter continuing to increase they reappear dark upon a luminous ground. This affords a ready means of determining which of the two coloured surfaces sends the most light: we place the one under the object bearer and incline it until the image disappears: the second is then established under the same inclination, and this latter is more lighted or darker, according as the image appears black or white: care must be taken to remove all light coming laterally.

(*To be continued.*)

## ON THE STEREOSCOPIC PICTURE EXECUTED IN THE SIXTEENTH CENTURY BY JACOPO CHIMENTI.*

BY SIR DAVID BREWSTER, K.H., F.R.S.

Copies of the photograph were also sent to Paris with the same result, as will be seen from the following extract from the *British Journal of Photography* for August 1860:—

"It will, doubtless, be in the recollection of our readers that lately an intimation was thrown out by Sir David Brewster relative to the supposed antiquity of the knowledge of stereoscopic principles, the supposition arising from the fact that an artist, named Jacopo Chimenti, who lived in the 16th century, had executed a pair of pictures, which are at present preserved in the Museum at Lille, and which, it was alleged, on being viewed in such a manner as to allow each eye to see only one of the designs, presented a stereoscopic effect. It is very unfortunate that when an announcement of any supposed fact is once made, and subsequently proved to be erroneous, it is almost impossible to correct the false impression as thoroughly as is desirable, because there must always exist many persons who read the assertion but not the contradiction, while those who see the contradiction without the previous erroneous statement can play but a very unimportant part in its rectification. Under these circumstances we consider it to be advisable to draw special attention to a paragraph in the letter of our Paris correspondent, M. Ernest Lacan, which was published in our last number, and from which we learn that, in order to settle the question satisfactorily, our countryman, Mr. Bingham, who is a resident in Paris, took photographic copies of the alleged pair of stereographs, and laid them before the members of the French Photographic Society at the July meeting.

"When placed in the stereoscope, the two pictures united perfectly, but did not present the smallest effect of relief.

"We think it is fair, therefore, to presume that, whatever may have been the object proposed by the artist in executing the two similar pictures, it was certainly not from any knowledge of the stereoscopic phenomenon, and that Sir David Brewster was in this instance wrong in his conjecture. It is but right to add that Sir David had not had ocular demonstration of the alleged fact when he threw out the suggestion."

The following is the letter of M. Ernest Lacan, the editor of *La Lumière*, above referred to:—

"The letter in which Sir David Brewster spoke of the two drawings of Chimenti existing in the Lille Museum, and presenting, according to the illustrious savant, the stereoscopic relief, has been reprinted in the *Lumière* and other special journals. We were all asking whether the invention which so greatly honours Wheatstone and Brewster really dated from the 16th century. Mr. Bingham, who has just returned from Lille, conceived the happy idea of reproducing the two designs in question, to offer them to the French Photographic Society. We all examined them with care, but no one detected in them the slightest difference. They appeared to all perfectly identical. In the stereoscope they are superposed, but without any effect of relief. For the present, then, we must be permitted to doubt that they were intended for the application Sir David attributes to them."

Upon authorities so high, Dr. Brown's observations of the stereoscopic effect of the pictures was pronounced incorrect; and though I was utterly ignorant of the existence of the photograph in England, excepting in the collection of the Prince Consort, and had never either seen it or heard of it, I have been charged by Mr. Wheatstone's friends with *dishonesty* in not having retracted the opinion which I had merely published, not as my own, but on the authority of Dr. Brown, who alone was bound to retract it, if erroneous.

This charge, and others equally false and groundless, have been publicly urged against me by Dr. W. B. Carpenter, F.R.S., Registrar to the University of London, and that, too, in language so malignant and libellous, that I shall probably be advised by my friends to seek redress in a Court of Law.

In reply to such a charge, I had no other defence than that I had not only never seen the photographs in question, but had never heard, directly nor indirectly, any other opinion about them than that of a competent judge who found them to be stereoscopic; and I added that as the evidence of Mr. Wheatstone and his friends, who were interested parties, was comparatively of little value, *I still believed that the pictures were truly stereoscopic.*

* Concluded from p. 138.

The paper on which this opinion was printed was hardly dry from the press, when I received, through the kindness of Professor Kuhlmann, the photograph which had excited so much interest, and which I now submit to the inspection of the Society. As in all stereoscopic pictures, it is difficult by a casual inspection of them to perceive any difference between the right- and left-eye picture, when they are taken at the proper angle; but when they are combined by converging the optic axes to a point between the pictures and the eye, as done by Dr. Brown, *their stereoscopic character is instantly seen.* As very few persons, however, are able to unite the pictures in this way, I had a copy of them taken by Mr. Moffat, and the pictures transposed, in order to be viewed in the stereoscope. This photograph, with the pictures transposed, is now before the Society; and I have no doubt that every person that looks at it in the stereoscope will see the figure in relief, though it is more distinct when seen by the convergency of the optic axes, as Chimenti of course intended it to be seen. As the photograph now before us has been reduced to about *one-fourth* of the original, the stereoscopic relief observed by Dr. Brown in the Museum at Lille must have been more distinct than in a reduced copy taken photographically.

It is hardly necessary to observe that a stereoscopic picture executed by the hand must be very imperfect compared with those obtained by the binocular camera. The artist fixes only certain points in his copy of the original drawing, and joins these points as skilfully as he can; but if the original is stippled, or drawn only in points, and if, with his compasses, he places these points, in his twin copy, at the proper binocular distances from the same points on the original, which may be easily calculated, the stereoscopic relief will be as perfect as if the two pictures had been taken in the binocular camera. I hope to be able to show such a stereoscopic picture to the Society, and also copies of Chimenti's drawings of the same size as the original, and with all the lines, points, and shades more distinctly separated than they can possibly be in the best reduced photograph.

Some of those persons who have not seen the stereoscopic effect of Chimenti's drawings, in consequence of *not knowing how to see it*, have been surprised at finding two perfectly similar drawings, as they believed them to be, placed side by side, and have been led to conjecture that one of them may have been a copy by a pupil of the Florentine artist. Both the figures, however, bear the name of Chimenti; and, as we have seen, the one is as essentially different from the other as the binocular views of a solid statue.

## PHOTOGRAPHY AT THE POLYTECHNIC INSTITUTION.

The Polytechnic Institution is one of the oldest favourites with the public as a place combining instruction and amusement, and has, moreover, many associations connected with photography. Recently, it has acquired a distinctive characteristic in the prominence which it gives to photographic illustration. By the aid of the magic lantern, or dissolving view apparatus on a very large scale, photographic transparencies receive the utmost possible effect. The series of photographs which are now exciting considerable attention consist of a selection from Mr. England's stereoscopic views of American scenery, published by the London Stereoscopic Company. These pictures, illuminated by the oxy-hydrogen lime light, are thrown on an immense screen, the disk covering seven hundred superficial feet, and notwithstanding this immense amplification, produce a very fine effect. The only faults we have to notice consist in a little hardness in some, and a little coldness in the tone in others.

First on the list is the Broadway, New York, an instantaneous view, giving a very good idea of that busy thoroughfare, and reminding us vividly of the day we first stood there. West Point, on the Hudson River, with its military academy, is a fine picturesque view, as is also the view of Sleepy-Hollow, rendered so famous by the legends of Washington Irving. Here we have the veritable spot where the "Headless Man," to the no small terror of the inhabitants of this dreamy region, performed his nocturnal excursions. Passing up the Hudson, we find ourselves amongst the Catskill Mountains, where Rip Van Winkle slept and dreamed. Some of the scenery here is very grand, and like the Hartz Mountains, fit dwelling place of elf and gnome. Here are the Catskill Falls, a deep gorge, with a cascade descending some hundreds of feet, dashing from rock to rock in wild confusion and turbulent beauty.

The chief attractions of this series are the superb views of Niagara. The falls in summer, with warm glowing atmosphere, soft and sunny, and in winter, when the spray is frozen into myriads of sparkling diamonds; whilst around are icicles of enormous size, hanging from the rocks, and reaching almost to the foot of the falls. The panorama from Prospect Point shows the American and Horse-shoe Falls, the figures in the foreground suggesting the vastness of the scene. This is a charming photograph, full of softness and atmosphere. The Lover's Walk, Niagara, is a well chosen view, with fine perspective, very sunny effect. Passing down the Niagara River, we get a representation of the longest suspension bridge in the world. The detail of this fairy-like structure is very fine. Here also we have the crowning work of Stephenson—the Victoria Bridge, Montreal. The St. Lawrence at Quebec, with its thousand ships, riding peacefully at anchor on the broad bosom of this mighty river, is another excellent view.

The Falls of Montmorenci, a cataract near Quebec, of two hundred feet in height, is a fine and telling picture. An ice cavern is amazingly effective and beautiful. Long icicles depending several feet from the roof glitter in dazzling rays of wondrous splendour, such subjects illustrating pre-eminently the excellence of photographic delineation.

The undoubted success of these transparencies is due as much to their photographic excellence as to the interest of the subjects. We are glad to believe that photographs must ere long largely, if not entirely, supersede the gaudy and unreal paintings which have hitherto formed the staple of views for the magic lantern.

## THE PICTURE GALLERY IN THE EXHIBITION OF 1862.*

The following description of the principles upon which the picture gallery, and we presume the photographic gallery, will be built and lighted will interest our readers:—

The chief desideratum of a picture gallery is an equally distributed light throughout, admitted in such a way as will prevent its rays being chiefly directly reflected from the surface of the picture to the eye of the visitor. A light, therefore, satisfying this condition, when the observer is standing at a convenient distance, is the only one which can be called perfect.

No one can have observed pictures lighted by ordinary windows without experiencing the unpleasant effect produced by the improper reflection of the rays, or glitter from the pictures, as it is called. It is for this reason that one is often puzzled where to find a place from which to see the whole of a large picture to advantage. This defect exists in many of the finest galleries, both in this country and on the Continent, and the result is that some pictures can scarcely be seen at all, while others can only be observed from one or two points, which are always more or less crowded, according to the merits of the subject.

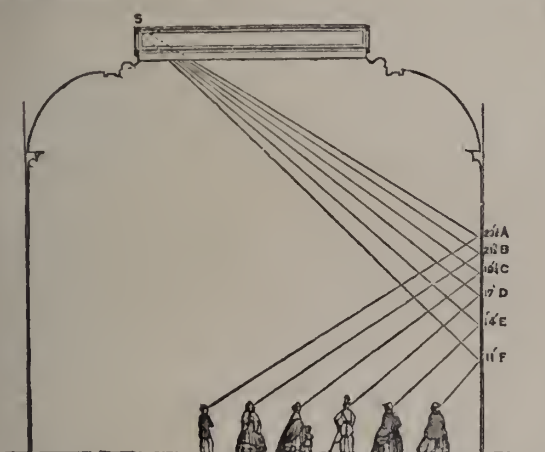
This is obviated by admitting the light at a particular angle from the roof, by means of a skylight extending along its entire length, and which in the present case measures 31 feet in width, that is, 15′ 6″ from the ridge on either side. The entire width of the opening, measured on a horizontal plane, is 29′ 2″. As will be seen by reference to the section, each room is 50 feet wide, and at a height of 32′ 9″, a cove, springing from a cornice on either side, reaches the height of the tie-bar of the principals (42′ 10″ above the floor), 12′ 4″ from the wall, thus leaving a space 25′ 4″ between the coves. In this space a transparent calico ceiling (hereafter to be replaced by ground glass) is introduced, which, however, is raised 2′ 4″ above the highest point of the cove, or 45′ 7″ from the floor. The space

* Lecture by Captain Philpotts at the Society of Arts.

between the highest point of the cove and the eave of the calico is occupied by louvres for ventilation.

These proportions will afford the gallery as much light as possible, and glitter from the surface of the pictures will be avoided. As regards the quantity of light admitted, it may be briefly stated that the opening for admission is exactly half the floor area of the gallery, the former being 25 feet wide, the latter 50. In dealing with the quantity of light, another important point must not be lost sight of, namely, the height of the opening from the floor and its consequent distance from the picture. In this gallery this is reduced to a minimum consistency with the avoidance of glitter, being only 45′ 7″ from the floor.

The following illustration will explain the question of glitter, or reflection of light, from the varnish of pictures:—Supposing a mirror to be hung against the entire surface of the wall. It will be seen, by referring to the diagram, that a ray of light from the skylight, at its extremity furthest from either wall, striking that wall at A, at a height of 23′ 3″ above the floor will, will be reflected so as to reach the eye, at E, of a beholder (say 5′ 3″ above the floor) standing 5′ on the other side of the centre of the room, or 30 feet from the mirror, and consequently all the rays striking below that point will fall below his eye, or, in other words, he will not be able to see the image of the skylight in the mirror at any point below 23′ 3″ from the floor, and, as a matter of course, there will be no glitter on the wall, or on pictures hung against it, below that point. Consequently to see pictures without glitter hung higher up, it will be necessary for the spectator to retire still further from the centre of the gallery.



Transverse Section of Picture Gallery, showing the way of admitting the the light to avoid glitter.

It will be seen from the diagram that this point, which is called the glitter point, alters with the position of the beholder. For instance, E, 5 feet from the wall, the glitter point is at F, 11 feet from the floor, while in coming closer it will descend in proportion. On the other hand, by receding to a distance of 10 feet, the wall may be seen without glitter to a height of 14 feet. Looking again to the same diagram, it will be seen that, apart from all considerations of reflection, a person desiring to see a picture at a height of 14 feet, would naturally retire 10 feet if not more from it, and the same may be said of the other heights and positions shown on the sectional diagram, so that in any position in which a person can conveniently examine a picture, he may be sure of having its surface free from glitter.

This system of lighting increases the difficulty of successfully treating the exterior of the building, for it prevents any windows being placed in the upper part of the side walls, but after the very successful application of these principles of lighting to picture galleries which have been constructed within the last few years at South Kensington, it was wisely determined to forego all other considerations, and apply the same principles to the rooms destined to receive the choicest works of art of the present age.

On ascending the stairs, the visitor enters a vestibule of similar proportions to the one below, from which he obtains one unbroken vista throughout the whole extent of the main gallery, and it is difficult to conceive a finer effect than that produced by contemplating the noble proportions of the rooms before him.

Entering the first on either side, he will find himself in a spacious hall, 325 feet long, 50 feet wide, and 43 feet high. Passing through this, he will enter one of the wing towers, which forms a room 52 feet by 45 feet, and 66 feet high; he will then enter another room 75 feet long, and of the same width and height as the first, from which he will pass into the end tower, whence he will have an uninterrupted view of the whole main gallery.

The interior decorations of these rooms will be very simple, and may be briefly described as a plain cove extending to each side of the skylight, and resting on a moulded cornice.

Arrangements for thorough ventilation, so essential to the preservation of the pictures and comfort of the visitors, are amply provided for, by admitting fresh air through apertures along the floor level, and allowing the vitiated air to escape through louvres in the skylight.

Descending to the ground floor, the same sized rooms are repeated, but as they are lighted by means of ordinary windows they will probably be devoted to other objects than those coming under the head of fine arts. The part of the picture gallery which will revert to the Society of Arts is the central hall, and the two large rooms, 325 feet long, on either side of it.

Before concluding this description of the Picture Gallery, its constructive details will be interesting. The foundations throughout are carried down to the gravel, here from 6 to 12 feet below the surface of the ground, in concrete, on which ordinary brick footings are laid. In the front wall the piers carrying the semi-circular arches are 12 feet wide, by 3′ 2″ thick, and the intervening panel having merely its own weight to support, is only 9″ work. The back wall is of rather a different construction. This is a plain wall from top to bottom, with numerous arches through it on the ground-floor; it is built for the most part hollow, with piers so placed that the weight of the floor and roof will come on them. This system of hollow walling gives the greatest strength with the least amount of material, and secures a straight face at either side. The floor of the picture gallery has been constructed of great strength, so as to bear with perfect safety the greatest load which can be brought on it. It is carried on girders 13½ by 12, resting on the side walls and intermediately supported by two cast-iron columns. These girders cross the building at central intervals of 12½ feet, and over them are laid joists 11 in. by 2½ in., two feet apart, to carry the floor-boards. A portion of this floor has been proved to 140 lbs. to the foot, which exceeds the greatest load it can have to bear when densely crowded with visitors. The walls in the picture gallery are lined throughout with wood, which is kept at a short distance from the brickwork, so as to guard against damp.

## DR. DRAPER'S INSTANTANEOUS DRY PROCESS.

An *Instantaneous* Dry Process is a startling announcement. It is of such tremendous import that there is danger of losing, for the moment, that calm philosophical temper which is so needful in the judgment upon momentous facts.

A dry process which can compete with the wet process in time of exposure, and desirable artistic effects must prevail. It would permit a division of labour which is the grand desideratum of economy in all the arts which are extensively practised. We may some day have photographic galleries when there shall be no occasion for the inconveniences of a silver bath, or collodion. When dry plates can be used for portraiture, their manufacture will become a totally distinct branch of business.

The new dry process is clearly given, and any one concerned may test its value by the actual trial. Dr. Henry Draper's exposition before the Society was satisfactory enough as far it went, but nice comparative experiments seem not yet to have been made. Let a dry and wet plate be exposed at the same time in the same light; let a dry plate be exposed and cut in half, one moiety to be developed in the usual way, and the other using hot water, &c. We have not had opportunity to make any trials ourself, since the meeting, but with Col. Pike we were shown the process by Dr. Draper. The doctor exposed a sixth dry plate, which had been prepared about fifteen months since by Col. Pike, in a Voigtlander quarter camera about one second. On development the plate proved to have been fully exposed. The exposure was upon the open street, in front of the University, with full aperture of lens, but the air was thick with a heavy snow storm. The experiment was satisfactory, but not decisive as to exact utility of the process. Before our next issue we shall probably have data enough upon which to found an ultimate judgment.

At the Society no rationale of the process was attempted; sufficient facts are perhaps not yet established on which to base one. We believe it is Dr. Draper's opinion that the heat and the water continue and exalt the first action of the light. We incline to think, however, that the hot water acts only mechanically, only in enabling the developer to penetrate more promptly; the action of the light is fully completed at the exposure, and that the density of the film may have little or no modification of the amount or nature of this action; but the density of the film has everything to do with the facility and extent of development. On our theory the development may take place just as well after the hot water treatment, when the plate is cold, and an iron developer may be used. This theory is a mere suggestion, and we leave it to stand or fall by the force of facts to be found out.—*American Journal of Photography.*

## COPYRIGHT (WORKS OF ART) BILL.

On Thursday, March 20th, the House of Commons went into Committee on this Bill.

The Solicitor-General stated that he had prepared some amendments with the view of giving effect to suggestions made by hon. members on former occasions.

Mr. C. Bentinck asked for some explanations with respect to the copyright in the copy of a picture, which it was proposed to give by this Bill. He was also anxious to know whether his hon. and learned friend (the Solicitor-General) was prepared with a clause providing for registration at Stationers'-hall, or some place else, in order that title in respect to copyright may be ascertained.

Mr. White directed the attention of the Solicitor-General to the necessity of providing, by some clause, that publishers of prints should put their names and the date of publication on those prints. For the last 10 years publishers had been much in the habit of publishing engravings without any name or date.

The Solicitor-General said it was intended to include in the Bill copies of original paintings, because any man knew that copies might be made under circumstances that would render the copying of those copies as injurious to the owner as if they were original works. As to the question of registration, it had occurred to him that that subject might be brought forward, and he had prepared two clauses providing for a registration of copyright. These he would bring up at the proper time. As to the point referred to by the hon. member for Brighton, they all knew that a practice existed among engravers of selling what were called "proofs before letters," which were without any name. He believed that every person who did that exposed himself to a great danger of losing his copyright. The case was provided for under an existing Act.

Mr. Henley put the case of an artist selling a picture, and retaining no copyright in that picture. If the artist afterwards made a duplicate original how would matters stand. They all knew that those things were often reproduced in that way, and it was difficult to determine between copies and duplicate originals. How was the second picture to stand? was there to be a copyright in it or not? He wished the hon. and learned gentleman would let all the questions under this Bill be decided by a court of record.

The Solicitor-General would consider before the bringing up of the report whether words should not be inserted to the effect that an original work being sold without copyright, no subsequent copy or repetition of the same work should be entitled to copyright.

Sir M. Ridley was glad that a system of registration was to be established. Such a system was absolutely necessary for the security of property.

Mr. H. Lewis thought it would be dangerous at present to include photographs in a Bill of this kind. Photography was not a fine art, but a mechanical process. At some future period it might be expedient to give protection to photographers.

The Solicitor-General remarked that, although, strictly and technically speaking, a photograph was not in one sense to be treated as a work of fine art, yet very considerable expense was frequently incurred in obtaining good photographs. Persons had gone to foreign countries—to the Crimea, Syria, and Egypt—for the purpose of obtaining a valuable series of photographs, and had thus entailed upon themselves a large expeniture of time, labour, and money. Was it just that the moment they returned home other persons should be allowed, by obtaining negatives from their positives, to enrich themselves at their expense? He could not consent to exclude photographs from the Bill.

Mr. Hennessy suggested that, at all events, photographic portraits should be excluded A visit to the Holy Land was not necessary for taking the portrait of the hon. and learned gentleman, and yet it would be hard to prevent the public from obtaining a copy of his likeness.

Mr. Henley inquired what was meant by "every offender shall forfeit to the persons aggrieved;" was it the man who painted, or who purchased the picture, or both?

The Solicitor-General said the words in practice sufficiently explained themselves. The person aggrieved would be the artist whose name was fraudulently used, the person on whom the fabricated work was fraudulently palmed off, or it might be both.

Mr. Henley then asked the right hon. gentleman whether he would consent to strike out those clauses giving summary jurisdiction to magistrates. It was hardly fair to throw upon them the decision of the questions which were to be determined not by reference to any Act of Parliament, but simply upon opinions given that a particular thing was painted by a particular person. The jurisdiction, moreover, was to be determined by the residence of the offender; and if the magistrate made a mistake as to his residence he was a wrongdoer from the beginning. Nothing was more difficult than to fix a man's residence, especially men of the class who would be likely to commit these offences. The hon. member for Cirencester was once questioned with regard to his residence, and replied that he resided sometimes at one place and sometimes at another, being a Lord of the Treasury. He was then asked where he slept, and he replied that he usually slept most in the House of Commons. The proper jurisdiction of the justice was to keep the peace, and had nothing to do with the settlement of disputes between artists and photographers, which were often carried on with the greatest bitterness. If a short and sharp way of settling differences were requisite, why not send the cases to the county courts?

The Solicitor-General said the clause to which the right hon. gentleman objected was taken, he believed, without alteration from two Acts *in pari materiâ*, which had not been found productive in practice of any of the inconveniences anticipated from this measure.

Mr. Henley thought the proceeding prescribed in the clause a most anomalous one. He moved the omission of the words, "summary proceeding before two or three justices."

The Solicitor-General was ready to adopt the words, "before any two justices."

The committee divided on the question that the words proposed to be left out stand part of the clause. The numbers were:—

| | |
|---|---|
| Ayes ... .. ... ... ... ... | 29 |
| Noes ... ... ... ... ... ... | 21 |
| Majority... ... ... ... | —8 |

The clause was then ordered to stand part of the Bill.

The remaining clauses were agreed to, and clauses were added,

The Solicitor-General undertaking that the Bill should be reprinted before the report was considered.

## Proceedings of Societies.

### North London Photographic Association.

The annual meeting of this Association was held in Myddelton Hall on the evening of Wednesday, March 19th, Mr. G. Shadbolt in the Chair.

The minutes of the previous meeting having been read, the following gentlemen were elected members of the Society :— Messrs. Homersham, Jones, Spicer, and Toulman.

The Secretary then read the following

#### Annual Report.

In addressing you on the Fifth Anniversary of the North London Photographic Association your Committee has little but congratulations to offer.

The success of the Association has been steady and progressive. The number of its members exceeds one hundred, and there are this evening several new names for election. The meetings have been well attended; the papers read have elicited more than ordinary interest; and the discussions have been conducted with greater freedom, ability, and energy—all tending to demonstrate the progress of our art and the social feeling pervading our Society.

The financial statement is satisfactory, showing a balance more than sufficient to defray all the liabilities of the Association.

Your Committee regrets the unavoidable delay in the distribution of the presentation photograph, but rests assured there will be ample compensation in the size and beauty of the picture; and your Committee takes this opportunity of thanking Mr. Bedford for his liberality in supplying so superior a photograph at a mere nominal cost to the Association.

Your Committee will be happy to receive contributions of unmounted photographs towards the completion of the first volume of the "Album" for circulation among the members, and begs leave to tender its best thanks to Mr. Bourne and other gentlemen who have already kindly presented specimens to the "folio."

Arrangements have been made by your Committee to provide at least one paper to be read at each meeting; and will, when practicable, announce its subject at the previous meeting, that members may come prepared to enter more largely into the discussions which invariably ensue, and which will tend to render the ordinary meetings even more attractive than at present.

The attendance of members of other Societies has been large; and your Committee will esteem it a privilege at all times to welcome those who, although not subscribers to the funds of this Association, come forward to aid by their presence and information the progress of photographic art.

Your Committee, in resigning office, is happy to state that its duties have been both light and agreeable. The readiness evinced by the members to communicate information, and the exceedingly pleasant tone pervading the discussions, have rendered the recurrence of the meetings a source of pleasure, and your Committee trusts that a state of affars so satisfactory may long be characteristic of this Association.

Treasurer in Account with the North London Photographic Association.

*We have this day examined the Treasurer's accounts, with the balance sheet, and find the same to be correct.*

W. Hislop, E. W. Foxlee. } Auditors.

After some conversation on the satisfactory state of the society's fund the report was adopted.

The Chairman called attention to a transparency exhibited by Mr. Martin, the dry plate on which it had been produced had been kept upwards of two years, having been prepared in August, 1859, and exposed in November, 1861.

The Secretary then read a letter from Mr. A. H. Wall, calling attention to the projected exhibition of the South London Society.

Mr. Hill asked if any one could state whether photographers copying engravings for their own pleasure, but not for sale, incurred any legal risk?

Mr. G. Wharton Simpson explained that the law of copyright in regard to engravings was not in a very clear or satisfactory state. The act rendered it imperative, in order to secure protection, that the name of the artist and the date of publication should be upon each print. As publishers were in the habit of issuing copies as "proofs before letters" without these essentials to protection, they really lost or at least jeopardized their copyright. This was, he believed, the legal position of the question, and therefore it would appear that photographers might without risk make such copies for their own pleasure. As to copying for the purpose of selling, he conceived that it was scarcely probable that any gentleman present would be likely to engage in piracy, on moral grounds, altogether apart from legal risk. It was possible that the new copyright now before Parliament might place the matter in a more certain and satisfactory position.

After fome further conversation on the subject the matter dropped.

The following gentlemen were elected officers of the society for the ensuing year :—

*President*—Mr. Charles Woodward, F.R.S.

*Vice-Presidents*—Messrs. G. Shadbolt and G. Dawson.

*Treasurer*—Mr. D. W. Hill.

*Committee*—Messrs. W. J. C. Moens, F. Bedford, G. Wharton Simpson, W. Hislop, T. Ross, T. A, Barber, J. Bingham, and E. W. Foxlee.

*Hon. Secretary*—John Barnett.

After the election of officers, Mr. England exhibited some of his exquisite transparencies of instantaneous and other pictures by the aid of the oxyhydrogen lime light, eliciting much admiration. During part of the exhibition an ordinary quarter-plate lens was substituted for the common lens of the lantern; a very marked improvement in illumination and definition was the result, and induced a general conviction that the effect was much superior, notwithstanding that, under the circumstances, a less amount of amplification was obtained.

The usual vote of thanks terminated the proceedings.

## Correspondence.

### FOREIGN SCIENCE.

[From our Special Correspondent.]

*Paris, 26th March*, 1862.

The Madrid Academy of Sciences offers, among other prizes, one for the solution of the following :—To determine the probable errors implicated in topographical plans deduced from two photographic perspective views, taking into account all the sources of error that may possibly exist. The prize will consist of a gold medal, and the sum of 6,000 reals (£30). The papers written in Spanish, or in Latin, must be addressed to Don Aguilar y Vela, perpetual Secretary of the Academy of Sciences, Madrid.

M. Criniale has published a new series of his photographic views in the Alps; and also four immense panoramic pictures, representing the series of the summits of the two great groups of Mont Blanc and Mont Rosa. These four pictures, formed each of eight whole-plate proofs, embrace horizons of many hundredths of degrees, from 20 to 35 miles. Taken under well considered and constant theoretical conditions, they are equally important, not only to topography and geography, but also to geology. They are no less remarkable from the elevation of the point of view from whence the photographs were taken, which was sometimes over 4,000 feet above the level of the ocean. They are truly masterpieces of the art of photography, and reflect much honour upon an intrepid and skilful amateur photographer. The negatives were taken on paraffine waxed-paper.

M. Leon Foucault has devised a new heliostat which is so ingeniously constructed as to apparently solve the problem attempted by S' Gravesande, Gambey, Silbermann and many other phisicists Brought to an almost absolute degree of perfection, the new heliostat will pass from the cabinet of physics to the observatory, and serve in a new mode of observing the stars. Moreover as, it can be constructed at a trifling cost, it will soon find its way into the operating room of the photographer, where it will be employed in those processes of enlarging and reduction which open an entirely new feature to the art Daguerre and Niepce. A more complete description of the instrument must be reserved for another occasion, stating now briefly that the axis, which in the heliostat represents the axis of the world, is no longer condemned to carry, at the expense of the regularity of the instrument, a reflecting mirror. This mirror is now sustained by a vertical rod, and may assume very large dimensions; that the direction of the reflected ray is absolutely fixed in space, that the orientation is made without calculations. The new instrument is characterised by all those new and ingenious details of construction which characterise the inventions of M. Foucault generally, and particularly his regulator for the electric light, the first of its kind that has been found practically useful. The inventive genius of the philosopher has been ably seconded by the mechanician, M. Jules Duboscq, who in fact suggested improvements in the electric-light regulator, and gave it its present vertical form.

M. Brettiger suggests a very simple method of reproducing by chemical means an engraving from a steel or copper plate. Dissolve in 1,500 parts of pure water 16 parts of pure, concentrated sulphuric acid, and to 200 parts of the mixture add ½ part of iodide of cadmium. This last mixture is poured into a dish, and the engraving is immersed in it, and left till it has become thoroughly impregnated with the liquid, it is then placed upon folded sheets of white blotting-paper, on a plate of glass, and the excess of moisture removed from the engraving: it is then placed printed side downwards upon a sheet of writing or of positive paper, and placed in a press. An impression is obtained as delicate as that furnished by photographic processes. The iodide of cadmium may be replaced by iodide of potassium. The reproduction is due to the reduction of the iodine by the Franckfort black in the ink of the engraving, and the liberated iodine acts upon the starch with which the paper is sized. The engraving will give a second impression without being returned to the solution.

When the engraving has been used several times, it is only necessary to wash it in water to remove the spots that may have formed. Lithographs and ordinary printed matter cannot be reproduced by this process, on account of the nature of the printing ink, but writing ink succeeds very well.

Unfortunately, these beautiful impressions become blue all over, and are gradually effaced, even if covered with a coat of varnish.

## MR. MELHUISH'S RAPID PRINTING PROCESS.

Dear Sir,—You will, I am sure, allow me to correct a slight inaccuracy in your report of the trial Mason *v.* Heath, and as the few words attributed to me appear, from the numerous enquiries I have received, to have excited a good deal of interest, I will state in full what I really did say.

*Plaintiff's Counsel.*—You have, I believe, devoted your attention for some years to photographic printing.

*A. J. Melhuish.*—Not more than to other branches of photography.

*P. C.*—You have printed largely for the late Prince Consort, have you not?

*A. J. M.*—I have.

*P. C.*—How many copies a day could you print from one negative?

*A. J. M.*—If I printed them by the same process I used for the late Prince Consort about 200 a day, certainly not less, I think considerably more.

*P. C.*—Have you ever printed as many as that from one negative in a day?

*A. J. M.*—No; but I have printed 60 or 70 in a little more than two hours, and as each print requires but *half a minute's exposure* (not *half a second* as stated in your report), I feel no hesitation in saying that I could print 200 a day from one plate.

And now that I am writing, a word to "A Photographer" (whose name, bye the bye, I should exceedingly like to know, for I don't at all like anonymous correspondents) who is so anxious to know what this "new process of Mr. Melhuish's is." It is simply a modification of Mr. Sutton's serum process, referring to which the Editor of the *Photographic Notes* thus writes:—"We had the pleasure of looking over a portfolio of these prints (Melhuish's serum prints) at the Palace, and were gratified to observe that none of them had faded; if Mr. Melhuish would, on some future occasion, publish his experience in development printing; we are sure his communication would be much appreciated."

Your correspondent also mentions that a short time since at a meeting of the Amateur Photographic Association I stated that in consequence of the bad light "I could not print much from the negatives sent in;" this is not what I said, but supposing it were, surely those bright photographic talents for which I am bound to give "A Photographer" credit until I know his name, must be, from some cause or other, somewhat obscured, else he would at once perceive that a process which would be suitable where 40,000 *copies* were required from *one negative* might not *necessarily* be equally applicable where but a *few copies* were required from each of *two or three thousand different negatives.* So that "A Photographer's" concluding exclamation, "How can I reconcile the two statements?" was quite uncalled for, and needs no reply.—I am, my dear sir, yours very truly, A. Melhuish,

*Hon. Sec. Amateur Photographic Association,*
26, *Haymarket.*

## ORGANIC SALTS IN DRY COLLODION.

Sir,—Probably some may require more particulars of the dry process published in last week's number of the News, so I have sent these lines for their information.

For simply washed and dried plates, it is only necessary to add to a clear and good working bath of 8 ozs., one grain of muriate of morphine dissolved in a little distilled water, and then filter it; more will answer and probably less. A dry process collodion, bromo-iodized, and iron development is best. If preferred, the muriate may be put in the collodion say ¼ grain to the ounce. I prepared some collodion with the acetate of morphine for a photographer, and was greatly surprised at his report of it, he said it was not more sensitive than the same collodion minus the acetates, and on trying both at once, in the same camera, to the same view, he obtained the natural clouds in *both;* now all this is very puzzling to me; can it arise from the nitrate of morphine dissolved in the bath, so that it communicates the peculiar quality of reproducing the clouds with plain bromo-iodized collodion? his bath was acidulated with nitric acid, mine with acetic, the nitric acid, I believe, would tend to decompose the little acetate of silver in the film, and so might possibly neutralize the accelerating action, for I am constrained to believe, that to take an instantaneous street view in the middle of February, with the success I met with, even with the quickest lenses, is not usual.

I am perfectly aware that the use of organic salts of silver in collodion is of old date, and do not claim any originality in the matter, I have merely worked out the principle enunciated by Hardwich in page 226 of his manual, 6th edition. If I had the means I should like trying an organic iodide and bromide in place of, or in conjunction with, the usual ones.

I must corroborate your correspondent's experience in the production of mealiness by adding acid to the paper sensitizing bath, I can produce it directly by that means, and banish it again with an excess of alkali.—I am sir, yours &c.,

Wm. Bartholomew.

## THE ROSIN PROCESS OF HERR SAUNDERS VAN LOO.

Sir,—I have seen in your estemed Photographic News, the translation of an article placed by me October 6th 1861, in the *Cosmos*, concerning; "Dry Collodion with Rosin."

As I desire to facilitate the experiments in this way to persons practising this method, I make haste to inform you that in the article alluded to, is not expresssed plainly the kind of pyroxyline suited to this method. The specimen called "rotten" in the valuable work of Mr. Hardwich (6th edition), is the desired one.

The ordinary sorts of pyroxyline do not adhere to the glass, and give foggy pictures. I operate on glasses from the size of quarter-plate to whole-plate and larger: in the latter case the edges of the film are fixed with alcoholic varnish.

By inserting this communication in your esteemed Photographic News, and giving me in a few words the account of the reception of this letter, you will oblige, your obedient servant,

D. J. Saunders Van Loo.

# Photographic Notes and Queries.

### Photographic Exchange Club.

Dear Sir,—Will you allow me to make a suggestion as to marking the prints for the Exchange Club, which is, that the members, if working dry plates, should state whether the plates are purchased ready prepared and sensitised, or prepared throughout by themselves, as if one member procures plates ready sensitized, another may go a step further and have them printed off by a professional; a third might even have them developed for him as well. I do not wish to cast any slur on those gentlemen who may procure prepared plates, as I know that everyone cannot give the necessary time; but still, I think, the man who takes his plate of glass, cleans, prepares, exposes, develops, and prints, is deserving a little more credit than the one who is only partially a photographer, even though the result may not be so good.

If you think anything in this may be likely to offend anyone, perhaps you would be kind enough to make the suggestion, without any remarks; I only make them to show why I propose it, and most certainly should be sorry to annoy any of my fellow members.—I am, sir, yours truly,

W. Larchin.

*Waltham Cross, March 4th*, 1862.

### Hints on Cameras, &c.

Dear Sir,—I beg to offer you a few hints in connection with your "Remarks on Apparatus in connection with Photography." In reference to your first article on cameras, it must be admitted there is nothing more essential to a photographer than a good made camera, no matter how perfect his skill or his lens: too many are made for lightness and portability, without combining with these efficiency. For instance, the dark slide is made so light that it is always getting out of order; the most useful size I find in practice is nine-eighths of an inch thick, instead of three-fourths or seven-eighths as usual, or even less; with nine-eighths you have two-eighths for the dark shutter, one-eighth between the loose frame and shutter, four-eighths for the loose frames, which will appear quite unnecessary, and two-eighths for the door. But I find the central space one of the best recommendations it has; for you find it gives the quality of a swing back. You may throw the plate out of its vertical position three-eighths any way you please, by removing the loose slide and placing a strip underneath it, so as to bring every part of the picture in focus. Suppose it to be a portrait, the picture the size the lens is intended to cover, and the face to be well defined; the lower part will be slightly out of focus, in consequence of its being brought too near the plate: by placing the strip of wood under the loose frame at the top, it will bring it into perfect focus.

The next thing I wish to call your attention to, is the rack and pinion movement. From what I have seen, I must think the method as bad as the principle is good, for those shown me have the rack attached to the sliding body, and the pinions to the base board. Now if the racks are fixed in the base board, and the pinions travel with the sliding body, it would be better; but a movement I think better still is obtained by sinking two ¼-inch brass rods half in the base board, and half in the sliding body or thereabouts, so the bearing is on the rods only. You would be surprised how easy the camera is adjusted, and the focus obtained with the greatest accuracy.

To mount card pictures, I use glue that will flow free from the brush, square the print $\frac{1}{16}$ less than the card top and sides (that I think neater than $\frac{1}{8}$ each way,) glue one end of the print, and place a piece of glass on the glued part, and glue the other end: then you find the glass form a handle to adjust it with, it prevents it curling as much as it does when held in the fingers, is much cleaner, and more manageable. If you think any of the hints of any service, you are at liberty to use them at your discretion; if they are any use, I will try and give you some on other apparatus.—Your obedient servant,

W. Nurse.

*Burnham, March* 4, 1862.

[In using a rack and pinion, the rack should always be attached to the part which travels, and the pinion to the part which is fixed. Our correspondent will find this if he attempts to work it on the principle he suggests.—Ed.]

### Painting Magic Lantern Slides.

Dear Sir,—I shall feel greatly obliged if you or any of your readers can give me any information on the subject of painting slides for the magic lantern. I much wish to try my hand on colouring some photographs, but my attempts have been complete failures. I some time since purchased a book published by one of the principal artist's colourmen, in which you are instructed to use moist water colours. It is perfectly clear that the writer cannot have tried the experiment, or he would not have recommended what is an utter impossibility. My own impression is that the article used is Canada balsam, or something of that nature, but how the colours are mixed, or how laid on evenly, I am at a loss to imagine.—I remain, dear sir, yours faithfully,

B. Jones.

*Cheltenham, March 10th*, 1862.

### Wet Collodion Out of Doors.

Sir,—Every little is a help, so I address you concerning the staining of plates, owing to their being carried a distance in out-door photography, I have found that a plate being carried, say five hundred yards, exposed, brought back and developed with every care, such as draining the plate, using filtering paper, &c.; the surplus solution of silver will run on to the plate-holder and back again to the sensitive plate, carrying organic matter with it, and by so doing, causing stains, in many cases spoiling a good negative. I have been served so, and naturally I looked round for something to stop this fault; at last I thought of *sponge*, so cut in pieces about half-inch square, and placed them in the lower corners of the plate-holder, on the back of the sensitive plate, and ever since have done away with stains. Moreover, I find the plates can be carried farther without the least fear of the nitrate solution injuring the collodion film; I have carried a plate a quarter of a mile and back without the least injury to film or stain on plate, and then developed without redipping in nitrate bath; by others using these exceeding simple things they might save many a good negative.—Remaining yours respectfully,

Geo. Yevrah.

## Talk in the Studio.

Pure Nitrate of Silver.—Photographers have for so long been accustomed to the use of nitrate of silver, containing more or less of impurity, that few persons expect to make a bath which works at once, giving rich negatives, without some doctoring. We have recently received from Mr. Solomon a sample purporting to be "pure recrystalized nitrate of silver," put up in sealed tubes, each containing an ounce, which, on trial, proves everything which we could wish. On adding the proper quantity of water and iodide and filtering, the first plate produced a rich negative, free from streaks, fog, or greyness; presenting a fine creamy bloom by reflected light, and a reddish brown deposit, with sufficient intensity, by transmitted light, when developed with iron. If the same quality can always be guaranteed at the price, which is very slightly in advance of that of the common quality, it will be a decided boon to photographers. It is certainly worth a trial.

Shaping Photographs.—An ingenious aid to the cutting of *cartes* and other photographs has just been introduced by Mr. Solomon. It consists of a plate of glass on which to cut, fixed in a frame which revolves on a centre. When the glass shape is placed on the picture in the usual way, and one side cut, it is necessary to turn round the picture and shape to cut the other side, in doing which there is great danger of moving the shape or guide from its position. In the contrivance of which we are speaking, the glass plate upon which both are placed to be cut, is moved round on its centre, obviating any risk of moving the guide, and materially facilitating rapid and correct cutting. Some very excellent and nicely finished guides of all shapes, made of thick plate-glass are also provided.

Photography is Avenged.—Most of our readers will be aware that the beauty of the interior of the International Exhibition is stated to be entirely spoiled by the French department being entirely boarded up into one large box, instead of being open, so as to contribute its quota to the grand *coup d'œil*. It is stated that one important object of this boarding is to furnish a huge screen on which to hang enlarged photographs, the chief of which is the portrait of a horse, life-size. If, as photographers believe, their art has been slighted in the programme of the Exhibition, it is here avenged, and asserts its importance with sufficient force to contribute largely, although indirectly, to spoiling the whole effect of the interior.

## To Correspondents.

Sigma.—It is customary in speaking of the enlargement of photographs to refer to lineal measurement. The table in the Photographic News Almanac refers to this measurement: thus, when a picture is stated to be enlarged four times, four diameters, or sixteen areas is meant. We have not seen the drying box to which you refer; nor can we undertake to say which form of drying box is best.

J. C. W.—You will doubtless be able to obtain the materials for the manufacture of collodion from any respectable photographic chemist. The house you mention is a wholesale house. If you wish to purchase very large quantities, your best plan will be to get the addresses of various establishments from the London Directory. If you send us a card, and a stamped and addressed envelope, we will roll it as you desire. No. 39 of the Photographic News is in print.

G. E. W.—We see no reason to doubt that the agent in question would send you the genuine lens of the maker for whom he is agent. As to its quality, we can, of course, say nothing. We have often repeated in this column that cheap French lenses not unfrequently turn out pretty good; but that for absolute certainty of obtaining a thoroughly good lens, we recommend those who can afford it, to apply to first class London makers. Having purchased a lens you cannot compel the dealer to refund the money. We believe the agent in question is a respectable man, and will do his best for you; but in such cases take care to be conciliatory instead of angry in your letters.

L. L. H.—Sugar of milk is made by evaporating whey until it crystallizes. Volumes iii. and v. of the Photographic News are in print, and may be had of the publisher. The other volumes are out of print.

A Westmoreland Laker.—We have not found the difficulty you mention in using albumen containing a little free ammonia. A correspondent recently recommended the use of acetic acid for the purpose of preserving the albumen. We have not tried the plan, but it may possibly answer your purpose. Why not try a dry collodion process, say either simply washed collodion, or the tannin process, since eggs are so scarce, dear, and difficult to get fresh in your neighbourhood?

M. H.—We have seen some very fine and delicate negatives on turpentine or camphine or waxed paper; but for small work, such as you name, we do not think that any paper process will equal collodion.

H. V C.—Each of the portrait specimens sent have good qualities, but they would each, with the amount of illumination they have had, have borne a trifle longer exposure. No. 2, with a very little more exposure and a little intensifying, would have made a very good picture. The stopping out of the sky in the stereograph has the effect of making all the rest of the picture look dingy. We prefer sheeting calico stretched upon a frame and painted dark grey, either in distemper or oil flatting, for a background. A blanket, carefully stretched, and the sitter placed three or four feet at least in advance, may be used with good effect. It is important to keep the blanket well out of focus, so as to prevent the appearance of texture in the background. There is no necessity to reject a silver bath so long as it is working well: add fresh strong solution from time to time to keep up the strength and quantity. We cannot with propriety recommend the collodion of any particular maker here. The one you name has the reputation of being very good, so have Thomas's, and Burfield and Rouch's bromo-iodized collodions, and also Ponting's. A sky ought never to need intensifying in excess of the rest of the picture; where anything of the kind is attempted, the destruction of harmony in the picture is the result. A little tint in the sky is infinitely preferable to a sky of white paper. Your formulæ all appear good: facilities for a little more control over the lighting of the sitter appear to be the only want.

G. S. S.—There is a "preparation" for sizing albumenized paper photographs, prior to the use of water colours, sold by Newman, of Soho Square, which answers admirably. In strengthening a toning bath of gold and acetate of soda, you should not add simply solution of chloride of gold, but a fresh quantity of unused solution, as made at first, of gold and acetate of soda.

J. W. Whelan.—We find there is no possible chance of obtaining space now at the International Exhibition. The space already allotted is in considerable excess of that which can be actually used. You will be able to exhibit at the Crystal Palace.

A. D.—The best mode of printing-in separate skies has repeatedly been described in our pages. See an article by Mr. Fry on p. 350 of our fourth volume.

B.—The triple lens which will suit your half-plate camera, is that intended for pictures 6 in. by 5 in., and is the one used by Mr. Wilson for his 7 in. by 4½ in. landscapes. As to whether it or the single lens is best for taking views is a point on which opinions differ. Its advantages are perfect freedom from distortion, great depth of definition, and including a very wide angle. The advocates of the single lens claim for it more brilliancy. 2. The reason why some difficulty exists in procuring efficient yellow glass, arises from the fact that efficiency cannot always be determined merely by colour, and those who deal in the material do not always test it. Hence it becomes necessary for each person to test his own before using it. There is no doubt but what the material used by the first-class professional photographers you name can be purchased by any one else; but those gentlemen have to test in the first instance just the same as any one else.

A. N.—You do not state with sufficient precision the nature of the redness which spoils your dry plates when developing. Is it a red deposit of a foggy nature, or does the whole film become red and transparent? So far as we can understand your description, the evil appears to arise from decomposition in imperfectly washed, or too long kept plates. Over exposure, in certain conditions, will sometimes produce similar results; sometimes the use of citric acid in the developer will remedy such an evil. The specimen you enclose is very good; the stopped out sky is its only defect.

G. Lewis.—The time required to develop a collodio-albumen negative with plain pyrogallic acid will vary according to the temperature and the exposure. A properly exposed plate, developed with a solution at a temperature of 60° Fah., will occupy from two to five minutes. Intensify with pyro, citric acid, and silver, as recommended by Mr. Mudd. Increasing the temperature of the developer will hasten its action, but this is not necessary except where the exposure has been short.

S. R. A.—We believe Bull, Brothers, whose advertisement you will find in our pages, make solid pedestals, &c., as well as profiles. Mr. Francis, Great Russell Street, also supplies them.

One that is Uninsured.—We do not know of any assurance office which makes a speciality of photographic materials or photographic lives. Any respectable office will undertake them.

G. G.—You may prevent the sliding tube of your lens from moving so easily as to shift by the slight touch of uncapping by a variety of means; but there is no especially prescribed method. A slight bulge in the tube will do it; or the introduction of a little india rubber in solution between the tubes, or in short anything that will make them "bite" against each other. 2. The only means of preventing your lantern from getting too hot, is to reduce the size of the flame, enlarge the lantern, or increase the amount or number of the apertures at the top, so as to allow the heated air more rapidly to escape.

A. Lane.—Our pages for some time past have contained various articles on card portraits and the various formulæ most suitable, so that it is difficult to select any especial numbers as referring to that subject. The number for Feb. 7 contains a brief article, embodying some useful hints on the subject. The Photographic News Almanac for this year contains a good deal of information on the subject.

E. Parsons.—If agitating with kaolin and then filtering does not clear your bath, add a few drops of a solution of common salt, or of citric acid, and agitate. This will cause a slight precipitate, which in falling will carry with it the colouring matter. 2. We have never tried the formula you name; but we should prefer a much weaker solution. When any especial formula is supplied with a collodion, it should be regarded as an intimation that the maker considers his collodion as working best under that especial treatment, and a trial should, at least, be given.

C. Eades.—Water-glass is made by igniting fifteen parts of powdered quartz with ten parts of crude potassa and one part of charcoal, till perfect vitrification takes place. This mass is then powdered and boiled with five times its weight of water for a few hours, until it is dissolved. It can be purchased ready prepared, and it will be better to obtain it so for experimental purposes. We do not think it will be found suitable for preserving electro-plated goods. In our hands it has always become efflorescent on exposure to the atmosphere.

R. H. Mason.—Your letter is withdrawn as you request.

Excelsior, J. H. K., and some other correspondents in our next.

Advertisements and Communications for the Publisher for the current number, to be addressed to the Office, 32 Paternoster Row, not later than 3 o'clock every Thursday. Post-Office Orders are to be made payable to Mr. Thomas Piper, at the Money-Order Office, St. Martin's-le-Grand.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 187.—April 4, 1862.

## BROMIDES IN INSTANTANEOUS COLLODION.

Where theories differ, practice must decide. For a long time past the value of bromides in collodion and iron development have been gradually obtaining recognition amongst photographers. There have always been, however, some who have remained steadily faithful to their first love, and believed only in the advantages of simply iodized collodion and pyrogallic acid development. Mr. Hardwich very tardily acknowleged the value of bromides, and never recognized their accelerating agency. Mr. Sutton has recently maintained, with steady iteration, that with pure chemicals simply iodized collodion, with pyrogallic acid developer, is more sensitive than bromo-iodized collodion with iron development. For our own part, as our readers know, we have always maintained, that whilst under good conditions very fine pictures might be obtained with moderate rapidity with a simple iodide and pyrogallic development, these conditions were not always easy to secure, as depending upon causes beyond the operator's control; and were uncertain and difficult to maintain: whilst with a bromo-iodide and iron development equal, or better results, could be obtained in good conditions, without the same risk of failure when the conditions were less favourable.

Knowing Mr. Sutton to be a careful experimentalist, and a first-rate practical photographer, we oppose our own experience and conclusions to his with considerable deference, although without hesitation. As possessing far more weight, however, than the most carefully conducted experiments, we point to the practice of every photographer who has acquired any celebrity for instantaneous productions. Success in these operations can only be the result of very carefully garnered experience, gained in actual practice: and practical men, who have bread to win as well as laurels, may generally be trusted and followed in their selection of formulæ and manipulations. Mr. Wilson, of Aberdeen, Mr. Blanchard, Major Webster Gordon, Dages and Harman, Mr. Samuel Fry, and others, whose instantaneous photographs the public are familiar with, all, without exception, use highly bromized collodion, as we have from time to time explained in these pages. We can now add another name to the same list.

Mr. England, whose experience is, perhaps, more extensive and varied than that of any photographer of the day, and whose process has hitherto been unpublished, has recently communicated to us many particulars of his formulæ and operations. Mr. England's experience exceeds that of some of his compeers, inasmuch as it has been more varied, his practice having been on the Continent and in America, as well as in this country. His instantaneous street scenes of Paris, we hesitate not to say, are unrivalled for delicacy, purity, harmony, perfect instantaneity, and freedom from chalky under-exposure. His views of Niagara partake of the same characteristics, as regards softness and rapidity. Mr. England habitually uses a greater proportion of bromide in his collodion than any photographer we know. His usual collodion for instantaneous work contains three grains of bromide of cadmium and three grains of iodide of ammonium to each ounce of collodion. If the subjects present great contrast, and there is risk of producing a hard picture, he then increases the proportion of bromide to four grains, and reduces the iodide to two grains. His mode of preparing his collodion so as to be able at a moment's notice to use a sample containing any desired proportion of the iodides and bromides is very convenient. With pyroxyline made at a moderately high temperature, and five parts of ether and three of alcohol, or sometimes equal proportions, he makes a normal collodion, adding just sufficient of the cotton to give a good film. One lot of this collodion has bromide of cadmium at the rate of 24 grains to the oz. added to it; another lot has iodide of ammonium in the same proportion added. With a bottle of each of these, properly settled and decanted, and a bottle of the normal collodion, a collodion ready for use at a minute's notice with any proportion of iodides and bromides may be produced. A drachm of each, containing the iodide and the bromide, to six drachms of the normal collodion, gives the proportion generally used for instantaneous work. The advantage of having the iodide and bromide dissolved in collodion instead of in alcohol as is customary, is, that there is no difficulty or doubt about altering the thickness by dilution, and the collodion is ready for use at once, without any fear of turbidity or precipitation, which sometimes occurs when alcoholic solutions of sensitizing salts are added to collodion. Mr. England has a profound faith, based upon experience, in the action of bromides in accelerating, and in producing harmonious negatives with short exposure. Accordingly, in proportion to the amount of rapidity required, or the amount of contrast in the subjects endangering hardness, an increased proportion of bromide is added.

Mr. England excites in a bath of pure silver as nearly neutral as possible, and develops with a strong solution of iron, varying the strength of the developer with the subject and the proportion of bromide, from twenty-five grains to fifty grains to the ounce of water. He frequently obtains the desired vigour with this alone; but sometimes intensifies with pyrogallic acid and silver.

In all the formula of successful professional photographers engaged in instantaneous work, a very large proportion of bromide is present; whilst we do not know one engaged professionally in this branch of our art who uses a simple iodide and pyrogallic acid development. We may mention, as strikingly similar to Mr. England's practice, although arrived at by independent experience, and without any concert or comparison of notes, that Mr. Blanchard returned a few weeks ago from a successful trip in pursuit of instantaneous photography, in which he informed us that he used five grains of bromide to four of iodide in his collodion. We may remark that with professional photographers under such circumstances, it is not a photographic *tour de force*, secured by a chance plate, that is aimed at. This was a journey many score of miles, taken expressly, in the early part of the gloomy month of March, to secure a series of instantaneous negatives of scenes in the restless bustle and hubbub of a country fair; and notwithstanding the season and weather the pictures were obtained.

We have another word to say on iron negatives, in regard to the proper quality of which we fear there is some misapprehension amongst some of our readers, and we must add either in the mind or in the language of our good friend Mr. Sutton. He has frequently recently spoken of "the flat, veiled, iron developed negatives," as though iron negatives were necessarily of this character. "A good pyro developed negative is certainly much pleasanter to print from than a flat, fogged, grey negative, developed with iron," he says in the last *Notes*. This is unquestionably true; but it is just as true that a good iron developed negative is more pleasant to print from than a flat, fogged, grey negative, developed with pyro. A good negative is always more pleasant to print from than a bad one, no matter how either may be produced. But no one knows better than Mr. Sutton that flat, veiled, grey negatives are produced by pyrogallic acid development if impure chemicals are used, especially in the silver bath; and that these characteristics are not confined to iron development. The negatives described as "flat, fogged, and grey," when produced by iron development are by far the worst negatives in existence, for they are generally thin as well, and are useless for producing brilliant prints. A pyro developed negative, even when fogged and grey, has generally sufficient thickness of deposit to allow by skilful printing, of moderately good pictures being produced from it; but with iron development, such a negative is hoplessly bad.

But the truth is that good iron negatives have none of these characteristics. Greyness is unnecessary, and fog is fatal. If Mr. Sutton will examine the iron negatives of any successful professional photographer, he will find all the characteristics he loves to see, and which we have seen in many of his own pyro negatives. We recently had an opportunity of examining some of Mr. Vernon Heath's landscape negatives on 12 by 10 plates, produced by iron development and bromo-iodized collodion. They were amongst the most perfect we have ever seen; with a fine bloom by reflected light, and a rich red smoke colour by transmitted light; no traces of fog, but with points of bare glass in the deep shadows, presenting a certain amount of positive character when examined by reflected light. The sole difference betwixt these and pyrogallic acid negatives, being found in the fact that to get prints of equal beauty and brilliancy from each, the pyro negatives would require at least four times as long exposure in the pressure frame as the others.

First class professional photographers who, without exception almost use iron, would not dream of tolerating any fog or veil on the shadows. Let anyone who has the opportunity, examine the negatives of Mr. T. R. Williams, which are as clean and brilliant, and free from fog or flatness as photographs can be produced. We have before us at the present moment an iron negative, by the late Mr. Lacy, which is by reflected light a brilliant positive, by transmitted light, a rich red negative, giving an exquisitely soft and delicate print. Such negatives photographers should always aim to get, whatever process they use; and they must not entertain the idea for a moment that flatness, fog, and greyness are the legitimate result of iron development.

---

Since the above article was in type, Mr. England has read a paper at the Photographic Society, in which he briefly described his method of working in instantaneous photography; we shall hope to give his method in his own words in an early number. He exhibited at the same time some of his instantaneous iron negatives taken as above described. If one characteristic was more striking than another it was their freedom from flatness, veil, or fog, and their clearness, delicacy, and brilliancy.

## THE CONTRACT FOR PHOTOGRAPHING IN THE INTERNATIONAL EXHIBITION OF 1862.

The following are the conditions upon which the contract for photographing in the Exhibition Building are to be based, with the additional one, elsewhere announced, but not here expressed, that the Commissioners do not bind themselves to accept the highest or any tender:—

The Commissioners for the Exhibition of 1862 undertake to grant the sole and exclusive privilege of taking photographs of and within the Exhibition Building, for a period extending from the 30th day of April, 1862, until the end of ten days after the close of the Exhibition, subject to the following conditions and regulations:—

1. The foregoing privilege gives the right of taking general views of the interior of the building and its arrangements, but does not give any right to take photographs of individual articles exhibited, without the consent, in writing, of the owners and exhibitors of such articles.

2. The photographs must be taken before 10 a.m., but Her Majesty's Commissioners reserve to themselves the right of making from time to time such rules, regulations, and conditions as to the hours within which, and the mode and places in which, the privilege may be exercised or otherwise, as they may think necessary.

3. Her Majesty's Commissioners will not provide any space or room for photographers, or for their processes of developing or preparing their plates or otherwise, all of which processes must be carried on beyond the limits of the Exhibition buildings.

4. The photographer and a limited number of assistants will be granted, during the continuance of the aforesaid privilege, free admission into the building, subject to all such byelaws or regulations as the Commissioners may from time to time make.

5. In the event of any dispute whatever arising either out of these Articles, or with respect to the true intent and meaning of them, the photographer shall agree to abide by the decision of Her Majesty's Commissioners absolutely and without appeal.

6. No sale of photographs will be permitted within the building.

A part of the tender, it would seem, is expected to consist of copies of the pictures produced, as the following form of tender is supplied:—

I hereby tender for the above privilege, and undertake to pay forthwith to Her Majesty's Commissioners the sum of £ as a consideration for the same, and to place at the disposal of the Commissioners, for the purpose of distribution, but not for sale, copies of every photograph which may taken in the building.

Signed this day of 1862.

Namo

Address

The *Times*, commenting on these conditions, observes "Many of the great photographers have anxiously looked forward to the publication of this document, and were prepared to offer considerable sums for the privilege of taking views, &c.; but the third condition of the Commissioners has, up to the present, almost entirely debarred any from making an offer, for if this rule is adhered to it would be simply impossible to take any views at all.

"Now, as it happens, there is not a single place within any moderate distance of the building which a photographer could now secure, while, even if there were fifty such, everyone at all acquainted with photography knows how futile it would be to take views in a building with a bad light, with plates brought from a distance of even a quarter of a mile or so. There is plenty of space near the eastern annexe which might be allotted to photographers without inconvenience, and, unless some such concession is made, the Commissioners are not likely to get any but a very small tender. The other conditions, to the effect that all photographs must be taken before 10 a.m., and none sold in the building, amount to nothing, as Her Majesty's Commissioners reserve to themselves the right of making, from time to time, such rules, regulations, and conditions as to the hours within which, and the mode and places in which, the privilege may be exercised or otherwise as they may think necessary."

## REMARKS UPON SOME OF THE APPARATUS EMPLOYED IN PHOTOGRAPHY.*

BY F. R. WINDOW.

### Cases for Cameras, &c.

The method of packing a camera for travelling or carrying it about in the field is a matter of individual taste, which every one must decide for himself, and upon which each has

* Continued from page 147.

probably his own opinion. I certainly have mine, and as it differs rather from that which appears to be generally held —judging by the cases mostly used—I think I cannot do better than add it to these "Remarks," less as a recommendation to be followed than as an observation to be taken for what it is worth.

The most ordinary ways of packing a camera for travelling are,—1st. To make the camera itself a perfect box containing all the necessary apparatus, neatly French polished, and with a handle on the top. 2nd. A leather case, with leather divisions inside, lined with baize, secured by straps and buckles, and carried by means of a leather handle or another strap.

The plan of converting the camera into a box, supposing it to be done so efficiently as to be perfectly weather-tight and strong, is extremely convenient. It is simple, light, and cheap. The working and more important parts of the camera, being inside, are protected from the weather and from injury by blows or other violence. The only suggestion I would make as an improvemet upon this type is of a sadly democratic nature. I should propose to renounce the vanities of French polish and varnish upon the outside of the "box," and substitute a good solid coat of dark paint, black or bronze. My reason is, that in the ordinary wear and tear consequent upon being much carried about, the varnish soon gets covered with scratches and scars, which for a French polished article is equivalent to being shabby and ill-looking, but a simply painted box may be hacked and scarred to a greater extent without *seeming* so bad, and at the worst a brushful of paint will suffice to restore it to its pristine beauty.

I confess I do not share in the general approbation of leather as a material for camera cases. It appears to me little suited for such a purpose. It is flexible, and affords but little protection against a fall or blow; and it must be remembered that in cameras packed in leather cases, the fragile working parts—slides, rising front, and focussing-screen—are mostly loose in the packing, and not protected by being inside the camera body or box. It is but little protrction against drenching rain, which, in addition, damages it own form sadly, and none at all agaiust damp atmosphere, by which both itself and its contents are covered with mildew. It is no protection against insects in tropical parts. It is not secured by any lock, which unsuits it for travelling separately by railway; finally, it is very expensive. I cannot find *any* recommendations to place against this array of disqualifications. True, a leather case *looks* very nice when it comes fresh from the hands of the maker, and a fair-weather photographer, journeying in his carriage, with his footman to carry his camera from it on to the ground, as I have seen, may keep it fresh and neat for a long time; but an ordinary photographer, roughing it in the usual manner, over hill and dale, through briar and brake, accepting what weather it pleases the heavens to send him, will find his leather case wofully shabby and distorted in shape, its inner partitions probably dilapidated, and its colour lost and stained at the end of a pedestrian tour. I do not mention this *pour dégoutor les autres*, but such at least is my personal experience.

I think the best travelling cover for a camera for all countries and climates is a well made tin case, of the dispatch box class, having a stout iron wire running round all the edges, lined with baize, and having separate divisions for the various loose parts, japanned black outside, or painted black, with a brass handle upon the narrowest side to carry it by.

This tin case is a little, very little, heavier than the leathern cover with all its straps and buckles, &c. It is a perfect protection against blows, rain, damp, or insects. It is closed with a lock, and it is much cheaper than a leather case.

The comparative neatness of the primitive appearance is certainly a matter of individual taste, for my part I prefer the look of the tin box. It is certain, however, that this wears better. Weather has no effect upon its appearauce, nor ordinary rough useage; if it by chance gets bossed the tinman at the corner of any village will set it right in a few minutes. Black japan looks the best at first, but good black paint is better for wear, and when it gets scratched or chipped another coat suffices to repair all damage. From the nature of the material a far better fit can be secured in all the fittings, therefore, the whole apparatus, whatever its description, can be packed into a smaller compass than in a case made of leather, with leather partitions.

It should by observed that the partitions in a tin box need not extend the whole width of the case, as in a leather one, but need only project sufficiently from either side to receive the edges of the slides and other parts. Fig. 11 shows the outside of such a box for a folding camera with the sliding front, focussing-screen, and wet plate slide. Fig. 12 gives the inside plan of one intended for a bellows camera, with the lens in position, the focussing-screen in its groove in the instrument, and divisions for four double backs.

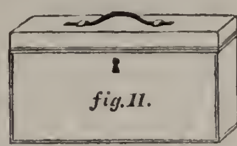

*fig.11.*

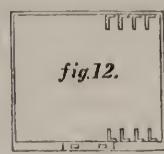

*fig.12.*

The baize lining can be fastened with glue upon the bottom and sides, but at the tops of these latter it should be strained over a strip of tin and fastened with rivets to the box. This will make a permanently good job and will prevent the lining from being torn out by constantly pulling tbe instrument in and out.

(*To be continued.*)

## Scientific Gossip.

Solvent for Cellylose — Preparation of Schweitzer's Liquid—New Blue Colour for Painting—Photography on Cellulose and Silk.

The curious discovery of Schweitzer that certain salts of copper dissolved in ammonia had the property of dissolving cellulose, silk, and several other organic substances which resist the action of ordinary solvents, has not been so much employed by the photographer as we might have been justified in supposing would be the case. Probably some of the oblivion into which this very useful solution has fallen, is due to the fact that its preparation was attended with great uncertainty, and there was considerable difficulty experienced in obtaining uniform results. To clear up some of the obscure points attending the preparation of the cupreous solvent, M. Peligot has been devoting attention to an investigation of the subject, and has now published a memoir, which leaves but little of the reaction unexplained. The ordinary liquid used to dissolve cellulose is formed by the simultaneous action of air and ammonia on copper. The process which has been found to succeed best for obtaining large quantities of this solution is to introduce finely divided copper into large flasks, together with a little concentrated solution of ammonia. The copper is best prepared by reducing sulphate of copper by metallic iron or zinc. This is thrown in the moist state round the sides of the flask, and a few minutes after the ammonia is introduced, the flask becomes heated and filled with thick white fumes, which being condensed on a cold wet body, give all the characteristic reactions of nitrite of ammonia. When the reaction seems finished, change by the aid of a bellows tbe atmosphere of the flask; repeat this operation several times at intervals, taking care to renew the surface of the metal by agitation. When the action is quite finished, invert and drain the flask, and wash it out several times with solution of ammonia. A blue liquid is obtained, which M. Peligot shows is composed of several different bodies, the principal one being a double salt of nitrite of ammonia and oxide of copper. To obtain this in large quantities, the blue liquid is to be evaporated to dryness on a water bath, the residue pulverised, and submitted to the action of boiling alcoholic ammonia. The filtered liquid on cooling deposits the salt in the form of needle-like prisms of a beautiful violet blue colour. This salt has a somewhat remarkable composition, containing

$$NO_3.CuO.NH_4O.HO.$$

A small quantity of the compound wrapped in paper and placed ou a steel anvil, detonates when struck with a hammer. It dissolves in contact with a little water, producing intense cold, and yielding a solution which possessses the curious solvent property on cellulose, &c., which is under discussion.

In his investigatiou on this compound, M. Peligot succeeded in discovering a *new* blue pigment of great beauty. The fine turquoise-blue precipitate, which is thrown down when a soluble salt of copper is decomposed by an excess of caustic potash, or soda, has often been regarded with admiration by artists; but unfortunately, chemists have not been able to prepare this body in a permanent form. It is a hydrated oxide of copper, CuO.HO, but it loses water almost immediately, and turns black even whilst it is being washed in cold water. When, however, the above-named nitrite of copper and ammonia is dissolved in a very small quantity of water, and then the solution greatly diluted, a similar turquoise-blue precipitate is obtained, having the same composition as the ordinary precipitated hydrated oxide, but possessing the property of resisting the action of boiling water, and able to bear a temperature of 212° without injury. This new blue hydrated oxide of copper, which may be ranked as a new and useful acquisition to science and the arts, absorbs atmospheric carbonic acid slowly, aud without changing colour. It is a very fiuely divided crystalline precipitate, and its beautiful colour will doubtless before long render it useful in painting, and for printing colouied stuffs and paper.

If this hydrate could only be produced under the above circumstances, its industrial uses would of course be very limited. But while studying its properties, the discoverer found several methods of preparing it from all the salts of copper soluble in water; particularly from sulphate of copper. It can in fact be obtained by treating with an alkali a salt of copper dissolved in water, to which a slight excess of ammonia has been previously mixed; also by pouring caustic potash or soda into a salt of copper mixed with an ammoniacal salt; or by adding a quantity of water to a slightly ammoniacal solution of nitrite of copper. Thus the expense of preparing this colouring matter is no obstacle. It must not be confounded with the article known as "English blue ash," this consists of carbonate of copper, the tint of which, though rather darker, is generally less pure than that of the hydrated oxide of copper.

To the photographer, however, this stable oxide of copper possesses other advantages, besides its capability of being employed as a pigment. By simply dissolving it in ammonia a liquid is obtained which is decidedly the best solvent for cellulose, and the other substances more or less soluble in Schweitzer's reagent. Concentrated ammonia dissolves from 7 to 8 per cent. of the hydrate, the solution having the deep blue colour common to all salts of copper in contact with excess of ammonia. From the case of its preparation and the many theoretical advantages which would be derived from employing pure cellulose or silk as the medium for photographic pictures, in preference to the nitro-compound, gun-cotton, there is little doubt that this solution would well repay any experimentalist for the time and trouble which he might devote to the subject. One of the advantages which this solution possesses over the old solvent formerly used is that the dissolved substance can be precipitated without alteration by the addition of an acid; whilst by operating under the same circumstances with the blue liquor, resulting from the action of air and ammonia on copper, the nitrous acid which becomes free, acts more or less energetically on the orgauic substances contained in the solution. It is, moreover, from the presence of this oxide, which is found in the liquid in simple solution in ammonia, that the liquid obtained by the direct action of air and ammonia on copper, derives the property of dissolving cellulose; for by placing this substance in contact with nitrite of copper and pure ammonia dissolved beforehand in a little water, it neither gelatinises nor disappears, as happens when we employ ether on ammouiacal solution of this oxide of copper, or the liquid named at the commencement of this article.

Soon after these solveuts were first made known to the photographers of this country in the pages of the Photographic News, we chrouicled a few attempts which had been made to employ them in photography. From these results and others which have since come to our knowledge, there can be little doubt that were the difficulties incidental to the first introduction of a new substance overcome, this cupreus solution of cellulose and silk would prove a very useful agent in the photographers' laboratory. Possibly it might never be found to have advantages which would enable it to compete with collodion, but there are several other directions in which such a solution of so ordinarily insoluble a material would be of the greatest value. Some of these applications are at present under trial, and will form the subject of another article. Others will doubtless suggest themselves to any one who experiments upon the subject. Our object at present is to draw the attention of experimenters to this neglected brauch of the art, and to induce them to take up so promising a field for investigation.

## APPLICATION OF PHOTOGRAPHY.*

### DOVE'S NEW PHOTOMETRIC PROCESS.

In the experiment with the Newton's coloured circle, we cannot obtain the intensity of a white disc, but only that resulting from the absorption of colour in particular. We may be satisfied that there is absorption with the coloured circle, by directing the photometer upon the turning circle, aud varying the inclination until there is compensation, then on turuing the circle to view the white surface under the same inclination. To measure the absorption it will suffice to place a black sector upon the white surface and gradually augment the dimensions.

If we divide a disc into 10 sections, alternately white and black, the quantity of light it sends to the eye in turning will be the same as if it were divided into 50 sections alternately white and black. But in the first case each interval acts upon the eye five times longer than in the second case and this must exercise some influence upon our appreciation of the lighting. To M. Dove it always seemed that brilliancy increased in this case until the velocity had attained a certain limit.

Itriated surfaces send more light in the direction of the striæ than perpendicularly, for in this direction shadow is produced. We may observe it upon a plate of white chalk radiated with a file or still better with plates of pearl.

For the same reason, the polish is influenced by the nature of the substance; thus a plate of brass is more brilliaut than a plate of copper.

To measure the lighting power of luminous sources, the difficulty, as is well known, is to have an invariable unity, a constant term of comparison; we employ an Argand lamp, a gas burner of known diameter, discharging gas under a constant pressure or rather of a platinum wire reddened by a current of determined intensity; but there is always some uncertainty between one experiment and another.

We place the horizontal microscope in position, then direct it alternately towards the two lights, the distance of which must be varied until the photographic proof lighted in front by the constant light, disappears. We place the two lights to be tested in the prolongation of the axis of the

* Concluded from p. 149.

microscope, by placing between the objective and the image, the light serving as unity; then mask the more distant light by a screen, next effect the compensation, then remove the tested light and the screen, and operate upon the second. This can all be done so rapidly, and in so short a space of time, that the type light will not have sensibly changed. In this manner we can measure the lighting power of the moon in its different phases; or the brilliancy of a platinum wire under the influence of currents of varying intensities; or the electric spark, or the light of Geisler's tubes. The comparison of optical instruments, with regard to the light, they transmit, is very simple. For a telescope, we know that when it is directed towards an object at an infinite distance, they emerge from the eye-piece parallel: it is sufficient to compare the lighting power of one section of this emergent luminous cylinder. To this end, we direct the telescope towards a point in the sky, then place the axis of the microscope in the prolongation of that of the telescope, the aperture of the object-bearer upon the aperture of the eye-piece: we then take the measure by removing or bringing nearer the constant type-light of the anterior portion of the photographic image. In comparing different instruments the operation is rapidly performed either under a serene or a covered sky. We operate in the same manner with a microscope. The light reflected by plane mirrors will be the same as that described for roughened surfaces. It happens that with a perfectly polished silver mirror, formed of a silvered plate of glass, there will be, at least for a certain incidence, more light reflected than from a metallic surface; that is, the light reflected by the surface of the glass will more than compensate for the loss produced by the glass covering the metallic plate.

This method is also important for studying the curved mirrors and convergent lenses employed in light-houses. M. Dove essayed to ascertain to what point the parallelism of the rays destroys the influence of distance upon the diminution of intensity. The instrument can also be employed as a diaphanometer in studying a fixed light under different atmospheric conditions. It can also be employed advantageously during eclipses of the sun.

Finally, by placing the microscope vertically in a room, the light which falls from above upon the object diminishes rapidly upon removing from the window, while that reflected by the mirror turned towards the sky remains always the same. By this method, therefore, we can ascertain if places are equally lighted, which is an advantage for photographic experiment, and is available also in medicine. We can also compare the intensity of the light of the sun at equal heights in both hemispheres. Lastly, the method has a practical application in appreciating colouring materials, the effect of which depends upon the quantity of light they reflect, and their colour. For the latter, we cannot easily make prismatic analysis with an opaque body, but this is not the case when acting by absorption. It will suffice to indicate by a given colouring matter, the luminous weakening it undergoes by the superposition of a given coloured glass, a weakening which may be measured with the aid of the photometric microscope.

M. Dove also points out the use of arragonite as a polariser. A prism of 45° must be cut, the edge of which is parallel to the faces of the prismatic crystal. With a prism of crown glass of 45° we achromatise one of the images: if the angle of this crown glass prism is 30° only, there is then a feeble colouring, which is shared by both images. In a similarly compound prism, the distance of the images is 3 : 2, in relation to a prism of Iceland spar, achromatised by a glass prism.

## DESCRIPTION OF A PROCESS FOR THE REDUCTION OF SILVER FROM ITS SOLUTIONS.

BY FRANKLIN PEALE.

It may be of service in the art to which the *American Journal of Photography* is devoted, to make its practitioners acquainted with the following process, for the recovery of silver in a metallic form, from its solutions.

The process is very extensively employed in the refinery of the Mint of the United States, where it was introduced by myself when melter and refiner of that establishment.

It is based on the well known affinities of chlorine and silver, and their ready separation by zinc and sulphuric acid. It had its origin in the laboratory of the Swedish chemist Arfwedson, and was used by Mr. P. N. Johnson, of London, in whose refinery I became familiar with its details, and was subsequently enabled to improve it very materially, by the substitution of a solution of salt, in place of the hydrochloric acid previously employed.

By adding in excess, a saturated solution of common salt to the solutions of nitrate of silver, the metal is thrown down, as an insoluble salt, the chloride of silver. The precipitate must then be carefully washed until it is entirely "sweetened," or freed from the presence of nitric acid.

Granulated zinc must then be added to the chloride, and stirred through the mass. The finer the zinc has been granulated, the more rapid will be the reduction Dilute sulphuric acid must also be added, and the whole stirred until the reduction is complete, which will be known by the entire disappearance of the white chloride, and its conversion into a grey powder. A new set of affinities takes place, with great rapidity, in this combination, and the chlorine is liberated from the silver, which takes its metallic form, as above stated, in the appearance of a grey powder.

The zinc having been added in excess, must now be removed by the addition of dilute sulphuric acid; after all action has ceased the solution of zinc must be decanted, or drawn off with a syphon, and the silver washed until "*sweet*," or free from acidulous matter, after which it may be dried by pressure or the simple application of heat in a pan over the fire, when it will be ready for melting, with the usual fluxes or re-solution with nitric acid.

This process, as you will perceive by my brief description, is rapid and easy; is not subject to loss; it will yield in the terms of trade, pure silver, of a quality from 994 to 998 thousandths fine, and is therefore well adapted to the preparation of pure nitrate of silver for the use of photographers and all others who have need of a reliable article.—*American Journal of Photography.*

## NATURE OF THE PHOTOGRAPHIC IMAGE.*

As an appendix to our notice of the recent researches on the composition of the photographic image, it will be of interest to our readers to note how near some of the early experimentalists on this subject were in arriving at the correct solution of this difficult problem.

As long ago as 1777 the illustrious Swedish chemist, Scheele, turned his attention to the action of the differently coloured rays of light upon silver compounds, and in a very rare treatise † he anticipated, by nearly three quarters of a century, the results and deductions of later times. The following account of one of his experiments is of sufficient interest to be worth transcribing at length:—

"I precipitated a solution of silver by sal-ammoniac; then I edulcorated and dried the precipitate, and exposed it to the beams of the sun for the space of two weeks, when the surface of the white paper grew black, after which I stirred the powder, and repeated the same several times. Hereupon I poured some caustic spirit of sal-ammoniac on this, in all appearance, black powder, and set it by for digestion. This menstruum dissolved a quantity of *luna cornua* (chloride of silver), though some black powder remained undissolved. The powder having been washed, was for the greater part dissolved by a pure acid of nitre, which by the operation acquired volatility. This solution I precipitated again by means of sal-ammoniac into horn silver. Hence it follows that the blackness which the *luna cornua* acquires from the sun's light *is silver by reduction*."

Again, Scheele writes:—

"I mixed so much of distilled water with well edulcorated horn silver as would just cover this powder. The half of this

* From the *London Review*: given as an appendix to a *résumé* of Mr. Malone's paper on that subject.

† Scheele, Traité de l'Air et du Feu.

mixture I poured into a white crystal phial, exposed it to the beams of the sun, and shook it several time each day; the other half I set by in a dark place. After having exposed the one mixture during the space of two weeks, I filtered the water standing over the *luna cornua*, grown already black; I let some of this water fall by drops in a solution of silver, which was immediately precipitated into horn silver."

From these extracts it will be seen that Scheele, as early as 1777, showed that the action of light upon chloride of silver was to separate a black powder from it; by digesting this in ammonia, the excess of undecomposed chloride of silver was dissolved away from the black powder, which was shown to be metallic silver, by its dissolving in nitric acid, with evolution of red vapours, and formation of ordinary nitrate of silver. He also showed that when pure chloride of silver was decomposed by light, under water, chlorine was given off, which could be detected in the supernatant liquid by the usual tests.

The matter since appears to have attracted little attention from philosophers until it was taken up by Robert Hunt, one of the earliest and most diligent workers on the subject of the chemical action of light, and an experimentalist, to whom photographers will always owe a debt of gratitude, for the valuable light he has thrown upon these obscure phenomena. In the first edition of his "Researches on Light," published in 1844, are given his first experiments on this subject. A long series of experiments were subsequently published by him in the *Philosophical Magazine*, and at the meetings of the British Association. These were all collected together, and their results given at pp. 79–80 of the second edition of his "Researches," published in 1854. He here states that many experiments were tried in order to ascertain the condition of the chloride of silver, after it had been darkened by exposure to light, but he only gives the details of the most satisfactory. He prepared pure chloride of silver with great care, and then, after it was perfectly washed, dried it.

"Five grains of this were put into a long test-tube full of distilled water, and placed in the sunshine to darken, the powder being frequently moved, that every part might be acted upon by the sun's rays. It was found, even after an exposure of a few minutes, that the water contained chloride; it became opaque on the addition of nitrate of silver, and this very gradually increased as the chloride darkened. The darkening process was continued for several hours, after which the solution was filtered to free it from chloride of silver, and nitrate of silver added to the silver solution; this precipitated chloride of silver, which, when connected, dried, and weighed, gave 1·4 grains on one occasion, 1·0 grain on another, and 1·5 grains on a third trial."

Mr. Hunt states that "it is evident from this that chlorine is liberated during the process of darkening."

Experiments were next tried in which the chloride of silver was formed on the surface of paper, to ascertain the effect of organic matter in modifying the action of light; the result being stated that "we have hence very satisfactory proof that metallic silver is eventually formed on the surface of the chloridated photographic papers, and that the under sensitive surface is preserved in the condition of a *subchloride of silver* by the opacity of the superficial coat."

From other experiments, Mr. Hunt states that he is inclined to believe that "the first action of the solar ray is to liberate one half of the combined chlorine, which is very readily, moisture being present, replaced by oxygen. By the continued action of the exciting cause the oxide is decomposed, and metallic silver, in a state of fine division, is formed over the surface."

An experiment is subsequently given to prove that oxygen is absorbed by the decomposing chloride.

It will be of interest to compare the results obtained by Spiller with the above experiments of Scheele and Hunt. In a paper published in the *Philosophical Magazine* for March, 1860, the first-named gentleman sums up his results in the form of three propositions:—

"1st. That chloride of silver, when decomposed by light, is separated into its elements.

"2nd. That this change does not usually extend to the whole bulk of the material operated upon, on account of the opacity of the darkened product mechanically protecting a certain portion of unaltered chloride of silver from the action of the light.

"3rd. That the degree and rapidity of reduction is influenced by the state of division of the particles, and by the presence of agents capable of absorbing the chlorine when liberated from its combination with silver."

These are stated to be in conformity with the previous results obtained by Dr. Guthrie, MM. Girard and Davanne, and generally also with those of M. Van Monkhoven, and to a certain extent opposed to the views advanced by Messrs. Hadow, Hardwich, Llewellyn, and Maskelyne in their joint report upon this subject, recently presented to the meeting of the British Association.

This subject appears to be one of considerable interest, judging from the correspondence which has reached us on the subject; but, notwithstanding the assistance with which we have been favoured by many correspondents, and our own inquiries into the matter, we are unable to find that the clear and satisfactory explanation given by Spiller, referred to in our previous article, has been *de facto* anticipated by any previous writer. As a fitting sequence to the above extracts, we will quote the entire paragraph in which Spiller's views are stated:—

"Passing in review the results obtained in the foregoing experiments, it will probably be considered that the weight of evidence tends to show that *the metal* is the ordinary product of the chemical action of light upon chloride of silver; and that the principal difficulty which has stood in the way of accepting this conclusion has, in great measure, to be accounted for by the often varying shades of colour presented by the reduced metal, and more especially the transition observed at the moment of removing the unaltered portion of material by the application of the fixing agent. If, in these several stages, the change in physical condition be considered in its proper connection, and due allowance be made for the very important influence known to be exercised over the light-reflecting capacity of these minutely divided particles by very slight modifications in their state of aggregation (quite irrespective of change in chemical constitution), there will then be no longer any difficulty in referring these results, with others of the same class—*e.g.*, the several varieties of gold prepared and examined by Professor Faraday,*—to a series, all of which are capable of similar explanations.

## AMMONIA NITRATE FOR ALBUMENIZED PAPER.†

I have noticed in the *Journal* some remarks regarding what is called an ammonia-nitrate process for albumen paper. I do not think there has been any such yet, if it is possible to use one. Some two years ago I made some albumen prints from view negatives by a so-called ammonia-nitrate process, suggested in your journal at that time.

That process was an ammonia-nitrate solution of sixty or more grains to the ounce in the ordinary manner, then making it strongly acid with nitric acid, silvering the paper in the ordinary way with a fillet of cotton; and after printing, before toning, carefully removing all the acid by soaking in carbonate of soda water. The theory was, I believe, that the acid coagulated the albumen before the ammonia could act, thus preserving the surface intact. I have one print of a view in North Carolina, made there in June, 1860, by that process, which will compare favourably with any we make now; but I do not think the ammonia improved the quality, for I think it did not play any part in the production. I think that coagulating the albumen before or rapidly at the time of silvering is an advantage, and the means by which it can be done at least cost and trouble, is the best.

Your correspondent recommends alcohol; I have been using ether for five or six months for the same purpose, with the same

* "Dr. Faraday showed that the *red* gold precipitated from solution by phosphorous became *violet* merely by the addition of chloride of sodium.—Notices of the meetings of the Royal Institution, June 13, 1856.—J. S."

† From the *American Journal of Photography*.

effect. The solution remains perfectly transparent after any amount of use, and the prints tone easier. My formula might be stated thus:—

| | |
|---|---|
| Water ... ... ... ... ... | 6 ounces |
| Silver ... ... ... ... ... | 1 ounce |
| Ammonia ... ... ... ... | 6 to 8 drops |
| Ether ... ... ... ... ... | 1 ounce. |

Filter and use.

If, in using, the proportion of alkalinity becomes greater, it should be removed with acid. The solution should always be so alkaline that it will turn reddened litmus blue, and *not much more.* It may be well to have a sufficient excess to remove any acidity in the paper, as there sometimes is, but further than the certainty of preventing the presence of the least trace of acid, the ammonia has no use; and the ether gives its greatest benefit by keeping the solution from discolouring. Possibly also it gives a better surface by coagulating it so quickly as to preserve it fine and smooth, instead of being honey-combed by partially dissolving, precisely like the difference between smooth glassy frozen ice, and the same ice after a surface thaw dulling its smooth brightness with millions of minute watery holes.

# Photographic Tourist.

## PHOTOGRAPHIC PENCILLINGS OF AN EASTERN TOUR.*

One of my next pictures—they are all before me in a goodly album—was that of high Olympus, rising grandly above a range of hills,—with water, and a strip of cultivated land, running into it, by way of foreground;—its snowy summit barely visible amidst the veiling clouds, and its majesty and beauty as impressive now as when it entranced the gaze of rare old Homer. I found the best time for this view to be when the sun was rather low towards the west, the white summit being at all other times so nearly invisible as to be quite lost in a photograph. I also photographed the Sultan's palace and the Seraglio; some various groups of Turkish ladies, whom I found assembled on the banks of the sweet waters one Friday (this I did with some fear of interruption, I must confess), when a kind of half pic-nic, half fair, seemed to be under weigh; and, of course, as many of the principal mosques as I could. A minaret or two also figure in my collection—a street scene from Pera—and a very singular contrivance which the fishermen here adopt, and which, when I used to see it in engravings of eastern scenes, puzzled me not a little to account for. Upon lofty piles, rising some thirty feet or more above the water, you see a rude little building, somewhat like a sentry-box, from which projects a long pole, seldom a straight one, whence ropes hang pendant in the water, and droop as they are passed over pullies into the box where the proprietor is ensconced. To these ropes the net is attached, and lowered into the water, which being very clear, enables the fishermen to see when any number of fish are over the net, to suddenly haul it up, and so effect a capture. These singular looking water-watch-boxes appeared so picturesque in the engravings above mentioned, that I used almost to regard them as clever contrivances, due chiefly to the imagination of the artist; but here they are in productions admitting of no such liberties, but looking as picturesque and novel as ever. To resume, I have photographs of some remains of the old wall of Constantine, in a picturesque state of dilapidation, consisting of a strong triple wall, towers, fosse, and gates; of a bird's-eye view, taken from a house-roof on the hill above Pera, which includes in its three pieces the three cities Stamboul, Pera, and Galata, and the Propontis and Golden Horn; of the old Hippodrome's neglected remains, so pathetically associated in our school-boy recollections with the great Belisarius in the height of triumphant fortune, and again with that poor old broken-hearted warrior when, forgotten and neglected, he begged from the meanest of his once worshipping army a scrap of refuse food. Nothing hardly remains there now but a shattered obelisk, and it is probable that in photographs, and in the bronze horses removed from here to decorate St. Mark's, at Venice, will soon be found the only relics of a spot so interesting to the historical student.

This account of my visit to Constantinople, however, must draw to a close, as I have other, and perhaps more interesting adventures to narrate, and places to describe, and I shall now, therefore, only add such information as may prove valuable to my photographic successors, and then push on.

The hotels and *cafés* are numerous enough, but in the name of all that's cleanly choose carefully. One of the best in repute is Mysseries, in Pera, recommended by Murray, although you will not receive a very favourable impression from its exterior. As to eating and drinking, good meat is scarce, good eggs are plentiful, vegetables are scarce and inferior, the famous sweetmeats deserve their excellent repute (although you will scarcely patronize these to the extent the Turks do), and good rice is not wanting. The strong coffee, sour milk and sugar and served up in little filagree nutshells half filled with grounds, require some practice to sip without a grimace; the not less well-known "Kobobs," consisting of fried spiced meat on skewers are not amiss, nor is the lemonade or sherbet. As although the natives have a great horror of absolute thieving, they will not hesitate to cheat, be on your guard in dealing with them. There is some advantage in bringing out gold with you, it being in demand and more valuable there than at home, and you will find also that in notes twenty-five piastres* are equivalent to twenty in silver. The natives won't make these things known to you so I do. I do not know that I need add any further information, so will here for the present conclude. M. H—n.

* Continued from page 130.

## NEGATIVES FOR ENLARGEMENT BY THE SOLAR CAMERA AND OTHER MEANS.

BY AUGUSTE TESTELIN.

Negatives for the production of enlarged photographs should possess certain qualities which do not usually characterise negatives intended for printing directly on paper. An amount of delicacy, purity, and transparency is required for the production of good enlargements, which rarely characterises, and indeed is unnecessary, in negatives for direct printing.

The chief characteristic of a negative suitable for enlargement is its transparency, which should be such that through its densest parts, the lightest traces of a delicate design may be distinguished.

The image, when examined by reflection, ought to be very brilliant, and even if slightly veiled in the lightest tints, should be clear from the numerous metallic spots which are easily remarked in those negatives which have been developed slowly. The transparent parts, should be very clear, while the most opaque portions do not bury the slightest details,

It is necessary to light the model very carefully, in order to preserve as much as possible a perfect resemblance, and too avoid too strong shadows, which always give hard proofs of a disagreeable aspect.

The best negatives are often those which are produced under a clear sky; but in such case the light should not fall directly on the sitter: it should be filtered through some light material drawn across the roof, and spread above the head of the sitter. Very little direct side light should be admitted.

The lighting, in order to produce the most favourable result, should be disposed to give effect to certain salient points of the figure; and, to avoid the exaggeration which might arise through this means, there should be placed near the model, and on the side opposite to that from which

* The value of a piastre is about 2½d English.

the light comes, a blue screen, stretched upon a frame, which will soften the shadows considerably.

The indications here given are but general, but the desired result may be easily obtained by slight modifications; and, to give an example, we should say that a *carte de visite* negative, in which the pupil of the eye and the eyelids are well defined, the hair well detailed, the dress well rendered, the general tone pure and transparent, with little vigorous points giving relief to the figure—such a negative, we would say, is susceptible of furnishing a magnificent enlarged proof on a sheet of paper 22½ by 17½, or even 32 by 24 inches.

It is absolutely necessary to use thin glasses, white and as free from blemish as possible. Common glass will not do, on account of the distortion which it causes in the image. The negatives should not be varnished; but they should be carefully washed and dried very evenly.

We cannot give in this article the details of the process, but have nevertheless thought that it would be useful to indicate the principal characteristics which should belong to this class of negatives. We will conclude by recommending our readers not to attempt the production of large negatives with lenses of short focus; for in all cases the negative to be enlarged should not be larger than 4 or 5 inches square, and should be taken with a whole-plate lens.—*Bulletin Belge de la Photographie.*

## DR. DRAPER'S TANNIN AND HOT WATER PROCESS.

BY CHARLES WAGER HULL.*

The development of tannin plates by the process suggested by Dr. Henry Draper at the February meeting of the Photographic Society has led to results in my hands always hoped for, but hardly anticipated. Beyond all manner of doubt tannin plates are, by this process, *as quick* working as any wet collodion plates that have ever come under my observation. This assertion is a fact *beyond all dispute.* How much quicker I leave each experimenter to judge for himself, proposing only to state in general terms what has been done, rather than ask what cannot be done.

Four tannin plates, alike in every respect, were exposed as rapidly as possible after each other, on the same subject. The light though good, was not brilliant, no clouds or other troubles interfered during exposure; thus all was fair in this important part of the experiment.

Number one was exposed two minutes; number two, one minute; number three, ten seconds; number four, six seconds. All were developed with the same pyro solution, namely, three grains pyro to one ounce of water, and filtered (fresh mixed). The solution of silver and citric acid, of course, was varied, and always should be when using hot water. The hotter the water the more citric acid and less silver, or the developer becomes turbid.

Number one and number two were developed in the usual way, first well soaked in ordinary water, as it runs from the tap. The proportion of citric acid and silver was sixty of the first named to twenty of the latter.

Numbers three and four were treated first to a dose of water 135° until the film was well soaked. During this part of the operation the developing glass warmed by filling with some of the same hot water as had been poured upon the plate. The plate was next drained, on the hand, the developing glass emptied of its hot water, and sufficient of the three grain pyro solution put in for the plate, by this means the developer was raised in temperature to about eighty degrees. It was then flowed on the plate, without the addition of any acid or silver, and a faint image at once appeared, there being for this first addition of developer enough silver always remaining on the sides of the glass. It may be well to remark in this place that if silver is added at first at all freely, a universal reduction at once takes place, which is ruinous.

The image, as stated, was faint, but all was there. The developer was poured back at once to the glass, and the plate was treated to a dose of the same hot water, until fairly heated up again. The developer was now added, a couple of drops of silver and acid solution, being of the proportion of twenty grains of silver to 120 grains of citric acid; with this the picture became stronger, but not strong enough; it was again poured off, more hot water used, a little more silver added to the developer, and so on, making in all some five or six applications of hot water, by which time the plate had gained all the strength which was needed. In these experiments a portrait or combination lens was used, with a one-quarter inch diaphragm.

The writer's conclusions are, that number one was properly timed, and proved a good negative with cold water development.

Number two was under-exposed, not worked in the shadows.

Number three was thin and grey, and the shadows were lacking in clearness, indicating over-exposure.

Number four was all that need be asked for intensity, half-tone, &c.

On the exhibition of these negatives at the meeting of the Society, last evening, these conclusions were fully agreed to you are well aware.

It is here easily seen that the assertion first made, that tannin plates by this process are at least as quick as wet ones is fully substantiated, the time being reduced from one hundred and twenty seconds to six seconds, or the one-twentieth of the old time; again, tannin requiring one hundred and twenty seconds wet, on the same subject, would require only twenty seconds, which, when compared with hot water tannin, is found to require three times as long; thus we have dry plates which require only one-third the wet exposure.

The beautiful cloud picture, made with instantaneous drop on tannin plate, by Mr. Augustus Wetmore, jun., is again a proof that tannin is as rapid as the wet.

Much has been said of late in your journal about "fossils" and mastodons" in photography, by some who practise the wet process only, and can't be coaxed into trying the dry, all of which is very well as a joke, but not desirable when discussing points of practical as well as scientific value.

When a writer of any process, good or bad, has prepared a dozen or two plates, and carefully exposed and developed the same by formulas which in other hands are good, then he may be allowed to speak and state his troubles, but to do so on some assumed theory, and no practice, is rather much in an art which can only progress by statement of facts, and not by assertion of fancies.

The assertion that I think my way of working much better than the way you say you work, and then resting satisfied, will leave the one asserting so far behind those who made the experiment, that he will be hard to find, buried as he will be beneath the rubbish of old formulas, good enough for special purposes, but not good enough for all.

Tannin process doubtless has its faults—what process is beyond improvement? It, however, is not troubled with any difficulties which do not in some degree beset the wet—its chief one being solarization; certainly the wet is not free from this.

In certainty of working it is better than the wet, in detail it is fully its equal, in vigour its superior. In ease and comfort there is no comparison, as all know who have worked both.

* *American Journal of Photography.*

## PHOTO-PAPYROGRAPHY.

In the annual report just presented by Colonel Sir Henry James, it is stated that a method has recently been discovered of producing a negative impression on paper, from which a single copy of a deed or other document can be printed on parchment in permanent ink, avoiding the necessity of transferring the negative copies to zinc or stone before printing. Sir H. James calls this art photo-papyrography. It will be useful where a single copy of a document, or only two or three copies are wanted. Examples of it have been placed in the libraries of the Houses of Lords and Commons. Photo-zincography is more and more proving its value; and a facsimile of "Domesday Book" will be published county by county, or at least wherever any gentleman will guarantee to pay for fifty copies of any county. The art of photo-zincography, which has been discovered and applied for the purpose of making the detailed topographical plans of the kingdom, has thus led to the production of the facsimile of the most ancient survey and terrier of the kingdom, a document such as no other country in the world possesses. The publication of the edition of 1783 is said to have cost the Government £38,000; the types were destroyed by a fire in 1800, and copies are so expensive and so rare, that few can either buy or even refer to one. But now, through this simple and inexpensive process, and by publishing in parts, any one can purchase the portion relating to the county in which he is more particularly interested, generally for 8s. or 10s., and the Government will not be put to any cost whatever. Authentic copies would be made of such documents as are required to be deposited in the public Record-office, and it is said that this would probably save an expenditure of £10,000 a-year. The process is about to be introduced in India and in Canada. A proposition is under consideration for sending a photographer to Simancas, in Spain, to copy some of the despatches in cypher deposited in the Royal archives there, and which are supposed to relate to important events, some time before and after the reign of Elizabeth.

## Proceedings of Societies.

### London Photographic Society.

The usual monthly meeting of the Photographic Society was held on the evening of Tuesday, April 1st. J. Glaisher, Esq., F.R.S., in the chair.

The minutes of the previous meeting having been read and confirmed,

The Chairman said that at the last meeting of the society it had been intimated that any gentleman who obtained information as to a suitable place for an exhibition of photographs, was desired to communicate with the secretary. No information on the subject had reached the secretary. The matter had been again discussed in council, and a determination had been come to that a committee should be appointed, to make enquiries and report. This committee was to consist of Messrs. Claudet, Vernon Heath, and Shadbolt.

Lieut.-Col. Stuart Wortley and Horatio Nelson King were elected members of the society.

A series of photographs of the eclipse of Dec. 31st, by Mr. Tucker, of Trinidad, taken at Guapo,* were exhibited by Mr. G. Wharton Simpson.

Dr. Diamond, the Secretary, said it had been suggested that this society should take some active steps in petitioning the House of Commons in the interest of photography, so as to strengthen the hands of the promoters of the new Copyright Bill. He had written to the Chief Baron on the subject, and had subsequently seen him. The Chief Baron thought that the end would be better served by a personal interview with the Solicitor General, who had charge of the Bill; he accordingly saw him, and explained to him fully the claims of photography in connection with the Bill. It appeared that many photographers had written to the Solicitor General, intimating that photographers did not desire that their art should be included in the protection of the intended Act. These gentlemen, it appeared, were those who lived by pirating the works of others. Members were probably aware that the Bill had been read a third time, and had passed the House of Commons the previous evening.

Mr. England then read an interesting paper on dry plates, with a few remarks on instantaneous wet plates. The dry process he preferred was the tannin, with a modification of his own, by which he had been able to secure a rapidity equal to that of ordinary wet collodion, with pyrogallic acid development. The chief peculiarity of this process consisted in the use of a very large proportion of bromide in the collodion, and in the use of honey with the tannin, the preservative solution containing 15 grains of each to an ounce of water. Plates so prepared would keep six months without deterioration. We hope to give Mr. England's paper in its entirety in an early number.

During the reading of this paper, a number of the exquisite instantaneous negatives of Paris were handed round for the inspection of members. They were especially distinguished by delicacy, purity, and freedom from fog. The dark slide used in obtaining instantaneous exposures was also shown. Instead of having a shutter attached to the lens, Mr. England prefers to have it attached to the dark slide. It consists of a guillotine, having a longitudinal slot the whole breadth of the plates, which on passing over the plate as the guillotine descends, gives the exposure. The width, or rather depth, of the slot can be adjusted at will, an aperture of about one inch being the least which could with advantage be used. A number of Mr. England's very perfect instantaneous views of Paris were laid on the table, and received much admiration.

Mr. Shadbolt thought the shutter exhibited was a considerable improvement on those usually employed for obtaining instantaneous exposures, inasmuch as it did not cut off the rays from a portion of the lens; but allowed the full action of the whole of the lens all the time. He remembered that Mr. Kibble, who was the first to take instantaneous pictures on dry plates, had a somewhat similar motion, but it moved in a lateral direction, being carried along by india-rubber springs, and he always liked the motion of the shutter to be in the opposite direction to that of objects in motion in the subject to be taken, so that they might receive the shortest possible exposure. Most of the members present were, doubtless, aware that Dr. Draper had been making use of tannin plates in America for instantaneous purposes. Perhaps American ideas of instantaneous exposures were not quite so precise as those in this country; but, at any rate, it would appear that pictures had been obtained with an exposure of a very few seconds. The method employed for shortening the exposure was the use of heat in developing. Probably, if heat were used in conjunction with plates prepared by Mr. England's method, very great rapidity would be obtained. The effect of the honey would, doubtless, be to keep open the pores in the film of collodion, which, as Dr. Hill Norris had shown, was an important element in rapidity.

Mr. England had tried heat in developing his plates, and had found that it caused the film to crack and leave the plate, which an edging of varnish did not in that case prevent. If it were not for that he had no doubt but that the exposure might be considerably shortened.

The Chairman thought that the discovery of an instantaneous dry process would be one of the greatest achievements yet effected in photography, and hopeless as such a thing had at one time appeared, recent events seemed to render it by no means impossible. He felt sure the meeting would readily express their thanks to Mr. England for his contributions in that direction, and for his interesting paper. Thanks were carried by acclamation.

Mr. Shadbolt said he had been requested by Dr. Carpenter to bring before the attention of the meeting a photographic copy of Chimenti's pictures, regarding which the recent discussion with Sir David Brewster had occurred. He regretted that there was not a stereoscope present; but he might state that he had himself carefully examined the pictures both with a stereoscope and without, and although in that instrument they did appear to present a certain amount of relief, they certainly did not appear to him to have been drawn by any one acquainted with the principles of binocular vision. Some parts only had relief, whilst others were either pseudoscopic or simply confused. The perpendicular lines did not coincide any more than the lateral lines, and many parts showed discrepancy altogether inconsistent with stereoscopic principles. Even if they had been much more perfect than they were, it did not prove that they were drawn with any knowledge of stereoscopic principles, for as Dr. Carpenter had pointed out, they might have been drawn from the same model simultaneously by two persons differently stationed, and thus getting different points of view.

Mr. England said when he was at Lille he had seen the originals. They appeared to him to have been one traced from the other, the slight alterations in drawing seeming to arise from not carefully following the traced outline in colouring. He had the power of viewing stereoscopic pictures stereoscopically without an instrument. These pictures in the original did not appear to him to be stereoscopic.

Professor Macdonald said he was present at Edinburgh when Sir David Brewster brought forward his paper. He had obtained a copy of the photographs of this picture, which he had not yet separated, so as to examine them in the stereoscope. He suggested as a reason why some persons appeared to see these pictures stereoscopically, whilst others failed to do so, that there was a great deal of difference in the physical organization of different persons, and that some persons from organization had great difficulty in obtaining the effect of stereoscopicity.

The Chairman said as regarded the two eyes of some persons each having a different focus, that was really the rule, and

* See Photographic News, p. 133, vol. v., March 21st, 1862.

the contrary the exception. In most cases persons had the power of accomodating their eyes to the stereoscope notwithstanding. Where the difference between the force of the two eyes was so great as not to permit this, a stereoscope with adjusting eye-pieces should be used.

Mr. Shadbolt said that the remark of Professor Macdonald would have had force as an explanation, if the persons who failed to see the stereoscopicity of these pictures failed in the same way with stereoscopic pictures generally; but where the failure only referred to these pictures, and not to others, the want must be in the pictures and not in the individual.

The Chairman announced that the Council had been taking into consideration means of giving increased interest to the meetings of the Society. As one method, it was suggested that members generally be invited to bring, from time to time, specimens of any interesting photographs they might have produced, or had access to. It was proposed to provide stereoscopes by which slides might be examined if brought as he suggested. He trusted members generally would feel that they could all in some way contribute to the interest of the meetings, and that by so doing all would be gainers.

It was then announced that the subject for the next meeting would be a paper "On Enlarging Photographs" by Mr. Vernon Heath.

It was also announced that the Soirée of the Society would be held in the large hall of King's College on the 25th inst.

---

### Amateur Photographic Association.

A Committee Meeting was held on Thursday, the 20th ult., at 26, Haymarket, to select the prize pictures for the season 1861-2, Sir Thomas Maryon Wilson in the chair.

The minutes of the last meeting having been read and confirmed, and the principles upon which the prizes were to be awarded discussed, a certain number of the pictures, selected by the various members of the Committee as entitled to competition, were laid upon the table.

#### AWARD OF THE PRIZES.

Class A.—Nos.
- $\frac{113}{1}$. *On the Teith, near Callander*, by W. Church, jun.
- $\frac{78}{13}$. *Hoar Frost: a Park Scene*, by the Earl of Caithness.
- $\frac{53}{13}$. *Corfu, from the Island of Vido*, by Major* J. D. Shakspeare.

Instead of the Twelve Guinea Medal, three smaller ones, of the value of Four Guineas each, to the respective producers of the above named works.

Class B.—No. $\frac{14}{13}$. *On the Banks of the Severn, near Winterdyne*, by Major Gresley.

#### The Seven Guinea Medal.

Class C.—No. $\frac{120}{11}$. *Fishing Party on the Coquet, Cumberland*, by Henry St. Vincent Ames.

#### The Five Guinea Medal.

Class D.—No. $\frac{58}{235}$. *Floral Festoons in Nature's Garden*, by G. S. Penney.

#### The Three Guinea Medal.

Besides that by Major Gresley, on which a prize has already been conferred, the one numbered $\frac{14}{7}$ is, perhaps, if possible, even more artistic in selection of subject, but not quite so perfect in execution. $\frac{14}{2}$ and $\frac{14}{4}$ are also particularly worthy of commendation; and indeed the whole of this gentleman's contributions display the work of a true artist.

Mr. A. C. Ainslie's, No. $\frac{100}{7}$, is very artistically rendered, exhibiting a field-gate in the shade of a handsome tree; and scarcely less so are *The Gate of Corfe Church*, Somerset, $\frac{100}{4}$; *The Grove at Barton Grange* $\frac{100}{1}$; and *The Waterwheel at Corfe*, $\frac{100}{6}$.

Mr. W. Prideaux's *Fishing House*, $\frac{179}{4}$, is a photographic gem.

Mr. E. Edward's *Cleft in the Rock*, near Aucher Church, Derby, $\frac{92}{23}$, elicited much admiration; as also his *Cloisters at Netley Abbey*, $\frac{82}{6}$, and many of his views in the *Isle of Wight*.

Captain Plaiffin's *Arab Girl Sitting by the Wayside*, $\frac{185}{10}$, is a highly interesting figure subject, admirably treated; and his landscapes, $\frac{184}{2}$ and $\frac{184}{3}$, are deserving of especial notice.

Mr. C. R. Grice's *Market Woman at Aix la Chapelle*, $\frac{114}{14}$, is a good companion to Captain Plaiffin's *Arab Girl*. These belong to a class of subjects that offers much scope for photographic illustration.

Lieut. J. A. Papillon's Chinese illustrations are unusually interesting—some, exhibiting the garden scenes, pre-eminently so.

Lieut.-Colonel Verschoyle has contributed many valuable negatives. *The Cheddar Cliffs*, $\frac{110}{39}$, and *Pier at Lynmouth*, $\frac{119}{46}$, are excellent.

Mr. Ebbage's *Kenilworth*, $\frac{18}{2}$, and scenes at and near Warwick.

The Earl of Caithness's *Avenue at Weston*, $\frac{78}{37}$.

Mr. D, C. Brown's *Scenes at Warkworth*, $\frac{61}{7}$, and $\frac{63}{2}$.

Mr. H. Whitfield's *Vale of Neath*, $\frac{60}{7}$ and $\frac{60}{8}$.

Mr. J. A. C. Branfill's *Pont Aberglaslyn*, $\frac{166}{2}$, *and Pass of Llanberis*, $\frac{166}{3}$.

All the above pictures elicited much admiration, as well as many of the subjects by Major Russell, and medical ones by Dr. Budd. The stereographic subjects are also many of them considered very fine.

In conclusion, the Committee congratulates the members upon the discovery and utilization of so many valuable negatives, of which but an insignificant fraction is indicated in the above list.

* Now Lieut.-Col. Shakspeare, we believe.—Ed.

---

## Correspondence.

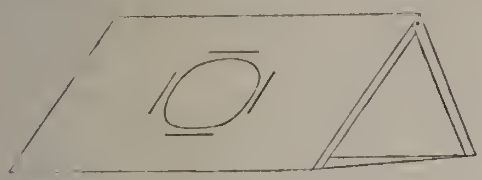
### PAINTING SLIDES FOR THE MAGIC LANTERN.

Sir—In answer to your correspondent who inquires about the preparation of the colours used in painting magic lantern slides, I give the following information. He is quite right in supposing the vehicle to be Canada balsam. The colours used are gamboge, asphaltum, burnt sienna, crimson lake, (in drops) and chinese blue; and sometimes vegetable black for vigorous touches. The various tints are got by a mixture of the above. The mode of preparation is as follows: first take gamboge one ounce and beat into small pieces, put them into a bottle containing two ounces of alcohol and set in a warm place to dissolve the colouring matter or the gamboge: this will take about two days. It must be well shaken from time to time to assist the solution. The supernatant liquor to be poured off the sediment on to a warm slab of glass or marble; the warmth being necessary to assist the evaporation of the alcohol. The colour should be kept in the centre of the slab with a palette knife: it will soon appear thick and opaque. A little Canada balsam must now be added and well worked in, and as soon as the alcohol is all out, the colour will resume its former transparency, and have a thicker consistency; if a little be tried on a glass it will show the color to be a rich yellow.

Next prepare the asphaltum: it is to be dissolved in turpentine and allowed to settle. A little of the liquor may be poured off and mixed at once with the balsam. The other colours, crimson lake, burnt sienna, and chinese blue, are to be ground on the slab in the order written; as the blue is very bad to clean off, it must be done last. The colours are to be reduced to a fine powder on the slab, and a little turpentine added with which the colour must be ground as fine as possible. It may be ascertained how they are going on by taking a little on a brush with some balsam and turpentine, and drying it on a piece of glass. It will take an hour, at least, to grind a piece about the size of a bean, unless you have a large slab and muller, which must be of either ground-glass or marble. The quantity used, however, in each picture is so small that little colour will cover a large number of pictures.

In painting, it is usual to lay on the sky pretty freely with a soft sable brush, a black one is best, and as soon as ready, in order to remove the marks of the brush, it must be dabbed with the end of the finger covered with a piece of kid glove. This requires practice to do well; its object is to give that grain which will be noticed in well painted views. Clouds must be wiped out with a piece of cork. With respect to the balsam, it is sold of qualities so different at different places, that I can only leave it to the judgment of your readers as to how thin it is to be made. I may remark, by the way, that success is only to be obtained by patience and careful working. If I resided near your correspondent I should be happy to give verbal instructions and a little practical aid, but that cannot be.

Now for the easel:—it should be either a thin board or



a piece of millboard with a hole cut in it the shape of the picture, just leaving a margin all round; pieces of wood should be glued on to keep the glass in its place, as it will be better sloped. To the sides of the board, two pieces of wood, by way of legs, are to be fastened on with pins, as in the diagram, turn this to the light, and place a piece of white paper on the table to reflect the light through the view.

The colours are best kept in little pots that have covers, such as I have seen used for lip-salve. A little water should be put over to keep them from drying when not in use. As much as wanted to be taken out for use on to a piece of glass with white paper under. Should your readers require further information I will do my best to reply.—I am yours truly, R. A. L.

## PAINTING MAGIC LANTERN SLIDES.

Dear Mr. Editor,—Having practised painting magic lantern slides, both for sale and exhibition, and frequently given lessons in the art, allow me to offer Mr. B. Jones the information he requires, I must premise that Mr. Jones must not hope to succeed to any degree of perfection, unless he has had some artistic practice, and thereby gained some knowledge of colour; if he has followed the department of miniature painting so much the better, as slide painting requires very neat handling, highly effective colouring, and exceedingly correct outline, as they have to bear being highly magnified, when every blemish becomes exaggerated and faults in outline appear extremely ridiculous. Mr. Jones is wrong in his conclusions, as regards the use of water colours; many of the best painters of slides use none other. As Mr. Jones merely wishes to colour photographs, he will find his task mere play compared with painting a slide from the outline to completion.

Supposing, then, he has a transparent positive on glass from a fully exposed negative—a landscape will be the most likely for him to succeed with—it must be varnished with a very hard varnish, such as turpentine will not easily act upon. He must contrive for himself a glass easel, under which, and lying flat on the table (while the easel with its glass plate stands in the usual position), must be placed a sheet of white paper, so that while he works he can see what progress he is making; he must also sit facing the light, which, if matters are properly arranged, will strike on the white paper, and be reflected through the picture he is painting. He must use colours ground very fine. Tube colours will do if not mixed too thin; they must be re-ground with mastic varnish just before use; those colours only which are transparent are of service; highly rectified turpentine, or camphine, is used as a vehicle. A clean rag must be added for wiping the fingers. Having everything in readiness and placed in proper position, the picture being on the easel he must begin with the sky, which we will suppose to be that of a fine day near sunset. Let him take a very little of the prussian blue on the tip of the second finger of the right hand, and dab the sky over about half way down, not caring for trees, buildings, or anything that may run into it but working all over it. Having by dabbing with the finger obtained a fine and even layer of colour, wipe the finger dry on the rag, and soften the blue upwards so that the top part is the colour wanted, but fading from that to tan glass: take then (the finger being wiped clean), some madder carmine and dab it on so as to blend it with the blue producing a gradation from blue to faint rose. Wipe the finger clean and with a little indian yellow blend into the rose so as produce a golden horizon. When all is done satisfactorily, with a paper stump wipe off the colour where not wanted; proceed to tint the other parts of the picture with sable pencils, never putting more colour than will appear clean and even, but strengthen the colours again and again if required, letting the picture dry between each coat, being very careful not to move the colour already laid, finish by scraping the highest lights out with the point of a penknife, then varnish. Be very careful to avoid dust, as every speck will show. When exhibited, there are many tricks of manipulation, but to enter into the whole process from beginning to end, would be subject sufficient for more than one article; the information now given, will I am sure enable Mr. Jones with a little perseverance, to paint a landscape respectably. Beautiful dioramic effects may be obtained by various appliances with a little ingenuity.—I am dear sir, yours truly, T. P. E.

[We have a letter on this subject from Mr. Gulliver, which will appear in our next. Another correspondent states that Cox's "Photographic Tourist" contains some information on the subject; and we may add, that an excellent work, giving detailed instructions for painting glass, is published by the Messrs. Rowney at a shilling.—Ed.]

## SALTS OF MORPHIA FOR DRY PLATES.

Sir,—I hope you will permit me to extricate myself from the voluminous correspondence I have received, and still receive, by stating in the next number of the News that I must decline answering letters *privately*, for it involves the use of so much time. To dry plate photographers the best formula for the morphined plates is this, add the muriate of morphine to the bath, this precipitates muriate or chloride of silver, which is then filtered out, and nitrate of morphine remains in solution, excite the plates in it, using a bromo-iodized dry collodion, expose when fresh from the bath, or wash away all nitrate of silver, and then expose before drying, or dry first and then expose, there is not very great variation in the sensitiveness either way.

The acetate of morphine I have used in the collodion only, it may be excited in the bath containing the nitrate of morphine, or the usual solution, and if there is to be any accelerating power the plates should be exposed fresh from the bath.

For the dry plates, plain pyrogallic acid and water development is productive of results, afterwards intensify with pyro, citric acid, and silver, these remarks hold good for the same plates washed and exposed before drying.

The keeping qualities of the plate must be good, there being nothing but iodide and bromide of silver, and the pyroxyline to decompose.—I am, sir, yours respectfully,

Wm. Bartholomew.

The Fine Art Copyright Bill.—The Bill for amending the law of copyright, as relating to works of fine art, was read a third time and passed the House of Commons on Monday evening last.

## Talk in the Studio.

Proposed Office for the International Sale of Photographs.—We have received from M. Edmond Potonié, of 6, Alderstrasse, Berlin, the prospectus of a projected office for the international sale of photographs. The object is to facilitate the distribution throughout the Continent of the best works of the best artists, and it is proposed to publish a universal catalogue of all photographs which are intended for the means of international sale. Depôts will be established in large cities. Photographers interested in the matter are requested to communicate with the gentleman above-named.

The late Prince Consort.—We have received from Mr. Wood, of Edinburgh, a lithographic portrait of His Royal Highness, the late Prince Consort, which, to photographers, possesses great interest as a rare illustration of the perfection with which the characteristics of a photograph may be reproduced in an artist's drawing on a lithographic stone. The portrait before us is from Rejlander's photograph of the Prince already noticed in these pages, and renders in an admirable manner all the photographic minutiæ with some superadded qualities within the power of the draughtsman, but not always under the control of the photographer. The portrait is very striking as a likeness, and very perfect as a specimen of lithographic art. Messrs. Schenk and Macfarlane, of Edinburgh, are the photographers; and Mr. Wood, of the same city, the publisher. We understand that the same gentleman is about to publish an enlarged lithograph of Rejlander's "John the Baptist."

The Power of Photography.—Photozincography is certainly a stupendous word, but its stupendousness is well suited to the art of which it is the verbal exponent. If photography works wonders, photozincography, in the matter of multiplying ancient manuscripts, works nothing short of miracles. If the bards of old Greece were astonished at the daring inventions of the men of their day, how would they marvel were they but conscious, as they lie peradventure beside their nectar, *ἑκὰς ἀνδρῶν ἀλφηστάων*, of the audacity of our age, which, not content with making the steam its bond-servant and the lightning its messenger, borrows the very rays of the orb "that. with surpassing glory crowned," looked from its "sole dominion like the God" of the new-born world, to produce us *à discretion* the long-forgotten records of ancient men and ancient times! The men of our day are bolder than Prometheus: he filched but a reedful of fire for mortals (*ναρθηκοπλήρωτον δὲ θηρῶμαι πυρὸς πηγὴν κλοπαίαν*), they press into their service the blessed sun itself. And he makes an unexceptionable servant. He is always up in the morning at the right time; he is always accurate; he is never weary; he never gossips; he is never impertinent; and though he may be said to drink a good deal, his beverage is principally water. He occasionally looks sulky, too, and sometimes appears to be absent, but it is only in appearance; he is always at his post, but nebulous enemies surround him and impede his action.—*The Critic.*

## To Correspondents.

J. E. B.—Many of the lenses by the maker you name are very good. Use your aceto-nitrate bath a little more acid; wash carefully to remove all free silver; add a little more citric acid to your developer, and develop more slowly. The use of a very powdery collodion, especially if over-iodized, will sometimes cause the whole of the image to be dissolved. Painting any portion of your glass with white lead will keep out a great deal of light. If you wish merely to keep eyes out of the room, there is a method of treating the glass with Epsom salts, which will effect this without stopping out much light. Your positives are pretty good; but some of the negatives would have been better for longer exposure. Avoid white backgrounds for portraiture. Some formulæ for varnishes have recently been published in the News. Those who have used that recently given by Mr. Fitch speak very highly of it. You can doubtless buy the white varnish at an oil shop. We apprehend that albumenized paper may be sent rolled and open at the ends, by book post. We cannot say with any certainty where you can get it certainly of good quality. We have recently seen fine samples, both from Sandford, Marion, and Bourquin. Your dry plate negative would apparently have been better for longer exposure or slower development. You need not apologize for troubling us. We shall always have pleasure in helping you to the best of our ability, so far as it is possible to do so in this column.

G. A.—Mr. Hannaford's or Mr. Bartholomew's modification of the Fothergill process consists in adding nitrate of silver to the albumen solution containing ammonia. The object is, primarily, to gain a more even coating of albumenite of silver; and secondly, to increase the sensitiveness. The proportions recommended are: the white of an egg, three ounces of water, and 12 minims of strong ammonia. To this, nitrate of silver is added, drop by drop: a precipitate is first caused, which is then redissolved by the ammonia. As soon as the precipitate ceases to be dissolved, stop. See Mr. Hannaford's paper on the subject at the South London Society on p. 183 of our fifth volume.

E. F.—We cannot give you definite information on the commercial value of stereo negatives. It entirely depends on the interest of the subject, and the excellence of the quality. We can only repeat our former advice; write to the various publishing houses, and send specimens. If they do not answer you, it is simply an indication that your subjects are not in demand. The fixing of diaphragms into compound lenses is the work of an optician; your own ingenuity may supply them for a temporary purpose.

A.—There is no secret in getting an even background, except careful and skilful manipulation. We can only conjecture which part of your manipulation is at fault from the specimen enclosed; but it seems probable that after washing away the iron. you applied pyro and silver at once to the plate, which not flowing evenly and taking kindly at once to the surface, deposited the silver in patches upon those parts it was first in perfect contact with. To avoid this, apply the pyro solution at first without silver, and pour it on and off once or twice, until it flows evenly; then return to the developing cup, and add a little silver; mix thoroughly, and apply again, when the deposit will be even and regular. With the exception of the uneven background, the photographic qualities of your specimen are very good. A little more grace might have been secured in the pose; the head is too much thrown back.

Juvenile.—There are many contrivances for rapid washing; but we have not seen any which it would have been wise to patent. We cannot, of course, say whether your plan is worth patenting, as we are in entire ignorance of its character. Not one photographic patent in ten pays its expenses. How do you assure yourself that the hypo is quite gone?

No. 35.—We should not recommend the addition of a third lens to a double combination for the purpose of shortening the focus. To have such an addition made by a first rate optician would be more costly than the result would probably be worth; and if done at random, or by an incompetent person, would be useless. We do not know who did this work for Mr. Archer; and from what we have heard of the results, we should not think it any particular gain to learn.

Non Success.—A creamy film in the bath depends on several causes: the character and quantity of the pyroxyline, the strength of the silver bath, and the quantity of iodides. &c. One of the likely means to secure it and obtain more intensity at the same time, is the addition of a little more pyroxyline to the collodion. A low temperature will sometimes keep the film of iodide of silver thin and blue.

One in Trouble.—If the use of kaolin, citric acid, or a chloride fail to clear your silver bath, the best plan will be to precipitate the silver in this and make a new one.

Col. Alb.—It is not desirable to dilute the albumen solution so largely as you propose. 2. Authorities differ as to the drying of collodio-albumen plates, in their first stage, in daylight. Mr. Wardley, an excellent authority, says emphatically that it injures the brilliancy of the negative. Where there is doubt on the subject follow the safest course.

S. B.—The solution of gallic acid for final application to Fothergill dry plates may be used in a dipping bath. It may be kept if closely corked and a little camphor added; but we should prefer to use it fresh. Careful manipulation is the only mode of preventing markings from the irregular flow of the albumen. Or if the whole of the free silver have been previously removed, such marks will not be so likely to occur.

Gold.—To precipitate the gold in your old toning baths add protosulphate of iron. This will throw down the gold in a dark powder.

A. B.—The proximate cause of the cracks in your varnish is probably damp. Imperfect washing after fixing, or the use of a bad varnish would aid the result. 2. About an ounce of acetate of soda to a pint of water; immerse the prints about ten minutes.

Focus.—Your letter has been mislaid. If you will write again we will answer by post to save delay.

A Novice.—There are several excellent instruction books published. One of the most recent and best is that by Mr. C. Jabez Hughes. Common earthenware dishes will do for printing solutions, but take care to keep each always to its own purpose.

J. H. Redin.—Mr. Fitch gives the recipe at the close of his paper. It is simply "white hard varnish" purchased at an oil shop, and diluted with methylated spirit to a proper consistency.

Excelsior.—The faults in your prints arise from the negatives as much as from the printing. No. 1 is from a poor under-exposed negative. No. 2 the negative is better but thin, and the positive is overprinted and over-toned. The quicker paper is dried after sensitizing the better, but it should not be done in even a subdued white light. It will not be injured by exciting at night and printing and toning next day. 2. The smaller the circle an arc of which your Latimer Clark camera travels, the greater the apparent amount of relief in the combined images, but at the same time the smaller more toy-like and unnatural the effect. The greater the circle, and the less convergence, the better and truer the effect. Of course the adjustment must be made with some reference to the position of the pictures on the plate.

F. G.—Other things being equal, it is possible to take equally good pictures on either wet or dry collodion plates. There is no necessity for dry plate pictures to be either coarse, spotty, or hard. Proper exposure and careful development, especially the latter, are the most important points.

Wm. Gillett.—You will find an article on the construction of glass rooms on p. 73 of our third volume.

A. Tyro.—Your prints were imperfectly fixed. Either the hypo was too weak or the prints did not remain in long enough. The first action which takes place on putting the prints in hypo is the formation of hyposulphite of silver, which is next dissolved by the excess of hyposulphite of soda. If the solution is not strong enough, or the prints are not left in long enough, the hyposulphite of silver is not dissolved, and becomes decomposed in the course of washing, producing the dirty, brown, speckled effects your prints show.

J. H.—A portrait combination with lenses of 12 inches diameter, and 60 inches focus, by a first class maker, would cost from £80 to £100, or possibly much more, so far as we can conjecture. The length of room required would entirely depend on the size of the figures you require to produce.

Gravity.—The use of a specific gravity bottle is to ascertain the strength of the fluids, by their relation in weight to a similar bulk of water. You will find the principles and mode of use explained on p. 248 of our third volume.

Several correspondents in our next.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 188.—*April* 11, 1862.

## TO ASCERTAIN THE EQUIVALENT FOCUS OF A COMBINATION OF LENSES.

The question is frequently asked: What is the simplest and best method of ascertaining the equivalent focus of a combination of lenses? Photographers are rarely familiar with the exact equivalent foci of the various lenses with which they are working. It has happened that amongst opticians the custom has obtained—more to meet the exigencies of the camera maker, than with any intention to mislead photographers—of stating the focus as measured from the back lens to the ground glass, which is, of course, always shorter, by an amount varying with the construction of the lens, than the real or equivalent focus. In answer to the above question a formula apparently very definite, has usually been supplied, and the querist has been directed to take a single lens, say a spectacle eye, and having as carefully as possible ascertained its focus, compare the size of the image formed by it on the ground glass of a camera, with the size of the image formed of the same object at the same distance, by the compound lens which is the subject of the enquiry, and then compute the length of the unknown focus by the relation between the respective images and the known focus. The rule has been stated thus: divide the known focal length of the single lens by the fraction representing the linear dimensions of the image formed by the single lens and the combination. Thus; let the focal length of the single lens equal 12 inches, and the images formed by it and the combination be as 3 to 2; then $12 \div \frac{3}{2} = 8$ inches, the equivalent focus of the combination required. Or to put the matter more popularly, proceed thus: suppose the focus of the single lens to be twelve inches, and the image formed be three inches in height; suppose also the height of the image of the compound lens under the same circumstances be two inches; then as three are to twelve so are two to eight: eight inches then would be the required focus of the combination. Now, although this is a very simple, and at first sight appears a very correct mode of going about the business; yet it is troublesome, and involves some sources of error; the standard of comparison—the focus of the spectacle eye—being an uncertain thing. Another method, which renders necessary a series of processes with a telescope—which, by the way, not every photographer possesses—is still more troublesome and complicated, and involves, therefore, still more sources of error. To avoid all this trouble, it has been sometimes recommended to get an approximate idea of the equivalent focus by computing it from the central stop, or from a point midway between the front and back lens. This method involves too much of assumption, and is altogether too much of the character of guess work, to be of any scientific value.

Happily there is, however, a much simpler method than any of these, and more free than any of them from sources of error. Let the querist proceed as follows:—take a map, an engraving, or sheet of letter-press, and fasten it flat against a well-lighted wall; now mark distinctly off a portion, say three inches. Proceed to draw out the camera and focus the subject accurately, taking care that the image is the exact size of the original, which will be ascertained clearly by observing that the three inches marked off in the original measure exactly those dimensions on the ground-glass. As most of our readers know, the camera is now extended just double the equivalent focus of the lens. But the question arises, from what part of the lens to the ground-glass shall we measure? This is just the point where the plan we are describing simplifies the matter; *now remove the lens altogether*, and measure the distance, from the object focussed, to the ground-glass; *one-fourth of that distance will be the equivalent focus of the combination of lenses, no matter what their construction.*

To illustrate: we have just tried this method upon a Dallmeyer's No. 1 triple achromatic lens in our possession, No. 2282. Extending the camera and focussing an engraving, carefully adjusting the length of the camera until the engraving and its image were exactly the same size, and the image perfectly sharp, we then removed the lens and measured the total distance between the engraving and the ground-glass: this we found to be $31\frac{6}{10}$ inches. Dividing this by 4 we obtain $7\frac{9}{10}$ inches, which is the equivalent focus of the lens in question. We may incidentally observe that measuring from the central stop to the ground-glass, we also found that in this instance the distance was as nearly as possible the same as the equivalent focus.

This plan is so simple in practice, and so correct in result, that our readers will have no trouble in future in ascertaining the exact focal length of any lens in their possession.

Regarding another interesting question associated with this, the method of ascertaining the extent of angle included, by the relation between the area of definition and the equivalent focus, it is not so easy to state the matter in a simple and popular form for the unscientific reader. But as it has become of late a favourite practice of the advocates of various lenses, to state that they include an angle of 60°, that statement may be very easily tested. If the diameter of a circle of perfect or satisfactory definition be equal to the equivalent focus of the lens, then it includes 60° in a circular picture; but as most views are cut into the form of a parallelogram, the extent of definition on the horizontal line should equal the equivalent focus of the lens, in order to include an angle of 60° as popularly understood.

## PHOTOGRAPHY IN AMERICA.

We have much pleasure in announcing that we shall in future be able to keep our readers very definitely informed of the progress of photography in America. We have derived, from time to time, much information which has been interesting and instructive from the pages of the American journals and from various transatlantic correspondents. We hope in future to supply that information in a more systematic form by direct correspondence with F. F. Thompson, Esq., Secretary of the American Photographic Society, and principal of a banking-house in New York. We append his introductory note, from which it will be seen that amateur photography is rapidly on the ascendant in the States, and that the dry collodion processes, which, until recently, received but little attention, are receiving considerable attention with very successful results:—

"2, *Wall Street, New York, March*, 20, 1862.

"Dear Sir,—Being one of your American subscribers, and having benefited much by reading your News, I think it would be a small return for me to send you whatever I can which may be of use to you.

"The number of amateurs in our country is rapidly increasing, and in time we expect to be as numerous as you are in the motherland, and even more so, for the American temper grasps fashion quickly, and a fashion here develops into "the rage." We have already organized "The Amateur Photographic Exchange Club," an informal association of very little machinery, but of very smooth workings, as your readers will see by the brief rules appended.

"Rules of the Amateur Photographic Exchange Club.

"1.—None but amateurs in the art shall be recognized as members, and the number shall not exceed forty.

"2.—No member shall forward for exchange any work not his own.

"3.—Every member shall forward each other member on or before the 15th of January, March, May, July, September, and November, at least one stereoscopic print, a copy of which has not been sent before, or its equivalent, mounted and finished.

"Every member shall keep a book account with each other member, charging each print sent, and crediting all received. Should any members desire to exchange with any others oftener than bi-monthly, they can do so by agreement.

"5.—Any one failing to send one print bi-monthly, shall be struck off the book of the party he fails to send to, unless satisfactory reason is given for his default.

"6.—All photographs must be properly labelled with a descriptive name, the name of the artist, and the date of the printing, and they must be guaranteed not to fade for two years; and if toned by experimental process, must be marked 'Experiment.'

"7.—Two unmounted prints shall be equivalent to one mounted and finished of the same size. Two card or quarter-plate pictures shall be equivalent to one stereoscopic, and two stereoscopic to one whole plate. Three paper stereographs shall be equivalent to one on glass.

The simplicity constitutes the success of the club. It has been in operation six months, and many hundred photographs of all sizes have changed hands.

"The dry processes have been adopted by almost all the pleasure-working fraternity, although two of our best artists, Coleman Sellers and Robert Shriver, still adhere to the old system of a tent, two assistants, wagon, water buckets 'and a' that, and a' that.' But we will convert even them this season, as there is proposed a grand photographic tour over the late battle fields, and when they, wet with perspiration, each one with a baggage-van, toil beside us dry, with camera and a dozen pictures under one arm, then we shall see 'a change come o'er the spirit of their dream.'

"The main reason of the slow introduction of dry plates here is universal use of iron developer, and consequent ignorance of the usage of pyrogallic.* Our galleries now use the sulph. pottass. to intensify negatives altogether, the finer results of pyro and silver being seldom if ever sought for.

"The hot water development of tannin plates is now the subject of the day with us. I presume you have ere this the particulars of the working of it. Portraits have been taken under a skylight on tannin dry plates in the usual wet collodion time, and developed by this process with perfect success; but as yet there is no unanimity of opinion about the certainty of success, but we fully agree that it is (in American slang) '*a big thing.*'

"Pardon me for writing you such a long letter in the start, for the ladies say the first call must always be a short one, and I'll promise to do better hereafter.—Yours respectfully, F. F. Thompson."

"*G. Wharton Simpson, Esq., Editor*
Photographic News, *London.*"

## ALCOLENE, OR COLLODION WITHOUT ETHER.

Every one who has experimented much in the manufacture of collodion is familiar with the fact that on adding absolute alcohol to pyroxyline made at a high temperature, the latter has become glutinous and has partially dissolved. Mr. Sutton has recently made some interesting experiments for utilizing the solution thus obtained, and for fixing the conditions under which it is produced. We extract from two recent numbers of the *Notes* his description of the characteristics and manufacture of the preparation which he has styled "Alcolene."

"Alcolene is a somewhat thick fluid, resembling a warm solution of starch. It is perfectly colourless when iodized with the usual potassium iodizer, and would probably remain without colour for any length of time. But in making this remark we must be understood to allude to the common iodide of potassium which gives a colourless alcoholic solution. The pure iodide, free from carbonate, is yellow, and this gives of course a yellow tint to the alcoholic solution, and therefore to the iodized Alcolene.

"When a glass plate is coated with Alcolene it flows upon the surface exactly like boiled oil, and as it sets slowly it may be run backwards and forwards over the same place without leaving the marks called curtains, which occur so frequently with common collodion containing a large per centage of ether. The best way of coating a plate seems to be to let the whole body of fluid, after the plate has been covered, flow back again over the plate, and then pour it off from the corner to which it was first allowed to run. Unless this is done, that is to say if the plate is coated in the usual way, there will be found a number of fine parallel diagonal lines in the film produced by the draining towards the bottom corner, and which cannot be got rid of by the ordinary mode of rocking the plate.

"The film requires at this season about three minutes to set, and may then be immersed in the nitrate bath. Strange to say, it exhibits the same greasy lines as a common collodion film when put into the bath, but these disappear in the usual way when the iodide of silver has been completely formed. It is an erroneous supposition, therefore, that these greasy lines proceed from the ether in the film. In order to make sure that ether had nothing to do with them we made a new bath, and the lines occurred in the same way as with an old bath. The greasy lines upon the film when it is first put into the nitrate bath proceed therefore from the repulsion which exists between pyroxyline and water; and this explains the occurrence of the lines a second time on putting a plate fresh from the nitrate bath in a bath of distilled water. This is a new fact which it has been interesting to establish. And another fact may be mentioned here, before we forget it, viz., that the yellow colour which iodide of potassium imparts to collodion is entirely due to the ether which the collodion contains; because Alcolene iodized with potassium is colourless, but takes the well-known yellow colour of iodized collodion as soon as ether is added to it.

"The excited film has a beautiful, even, delicate appearance, and is not what is called creamy; its characteristic quality being freedom from all kinds of markings, curtains, and irregularities. In fact there is no collodion gives so faultless a film as Alcolene. The nearest approach to it is that given by collodion with alcohol largely in excess of the ether.

"The exposure in the camera is the same as with the best samples of common collodion. There is, however, this remarkable property with alcolene, that the negative does not become reddened and solarized in the overexposed parts. We have given to one-half of a plate exposed in a stereoscopic camera, sufficient exposure to bring out all the details of the deepest shadows and greens, and to the other half of the same plate four times that exposure, without solarizing any part of the negative, or producing any difference in the density of the two pictures. The subject was a whitewashed house in full sunshine, with a background of dark rocks and evergreens in shadow; and difficult as such subjects are, the negative was soft and even, and quite clean in the transparent parts. It seems, therefore, that you cannot on the one hand easily solarize a negative upon alcolene, or on the other hand for it by over-exposure. These may turn out to be valuable properties of this compound, whether used alone, or added to other collodion.

"When the iodizer contains the usual quantity of water the developer flows freely upon the film; but when the iodizer contains no water, as in the case of iodide of cadmium dissolved in absolute alcohol, the developer will not flow at all, but shrinks from the film like water from a greasy surface.

"The cadmium iodizer does not gelatinize alcolene, and when it is made with alcohol of the proper strength (·820), the compound works well.

"With respect to the strength and adhesiveness of the film. It might be supposed that such a substance as alcolene would adhere tightly to the glass, like starch, or gum arabic, but the contrary is the case. The film is very tender and skinny, and care must be taken in the final washing, or the negative will be torn and destroyed. There is, however, a very simple remedy for this evil, viz., instead of drying and polishing the plates, as usual, to coat them, while wet, with albumen, and then apply the alcolene to the albumenized plate, when dry. We have taken some capital negatives in this way, and they may be washed with considerable violence under the pump, without injuring the film.

* In a recent conversation with a photographer who had just returned from the States, he informed us that pyrogallic acid was not kept by dealers in New York. He had to try photographic house after photographic house, without success, and finally got it at an establishment where rare photographic chemicals were kept.—Ed.

"The character of negatives taken with alcolene is remarkable softness and delicacy, and they scarcely acquire the necessary density without a drop or two of silver in the developer. This is a kind of negative greatly to be preferred to one in which density is too easily obtained.

"A variety of uses for collodion without ether will no doubt occur to our readers. For instance, in hot climates where common collodion actually boils upon the plate, or sets so quickly as to be unmanageable, alcolene will be the right thing to use. Or where good ether cannot be procured, or if it is dangerous in the transport, alcolene will again be serviceable. We cannot at present recommend it as a complete substitute for collodion, on the faith of a few experiments, because that would be getting on a great deal to fast, and overlooking some qualities, which may be considered defects, but it does not certainly seem to us that the total exclusion of ether from collodion may, for many purposes, and in many cases, prove to be a great gain.

"Some of our readers are probably aware that an excited collodion film, fresh from the nitrate bath, may be preserved for a long time by pouring plain collodion upon it. The second film of collodion does not adhere to the first, and the nitrate of silver imprisoned between the two films cannot lose its moisture, and by becoming concentrated attack the iodide of silver in the first film. Now plain alcolene, thinned with an equal quantity of alcohol, may be used in the same way as a preservative to a wet plate.

"To make Alcolene, proceed thus:—

"Take a slop-bason, capable of holding about a pint. Make it perfectly clean and dry, and put into it, first 4 ounces of oil of vitriol, s.g. 1·83, and next 3¼ ounces of nitric acid, s.g. 1·400. Stir the acids well together with a glass rod, and while the mixture is still at its highest temperature, put the bason into a pie dish, and pour into the latter as much boiling water as will be nearly but not quite enough to cause the bason to float. The temperature of the mixed acids will now be about 175°. Put the whole affair up a chimney, up which the fumes of the acid can escape; and immediately begin to put in cotton wool which has been previously pulled out into thin flat tufts. The best plan is for an assistant to put in the cotton wool a tuft at a time, while you immerse it in the liquid, and stir it about with a couple of glass rods. The cotton wool should be the best corded and bleached kind, such as is sold by surgical instrument makers, at about three shillings per pound. Put in as much as you can easily manipulate in the liquid, and leave it in five minutes, counting from the time of putting in the last tuft. Then remove the bason from the pie dish, drain off the acids quickly into a waste acid bottle, and upset the pyroxyline into a pail of clean water, in which rouse it about with the glass rods for a few seconds and then change the water, and repeat this thorough washing several times. Lastly, leave the pyroxyline to soak all night in water, and the following day wash it well again in several changes of water, and spread it out upon a table, or window sill, to dry spontaneously. When dry it will be ready to be dissolved in the alcohol.

"The success of the operation depends chiefly upon using acids of the exact strength indicated, for if they are too weak, the cotton will dissolve in the acid mixture, and if too strong it will not dissolve in the alcohol. The pyroxyline is also very short and powdery, and unless much care is taken a great deal of it will be lost in the washing waters. The best plan will be to procure the acids of the proper strength, and the same that we always use in making alcolene, from Mr. Baily, of Wolverhampton, who will supply the right thing.

"When the pyroxyline is dry, dissolve it by adding to absolute alcohol, s.g. ·805, about as much as the liquid will cover. Shake the bottle well, and in a few minutes the whole will dissolve to a rather thick solution. Iodize by adding any of the usual iodides or bromides dissolved in alcohol, s.g. ·820, in the usual proportion; that is, one part of iodizer to three parts of plain alcolene, one ounce of which will contain about four grains of the iodide employed. The following day it will be ready for use, and when iodized may probably be preserved for a very long time without deterioration.

"We have given these minute and familiar directions for making alcolene, chiefly for the benefit of those readers who live in those places where good ether and good collodion are not always to be got, or where the heat of the climate renders the use of common collodion open to many difficulties and objections. This journal will reach many such readers months before they could procure alcolene from England, and even if they have never before made their own collodion, our directions, if implicitly followed, will yield a good result. It seems probable that alcolene may have many important uses, and we know of no practical objection to it, which may not be easily overcome by the means stated in the last number. We do not, however, recommend it as a substitute for collodion under ordinary circumstances, but simply as a valuable addition to common collodion which is working badly, either from excess of ether, or from the too skinny character of the pyroxyline. We omitted in the former article to state a good quality of alcolene, viz., that although made with very weak acids, the film is entirely transparent, and free from opalescence."

## REMARKS UPON SOME OF THE APPARATUS EMPLOYED IN PHOTOGRAPHY.*

BY F. R. WINDOW.

### Camera Stands.

The principal qualities requisite in a camera stand for the studio are, steadiness, and an easy action of the mechanical parts for raising and lowering the table. There are many designs to be had which perfectly fulfil these conditions.

From its nature this piece of apparatus is almost of necessity somewhat clumsy in appearance when made of wood, as is generally the case, because weight is required to produce the desired firmness, steadiness might be obtained with a lighter section of material by spreading out the base, as is effected with the field tripod stand, but this would be inconvenient in the glass-room, as it would take up too much valuable space.

All studio camera stands should have, besides the principal vertical movement, two other movements by which the camera may be tilted in either direction; but these last should only be used upon very rare and exceptional occasions, excepting for the purpose of placing the camera upon a horizontal level when the floor of the studio chances to be inclined in any direction, and renders a correction in this manner necessary. Generally speaking, portraits are taken with a camera not furnished with a swing-back, and therefore the instrument must be placed perfectly level in order to secure a true and undistorted image of the object placed opposite to it. A neglect of this principle is one of the causes of the want of success some people experience as a rule in getting satisfactory and characteristic likenesses of their sitters; it is also the source of sloping floors, tumble-down walls, and ricketty furniture. In short, it produces a distorted and not a true copy of the object. I have been surprised sometimes to see in publications, where one would not have expected to find such advice, directions given to cock the camera up or down and point the lens at a specified part of the sitter's body in order to get all parts in focus. The picture resulting from such a proceeding, however, well in focus, will inevitably be a misrepresentation of the subject. If an object cannot be brought entirely into proper focus when the camera is strictly level, it is a sign that the powers of the lens are being too highly taxed, and the proper remedy is either to increase the distance between the lens and the object, or to employ a smaller diaphragm.

To facilitate placing the camera perfectly level, it is useful to have a circular spirit level let into the table of the camera stand, below the general surface, so that the camera may be placed over it without touching. This will be found a very useful addition, and quite worth the extra two or three shillings that it costs.

A tray or shelf should be contrived upon each side of the stand, somewhere below the table, one for the focussing-screen, the other for the plate-slide. It will be found very convenient to have regular places in which to deposit them, and where they are ready to hand. The plate-slide has always to be placed somewhere while the focus is being finally adjusted; it must not be laid flat upon table

* Continued from page 159.

or chair, as the drained nitrate should not be encouraged to flow over the plate again, and if stood, as it often is, upon the ground, leaning up against the camera stand, it is very liable to be knocked over, a fate which also not unfrequently happens to the focussing-screen, when this latter is separate from the camera. The trays should, of course, be of a proper form to hold the plate-slide in a nearly vertical position.

The portable tripod stand for field use is admirably suited to its work, and it is difficult to imagine any great improvement being made upon it. Care should be taken to select a triangle top suitable in size to the camera it has to support, as, if the former be too small, it is difficult to secure the perfect firmness of the instrument.

As this triangle cannot conveniently be made to hold a spirit level, it is very advisable, for the reasons given above, if the photographer does not use a camera with a swing back, to carry in the pocket a small circular spirit level, and to place it upon the top of the stand before screwing on the camera, or upon the camera itself when fixed, to enable it to be adjusted quite level before taking the picture. The fall of the country is very apt to deceive the eye. Attention to this is more particularly necessary when working with a binocular camera.

(*To be continued.*)

## PHOTOGRAPHIC CHEMICALS:

### Their Manufacture, Adulterations, and Analysis.

*Sulphides* (continued).—*Sulphide of lead.*—This sulphide is of importance to the photographer in a negative sense, as it is a body to be avoided rather than used; a knowledge of its properties may, however, on that account be very useful. It occurs native in the form of galena, a beautiful mineral of a metallic lustre, and breaking readily into cubes. From its pretty sparkling appearance, it is much used at the present time for ornamenting ladies' head-dresses, &c. Lead and sulphur have a great affinity for each other, and as there is almost always sulphuretted hydrogen in the atmosphere of large towns, compounds of lead are certain to absorb sulphur and tarnish. This is strikingly seen on the fronts of houses which are painted with white lead. At intervals along a street coloured in this way, there is occasionally an appearance as if a gigantic brush dipped in mud had been dabbed over the painted surface. This discolouration may usually be traced to the presence of a neighbouring gully hole, and the streets which mostly suffer in this way are those in which the sewers are imperfect. The same discolouration is met with in photographic miniatures, in which white lead is one of the colours used. Owing to the annoyance caused by this, the employment of lead compounds for this purpose is ceasing in great measure; the permanent zinc white taking the place of white lead. As explained above, sulphide of lead in the native state has a metallic lustre; when formed artificially by the action of sulphuretted hydrogen on a surface of white lead, it takes various shades of slate colour or brown, according to the depth of tarnish, but seldom appearing black. When precipitated from solutions by hydrosulphuric acid or an alkaline sulphide, it appears as a brown black powder.

There are several sulphides of iron, only the most interesting of which however need be noticed.

*Protosulphide of iron* is prepared on the large scale in several ways. One of the most instructive modes of making it may be met with in most books of chemical experiments. If a poker be heated red hot in the fire, and a roll of sulphur pressed against the hot end, the two will unite and form this sulphide, which being readily fusible, falls in drops, giving an appearance as if the iron were melting. Sulphide of iron is of great value in the laboratory as a source for hydrosulphuric acid. When acted on by dilute sulphuric or hydrochloric acid, it evolves this gas in a state of considerable purity, and is thus of daily employment for chemical purposes. According to Braconnot, the black mud at the bottom of drains contains hydrated sulphide of iron, probably formed by the putrefaction of organic substance in contact with the ferric oxide of earthy matters, and to this it owes its black colour and peculiar smell. Hence when exposed to the air it loses its odour and colour, and afterwards resembles ordinary vegetable mould. With acids it evolves abundance of sulphuretted hydrogen. The black colour of the soil in cesspools, pits, ponds, and morasses, and of the earth under the pavements of the streets, is likewise due to the presence of this sulphide of iron; the ready decomposition of which is the chief cause of the presence of sulphuretted hydrogen in the atmosphere.

Another sulphide of iron which possesses some interest is the bisulphide. This, from its yellow colour, has been frequently mistaken for gold; and we have even heard of considerable sums of money being sunk in mining work, when a very slight knowledge of chemistry would have shown the managers that the only yellow body they had a chance of getting was iron pyrites, as this sulphide is called. The distinctions between this mineral and gold are numerous, and of ready application. In the first place, a touch with a penknife shows that gold scales are soft and easily indented, whereas iron pyrites is hard and brittle. Again, if the two are sprinkled on a red hot shovel, the gold will be unaltered, whilst the sulphide of iron forms sulphurous acid, easily recognised by its powerful odour. If nitric acid be poured over gold, no action takes place; but if the yellow body be iron pyrites, a strong action, with evolution of red fumes, is at once produced. Gold also is about four times as heavy, bulk for bulk, as iron pyrites; so that to a person with very slight chemical knowledge, the mistaking of the one for the other would be simply impossible.

*Sulphide of Mercury*, or *Cinnabar*, is largely used as a pigment; it is one of those valuable colours which is unaffected by a sulphuretted atmosphere, being already saturated with sulphur. Cinnabar is also a very frequent ore of mercury. It is of a very beautiful red colour, the shade varying from deep carmine to yellowish red, according to the mode of preparation. When gently heated over a lamp it becomes brownish; at 250° C., quite brown, and at a higher temperature black; but if the heat has not been strong enough to cause it to volatilise, it recovers its fine scarlet colour on cooling. When strongly heated in the air it burns with a blue flame, yielding sulphurous acid and metallic mercury. Cinnabar is frequently adulterated with brick-dust, oxide of iron, red-lead, and dragon's blood. *Brick-dust* may be detected by heating the cinnabar in an iron spoon, the sulphide of mercury going off whilst the brick-dust is left behind. *Oxide of iron* may be detected in the same way; or it may be dissolved out by boiling hydrochloric acid, and then precipitated in the filtered liquid by addition of ammonia, or converted into prussian blue by nearly neutralising with ammonia and then adding acetate of soda and ferro-cyanide of potassium. *Red-lead* may be detected also by heating the substance, being left behind in the form of a fused protoxide. On boiling the cinnabar with hydrochloric acid it yields chloride of lead with evolution of chlorine. *Dragon's blood* may be detected by the empyreumatic odour which it gives on the application of heat; it also communicates a red colour to alcohol. One of the most curious modes of formation of cinnabar is that discovered by Martius. He places the ingredients for the formation of cinnabar in bottles closed with corks, and packs them in a box which is fastened to the upper beam of a saw-mill. In 24 to 36 hours, at ordinary temperatures, the most beautiful cinnabar is produced; it is afterwards washed and dried. This method not only has the advantage of dispensing with the labour of trituration, but it likewise prevents the hitherto unexplained passage of the cinnabar into the brown state, which is so liable to take place on the application of heat. The ingredients employed vary slightly, according to different modes of preparation. In general they consist of metallic mercury with flowers of sulphur and potash ley, or a solution of pentasulphide of potassium. It may also be prepared by sublimation. In this way the beautiful Chinese cinnabar is prepared. I part of sulphur and 4 parts of mercury are sublimed in an earthen vessel, to which an iron cover, kept constantly moist, is luted. In twenty-four hours the vessel is allowed to cool and is broken; the purer portion of the cinnabar is powdered up and sifted into water, and the fine sediment afterwards collected apart and dried. This cinnabar inclines to carmine colour, and is very expensive, lately, however, means have been found to imitate it in Europe by subliming common cinnabar with sulphide of antimony and then treating the product with solution of liver of sulphur.

## ON SULPHATE OF IRON AS A DEVELOPING AGENT.

BY M. ADOLPHE MARTIN.

Many photographers now employ sulphate of iron as a developing agent for collodion negatives, because they prefer it to pyrogallic acid; nevertheless the latter is preferable in many circumstances. In studying the production of photographic pictures by the aid of sulphate of iron—in order to avoid the reduction that frequently occurs in the surface of the solution, and settles upon the film, from which it is impossible to remove it—I have been led to employ acetic ether, which sufficiently retards the appearance of the image, to avoid this reduction, and also the lines arising from the solution being poured on to the film in sufficient quantity. I have already communicated the result to the French Photographic Society.

But there remains another difficulty to be overcome. The sulphate of iron yields *grey* negatives which acquire sufficient intensity in the high lights only on condition of a little opacity. This is due to the crystalline state under which the reduced silver is found; and the crystals are larger and better formed in proportion as the sulphate of iron bath is more or less acid. This state of the silver does very well for direct positives but not for negatives.

I have thought by eliminating the free sulphuric acid and substituting for it an equivalent quantity of acetic acid, we might entirely avoid this inconvenience and secure to the developing solution the acidity required for it, so that the proof should not become stained by a reduction taking place in the interior of the solution.

I have arrived at the composition of the following developing solution, which is, perhaps, a little complicated, but which has during four months given me and others who have adopted it, the best results, and who have urged me to make it public.

Dissolve 100 parts of sulphate of iron in 500 parts of water; and if the liquid be not perfectly clear, filter it. Pour into it 25 parts of a very clear solution of acetate of lead, of the strength of 10 per cent, a precipitate is formed which must be allowed to subside. The liquid is then filtered, and 25 parts of acetic acid added; lastly, 450 parts of water containing 5 parts of acetic ether, and 5 parts of commercial nitric ether, is added to the above.

The liquid resulting from these mixtures may be preserved for a considerable length of time in well stoppered bottles.

The reaction is easily understood; by double decomposition sulphate of lead and acetate of iron are formed, which meeting with the free sulphuric acid, give rise to sulphate of iron again and free acetic acid.

The proportion of 10 per cent of sulphate of iron, answers very well in the circumstances under which I work, but it may be modified to suit the wishes of the operator.

## ON THE ACTION OF IODINE IN THE SILVER BATH.

BY M. L'ABBE' LABORDE.

I learn from the Society's *Bulletin* that Messrs. Girard and Thouret have obtained results entirely different from those published in my note upon the action of iodine in the silver bath.

I have therefore repeated my experiments, and again proved the accuracy of all that I have advanced, so long as I maintain things in the same condition. I could not attribute to the impurities of the iodides dissolved in the nitrate of silver the neutrality it maintained, notwithstanding the presence of iodine; for I have always prepared the iodide of silver by precipitating it from a mixture of nitrate of silver and iodide of potassium, and washing it in several waters before saturating the silver bath with it.* I then directed my attention to the solution of silver, which, as will be shown, exhibits a peculiar composition.

Before undertaking this research, I found it much easier to prepare a solution of ordinary nitrate of silver, saturating it with iodide, and after proving its neutrality, to introduce the iodine. I repeated this experiment several times, and like MM. Girard and Thouret, I recognized that in these conditions the silver bath quickly becomes acid, notwithstanding that it is saturated with iodine.

As the effect of the iodine depends upon the solution I employ, I shall endeavour to omit nothing while describing its preparation. Those who have justly reproached me with being too laconic, will pardon me any superfluous details, and not forget that my aim is to prepare a silver bath capable of giving an impressionable film of the greatest possible sensitiveness.

I dissolve some pieces of silver coin in nitric acid, and I then precipitate the silver by pure copper, such as the plates formed by the galvanoplastic process for daguerreotype purposes. After simply decanting the nitrate of copper, I throw a little hydrochloric acid upon the silver powder, and allow it to act for about an hour, and then wash it in several waters. I next dissolve the silver powder in nitric acid, introducing small portions of the metal at a time in order to avoid too great liberation of gas, and when the cold acid will dissolve no more, I gently warm it, and continue adding the silver powder so long as it is dissolved. The solution is evaporated to dryness; but I never fuse the nitrate of silver: this operation has too many objections. In this way I obtain a very acid salt, 140 grains of which I dissolve in 1,000 grains of water. I neutralize it by freshly precipitated carbonate of silver, added in slight excess; and I saturate this solution with iodide of silver, prepared in the way described above. I then add 1,000 grains of water, and filter. The method I have already advised for saturating the silver bath with iodide must be followed step by step. If the water it must finally contain be added in advance, it will never take up the quantity of iodide it ought to dissolve, even when we add iodide in excess. In fact, if we add a small quantity of water to a concentrated solution of silver, and which we believe is saturated because the iodide was added in excess, a yellowish cloud is formed, which is immediately redissolved; this fully proves that the solution was not saturated, since after having diminished its capacity for saturation by the water added, it is still capable of dissolving the iodide of silver thus presented to it in a state of minute division. Upon adding a further quantity of water, the weakened nitrate of silver finally rejects what it can no longer dissolve. The silver bath I employ, well saturated with iodide, contains then a feeble proportion of carbonate of silver, for this salt is slightly soluble in water. The part played by the carbonate of silver is easily understood: it neutralizes the acid in proportion as it is produced by the influence of the iodine; but when its action is exhausted, the solution quickly becomes acid. We must then seek another cause.

I have never employed iodine except in such silver baths as have already been in use, and which gave foggy negatives; for in practical photography, so long as a silver bath yields proofs entirely satisfactory, we should avoid "doctoring" it. I make use of a collodion iodized with iodide of cadmium;

* We must remark on this head that the iodide of potassium of commerce is always alkaline, and frequently contains as much as three per cent. of carbonate of potassa.—(A. Girard.)

and to increase its sensitiveness, I add a little nitrate of potassa to it. I have always filtered the alcoholic solution of this iodide before adding it to the collodion—not to separate any oxy-iodide from it, the presence of which I did not suspect prior to the recent communications of M. Martin —but because it is always a good precaution. It is true that by not employing absolute alcohol, I should have dissolved in part this oxy-iodide, and put in action the causes noted by M. Girard, as to verify them upon proofs was not an easy thing to do. I thought of nitrate of cadmium, which is found in large proportion in old silver baths, as every proof leaves a proportion equivalent to the iodide of silver it removes from it. To distinguish its special action I have dissolved it in a solution of silver, saturated with iodide, the acidity of which quickly manifested itself under the influence of the iodine; the presence of the nitrate of cadmium had retarded the acid reaction to such a degree that many days elapsed before it became very evident. I have obtained in a lesser degree the same effect from the acetate of silver dissolved in the bath. I made this second experiment because the ether introduced into the silver bath may acidify it in contact with the air, and transform the carbonate of silver into acetate.

I believe therefore that I am able to attribute to the carbonate of silver and to the nitrate of cadmium the neutrality which appears to persist in the argentiferous solution, notwithstanding the presence of iodine.

Iodide of potassium and iodide of ammonium do not communicate to the silver bath the same properties, for the nitrates are inactive. The nitrite of silver also has no action in this direction. I have been able to satisfy myself of it, as the collodion contained a little nitrite of potassa.

In these experiments we must take into account the secondary actions which I pointed out in my first note: thus, when fragments of iodine float about for a long time, or form bubbles of air in the bath, we perceive them quickly surrounded with the yellow iodide and produce a sensible acidity. To remove these causes foreign to the principal fact, we may at first throw very little of the silver solution upon the iodine, moisten it completely by agitating it, and replace this liquid by that we desire to test.

We must also beware of a fact which I believe it will be useful to note:—When the acidity of the silver bath is very feeble, and we proceed to test it with litmus paper, we must note its action at the very first moments; for after a short time the nitrate of silver forms with the colouring matter of the litmus a greenish-blue lake, which entirely masks the acid reaction; and if, as often happens under other circumstances, we wait, in order to give the acidity time to manifest itself more clearly, this blue tint acts upon the colour of the paper, and tends us to believe in an alkaline reaction, when in reality it is acid.

If it be desired to explain the apparent inaction of the iodine amid the circumstances above mentioned, we may say that it envelopes itself in an invisible film of iodide, which the nitrate of silver saturated in advance, can no longer dissolve, or even penetrate, except with extreme slowness in in presence of nitrate of cadmium: resembling in this respect, nearly, the passivity of iron in nitric acid when covered with an invisible film of oxide, which protects it from all ulterior action.

We may comprehend more easily the impotence of nitrate of silver, if we consider that it is in some measure saturated with iodide in a bath often used, because every operation weakens the nitrate of silver, without however, precipitating the iodide. It is true that it is replaced by nitrate of cadmium, but we may satisfy ourselves by direct experiment that the nitrate of cadmium, does not dissolve iodide of silver. It is recognised now, that, that to obtain a negative, the impressioned film must necessarily present itself to the to the developing agent with a tendency to acidity; a tendency which it will have derived either from the free iodide of the collodion, or from the silver bath. This acidity may be feeble enough to escape chemical tests, and still suffice to consolidate the purity of the whites, with the the maximum of sensitiveness. This is not the only case in which extremely delicate causes produce a new order of things in photography. We know, for example, the injurious action of hydrocarbon vapours: the quantity of these vapours acting at a given moment upon the sensitized film is so minute, that no reagent in chemistry can manifest its presence, while in photography, in the eyes of the enthusiastic photographer, it reveals itself by a failure. The slow and progressive action of iodine, in the conditions under which I employed it, has appeared to me excellent to produce this simple tendency to acidity, which I have often called apparent neutrality. We may perhaps, apply it to other baths, by diminishing the dose, and suspending its action when it is sufficient.

In all this we clearly perceive the nitric acid at work: but, the thing I cannot now explain, if the nitric acid be added directly, in homeopathic dose, it does not produce the same effects.

Since the efficacy of the iodine depends upon the nature of the silver bath, I ought to have spoken of it in my first note. I candidly confess that the method of preparing this solution, has become so much a habit with me, that it never occurred to me to mention it even to myself. I should then probably have tried the ordinary solution, and this would have led me to the completion of my communication.

I thank M. M. Girard and Thouret for making known the result of their experiments, and thus warned those whom I had temporarily set upon a wrong road.

## ON WASHING NEGATIVES TAKEN BY THE LINSEED OIL PROCESS.

BY M. L'ABBE' LABORDE.

Having the intention of resuming my experiments upon linseed oil employed as a sensitive varnish, I beg to refer to a note I addressed to the French Photographic Society on this subject, in August 1858. I concluded this by asking the co-operation of all those photographers who are stimulated by a new agent, to make researches; and in order to put them on the way which alone I believe will lead to success, I was careful to fully explain, in what the real obstacle consists. This very obstacle has been surmounted in a very ingenious manner by M. Fargier, in another process. I congratulate him upon it, as his success seems to justify my observations, and if I take the liberty of introducing them here, it is in order to be able to apply them to the linseed oil process, as I understand it, without being accused of plagiarism.

I copy them verbatim, as follows:

"I must point out the principal defect in this linseed oil process; the light tones of the negative disappear in the positive, when we pour upon the former ether, in order to remove the non-impressed parts; but yet they exist before this part of the operation; for upon breathing on the proof, after removing it from the negative, we may perceive all the details of the picture faintly. Upon this subject I shall make a remark equally important for the linseed oil process, as for the Bitumen of Judea process; in the sensitive film, however thin it may be, we must distinguish two surfaces; the one external, the other internal, applied to the very substance that supports it. The insolubility produced by the light, commences upon the external surface, because it is in contact with the air, which favours this action; in the parts most lighted, it penetrates little by little, until the inner surface becomes equally insoluble; but under the semi-transparent portions of the negative, it stops at the external surface, or penetrates it more or less, so that the interior surface retains nearly its original solubility. The ether afterwards spread upon a film thus modified, first dissolves the parts which were entirely sheltered from light; then, without dissolving them entirely, it little by little removes, in some measure, the parts feebly impressed, because, fixed upon the external surface, they rest upon a basis which has retained its solubility."

## THE TANNIN PROCESS — TRANSPARENCIES — INSTANTANEOUS PHOTOGRAPHY.

BY WILLIAM ENGLAND.*

As it is most desirable that everything coming under the observation or practice of the photographer tending to the advancement and development of the art should be made known, I venture to occupy your time with a few remarks. An additional inducement to me to ask your attention, is the interest you manifested in the pictures which I had the honour of exhibiting before you at the last meeting of this society. It is to the method by which those pictures were produced that I propose to call your attention. I do not pretend that I have much to say with which many gentlemen present are unacquainted, neither can I lay claim to much that is original, therefore it is chiefly to the details of manipulation I shall confine my observations.

The process I adopt is that known as "Major Russell's Tannin Process." I have tried many others, but have not been successful. Taupenot's gives impressions too hard and strong in the lights, faults which the utmost care in developing has not overcome. The same, too, may be said of the Fothergill process, so far as my experience proves, besides the many difficulties of manipulation; such, for instance, as washing the plate too much or too little, and the unevenness of development, due no doubt, to the albumen coating being porous in some places and horny in others, causing the print when finished to present a very patchy appearance. I do not say that all these faults are to be placed to these processes. Probably by very long practice they may be overcome, and good results obtained; but I really believe that the simplicity of the tannin process places it at the head of all other methods, and that with it finer results may be obtained, not only as transparencies for the lantern or stereoscope, to which it is so well adapted by the soft and beautifully warm tones produced, but also in the production of negatives.

Much has been said and written upon the long exposure required for tannin plates, and the great inconvenience of the film leaving the glass during development. In answer to the first objection, I may say that with a slight modification, to which I shall presently refer, and the choice of a suitable collodion, I have been able to reduce the time of exposure to the average length given to wet collodion developed with pyrogallic acid; and I have no doubt that were it possible to prepare a solution of iron, or some other equally energetic developer, suitable for developing tannin plates, pictures might be produced absolutely instantaneously. As to the film leaving the plate, I at first found some difficulty, particularly with very new collodion. I could not make up mind to albumenize or gelatinize my glasses, as recommended by some operators, previous to coating with collodion, not only on account of the time it occupies, but also the difficulty of getting a plate so prepared free from spots and dust. I can now, after considerable practice, prepare them in large sizes, and then cut to steroscopic without injury to the delicate film, by which means a saving of time is effected.

The collodion most suitable, so far as my experience enables me to speak, is prepared in the following manner:—To 5 parts of ether and 3 of alcohol, add sufficient pyroxyline to give a tolerably thick film. So soon as well settled, decant into another bottle, and measure off two portions of 10 drachms each: to one add 40 grains of bromide of cadmium, and to the other 30 grains of iodide of ammonium; shake till dissolved, and put by to settle. When thoroughly settled, add 1 drachm of each to 6 parts of plain collodion. I have tried various methods of iodizing, and prefer this mode to any other, not only on account of its being more free from spots, but also that immediately after iodizing it is in as good a condition for working as the usual collodion after being iodized some days.

During a great number of experiments in trying to increase the sensitiveness of dry plates, I found that the addition of honey had a remarkable accelerating effect, and by rendering the film less horny assists materially the development of the image. I am quite aware that the use of honey in photography is not new. We all remember the charming productions of Mr. Llewellyn and Mr. Maxwell Lyte; but honey used simply or in combination with acid, as in the oxymel process, leaves the plates tacky and liable to injury from dust. This is not the case by using it in the proportions I shall presently recommend in combination with tannin. By following this method, and using collodion prepared as before-mentioned, the time of exposure for stereoscopic pictures in a good light would average not more than from ten to fifteen seconds.

After cleaning and coating the glass, sensitize in a 40-grain bath, and wash in a second bath of distilled water, to which has been added 30 or 40 drops of acetic acid. The plate may remain in the latter while a second is being prepared. The plate is then thoroughly washed under a tap, and coated with the tannin solution composed of 15 grains of tannin and 15 grains of honey to the ounce of water. It is then ready to be placed in the box to dry.

I may here remark on the great care necessary to avoid stains. If possible, a silver dipper should be used, being more convenient to hold the plate in washing. When necessary to handle the plate, do so with a piece of blotting-paper; also, in coating the plate with tannin, lay a piece between the plate and fingers.

The drying box I find convenient has three shelves, and up one side is fixed a tin tube, under which a spirit-lamp may be placed.

After the necessary number of plates has been placed in the box, it should not be opened till they are perfectly dry, otherwise a stain will appear across the plate where the action of drying has been checked by the admission of cold air to the box. Daguerreotypists will readily understand this from the difficulties they may have experienced in drying off Daguerreotype plates, particularly the larger sizes.

To prevent the film leaving the glass, an excellent plan is to pass a sable pencil, previously dipped in a solution of white wax and benzole, round the edge of the plate to the extent, say of one-eighth of an inch. This, for the purpose, is far superior to spirit varnish. The plates may then be stowed away ready for use, and, if properly prepared, will keep six months.

On removal from the camera, place the plate in a bath prepared with 10 grains of nitrate of silver and 5 drops of acetic acid to the ounce of water, allowing it to remain about one minute. By the adoption of this plan for dry plates, the action of the developer is almost as rapid as in the wet process. Afterwards develop with the usual 3-grain solution of pyrogallic acid. The development is so similar to wet collodion that I need not remark further than that no fear need be entertained of the film breaking up, the edges being kept perfectly dry and tight by the wax border.

The second subject of my paper is the printing of transparencies. The mode of preparing the dry plates is much the same, except that for this purpose old collodion must be used. If of a dark red so much the better; otherwise in printing from a strong negative it is impossible to get an impression clean and well-defined, on account of the tendency of new collodion to solarize and present a weak and foggy impression: better tones will also be obtained by reducing the coating solution to 10 grains of tannin and 5 grains of honey to the ounce of water; the developer should likewise contain citric instead of acetic acid, as recommended by Major Russell; and unless a considerable amount of silver is added, the print is sure to be red or reddish brown, instead or purple. Pictures for the lantern should be thin, very clean, and well defined; not developed so deeply as those for the stereoscope.

I will conclude by making a few remarks upon instantaneous photography; and here I may say that a very large amount of patience is necessary, and that failures are very plentiful—bad light, the absence of the sun at the identical moment the plate is most sensitive, the variations in the quality of the chemical agents employed, and, above all, the difficulties that attend the nitrate bath, which will sometimes unaccountably persist in giving foggy impressions. Again, we get beautifully clear plates, but with very little impression beyond the high lights. Now all this is very disagreeable; but such is the case at present, and will continue to be, I fear, until we have a dry process sufficiently sensitive. Where time of exposure is no object, of course we do not meet with these troubles.

The collodion used in taking the negatives of the impressions I have the honour of placing before you, was prepared in precisely the same way as before-mentioned, except that in iodizing, I use 3 grains of bromide of cadmium, and the same amount of iodide of ammonium, to each ounce of collodion.

I am an advocate for the liberal use of bromides, having experienced their beneficial effects, particularly in photographing objects presenting violent contrasts of lights and shades. Under

* Read at a meeting of the Photographic Society on Tuesday evening, April 1.

such circumstances I should use the bromide considerably in excess of the iodides.

The nitrate bath should be of the strength of 40 grains, saturated with iodide of potassium, and perfectly neutral.

I need scarcely remark that the utmost care is necessary in the preparation of the bath, also in the selection of nitrate of silver, which should be pure recrystallized, otherwise the amount of acid to prevent the plate fogging will materially injure the sensitiveness. We do not experience this so much in ordinary working, where the time of exposing the plate is not limited. With every caution in preserving the bath from injury, I have never been able, in working instantaneously, to use it more than five or six days; after that its sensitizing properties diminish rapidly, but it is still very good for general purposes. Another important point, too, is to expose the plate within a very short time after its removal from the nitrate bath, or it will lose much of its sensitiveness. Here is one great cause of its failure, as oftentimes the sun disappears behind a cloud just as the plate is no ready. There is no remedy but to try again.

A word or two may here be said upon the form of lens best adapted for rapid working. For street views and public buildings, I find it a great advantage to be provided with three sets of double achromatic of the respective focal lengths of 5½, 4½, and 3½ inches. By this means one is enabled to enlarge or reduce the image to the size suited to the plate. I prefer using the first-named, being with that enabled to use a larger stop; but in copying architectural subjects in crowded localities, want of space oftentimes compels one to resort to a lens of shorter focus, and consequently a smaller stop. In all cases it may not be convenient to be so liberally provided. To those not having at command a variety, I would recommend a lens of 4½-inch focus as being the one most useful. Cannot some of our best opticians construct for us a lens which would enable us to vary the size of our picture where distance, or rather the want of distance, confines us to one spot? What, for instance, displays worse taste than copying a public building, leaving out foreground and sky? and yet the operator is sometimes reduced to this or leave out altogether.

I have made many experiments in the mode of exposing the plate, in placing the shutter in front of the lens; also immediately behind it; and lastly, near to the plate, which answers perfectly. I have found, by using the drop in front of the lens, a want of definition in the corners of the negatives. I mentioned this fact some time since to my friend Mr. Dallmeyer, and should be pleased to hear if he has devoted any attention to the subject. By placing the shutter on the dark slide, and having a contrivance to lessen the size of the slot, we can get different lengths of exposure, which is sometimes an advantage, although, of course, it is advisable in all cases to give the shortest amount of exposure the sensitiveness of the plate will allow, otherwise moving objects will not be well defined.

The developer I generally use is proto-sulphate of iron, 2 oz.; water 1 pint; acetic acid, the least possible amount, which I determine according to the temperature, varying from 4 to 8 drachms. Should too much be added, it is not so easy to develop objects in the shade. After the impression is fully developed, strengthen with pyrogallic acid.

I have now, gentlemen, given you the details of my mode of operating, and should I not have made myself sufficiently understood, I shall be happy to answer any question. In conclusion, I beg to thank you for your patient attention, and to assure you that I shall be pleased if what I have said should elicit further information from the members present.

## PHOTOGRAPHIC MICROGRAPHY.

BY A. L. NEYT.*

The study, so full of attraction and mystery, of the infinitely minute in creation, by the microscope, has induced me to seek some practical method as a substitute for drawing,s designed by the hand, or by the aid of the camera lucida, a mode of reproduction at the same time more rapid and more exact. Until the present time, micrographists are constrained to design their own drawings, and, if they wish to publish, entrust to engravers who are strangers to the science, the retracing of these designs. In this way important details are often neglected or falsified; for it is very difficult to an artist, and even to some scientific observers, to avoid following their own views or fancy in rendering those parts which the microscope has not perfectly resolved. It thus happens that new discoveries often give rise to discussions, and, as it is at times difficult to preserve an object more than a few hours, it becomes impossible to submit it to other observers, in order to decide the matter more positively. I have thought that photography could remove these obstacles, by furnishing a means, rapid and faithful, of reproducing the observations made by the microscope.

At the period when I commenced my researches, I was ignorant of the fact that M. Bertsch, of Paris, who has rendered much service to science, had already produced several photographic proofs of microscopic objects. An English photographer, and also another in Munich, have been equally engaged in these experiments; but no one has up to the present moment reproduced living animalcules, such as *infusoria*, and it is upon this branch of the science that I have directed my efforts. I send you herewith some examples of my labours.

The apparatus of which I have made use is the heliographic microscope of M. Bertsch, constructed by M. Hartnack, a worthy successor of the celebrated Oberhaeuser, his uncle. This instrument is very perfect, as well in its mechanical as its optical arrangements.

The general appearance is similar to an ordinary solar microscope. The mirror with parallatic movement, serving to reflect the solar rays in a constant direction, is replaced by a large prism, which gives a complete reflection, and offers less resistance to the wind. The stability is thus very great. The achromatic condensing lens is 2¾ inches in diameter. The focus is provided with three converging lenses, which may be used either alone or simultaneously, according to the power of the object-glasses employed.

I have attached to this, two diverging lenses, completory to the focus of the condensing lens, in order to obtain a beam of parallel light in cases where I use lenses of large field, such as are necessary to obtain great sharpness. The apparatus is achromatised in such a way as to make the foci yellow and violet rays correspond, these latter being the actinic rays. In ordinary apparatus, as is known, it is the yellow and red rays which are united; but in this case, too much heat would be developed on the object to be reproduced; besides which, we should have a visual focus which would not coincide with the chemical focus, and this would give rise to an almost insurmountable difficulty in focussing, an operation already more than sufficiently delicate. The microscope constructed by Hartnack transmits all the rays horizontally; we are obliged, therefore, to work on a vertical plane, which is very troublesome when operating on liquids, which is necessary in the reproduction of *infusoria*.

The little glass which covers the object is retained, it is true, by the drop of water; but, if it be a little too heavy, the whole of it glides insensibly from its position, and delays the work. If this do not happen, another obstacle presents itself: the water has a tendency to form near the edges of the thin covering glass a greater depth than at the centre. The animalcules seek refuge incessantly in this greater depth of water, finding here greater liberty, and they are, consequently, always going out of the field of the apparatus. To obviate this inconvenience, I have brought the plate of the instrument into a horizontal position, interposing under the focus an illuminating prism, and then *immediately* above the object-glass a second prism (this is of quartz, and as small as possible), which sends the rays in a horizontal direction. In this way the difficulties detailed above may be removed, and, for the rest, all remains in the same condition as before. The loss of light arising from the interposition of two prisms is nearly *nil*.

Directly under the object is placed a graduated series of diaphragms. I have added to these at the point where the rays leave the instrument, when I use it horizontally or in the

* *Bulletin Belge de la Photographie.*

dark chamber (if I have it bent), compensating prisms. I throw the image on the focussing-glass of an ordinary camera without a bottom, and I focus. This done, it remains to regulate the focus. By varying the position which it occupies, a greater or less intensity of light may be obtained. When the focus is brought exactly on the object, the image of the sun is formed at the same time upon the screen or ground-glass. By throwing the focus a little behind, a blue point appears in the centre of the field, which, however, disappears in the enlargement. The adjustment of the lenses should be arrested when this point spreads itself over the whole surface of the image, as this is the light possessing the most actinic power. The remainder of the operation consists in receiving the image on the sensitive glass, in the same way as taking an ordinary portrait or view, the microscope in this instance acting as the object-glass. While I am uncovering the sensitized glass in the camera I intercept the light by means of a yellow-coloured glass, taking great care that the room is well shaded from light. I then withdraw the yellow glass rapidly, in order that every part of the picture shall be equally exposed. The length of exposure varies with the enlargement employed. In good sunlight a linear enlargement of twelve hundred times may be obtained in seven or eight seconds at the most. Those of about three hundred times require but the fraction of a second. I, in this case, replace the yellow glass by a shutter, in which the duration of the exposure is regulated by a little wing similar to that which is applied to the striking of a clock.

The process which I regard as the most suitable for the purpose is the wet collodion process. The remainder of the operations are in every respect similar to the ordinary well-known methods of operating. In the reproduction of *infusoria* a great difficulty presents itself—namely, their very rapid movements among themselves, the effect of which is increased by the enlargement. However rapid the operation may be, it is still too long to seize the vibratory motion of these *ciliæ*. To kill them by poison is not quick enough, and deforms some of them. In order to attain the object in view I have recourse to the electric spark or to a galvanic current. I attach to the stage the two poles of a Daniell's battery, or of a small induction coil in such a way that the poles shall be in contact with the drop of water. The circuit is interrupted near the source of the current which I have near my hand. I follow the movements of the *infusoria* on the glass by means of the yellow glass. When I consider the position favourable, I complete the current by simple contact. The animalcule is killed as with a thunder-stroke in the place I have chosen. With a little practice this operation becomes simple and easy.

When it is desired to reproduce objects of a yellow or brown colour, which colour does not give the actinic rays, I avail myself of a small polarising apparatus, which I introduce under the object at the point of the focus. In this manner I can modify the tint generally, and render it more photogenic.

The application of photography to the reproduction of microscopic observations may be made, I think, to render great service to science, by allowing the possibility of supplying the public at a low price with engravings of microscopic investigations, these plates having hitherto been of a very high price. It will be possible also to furnish impressions of these plates on copper, engraved by the ingenious process of M. Chas. Nègre. These plates will possess incontestable accuracy, and a delicacy to which the hand of man could never attain, and would be producible at a price which will be much reduced when compared to that of engravings.

## THE *SATURDAY REVIEW* ON PHOTOGRAPHY.

The *Saturday Review*, always severe, often inconsistent, and seldom just, has recently indulged in one of those atrabilious outbursts for which it has acquired a certain notoriety. Photography in this instance is the subject of its spleen. The article to which we refer is headed "Fashion," and contains incidental flings at petticoats and preaching, crinolines and sermons; but the fashion at which it rails in "good set terms" is photography. It will amuse our readers if nothing more; here is a sample :—

"Photography, again, is a fashion that perhaps may last longer than all the nuisances it entails might lead one to expect. It certainly brings nuisances with it that may make the most patient man wish the sun had never been put to this horrible purpose. Sitting to a photographer is not quite so bad as going to a dentist, but it is something near it. In the first place, the leading photographers make appointments or grant a sitting as if they were high Government officials giving away clerks' places to troublesome but deserving people. Then the photographer himself is a trial. Probably he finds his sitters bores, and he would make a much less lucrative thing of it if he allowed the sitter and the sitter's friends to interfere. Still it is a nuisance for a lady to be carried off from her husband or other male person in charge, and be treated by a smirking fifth-rate artist for half an hour as something between a convict and a baby. In the case, more especially, of young girls, we must add that this system of separate sittings is something much worse than a nuisance, and ought to be resolutely put down. Then the eminent photographer who thinks himself sure of his business is the most audacious of men. There is nothing he will not say to put down criticism and inquiry. A lady went lately to be taken with a little girl. The money was paid, and in about a week or ten days the thing was pronounced to be ready. The lady was all very well, and so was the upper part of the little girl's figure, but below the petticoat she shaded off into two faint wavy columns like the reflection of trees in water. Remonstrance was made, and the eminent photographer had the assurance to say that artists had now given up putting in legs. Then a quiet, unoffending man is sometimes overwhelmed with what seems to him the joke and mockery of the attitude in which, under the eminent photographer's directions, he is offered to his friends. A gentleman of a solid, humdrum appearance, with only that sort of romance about him which women cannot detect, was recently persuaded to sit. He sat, and the eminent photographer did his best. But it was a failure, and two or three more sittings came off in vain. At last the eminent photographer expressed himself much pleased. By the judicious introduction of a background, and a few objects being placed so as to break the stiffness, success had been achieved; and this is what the photograph presented. The unfortunate man was standing with his back to the Lago di Garda. He was placed on the top of a grand marble staircase, near a splendid balustrade. In one hand he held a very new borrowed silk umbrella, and he was supported on the other side by a friend's hat. It is bad enough to be depicted in this way, but the mere being depicted is a very small portion of the whole business. After the photographs are sent home comes the worry for them. There is some sort of pleasure in giving them to very near relatives and very dear friends. We all like to fancy that there are a chosen few who really care to have a likeness of us, although it does represent us bareheaded, and surveying a new hat on the banks of an Italian lake. But the demand for photographs is not limited to relations or friends. It is scarcely limited to acquaintances. Anyone who has ever seen you, or has seen anybody that has seen you, or knows anyone that says he has seen a person who thought that he had seen you, considers himself entitled to ask you for your photograph, and to make you pay eighteen-pence in order to comply with the demand. There is no compliment in it. The claimant does not care about you or your likeness in the least. But he or she has a photograph book, and, as it must be filled, you are invited to act as padding to that volume, and to fill a vacant space between Prince Max of Hesse Darmstadt and the amiable owner's third brother, as he appears in the comic costume of a navvie. It is not even grown-up people only who ask in this preposterous way for photographs. Children and babies have got their photograph books, and say that they really must have your likeness. They protest they will not know what to do with their miserable young lives unless you consent to pay the eighteen-pence for them, and figure in their collection. This is terrible. People who are not accustomed to them do not generally much care for infants in arms, but those precious darlings will rise in estimation now. They may have an awkward habit of bending suddenly in the back, as if they were made of soft leather, but at any rato thoy cannot possibly ask for your photograph.

"We do not for a moment dream that the fashion of photograph collecting will die out. In tho first place, tho gain of having cheap portraits of friends is so great that there is a solid advantage in photographs which would countorbalance a great many nuisances of a very serious sort. And then the collections when mado are very useful. They supply a fund of talk to people who have nothing to say. Everyono can find something to remark about a collection of photographs. Either they do not know the people represented in it, or they do know them, or they wonder whether they know them. Then, if they know them, they can say they are like or unlike; or they can pay adroit compliments, and make acceptable remarks on the photographs most cherished by the collector; or they can gratify a little quiet malice, and say that they never could havo believed so very unfavourable a likeness is a true one, and yet every one knows tho sun must bo right. It is this fund of easy small-talk which will be the real foundation of the permanent success of photography as a fashion. It might easily have happened that photograph books would have shared the fato of albums. Thirty years ago, young ladies used to keep albums, and people used to be decoyed or frightened into writing in them. Authors of all sizes and degrees of reputation were entreated to add their mite. Charles Lamb's letters, for example, are full of references to the albums he had been writing in. But the weak point of albums was that, where they were not occupied by magnificent water-colour representations of perfectly round roses in tho fullest bloom, they were too intellectual. People in an ordinary drawing-room think there is a sort of plot to find them out if any demand is made on their intellect; and to write verses, or even to copy correctly a piece of poetry out of a standard author, is dangerous and embarrassing. It is true that writers in albums were occasionally allowed to get off by writing out in their best hand one of the poorest and best-known riddles they could recollect, such as "Why is Athens like the wick of a candle?" but even this is precarious, for the answer has to be remembered and understood. In photographs all is plain sailing. All that has to be done is to make gossiping remarks about other people, and this is a duty to which the most timid intellects feel competent.

"Photographs are, then, a fashion; but it is possible they may be what, considering tho mutability of human things, deserves to be called a permanent fashion, because they tend to supply a want that will always bo felt. It is the same with ladies' novels, and other records of the inner life and language of young women. This species of composition is a fashion of the day. Half a century ago the dear creatures either had no self-inquiring, dreamy life-shadowings, or else they kept them locked up. Now printers can hardly print fast enough to keep pace with all the outpourings of lady novelists. The supply is like that of an Artesian well—it is perennial and ever-flowing. We venture to say that if anyone offered a small prize for a tale of woman's feelings, there would be at least five thousand competitors. It is a fashion that we do not take much interest in; but we admit that it gives something that was wanted. Most women have a latent gush in them; and if the gush does not flow out in marriage, it gladly finds vent in print. As long as there are single women with unrequited feelings, or married women who can make this sort of production pay, and as long as printing is cheap, so long will the lady's novel last. Perhaps it will improve, but anyhow it will go on. There are other fashions, as to which it is more difficult to guess whether they will last or not. Morning calls, for example, seemed a deep-rooted habit of English society, and yet they are almost a thing of the past. Will sermons go too? * * * will the ordinary half-hour cut and dry discourse, in which neither the preacher nor the congregation pretend to take the slighest interest, go on in England? Very likely it may; for it serves somo objects, though not very high ones. And if it is objected that we cannot believe our posterity will always stand what does not please or profit them, the answer is, that we stand the sermon, and we stand being submerged under confluent waves of crinoline at dinner, and we stand audacious children squeezing out our photographs from us. And if we can stand all this, why should not others? There must be some burdens that are always borne, and some fashions that do not pass away."

## Proceedings of Societies.

### American Photographical Society.

The regular meeting of this society was held at the New York University, on tho evening of March 10th, President Draper in the chair.

After some local business of minor importance, Professors O. N. Rood and Edwin Emerson, of the Troy University, were elected honorary members.

President Draper suggested that communications on Electrotypography be invited and received by tho society, to be preceded of course by Photographic matters.

On motion it was so resolved.

Professor Seely made a few remarks on iridium, used as a strengthener of negatives, and showed two negatives so treated.

Mr. Rutherford spoke against tho propriety of producing any metallic deposit on the surface of a negative, as there must be a deposit also formed at the edges of the fine lines, thus destroying the sharpness to a degree. To change the subject, he asked for information about tho *hot water accelerator* for tannin plates.

Mr. Hull had tried the hot water development with great success. He exhibited three tannin negatives of the same subject, and taken at the same timo. One exposed one and a half minutes, and developed cold in the usual manner; the second after ten seconds exposure, and tho third after six seconds exposure were developed by tho hot water treatment. The six seconds negative was the best of all.

Colonel Pike had taken some instantaneous pictures on tannin plates, using an instantaneous shutter on his camera and developing hot. He showed a remarkably clear and bright street view taken in this way. He also exhibited to the society his shutter and mode of working it, by which he could regulate tho exposure to the fiftieth part of one second. He always left a trace of nitrate of silver in his tannin plates, *a la* Fothergill, and found the sensitiveness very much increased, but the keeping qualities of the plate were deteriorated. He also added sugar or rock candy to his tannin solution, as it increased the density.

Mr. Thompson had obtained an instantaneous picture on a fresh tannin plate, using a pair of short focus Ross' view lens quarter of an inch diaphragm. The negative was very clear, tho time on a church clock half a mile distant being distinctly visible under a lens.

In answer to a question, Colonel Pike said he used albumen to coat the glass with in preference to gelatine, as recommended by Major Russell. He found the latter had a harsh effect on the picture.

Mr. Hull opposed albumen or any other coating for the glass before collodionizing. He exhibited a number of prints from negatives without any film between the glass and collodion. The best way is to simply run an edge of albumen with a camel-hair pencil, around the plate. This would effectually hold the film in developing and washing. He found that there was less action of light where the albumen had been used than in the centre of the plate. He found that pictures on these plates would keep a month or more between exposure and development.

Mr. Wetmore showed the Society a card portrait taken on a tannin dry plate, under a ground-glass sky-light, with one minute's exposure. The negative was developed with hot water treating, and the resulting print from it was very clear and distinct, even in the deepest shadows of tho drapery. He also passed around an instantaneous cloud picture on the same kind of plate.

Professor Joy called attention to Professor Emerson's improvement in the stereoscope, as manufactured by Messrs. Anthony. It consists, as we see by the one now under inspection, of a mechanical contrivance to move both lenses apart or together simultaneously while looking through them, thus enabling any person to "catch" the stereoscopic effect with ease. Pictures five inches in diameter, mounted as stereographs, could be viewed without pain to the eyes.

Mr. Thompson had had one made by Mr. Anthony with whole lenses, which he considered an improvement on the half cut lenses now used. Professor Emerson's improvement was endorsed by all who had seen it.

A number of fine calotype negatives and photographs of large size were presented to the Society's Museum by several gentlemen, and were much commented upon and admired by the members present.

On motion, adjourned to the second Monday in April.

## Correspondence.

### FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

*Paris, 9th April,* 1862.

Among the most remarkable photographic productions that will figure in your approaching universal exhibition, are some pictures of very large dimensions, representing views in Egypt, taken by M. Cammas. Specimens were exhibited at the last meeting of our Photographic Society, and excited much admiration. Herr Pretsch also presented some new proofs of heliographic engraving in relief, obtained by the process he published in 1854, in France and in England. He insisted that his proofs were not retouched, although the existence of a *grain* over the plate might, at first sight, render this hypothesis possible.

M. Gerard remarked, that having recently had occasion to examine Herr Pretsch's process of engraving, he found in the description given by the inventor, an indication which has possibly not been sufficiently remarked upon, but which would doubtless furnish an explanation of the cause of the general grain in the plates, and consequently exculpate Herr Pretsch from the charge of retouching. M. Gerard stated that, after having caused chromatised gelatine to be soaked in water, and before taking in relief the impression thus produced, he washed it with alcohol; and it is probably owing to the superficial contraction which is exercised by the alcohol, and a general cracking of the whole surface that ensues, that the effects of grain remarked upon the proofs of M. Pretsch are due.

M. Regnault, the president of our photographic society, has made an appeal to the generosity of those who are in possession of proofs which may possess an historic interest in the art of photography. The society already possesses specimens of the first efforts of Daguerre, Talbot, Bayard, Niepce de Saint Victor, Taupenot, and others. A collection of all these works must necessarily possess the deepest interest, and the president thinks that all who have it in their power to enrich it will take pleasure in so doing. Among the more recent contributions to the collection are some positives obtained by the last carbon printing process of M. Poitevin, presented by M. Vidal, of Marseilles; and a positive and a negative upon albumen, obtained in the earliest days of M. Niepce de Saint Victor's albumen process on glass.

M. Balsamo, of Lucca, has made a communication on the subject of his phosphorus process, he says: "I have only just seen Dr. Schnauss's remarks in the *Moniteur* on my phosphorus process. The proofs I have obtained are perhaps not first-rate, for want of good negatives and suitable apparatus, but they sufficiently demonstrate the facts announced in my *Mémoire.* Instead of attributing the ill-success of my experiments to charlatanism, Dr. Schnauss had better seek the cause in some peculiarity which has escaped his notice. He is wrong when suggesting the application of heat; by warming the sensitized paper a chemical action is produced directly opposed to photogenic action. To make sure of obtaining an image upon the paper saturated with the phospho-hydrochloric-cupric solution, it must be left to dry spontaneously at the ordinary temperature. I beg, therefore, that Dr. Schnauss will repeat his experiments without exposing the paper to the action of heat, for solar heat suffices to remove all sensitiveness from the paper. He will then see that my theoretical explanations have a practical value, and that the word charlatanism exists neither in my dictionary nor in that of urbanity. He will render me justice, and I shall then pursue photo-chemical phenomena hopefully. I can tell him that I have not only obtained the solution of phosphorus, which he regards as a new phenomenon, but also the black modification of it by an electric polarization of the phosphorus in hydrochloric acid.

Our society is not indifferent to the result of the action for piracy, in which Messrs. Mayer and Pierson were cast, as it involves a question of the deepest interest to photographic property. A committee is now engaged in the examining what measures it may be advisable to take, and to place the matter before the Commission appointed for the preparation of a law upon literary and artistic property.

Messrs. Gilles, frères, have recently constructed what may justly be termed a universal camera. The focus ranges from ½ inch to 70 inches; it enables the operator to take pictures of every size, from the *carte de visite* to half life size, with objectives from ¼ inch focus to 6 inches.

M. Adolphe Martin has made an important communication on sulphate of iron developing solution, which will doubtless remove any objections that may now exist for this substitute for pyrogallic acid; and M. the Abbé Laborde, has replied to the objections raised against his theory of the action of iodine in the sensitizing silver bath; he has also made a communication respecting the washing of proofs in the linseed oil process, which may have the effect of rendering that process practicable.

Some cannon have recently been cast in Austria, composed of a new alloy which is said to be more tenacious than the best iron; it is composed of 600 parts of copper, 382 of zinc, and 18 of iron; it is easily forged and bored, and while cold will bend without breaking. Another alloy, as a substitute for silver, is proposed by M. Trabuc, of Nisines; it consists of banca tin 375 parts, nickel 55, regulus of antimony 50, bismuth 20. One-third of the tin is placed at the bottom of a crucible of suitable dimensions, together with the nickel, antimony, and bismuth; upon this first layer a second third of the tin is deposited and covered with charcoal to the depth of 1½-inches; the crucible being covered up, it is heated to a white heat, then with the aid of a iron rod, also heated, we ascertain if the nickel be melted and the antimony be reduced, in that case the remaining portion of tin is passed through the charcoal, and the whole stirred until a perfect mixture of the different metals is obtained, it is then cast into ingots or other forms. The colour of this alloy is silver white, and it resists the action of vinegar and other vegetable acids.

### PAINTING LANTERN SLIDES—GLASS GUIDES —ROSS LENSES.

Sir,—A friend of mine, who painted some slides for me, used the usual oil tube colours, which he pressed out of the tubes on to a little clean blotting paper, in order to absorb the superfluous oil, and then mixed the various tints with a medium composed of about equal parts of copal varnish and turpentine. The glass, I believe, was formerly prepared by pouring over a very thin solution of Canada balsam and turpentine. There is, I believe, a young man residing in Cheltenham who colours magic lantern slides.

I have lately cut out some glass guides from thick ground glass, and they have the advantage of not slipping about like the polished glass, and yet are sufficiently transparent to allow one to see where to put them on the carte de visite stereo slide, &c.

My glass room being very short I have been using Ross's new stereo lenses for carte de visite portraits, using diaphragm No. 5, they fill out so well, and give so sharp a picture, that I am induced to recommend others who have those lenses to give them a trial for that purpose; eight to fifteen seconds is generally sufficient exposure. I enclose two prints from negatives taken with these lenses. The vase and stand I have copied from Messrs. Bull's work, best made, the high lights much darker than the originals, and now they seem to me to be too light.—Yours truly, Thomas Gulliver.

17, *Heathfield Street, Swansea.*

[The pictures are exceedingly well covered for a lens of such short focus, and which, it should be borne in mind, was never intended by the maker for such work. Where the glass room will permit, we recommend the use of lenses of much longer focus.—Ed.]

## Talk in the Studio.

The Alkaline Dry Process.—A correspondent of *Humphrey's Journal* says:—"I have been lately trying the various dry processes—the tannin, resin, and sinc-preservative process—so as to be ready for the field next spring, and have obtained good negatives from either. Last evening, having read in the *Journal* Bartholomew's new and simple gelatine-alkaline process, I set right to work and dried six plates, which I exposed and fixed this morning, all with perfect success. They are all they claimed to be; not one showed even an inclination to peeling or blistering, without any precautions taken, and *par excellence*, seem fit for in-door animated views. What a boon this will be!" Have any of our readers in this country tried the process further?

Amateur Photographic Association Prize Prints.—We have recently had an opportunity of looking over the prizes and other prints from negatives contributed to the Amateur Photographic Association. The prizes are all excellent pictures: perhaps that of Lieut.-Col. Shakspeare, of "Corfu from the Island of Vido" is in many respects the finest, both as a work of art, and as a specimen of skilfully surmounted photographic difficulties. The picture, when trimmed and mounted, measures 13 inches by 9 inches, and is apparently an instantaneous picture. It possesses an exquisitely perfect natural sky with delicate clouds, the soft refections of which in the water are charmingly rendered. "Hoar Frost: a park scene," by the Earl of Caithness, is a very perfect piece of photography, but is too mechanical in composition to please our taste. The other prizes are also good in many respects. Tastes will, of course, always vary; but we fancy that some which have only received honourable mention are superior to some which have received prizes, especially in artistic characteristics. Our own choice would certainly have fallen upon some of the productions of Captain Plaiflin, Mr. Edwards, or Mr. Ebbage for some of the prizes. Mr. Coles' "Bow Church" taken on a tannin plate, which we don't see mentioned at all, is exceedingly delicate and fine. There are many good pictures in the portfolio, which we cannot refer to in detail. There is, of course, as we from our Exchange-Club experience anticipated, a large mass of mediocre photography and common-place subjects; but very little, nothing that we remember, absolutely bad. The varied exhibitions of British and Foreign Photography, which photographers will have an opportunity of inspecting during the coming summer, will, we trust, give a fresh impetus to the artistic progress of photography, which we so often see desirable.

## To Correspondents.

*** To Advertisers and the Trade.—Next week the Photographic News will be published on THURSDAY.

D. D.—Where it is convenient, a glass room should be built so that the sitter should face north or north-east, in order to secure a steady light all day long. Whichever direction it be built in, it is important to have an open expanse of light uninterrupted by high buildings, &c. The size must largely depend upon the class of operations intended; for moderate purposes 25 feet to 30 feet long, and 14 feet to 18 feet wide, will give a good size. The height about 8 feet in the lowest part, running up to about 14 feet. Decidedly as much glass at the sides as you conveniently can.

F. P.—In asking "what is the size of a whole plate lens," we presume you mean of what diameter are the lenses in the combination. They vary in lenses of different makers: from 3 inches to 4½ inches.

Thomas Martin.—The object of acetate of soda is to convert any free nitrate of silver into an acetate of silver; but as we have no means of estimating correctly the quantity of free nitrate in the prints, it is difficult to state what quantity of acetate will be required. The only plan is to use the solution over and over, and strengthen from time to time, when a precipitate of acetate of silver ceases to be formed. 2. In developing large plates the plan of first washing the plate with a little distilled water, then applying the developer, and afterwards adding the silver and distilled water is, an excellent method of avoiding stains, and also conduces to softness. We see no objection to the plan at all.

W. G. H.—We do not know of any.

Cornish Chough.—We will take an early opportunity of trying the collodion and reporting upon it. The operation of the oxides of methyl in collodion is but little understood. There is a strong prejudice against their use in many quarters, which we conceive to be without good ground, as after considerable experience we never detected any injurious results. Their operation in discharging the colour from free iodine, or preventing its formation, is generally observed only when a bromide is present as well. The reason is not understood. A very excellent plan of precipitating excess of acetate of silver is to weaken the bath by the addition of an equal volume of distilled water, lower the temperature as much as possible, and filter out the precipitate which will fall. Then make up to the proper strength.

Bolus.—You will get the feet of your sitters better lighted by extending the amount of glass in the sides of your room. Your screens for arranging the disposition of light and shadow may be of white calico; judgment and taste alone can guide you as to their disposal, as they will continually require varying to suit circumstances.

E. Clark.—Either of the iodizing formulæ referred to will give good results; but we prefer that on p. 84 as being the one we generally use, and have most experience with; we think it will possess greater keeping qualities than the other. We see no reason why you should not succeed in iodizing for yourself. If not try No. 1 or No 3, or a mixture of either with No. 2.

Nonplussed.—You kept the solution too long, and the gold has been gradually reduced in the form of a dark powder as you describe. Never mix more than you will use in a few weeks at most. 2. The addition of any acid to a solution of hyposulphite of soda tends to decompose it. The addition of a strong acid like nitric would certainly do so; the milkiness and the smell of rotten eggs you describe indicate that decomposition has ensued. The bath may still be used for fixing negatives, but it is so much weaker than before. The addition of a few drops of *acetic* acid has been recommended for the fixation of collodio-albumen plates; but it is not necessary with wet collodion plates.

A. R.—A light bluish grey is a good colour for the inside of a glass room.

J. H.—The Referees of the Photographic Exchange Club are obliged by your kind suggestion; but they have undertaken their work without desire for reward. In any case it will be obvious to you, that whilst we might be willing to give publicity to your wish as regards our colleagues in the matter, being ourselves concerned, we cannot with any propriety insert your suggestion in our pages.

Young Photo.—If your lenses admit of the arrangement, you may use the front lens, reversed, as a landscape lens. Or you may use the combination as it is, well stoppered down. Try either the tannin or the collodio-albumen process; the first is the simplest, the latter the most certain. You will find a good deal of information in the Almanac which you have by this time received. Mr. Hughes' recently published shilling Manual will also help you.

Subscriber.—The best method of becoming familiar with all connected with alkaline toning, is to read the various communications on the subject which have appeared from time to time in our pages. There is no work published on the subject. The Photographic News Almanac contains a concise and clear statement of the various formulæ recommended.

An Amateur Subscriber.—It is probable that a less proportion of a bromide would be desirable for a portrait collodion than Mr. England uses in his instantaneous collodion for views. We have never found that for portraiture it was desirable to use more than one grain of bromide to the ounce. We will endeavour to obtain some further information regarding the dark slide. All, or the greater part of Mr. Wilson's stereoscopic views are taken with a single lens of six inches focus. There is not a triple lens made, we believe, for stereoscopic work. It is for views 7 + 4½ that Mr. Wilson uses the triple.

No. 35.—You mistook our meaning. We did not for a moment doubt that some of the lenses referred to were good, or even *very* good; but from our information we believed them to be uncertain, the result largely depending upon chance. The gentleman to whom you refer is a good professional authority in chemistry, but not, we believe, in optics or practical photography. We are obliged, however, for your communication.

Simplex.—The best arrangement for groups is an irregular crescent. By having the ends nearest to the lens and the centre the most distant, you favor the curvature of field which exists. If your lens does not cover a group so arranged it is faulty. Put a smaller stop in. Be careful to avoid inartistic formality in such an arrangement. 2. When the diaphragm cuts off a portion of the subject it is in the wrong place, too far forward. We are glad you find Mr. Window's articles of so much service. They will, we believe, treat of the subject you name before they are concluded.

W. H. T. N.—You have made a mistake. We nowhere stated that "stereoscopic vision is attained by converging the axes of the eyes until the left eye sees the right hand half of the picture, and *vice versa*." Sir David Brewster, in endeavouring to prove that Chimenti's pictures are stereoscopic, says that the originals are so mounted as to render necessary such convergence, and that if transposed they would be seen by the ordinary process of stereoscopic vision. We remark that the fact of their being mounted in a mode which would require a mode of examining them which is always difficult and often impossible, is an argument against any idea or intention of stereoscopicity in the artist. There need be neither convergence nor divergence of the optic axes in stereoscopic vision; but simply parallelism, each eye being fixed straight on the picture before it. See below.

Painting Transparencies.—From a mistake in reading the MS., an error occurs in the tenth line from the top of the column, in the communication of T. P. E. For "fading to tan glass," read "fading to bare glass."

T. P. E.—We are obliged by your offer, and shall have pleasure in receiving your communication.

North Briton.—We will take an early opportunity of ascertaining, and let you know.

Juvenile.—A few drops of a saturated solution of proto-nitrate of mercury in the last washing water, is perhaps the most delicate test for hypo, and will produce a dark turbidity if but an infinitesimal portion of hypo be present. But if we remember rightly, the committee appointed some years ago to report on the causes of fading, after trying this and all other suitable tests, came to the conclusion that there was no chemical test sufficiently delicate to determine absolutely when all hypo was removed, and that extreme care was the only safeguard. We cannot tell you what other machines have really done, but there have been others which professed to do similar things to this of yours. We do not doubt at all the possibility of sufficient washing being effected, by proper care, in an hour or two; but in the absence of strong proof, we doubt the wisdom of expending the cost of a patent in such a matter.

Thomas Bell.—See answer to Juvenile. We will endeavour to test the prints as far as possible at an early opportunity.

W. Deane.—The most probable cause of the spots in the negative which, from seeing the print, we can suggest, is some accumulation of a precipitate in the bath, which wants filtering out. A precipitate of iodide of silver, or dust, or almost anything of that kind at the bottom of the bath, might cause such spots at the bottom of the plate, which would stir the turbidity slightly up.

W. W. S.—You shall receive attention.

Several correspondents in our next.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 189.—April 17, 1862.

## THE SOUTH LONDON PHOTOGRAPHIC EXHIBITION.

There is one clause in the "Rules for Exhibitors" in the forthcoming Exhibition of the South London Photographic Society, which, on reflection, appears to have been adopted without sufficient consideration of all its bearings. In order to secure in its fullest sense the photographic character of the Exhibition, the committee, in adopting a rule generally made, but rarely observed—that of requiring an untouched copy to accompany each coloured picture—resolved to insist upon its rigid observance. In doing this they intended to give emphasis to the fact, that in a photographic exhibition, coloured portraits—without a disparagement to the position of the colourist—were merely admitted as illustrating one of the applications of photography; and to render clear the nature and extent of this application, it was important that an uncoloured copy should be present for comparison. In order to make this condition stringent, and without thinking of the damaging effect on the general harmony of arrangement, it was resolved, that "coloured photographs would only be admissible when accompanied, *in the same frame*, with untouched specimens." A very little reflection will suffice to show that a most unsatisfactory, spotty, inharmonious, incongruous effect might result if this rule were rigorously carried out. The immediate juxta-position of things not intended for comparison, might often, in an artistic sense, be injurious to each, and have a bad effect, without either in itself being faulty. The untouched photograph, and the painting upon the photograph, might each be excellent, whilst the result of their contact and contrast might be more or less damaging to both. The monochrome and the painting glowing with colour each may have their special excellencies, but they do not harmonize. As M. Claudet observes, in a courteous letter to the Secretary, promising to contribute, no man of taste would hang engravings on the same wall as paintings or water-colour drawings; he would keep each in separate apartments, if he wished each to have their true value or produce a perfect ensemble.

We are authorized to state, therefore, that the committee having re-considered the question, have resolved to rescind such part of the seventh rule, as renders it necessary to place the uncoloured duplicate *in the same frame* as the coloured picture. It will still be imperative that coloured specimens be accompanied by untouched copies, the arrangement of such copies in the Exhibition being left to the discretion of the hanging committee. We trust that this decision will contribute to the satisfaction of exhibitors, and to the general effect of the Exhibition.

## THE PHOTOGRAPHIC DEPARTMENT AT THE INTERNATIONAL EXHIBITION.

The majority of the photographic contributors in the English department are now in the building, and are rapidly in the course of unpacking and arranging. Notwithstanding the thankless task imposed upon the gentlemen forming the photographic committee, they have worked heartily and energetically to make the most of the facilities placed at their disposal, aiming with limited means to satisfy extensive demands. Many of those, whose applications were at first refused, have, by the judicious management of space, by inducing some who received allotments in the photographic department to accept of space in other classes, and by other means, now received allotments according to priority of merit. Many are still, of course, disappointed at the amount or position of the space awarded to them, especially amongst exhibitors of apparatus. Some who especially require brilliant light have had dark corners allotted. Some who have prepared square cases have received oblong space for them. As far as it is possible all these defects are remedied; the most courteous anxiety to make satisfactory arrangements being manifested by the committee, and by Mr. Peter Le Neve Foster, the superintendent of the department, but the task of fitting square pegs into round holes can never issue with entire success.

The fact is, the space is so much too limited that anything like satisfactory results can scarcely be anticipated. As for the position in the building, it is one which will effectually keep the exhibition select. The Commissioners, as if ironically answering the outcry of photographers for the elevation of their art, have exalted it with a vengeance, placing it high above the picture galleries and everything else. We venture to predict that none but those actually interested in the matter, and seeking for the photographs, or it may be stray visitors who have lost themselves in wandering up interminable flights of steps, will undertake the task of mounting to the photographic department.

No official announcement of the jurors in the various departments has been made; but it is understood that Dr. Diamond, Sir David Brewster, and M. Claudet have been appointed to make the awards in Class XIV, which will include, we presume, all the photographic departments. As a whole, we fear this appointment will not give unmixed satisfaction. As regards the first-named gentleman the appointment is doubtless unexceptionable: the long connection of Dr. Diamond with photography, his high attainments in the various branches of the art, his representative position as Secretary of the Photographic Society, and the personal esteem in which he is held by photographers generally, all conduce to stamp him as pre-eminently fitted to fulfil such duties with efficiency, and to secure the confidence of the photographic public in his decisions. Regarding Sir David Brewster we regret to say we cannot express any such confidence. Willingly recognizing his high character and labours as a man of science, we cannot so readily admit his judgment in matters photographic. In the optics of photography his name has been identified with some crotchets which have had no confirmation in the practice of able photographers. Of his general acquaintance with photography we have no knowledge, but what we have recently gleaned from an article in the *North British Review*, which is publicly attributed to his pen. We have not hitherto called the attention of our readers to this article, as we are in the habit of doing with regard to any photographic contributions in periodicals devoted to general literature, simply because we have hesitated to couple a name so high as that of Sir David Brewster with the amount of misinformation and inexact statement with which the article abounds. Regarding the last-named gentleman, M. Claudet, no one will doubt for a moment his photographic knowledge or ability, his deep love of the art, and concern for its honour—yet we hesitate in acknowledging his fitness for the office. In the first place, and chiefly, because the appointment is a great injustice to himself. M. Claudet is a large and very worthy contributor to this department, and he has at no remote period taken prizes in exhibitions of photographs. As an exhibitor here he is manifestly disqualified from pronouncing as a juror upon his own works; and is, therefore, debarred from all chance of that recognition which it is probable his contributions may merit; for even if his coadjutors were disposed to confer any honour on his works, his delicacy would doubtless revolt from appending his name to a decision which contained an award in favour of his own pictures. There are other sound reasons why, we conceive, a professional photographer is scarcely desirable as a juror; for without doubting the honourable impartiality which will doubtless characterise his judgment, other professional photographers may naturally feel that they would rather not have been judged by one with whom they are in business competition.

Regarding the contract for photographing in the Exhibition it appears that no tender whatever has yet been made. The *Times* says:—

"No tenders have yet been received for the right of taking photographs in the building during the time of the Exhibition. Some of the first firms in the kingdom are willing, we believe, to give the Commissioners very large sums for this privilege, but all are at present withheld from making an offer by the most absurd condition with which they are clogged—namely, that the Commissioners will not provide any space or room for photographers, or for their processes of developing or preparing their plates or otherwise, all of which processes must be carried on beyond the limits of the Exhibition buildings. If this rule is adhered to, not a single shilling will be offered for the privilege, for, as any practical photographer can tell the Commissioners, the so-called privilege of taking views will be utterly worthless, unless they have some place in the building in which to prepare and develop their plates. In the form of tender issued there is no date put as to the time before which the offer is to be sent in, and, above all, the photographers most justly complain that they are required, when stating the sum which they are willing to pay for the right, to state also how many copies of every photograph 'which may be taken in the building they are willing to place at the disposal of the Commissioners for distribution, but not for sale.' If in the tenders for refreshments the contractor was called upon to specify how many free dinner tickets each day would be placed at the disposal of the Commissioners for distribution, but not for sale, the public, we think, would express their opinion very freely upon the nature of such an agreement, and we confess we are at a loss to see the difference in principle between such an arrangement and that which the Commissioners expect to make with the photographers."

We are unwilling to impute motives, but it has been suggested that the Commissioners do not expect or desire competition, wishing to place the job in certain hands; but that, since they must for decency's sake advertise for tenders, they fetter them with impossible conditions. An appearance of justice and impartiality must be preserved: as in regard to the election of juries, contributors were requested to nominate men in whom they placed confidence, whilst the authorities, it appears, had no intention to be guided—certainly not governed—by such nominations in making the appointment.

## HOT DEVELOPMENT, AN AMERICAN DISCOVERY.

Our American cousins have a funny habit of claiming all the discoveries in science and art. Photographers are at the present moment in a high state of excitement regarding the accelerating influence of heat in developing dry plates. In the Photographic News, for March 7th, Dr. Draper, of New York, communicated the results of some experiments he had recently laid before the American Photographic Society, in which, by the aid of hot development, he had secured instantaneous pictures on tannin plates. This was a gratifying application of the principle of hot development to tannin plates, and the announcement was novel. It is quite possible that with Dr. Draper the idea was original, and that the merit of independent discovery is due to him. Nevertheless our readers will be somewhat amused to find this recent application of an old principle described as the *discovery* of that principle. *Mr. Coleman Sellers,* whose name our readers may remember as the writer of some interesting letters in American Journals, writing to a British contemporary, recently, says:—

"To quote from a New York letter:—'We are all in *hot water* here. Try Dr. Draper's process, and you will soon be *warm* in your praise of it.' Much positive information has reached me, all tending to prove that it is the greatest discovery in the art that has been presented to us for several years. It is one of those remarkably simple discoveries which we cannot but wonder have not been developed sooner. As far as I have been able to learn, it has only been applied so far to tannin plates; but there can be but very little doubt that it will be of equal advantage in the treatment of other dry plates."

Most of our readers are familiar with the fact, that upwards of ten years ago M. Ferrier used hot development with albumen dry plates. For years past, Mr. Mudd has used hot development with collodio-albumen plates, and has secured considerable diminution in exposure by its use. Little less than twelve months ago, M. Roman re-discovered the value of heat in developing collodio-albumen plates, and announced that by the method he described, and hot development, dry plates might be worked with a rapidity equalling that of the wet process; and various other communications to the same effect have appeared from time to time in the English journals. The singular part of the business follows, however; American photographers may, of course, be pardoned for not always seeing English photographic papers; but it is a fact that most of the communications on the subject have been reprinted in the American photographic journals; and without instituting any rigid search, we have laid our hand in one minute on two communications in the *American Journal of Photography,* extracted from the Photographic News during last summer, solely devoted to the accelerating influence of hot development. The *American Journal* of the 1st of August 1861, contains a brief general statement of the case from our own pen, and the same journal of the 15th of August, quotes detailed particulars of manipulation from an article contributed to our pages a few weeks previously by the Rev. J. Galloway Cowan, and it is somewhat singular that the method of using *hot water* previous to the developer, and not simply a hot developer, is distinctly described in the article in question.

We hope shortly to have something to say on the general subject which Dr. Draper's fortunate application has given a fresh interest to; we now merely make the reclamation, not for ourselves, but on behalf of the Old World. It is a little amusing to find a man like Mr. Sellers *naively* remarking of a thing done long ago, that "there can be very little doubt that it *will be* of equal advantage in the treatment of other dry plates."

## Scientific Gossip.

Composition of the Photographic Image—The Three Theories—New Method of Photometry.

The composition of the photographic image—a problem in in photo-chemistry which has of late been so frequently discussed in the pages of the Photographic News, deserves attentive consideration from the circumstance that it constitutes almost the theoretical basis of the art of photography. In a recent number we gave an article (from the *London Review*) which seemed to give a very good general statement of our present knowlege on the subject. The importance of the subject induces us to give insertion to a few remarks bearing upon the present position of this interesting chemical inquiry which have been communicated to us by an esteemed friend and well-known man of science. The writer, under the signature "Experientia" commences:—

"The nature of the decomposing action of sunlight upon the chloride of silver appears to have formed one of the very earliest subjects of experimental investigation on the part of several distinguished philosophers, whose researches may be taken as indicating both the dawn and provisional establishment of the fundamental principles of our modern art. Irrespective of the fact that the alchemists were acquainted with horn silver, and its property of becoming blackened on exposure to the sun's rays, the subject seems to have been specially taken up by Wedgwood, Davy, Scheele, Bucholz, Berthollet, Draper, Herschel, Daguerre, and Talbot; besides being treated of more recently by many of our most competent authorities in science. A special report was prepared for the meeting of the British Association in 1859, setting forth a *resumé* of all that was known at that period with respect to the composition of the photographic image. The conclusions expressed in this report have been controverted by later experimentalists, whose results are briefly alluded to in the notices lately appearing in the Photographic News; and notwithstanding the fact of so much attention having already been given to the study of the question, chemists have not yet arrived at an unanimous decision in regard to the precise nature of the change brought about by the action of sunlight upon the chloride, bromide, iodide, and other salts of silver, especially under the modifying circumstances introduced by the presence of different forms of organic matter. So far only as the simple problem of the decomposition by light of the pure chloride of silver is concerned, there appear to be no less than three distinct views advanced in explanation.

"1. The supposition according to which the white protochloride of silver undergoes gradual decomposition, affording metallic silver as the ultimate product, but at an earlier stage an intermediate compound, which has been termed subchloride of silver.

"This view was advanced by Messrs. Hadow, Hardwich, Llewellyn, and Maskelyne in their joint report to the British Association.

"2. That which asserts the decomposition to consist merely in the separation of the elements chlorine and silver, not recognising any intermediate stage in the process of reduction.

"MM. Girard and Davanne, Mulder, Van Monkoven, Dr. Guthrie, Mr. Spiller, Mr. Malone, and Mr. Crookes are among those who have advocated this mode of explanation.

"3. The opinion according to which the chloride of silver absorbs oxygen at the same time that it loses chlorine, but with the ultimate formation of metallic silver.

"Mr. Robert Hunt, in advancing this statement, explanatory of the chemical change, includes the elements of water in the decomposition, and refers to the probability of subchloride of silver being formed as the product of partial reduction.

"This third hypothesis has not been confirmed by the results of later investigation; but it will be sufficiently apparent from the discrepancy in these several accounts that much remains to be worked out in connection with this interesting chemical problem, and that notwithstanding the evidence gathered from moderate research, there is yet room for diversity of opinion. More facts are wanted for the satisfactory elaboration of the inquiry in all its phases, and it is certain that renewed experiment, pursued conjointly with the discussion of the results, will greatly contribute towards the attainment of more precise theoretical means, by which the interpretation of these important photographic phenomena will be placed eventually on an indisputable scientific basis."

Professor Dove has proposed a most ingenious and accurate method of photography, which will, doubtless, prove of considerable use to scientific photographers and others engaged in the measurement of light. The method has the advantage over those now in use, that it is equally applicable to the determination of the intensity of light proceeding from a bright or faintly luminous body, whether it be white or coloured, transparent or opaque; it is suitable also to determine the amount of light transmitted by photographic lenses and other optical instruments. The apparatus used is the compound microscope, which is usually brought into a horizontal position; a minute photograph representing black letters on a white (transparent) ground, or simply a cross on a similar ground is placed on the stage, and viewed under a power of from 20 to 60 diameters. The letters will, of course, appear by transmitted light, black on a white ground; and white on a black ground, by reflected light; while the two illuminations can readily be balanced, so that the letters are made to disappear. This is, perhaps, most elegantly effected by the use of two Nicol's prisms, one placed under the stage, the other directly behind the objective or the eye-piece. By the revolution of either prism the transmitted light is weakened till the compensation is exactly effected, and the letters made invisible. The compensation may also be effected by reducing the size of the aperture under the stage, or by varying the distance of the luminous body which stands on the axis of the microscope. The light furnished by two candles is compared by placing them one at a time in the prolongation of the axis of the compound body, and varying their distance from the microscope till the compensation has been made for each separately. Their distances from the microscope is measured, and furnish the data for calculating the relative amounts of light emitted, the zero of the scale being the microscope photograph. The intensity of the light in various parts of the spectrum is measured by allowing different portions of it to fall on the under side of the photograph and effecting compensation. Nothing can be simpler than the application of this method to the determination of the equality, or inequality, in the amount of light transmitted by, or reflected from, differently coloured substances. Dove recommends that photographs should be especially executed for this photometer, and it has in fact been found that some are more delicate in their indications than others; the letters or figures ought to be very sharp at the edges, for if they are surrounded by an outline differing a little in density from the central portions, this in practice becomes a dividing band between two shades, and renders compensation difficult. It would also be as well to remove the iodide of silver by cyanide of potassium, instead of hyposulphite of soda, as the letters then appear considerably brighter by reflected light. It is desirable that the sensibility of this new method, as compared with others now in use, should be tested by a carefully made series of numerical determinations.

## REMARKS UPON SOME OF THE APPARATUS EMPLOYED IN PHOTOGRAPHY.*

BY F. R. WINDOW.

*Baths and Dippers.*—The baths used in photography are of two classes; the vertical bath, and the horizontal bath. The former is at present the most generally used.

The materials of which baths are made are various. Glass, porcelain, gutta percha, india rubber, slate, ebonite, and wood have all been employed for this purpose, and although undoubtedly some of them are better than others, for general use, for reasons which I will presently examine, an efficient bath may be constructed with any of them.

The office of the bath is to hold the solution of nitrate of silver by which the iodized plate is rendered sensitive to light. The substance of which it is formed must therefore be inactive with regard to nitrate of silver. But this is not the only requisite. It is essential that the bath liquid should always be limpid and clear but when in work it is constantly depositing upon the bottom and sides of the vessel, sundry particles, sometimes of silver reduced by light and organic matter, sometimes of iodide of silver from being supersaturated with this salt, sometimes of dirt or impurities that have fallen into it. The receptacle, therefore, should be of a form and material easy to be cleaned, and especially of a nature easy to determine whether it be clean or not. The ordinary

* Continued from page 172.

vertical dipping-bath is of a very inconvenient form for cleaning, and when made of an opaque material, for ascertaining with certainty whether it be really clean. Glass and white porcelain ware are the most satisfactory in this respect, as the dirt can be seen upon their surface; but the cleanliness of baths made of the other substances named must be taken a good deal on credit.

The form of a vertical dipping-bath is naturally in a great measure determined by its intended use. It must be a deep trough larger all ways than the plates that are to be sensitized in it, and of little breadth so as to economise the silver solution. There should be no sharp interior angles or corners, as the dirt collecting in these is difficult to clean out, so they should be carefully filled in and rounded. The interior surface should be smooth, because asperities encourage the deposit of the dissolved iodide of silver from the liquid. Finally there should be a spout or lip to facilitate the emptying of the bath without spilling any of the solution. Few of the vertical dipping baths generally manufactured for sale fulfil completely *all* these conditions.

Vertical porcelain baths, as mostly made, approach nearest to the desired conditions of form and surface, but the interior angles are rarely rounded off sufficiently to make the cleaming of them an easy operatiou. If this fault were corrected they would be very perfect baths, and leave little to be desired.

The cast glass baths of commerce, do not, I think, as a rule, come up to the standard of workmanship we have a right to expect from the trade which can produce the exquisite *mousseline* wine glasses which we see upou our dinner tables and the beautiful apparatus that aid the experiments of the chemist and electrician. They are characterized by a smooth internal surface, and generally also by the absence of any interior angles, which qualities render them very valuable, and causes their deficiences to be the more regretted. The great thickness of the material is probably one cause of their high cost, which for large baths is almost prohibition for a poor person; but I believe this excessive thickness is a mistake when given with the idea of increasing the strength of the vessel, because thick glass castings from their necessarily inferior quality, and the greater difficulty in annealing them, are frequently more liable to fracture than those of lighter substance or of blown glass, even where great care is taken in their manufacture; and also because photographic baths intended for the studio from their very nature are so little exposed to rough usage that precautions to give them extra strength seem unnecessary. Where we consider the thinness of the glass of some of those large bells which are used inverted as aquaria, containing often four to five gallons of water, and which are employed with safety for that purpose, it seems needless to more than double that thickness for vessels intended to hold one or two pints. Again, they are generally made too broad from back to front which uecessitates a larger quantity of bath liquid then should be required. Three quarters of an inch, inside measurement is amply sufficient in my opinion, but if it be found that some customers prefer broader baths, I thiuk a certain proportion should be made each way so that the purchaser may have the opportunity of choosing for himself. Also the sides in many cases are not parallel to those opposite, and frequently both sides are curved, sometimes inwards, sometimes outwards. It is held by some to be advisable that the front side of a dipping bath should be slightly curved outwards, that the collodion may not be rubbed against it. I am hardly of opinion that this is necessary, as such an accident can only arise from the extreme carelessuess of an operator, and such a form largely increases the quantity of liquid required to fill the bath; but in any case the side against which the back of the plate is to rest must be flat, as if it curved outwards it would have a tendency to push the plate off the dipper, and for either side of a bath to curve inwards, which happens from the soft casting bending while being annealed, is clearly bad. Lastly, glass baths, as now supplied to us, have no lip, and when they are very full it is a matter of considerable difficulty to return the liquid into the bottle without spilliug any of it, unless a syphon is employed.

Seeing the excellence to which glass manufactures have arrived, I am sure that there would be no difficulty iu obtaining a cheaper and more suitable glass bath if the makers were better acquainted with the shortcomings of those now manufactured, and the real requirements of the case. They cannot do better than take for models for a cast glass bath some of the best gutta percha baths with the only difference of having care to rouud off all the inner corners and angles, the same as in the cast glass baths made at present

I am of opiniou however that a very effective and more satisfactory bath can be made of blown glass, in the same manner as cheap tumblers, which are blown iuto a mould. In point of strength blown glass is as superior to cast glass, as wrought iron is to cast iron, therefore a great diminutiou in the thickness might be allowed with safety, and as such an article would be easier to manufacture than the thick unwieldly castings now supplied, it would probably be made better, more workmanlike in fashion, and more agreeable to the eye as well as better suited to its purpose. I do not thiuk it necessary to do more than allude to the *built* glass baths which have (fortunately) long ceased to be a part of the apparatus used in photography. They were always a source of misfortune and vexation, though it must be admitted they were at least as much sinned against as sinning, for they were generally constructed with little science or care, and cemented with a material, ofteu unsuited for such a purpose. *Requiescat in pace.*

Gutta percha baths have been much praised, and equally much abused, according as the writer got a pure gutta percha bath, or one made with an adulterated or unclean specimen of the gum. A clean, pure gutta percha bath may be used without the remotest danger; but it is very probable that many baths of good gutta percha, have been condemned from impurities having collected on their surface, either of the mould in manufacture, or otherwise during use, which, combining with the uitrate of silver, have spoiled the bath liquid. The great drawback to gutta percha for a vertical dipping bath, is the impossibility of ascertaining with certainty if it be clean which is rendered still more important from the tenacity with which some chemical stains adhere to this material. (We all know that gutta percha trays cannot be used for developing wax paper negatives, because the deposit upon them, which always occurs in that process, cannot be with certainty cleared away, and the silver is constantly being thrown dowu on the tray instead of on the pictures.) A simple sensitizing bath liquid, does not give any deposit that cannot be rubbed off with ease, therefore *when once clean*, a pure gutta percha bath may safely be used, but more than ordinary care should be taken in washing it out frequently, as the eye caunot examine every part of it, and detect dirt as in a glass or white porcelain bath. The only objection to the form of the gutta percha baths of commerce is the sharp inside corners and angles, which are difficult to clean out. They might easily be corrected. These baths are especially valuable to the laudscape photographer, since they can be carried about without danger of breaking.

The same remarks apply to ebonite baths as to gutta percha. I am not aware of any advantage they have over the latter. Great stress is laid in the announcements of this material, that it will bear a temperature of over 212° Fah. without injury, but this is a property without much value in general practice for dipping baths. In the few exceptional cases when such a property may be desirable it would be best to employ one made of porcelaiu.

(*To be continued.*)

## SOME EXPERIMENTS WITH A NITRATE BATH.

BY VALENTINE BLANCHARD.

Some time ago, during some experiments made to induce a refractory bath to abandon its wayward conduct and return to the society of well behaved and orderly baths, I came upon some very curious results.

The bath was an old one of about fifty ounces, and contained both nitric and acetic acids. A quantity of carbonate of soda, as much as could be heaped up on a shilling, was introduced. The bath was then filtered and put away for several days. On trying a plate in it, before adding acid to neutralize the alkalinity, I was astonished to find a negative start into being with a speed truly electric. Like a flash of lightning the image made its appearance immediately after the application of the developer, which was protosulphate of iron, about thirty grains to the ounce, and there was no need of further intensifying, for it was a negative perfect in every particular.

I tested the bath with litmus paper and found it decidedly alkaline. This went to confirm a pet theory which I have long entertained, but have never been able to successfully work out, viz., that that which we call fog in an alkaline bath is such an exalted state of sensitiveness as to be with the ordinary methods of manipulation quite unmangeable. Hennah several years ago mentioned in his hand-book some curious and unaccountable results somewhat similar to those I describe, but until lately I have never met with any one who have in the course of their photographic experience stumbled upon such a curious phenomenon as an alkaline bath giving good negatives.

Some short time ago the editor of the News described just such a case. A bath was sent to him to tame, for it was pronounced by the owner refractory and incurable. The bath, when made alkaline with carbonate of soda, gave good results, but when acid was added it fogged, and continued to do so in an exact proportion to the amount of acid added. This I at once saw was exactly a parallel case to the one I have described, and I determined, therefore, the first moment I could spare, to try and bring about the same results with a new bath. Accordingly, some weeks ago, I made a bath 35 grains of silver to the ounce of water, employing the ordinary silver for the purpose. After saturation with iodide of silver, I filtered it, and then added 12 drops of glacial acetic acid, solid at 50°. I now introduced as much carbonate of soda as I could conveniently put on sixpence and after well shaking it, and letting it remain at rest some time, I filtered it. Three weeks afterwards I returned to my experiments, and succeeded in getting some very good pictures. But on making up the iron developer to about fifty grains to the ounce, I at once obtained negatives that were so dense as to require in some cases no after treatment, indeed, a few drops of silver in the iron solution proved sufficient at any time to give the requisite amount of density. The strking peculiarity about these negatives so obtained is the rapidity with which they start into being, and the vigorous appearance they present to the eye immediately after the application of the developer.

It is, I believe, absolutely necessary to use a collodion containing a fair amount of bromide in order to produce the best results.

There has always been a difference of opinion as to the accelerating influence of acetate of silver in the bath. Some years ago, when pyrogallic acid was invariably used as the developer for negatives, acetate was largely introduced into the bath by many; but lately, since iron has come so generally into use, its employment has been completely abandoned. The result of the experiments I have recorded have proved thus far so satisfactory that I am induced to believe that with a collodion containing two grains of bromide to the ounce, and with a developer of iron fifty grains to the ounce, negatives can be produced in a shorter space of time, and possessing more vigour, combined with delicacy of detail than can be produced by the usual method.

I hope to have more to say on this subject shortly.

## ON PHOTOGRAPHIC REPRODUCTIONS.

BY ALFRED H. WALL.*

We have in photography a discovery which is to art what the printing press was to literature; and of the great masters in art it may be more truly *now* said than at any other time—"Their conceptions are no longer pent up in galleries open to but a few: they meet us in our houses, and are the household pleasures of millions. Works designed for emperors, popes, and nobles find their way, in no poor representations, into humble dwellings, and sometimes give a consciousness of kindred powers to the child of poverty." The engraver may translate into monochrome every line and tint of a painting accurately enough; but so surely will his own individualism, his own peculiar "*manner*," find expression in his reproduction, that even the finest of such are no less representative of the original painting than of the copyist and engraver. The truth of this seems very widely and generally recognised. The *Athenæum* remarked not long since, when speaking of the pictures at Hampton Court:—"Copies multiplied by this—the photographic—process would render more service to students than any lithographs or line engravings now current; and the *Times*, otherwise no friend to the art-claims of photography, said, not long since:—"A photograph of a drawing in black and white, sepia or gray, is hardly distinguishable from the original: and even when the original is in red chalk, the photographic reproduction, darkened as it is, has a precision and spirit that give it a value beyond the most careful copy that can be made by hand." Of paintings the same influential authority says:—"The practice of having their pictures photographed is largely spreading among our painters, and the fact shows, what no man who has the the painter's feeling needs proof of, that photographs of pictures have qualities that more than make up for their inevitable untruthfulness in rendering certain colours. They render the spirit and expression of the originals with an effect they may well drive the engraver to despair. * * What line engraving can stand beside even the most unsatisfactory of these photographs as a representative of the original for those, who love, above all, the essence and spirit of a picture?" But without further quotations it will be at once apparent that a branch of art which can reproduce with such extraordinary fidelity, rapidity, and comparative cheapness, the noblest and grandest works of high art—extending their influence, multiplying their admirers, and inspiring with their perfections the loftiest art-patron and the lowliest art-stuent—must, sooner or later, exercise remarkable power in educating and refining the popular taste in art.

The capability of photography as a reproductive art agent being admitted, there is another view of the subject to which I am desirous of next briefly calling attention.

In the year 1773 you would have found in all London only two small shops devoted to the print trade. These dealt chiefly in engravings *imported* from Germany, Flanders, Holland, and France; while the very few inferior English engravers in this country could scarcely preserve themselves and their families from destitution.† So rapidly did the art emerge from this degraded condition that only nine years afterwards it was stated in the House of Lords that, as as articles of *export*, engravings produced the country £200,000 per annum. This great change was chiefly brought about, we must remember, by the application of engraving to the reproduction in monochrome of paintings and other similar works of art. William Hogarth, our great English painter, was the first to bring the obscure and ignoble art into high esteem and popular favour, by applying his skill as an engraver to the reproduction of his own immortal works; and, by thus demonstrating the commercial, educational, and industrial capabilities of engraving

* Read at a meeting of the South London Photographic Society, April 10th, 1862.

† Roquet.

as allied to painting, awakened a spirit of enterprise which speedily created a new and very flourishing branch of trade.* Now, if the most important element of this branch of trade is, as appears probable, about to pass into the grasp of photography, it is of absolute national importance that so valuable a department should be properly cared for, cultivated and encouraged. The difference between exportiug and importing the productions of any art is the difference between wealth and poverty for its professors—the difference between ignoble obscurity and honourable eminence for the art. Remembering this, it surely becomes members of a Society like our own to give such department careful study, and its process their full share of culture.

If "the highest value of the arts of design consists" (as was said by one of our recognised authorities on the administrative economy of the fine arts) "not in their power to minister to the luxury and splendour of the few, but in their eminent capability to promote the fitting culture and education of all," then may photography fairly lay claim to such value. Indeed, in the mere act by which the Art and Science Department of the South Kensington Museum re solved, in 1858, to publish at cost price photographic reproductions of works by eminent masters, the claim of photography to such distinction was publicly recognised and acknowledged. In the face of such facts as these, then, it seems difficult to understand why Her Majesty's Commissioners for the International Exhibition could have evinced so little policy, foresight, or common sense as they did in classifying the tools of the art and its productions as the result of equal skill and intelligence. If only in this one of its very numerous and valuable applications, the art had the very strongest claims to receive at their hands a more than common share of honour and encouragement, instead of this act of injustice and discouragement. For these reasons, therefore, I bring my subject unhesitatingly before you this eveuing, trusting that both upon this aud upon future occasions it may receive from us that meed of interest and research to which it has so paramount a claim. For myself, as I have no new facts to advance, no scientific experiments to chronicle, no very great experience to speak about, some apology may be due, which I now duly proffer. My further remarks will be chiefly devoted to a few practical hints, rather intended to elicit in discussion more valuable conclusions and opinions than to stand upon their own consequence. There is one circumstance of some significance, however, which I may mention before proceeding. In the last French Exposition of Photography there were nearly two hundred specimens of reproductions of drawings and paintings by celebrated masters: in the London Exhibition there were, perhaps, not a dozen. I shall first speak—

### Of Copying Engravings.

Choice rare prints are costly things, and their reproduction, as a commercial speculation, would doubtless frequently prove very remunerative. But the cost of copying and reproducing by engraving such works, say, as Marc Antonio's "Adam and Eve," which sold for 150 guineas, or the celebrated sabre portrait of Rembrandt, which fetched £600, would be so serious a consideration as to be unworthy of any enterprising print publisher's attention; and thus many an invaluable work of art passes secretly out of existence. Aided by the camera this no longer need be the case, as few or many copies may be reproduced at an expense fairly proportioned to the number required. These old engravings are frequeutly so stained and discoloured as to render their copying a matter of no small difficulty; it may, therefore, be serviceable if I give a method, which will be found most effectual and easy, which restores the whites, and the clearness, sharpness, and strength of the lines. It is simply taking equal portions by weight of strong muriatic acid and water, and adding three parts of this to one of the red oxide of lead. The discoloured prints are then steeped in this and taken out when restored.

In copying from a flat surface the question of focus is very much simplified; but, as with a good lens the engraving is apt to appear tolerably sharp on the ground-glass when the perfection of sharpness is not yet reached, one ought not to be too easily satisfied. The collodion should give good iutensity and not be too new: a slight addition of free iodine secures transparency in the blacks. I prefer copying in direct sunlight, and developing with a weak iron developer (iron eight grains, acetic acid twenty minims), not too new, intensifying afterwards with pyro and silver. The collodion, although it should not be in what would be called its best state (for portraits or views), should record the most delicate lines with great clearness and precision. Of course over-exposure, over-development, and everything which tends to mar the perfect transparency of the blacks, or destroy the more refined details of the graver, must be avoided—pure white and clear blacks being the elements of success. (I feel ashamed to mention these simple things here, although they may be useful in some quarters, perhaps.) When the destruction of the print is of small consequence, and the margin is very much torn, stained, or discoloured, this may of course be cut away and the print be placed against a piece of white board or paper for copying. In selecting a print for copying we should remember that there is a vast difference between a really good proof and those feeble, chalky impressions from worn out plates which are to be found in the shops of cheap printsellers.

But copying engravings is a very simple matter compared with the

### Copying of Paintings.

Here more real and tangible difficulties meet us—difficulties which in theory look so truly formidable that one can only wonder when in practice they are so gloriously overcome. The amazing success with which Mr. Thurston Thompson has reproduced the wonderful creations of Turner's genius in the specimens before us, must convince us that such difficulties only exist to be conquered. But the victory is not always *easily* won. It is only after loug experience and many experiments in photographing the more difficult paintings we succeed in making every step in the process a triumph over some enemy or another, until the end is gained —getting over this in the exposure, mastering that in the development, securing something else in the intensifying, and managing other points in the printing, so as eventually to secure what, after all, some worthy gentleman amateur, who has just mastered a shilling manual, and taken his fourth "picture" from nature, will perhaps sneeringly denounce as *only* a copy. Knowing that the bromides are more sensitive to the colours called non-actinic, and the iodides to those of the other eud of the scale, it at once strikes us that the judicious combination of both, with reference to the warm or cold characteristics of the paiuting, is the most hopeful thing for success. In a general way the bromised collodion will give the most satisfactory results.

And here I must pause. The simple fact is that I have now only just time to lay down my pen and start for this evening's meeting—my paper, in consequence of the accumulating business of the Society's Exhibition, having been delayed until there was not sufficient time remaining for its conclusion. I must therefore beg your pardon, and come at once to a few experiments made to test the power of certain combinations of the iodides and bromides in rendering certain coloured diagrams.

I took a sample of collodion and bottled off twelve separate ounces in twelve small bottles. No. 1 contained five grains of bromide of cadmium and two and a-half grains of iodide of ammonium. No. 2 contained five grains of bromide of ammonium. No. 3 five grains of bromide of cadmium and two grains of iodide of potassium. No. 4 contained as much of the iodide of potassium as it would take up. No. 5 contained five grains of iodide of ammonium.

* Alderman Boydell—once the poor engraver, afterwards as a follower in the steps of Hogarth, the great print publisher—being at the Royal Academy dinner, his health was drunk by Sir Joshua Reynolds, at the suggestion of Burke, as "the commercial Mæcenas of England."

No. 6 two and a-half grains of bromide of ammonium, and as much of the iodide of potassium as it would take up. No. 7 contained one grain of bromide of cadmium, ditto bromide of ammonium, and as much as it would take up of the iodide of potassium. No. 8 contained two grains of bromide of cadmium to as much of the iodide of potassium as would dissolve. No. 9 contained the same proportion of the iodide of potassium, with two and a-half grains of iodide of ammonium. No. 10 contained iodide of ammonium four grains, bromide of cadmium one grain, iodide of potassium and bromide of ammonium ditto. No. 11 held five grains of bromide of cadmium; and No. 12 one grain of bromide of cadmium, two grains of bromide of ammonium, and five grains of iodide of ammonium.

Desiring merely to test the qualities of these various samples for reproducing the correct *chiaroscuro* of the coloured diagrams, I simply developed with iron without intensifying, and shall now lay the result before you in the twelve negatives, and twelve prints from the same.

In conclusion, I promise to resume this subject at some future time, when, my engagements being less numerous and urgent, I shall be able to devote a larger share of time and attention to some experiments of a more conclusive character. I think in the specimens of my experiments some foundation will be found in a discussion of greater value than my paper—even had it been completed—could have boasted.

Thanking you for your polite attention, I now place the subject in your hands.

## INSTANTANEOUS PHOTOGRAPHY.*

The production of instantaneous pictures has been a favourite subject for speculation and experiment from the earliest history of the art, and soon after the discovery of the collodion process began to be regarded as *un fait accompli*. Many photographers will remember the early photographs of birds, &c., taken instantaneously by Count de Montizon in the Zoological Gardens, and the cloud-and-water pieces of Legray. The writer has in his possession a photograph taken by Dr. Diamond ten years ago, which unites in itself the two facts, generally regarded as of modern date, of being a *carte de visite* in size and style, and of being an instantaneous equestrian group. Most old photographers have, in fact, occasionally produced instantaneous pictures, either by chance or design. It has only been comparatively recently, however, that the art of instantaneous photography has been systematized, or that any attempt has been made to lay down and control the conditions for its successful practice.

Very early indeed in the history of the collodion process, experiments were made with a view to obtain increased sensibility, and a variety of organic and inorganic compounds were added both to the collodion and the bath; but all were gradually abandoned as at best of doubtful and uncertain advantage. The process suggested in 1854 by Mr. Maxwell Lyte of covering the excited plate with a solution of nitro-glucose and silver, by which he obtained perfect pictures of moving bodies with a landscape lens and very small aperture, scarcely received a fair trial, we fear, as indeed processes involving any complication either of formula or manipulation rarely do. For years past all extraneous aids to extreme sensitiveness have been discarded, and the recognized methods of securing the most rapid results, were briefly and generally comprised in good chemicals in good condition, good lenses, and good light.

Good chemicals consisted in a bath of pure nitrate of silver, as nearly neutral as possible, good collodion newly iodized, and pyrogallic acid development. The great difficulty consisted in the uncertain and ever-changing conditions of the collodion. The sample, which possessed sufficient sensibility to produce in a good light instantaneous pictures one day, was frequently comparatively useless a few days afterwards. The introduction of iodide of cadmium in place of the salt of potassium effected an immense improvement in the stability of collodion, and facilitated considerably systematic attempts at rapid exposures, although many experienced photographers still believe that by far the greatest amount of sensitiveness possible in photography when combined with perfect results, is attained by the use of a collodion made from good pyroxyline and pure solvents, newly iodized with a pure alkaline iodizer, excited in a neutral bath of pure nitrate of silver, and developed with pyrogallic acid containing a *minimum* of acetic acid. Our chief object in the present article is, however, to give a *résumé* of the different formulæ, which have either been published, or are gathered from private sources, used by various photographers whose published instantaneous pictures have received the stamp of public approbation. In the processes to which we refer there is a singular uniformity of principle, a collodion containing a large proportion of some bromide as well as iodide, and iron development, being used in almost every instance.

Mr. Wilson, of Aberdeen, leads the van of professional instantaneous photographers. His charming pictures of breaking waves and flying clouds, of gun practice in which not a wreath of smoke is blurred, of steam vessels and of street scenes, are familiar to every one, and admired by all. His operations are very simple; he uses the best bromo-iodized collodion he can buy, not confining himself to the product of any one maker, and sometimes using a mixture of several; a thirty-grain nitrate of silver bath, as nearly neutral as possible. For stereoscopic work the lenses are single lenses of six inches focus, with a stop of about half an inch diameter; for larger instantaneous views a triplet with full aperture. The developer used is a 30-grain solution of iron, with 30 minims of glacial acetic acid. The pictures produced by this formula rarely attain sufficient vigour in the first process of development, but require further intensifying by some process. The method employed by Mr. Wilson is a very simple one; it consists merely in washing well, and flooding the plate again with 30-grain silver solution, and again developing with iron, and so on repeatedly until the right amount of intensity is obtained.

Mr. England's method of producing instantaneous pictures will be found briefly described by himself in a paper read at the last meeting of the Society, when it was illustrated by the exhibition of some very pure delicate negatives. In principle, it will be seen that Mr. England's method resembles in many respects that of Mr. Wilson. The bromide, it will be seen, is used in unusually large proportions, generally equalling the iodide in amount, and sometimes even exceeding it. An old empirical formula used to obtain at one time, to the effect that when bromides were used the amount of the iodide should be increased by a proportion equalling the amount of bromide added: thus, if 3½ grains of iodide to the ounce of collodion were considered the right amount to be used alone, 4½ grains would be required if 1 grain of bromide were added. Mr. England's formula appears to be directly opposed to this notion, and has the advantage of successful results to guarantee its value. A neutral silver bath, and very strong iron developer, also form parts of Mr. England's method, the latter being sometimes used as strong as 48 grains to the ounce. His negatives also require same intensifying after development; and this he effects in the manner now very common, by the use of pyrogallic acid and silver. Nothing could exceed the beauty of the negatives exhibited at the meeting of the Society, or speak more highly for the method by which they were produced.

In another page a notice will be found of a series of very fine instantaneous views of street scenes and of marine subjects produced by Mr. Blanchard. The process he details is similar in principle to the two already described. A bromo-iodized collodion is used, the proportion of bromide being varied according to the state of the light and character of the subject, the proportions being from 1 grain to 5 grains of bromide of cadmium to each ounce of collodion, and in all cases 4 grains of iodide of cadmium to each ounce of collodion. The difficulty arising from glutinosity, which is sometimes experienced where the salts of cadmium are employed solely, is avoided by the use of a pyroxyline made at a high temperature, with a full proportion of water, which is very soluble and tends to give a very fluid collodion, limpid, and structureless. A 35-grain nitrate bath is used, which has been first neutralized with oxide of silver and then acidified in the slightest possible degree with nitric acid to ensure clean working. An iron developer, varying with the temperature from 15 grains to 30 grains, and a minimum of acetic acid is used. The amount of intensity obtained by simple development here again is insufficient for printing, and intensifying is resorted to. Mr. Blanchard's method is, in all cases, to leave this to be done at home, as it not only wastes time but is inconvenient to effect comfortably in the developing-box uses for the field operations. The plate is kept moist by means of a coat-

* From the *Photographic Journal*.

ing of glycerine and water. When about to be intensified, it is well washed and flooded with a solution of iodine and iodide of potassium, about two grains of each, in water; this is washed off in a few minutes, and a solution of pyrogallic acid, with a little silver added, is applied to the plate until the right intensity is obtained.

Both Mr. England and Mr. Blanchard, unlike Mr. Wilson, use portrait combinations for producing their instantaneous views, and each use lenses of different focal length and different stops for different subjects. In street views the curvature of field incident to combinations of lenses does not become a serious evil: we believe, however, that the rapid portrait lenses recently made by some of our best opticians give a flatness of field not to be exceeded by single lenses. Where from the nature of the subject, and the the amount of light, view lenses can be used for landscape work, they will doubtless be preferable; but as in instantaneous work rapidity of action is the first consideration, there can be no question as to the superiority of combinations for many purposes.

The modes proposed of uncovering and covering the lens to obtain the minimum of exposure are various, each operator having some favourite method. Mr. Wilson frequently uses his Scotch cap, moving it off the lens and on again as rapidly as possible. Mr. England's clever contrivance, described in another page, seems as perfect in principle as it is found efficient in practice. Mr. Blanchard's practice is similar in principle to that of Mr. Wilson, only he uses a piece of wood with a ledge to rest upon the lenses, instead of the Scotch cap. We have seen other impromptu contrivances of the same kind made to answer the purpose perfectly; the argument in their favour is, that anything so under the control of the operator gives him more latitude in varying the rapidity of the exposure with the character of the subject than any contrivance depending upon the action of a spring or its own momentum no matter how acquired.

The general conclusion to be deduced, then, from the practice of professional instantaneous photographers, appears to point out highly bromized collodion and strong iron-developing solution, in conjunction with a nitrate bath of pure silver as nearly neutral as possible, together with good lenses and good light, as the necessary agents in producing instantaneous pictures. We have before us a series of examples of the instantaneous productions of other professional and amateur photographers, together with statements of the formulæ and manipulations used; but we have thought it desirable rather to refer to pictures with which the public is familiar, and afford an opportunity of comparing processes with published results. In the majority of instances, however, we find, when the proportions of the sensitizing salts are given, that from one-third to an equal quantity of a bromide is added with the iodide, and that the salts of cadmium are generally preferred. In some instances the collodion of different commercial manufactures is quoted, and in these cases we find that those collodions which have the reputation of containing cadmium, and containing bromides, are generally referred to; and also that it is a very common circumstance to find that a mixture of the collodions of two different makers is found better than either singly. It must not be forgotten that in instantaneous photography pre-eminently, the best chemicals, the best formulæ, and the best apparatus, will be of little avail, without great judgment, skill, and care at every stage of the operations.

This hasty sketch of the rapid processes in use would be very incomplete without some reference to the rapid dry processes at present exciting public attention. We notice in another page some instantaneous views taken on dry plates prepared by Dr. Hill Norris. This process is, unfortunately, a secret one, and as such scarcely of legitimate interest for discussion in our pages. There are two facts in regard to them of which, however, we are in a position to speak with certainty, the information having been derived directly from Dr. Hill Norris himself. These facts are, that they are not prepared with a simply iodized collodion; and that their sensitiveness does not depend on the presence of free nitrate of silver, as every effort is made by washing to remove every trace of a soluble salt of silver from the film. Mr. England has by his process, he states, prepared dry plates which equal in sensitiveness ordinary iodized collodion when developed by pyrogallic acid. But the chief source of rapidity to which attention has recently been directed is the aid of heat in developing. Old photographers remember that many years ago Ferrier, Martin, and others, used hot solutions of gallic and pyrogallic acid for developing albumen plates. Mr. Mudd in this country, and more recently M. Roman on the Continent, have pointed out the fact, that the use of hot developing solutions permitted a considerable shortening of the exposure in collodio-albumen plates. More recently still, Dr. Draper and others, in America, state that good pictures have been obtained on ordinary tannin plates, by an exposure of two or three seconds, when heat has been used in developing; whereas the same plates required an exposure of an equal number of minutes when the ordinary processes of developing were adopted.

These facts are important and interesting, but they require the verification of successful repetition in this country. We shall refer to this subject in our next, when we hope to be able to state the results of some experiments.

## MATERIALS FOR SILVER BATHS.

BY NICHOLAS PIKE.*

Within the past year quite a number of articles have been contributed to the photographic journals published in this city, on the peculiar merits of the recently introduced wooden baths the holding nitrate of silver solution for photographic purpose. These articles are, in my opinion, likely to lead the professional community, and more especially those who are living in the rural districts, into an error. For some time past I have experimented with many different materials in constructing baths for holding silver solution, and particularly with wood.

It is well known that by a careful examination of a cross section of any kind of wood, with a good microscope, it reveals to us at once that it is not solid, but composed of a vast number of small tubes ramifying through every part, and even the oldest and most compact species are nothing more than a collection of vessels and cells, which consist of extremely thin and delicate membranes. In selecting specimens for my experiments, I examined, microscopically, more than thirty different kinds of wood in order to make use of those which were most compact and which contained the most minute vessels and cells.

The baths were carefully made, and a good coating of shellac was used inside, but in every instance in a few months the silver solution became injured by the decomposition of the shellac, which would crack and peel off. This decomposition would be more rapid when the solution was slightly acid. In a large bath which was in use about ten months, the shellac was completely dissolved away, and the silver solution permeated the wood in such a manner that I recovered three ounces of metallic silver on reducing it to ashes; and from the bottom of another bath which only measured fourteen inches in length, by two in width, and one in thickness, I recovered one ounce and eleven grains. The solution had remained in this bath undisturbed for sixteen months. The sides and ends I have not yet examined chemically, but am sure they are rich in silver, as a microscopic examination of a longitudinal section reveals the fact that the medullary system is completely filled with the precious metal. The solution has permeated every part and has crystallised on the outside.

My next experiments were with the common porcelain bath, such as are usually sold by the trade. I have had three or four of these baths filled with silver for the past three years, and in every instance I have found them to absorb and injure the solution. After they have been in use ten or twelve months the glazing begins to crack, and owing to their porous nature the solution permeates through and crystallises on the outside, and in a short time the bath becomes completely saturated. From a bath of this kind, which Mr. Davis, of Brooklyn, had in use, I took sixty-four grains of metallic silver which had formed on the outside in the short space of twelve hours. I reduced this bath to powder, and from a small portion I extracted one ounce and twenty-three grains of pure silver, and I have not the least doubt that from the balance I shall procure two or three

* Read before the American Photographical Society Monday evening Feb. 10th, 1862.

ounces more. From a small porcelain dish used for holding the floating bath for silvering paper which had been in use for eight years, I obtained one ounce and forty-five grains. This proves conclusively that porcelain, and all kinds of ware of a similar description are unfit for photographic purposes.

I had in use a bath made expressly for me in England of a composition of gutta-percha, which was highly recommended to me and warranted to last an indefinite length of time; but this, like all others made of a similar material, soon contaminated the solution, and was in a short time laid by unfit for further use. I have now in use the bath made of French glass plate, invented by Mr. Huffnagel of this city. The bath is strongly secured in a wooden box, and can be transported without danger of being broken. It is, in my opinion, the best bath in use, and the profession generally are indebted to him for his valuable invention. They are sold at a moderate price. Having studied for many years the delightful art of photography, and being only an amateur, I have no interest whatever in the matter of baths, other than to do good to the profession as well as to place my fellow amateurs on the right track.

## Proceedings of Societies.

### South London Photographic Society.

The usual monthly meeting was held at the City of London College on the evening of Thursday, April 10th. The Rev. F. F. Statham, B.A., F.G.S., in the chair.

The minutes of a previous meeting having been read and confirmed, the following gentlemen were elected members of the Society:—Messrs. Larchin, Macarthy, Heaton, and Lloyd.

Mr. Martin exhibited some fine stereographs by Mr. Alfred Pellett, some of which, consisting chiefly of huge icicles, something like Mr. England's "Ice Cavern," were very interesting, as were also those of the graves of Wordsworth and Hartley Coleridge.

Some stereographs by Captain Scott were also shown. The cases in which these slides were shown resembled books and were much admired. An album for *cartes de visite*, manufactured by M. Bourquin, was shown by Mr. Hart, as possessing many features of interest and novelty, and received much admiration.

Mr. S. Davis had pleasure in announcing that from the communications received there appeared every probability of the Exhibition being very successful. The warm feelings of interest in the matter already expressed by other societies was very gratifying, and he hoped they would still receive such further co-operation of the same kind as should aid them in opening an exhibition in every way worthy of the present exalted state of the art.

The Chairman stated that Dr. Diamond, Secretary of the Photographic Society, had very kindly intimated, through Mr. Simpson, that any members of the South London Society who might feel desirous of attending the Photographic Soirée at King's College on the evening of Friday the 25th inst., would receive a ticket on handing their names and addresses to Mr. Simpson, who would forward them to Dr. Diamond.

A vote of thanks to Dr. Diamond and the Council of the Photographic Society, for their liberal courtesy in this matter, was passed by acclamation.

Mr. A. H. Wall then read his paper "On Photographic Reproductions (see p. 185). He explained that the pressure of duties, public and private, had prevented him from making the paper as complete as he could have desired, but he hoped to return to the subject at some future period. In the course of the evening a very magnificent series of reproductions from Turner's paintings were exhibited in illustration of the paper. These copies, which were produced by Mr. Thurston Thompson, as yet are unpublished, but were kindly lent by that gentleman to Mr. J. G. Cole, to bring to the meeting in illustration of the paper. Those who are familiar with the paintings of Turner, in the South Kensington Museum, and remember the startling masses of vivid colour which distinguish some of them, will readily understand the difficulty of translating them into monochrome by means of photography. The pictures were about 15 inches by 11 inches, and included some of Turner's most popular pictures. "The 'Fighting *Temeraire*' towed to her last berth," is a marvellous reproduction of a picture presenting very great photographic difficulties. The "Rebuilding of Carthage" is one of the most perfect reproductions we have ever seen, and in the photograph seems as full of atmosphere as in the celebrated picture intended by Turner to rival the productions of Claude. "A Storm at Sea," "Whalers," "The Trogan Fleet," and others of the great pictures were equally well rendered, and all more or less effective. Some exquisite reproductions of *bas reliefs* in terra cotta, also by Mr. Thompson, were exhibited; and together with those of the paintings were much admired. Mr. Cole stated that the lens used in these reproductions was one of Ross's orthographic lenses.

The Chairman in moving votes of thanks to Mr. Wall and to Mr. Thurston Thompson, commented on the vast importance of the art of photographic reproduction as a means of opening to the public those treasures of high art which were now limited to the possession of a few persons. As to the capability of photography to do justice to paintings generally, a more striking proof could scarcely be adduced than the remarkably fine specimens which Mr. Thurston's courtesy had placed before the meeting. More difficult subjects for photography than Turner's paintings could not have been chosen. Notwithstanding their great beauty, there was, as every one knew, not merely the varied and brilliant colours to deal with, but a peculiar indistinctness, which, however perfect in its effect in the painting, was necessarily very difficult to translate into photographic monochrome. Perhaps it was from the fact of the general indistinctness of outline in the paintings that a common feeling prevailed that his paintings were improved by engraving, a decision being there supplied which some persons fancied the paintings lacked, especially those of his latter period. These photographs possessed so much of the atmospheric charm belonging to the paintings, that one was irresistibly led to the conclusion that they were just what Turner would have painted if he had worked in sepia instead of in colour. He thought the publication of such reproductions could not fail to have a good effect upon the art education of the country.

Mr. Wall, without any disrespect, wished to record his protest against the idea that Turner's pictures were better in the engravings than in the originals.

The Chairman had simply expressed a commonly felt conviction.

Mr. Sebastian Davis thought that the sentiment and true character of many of Turner's pictures was better felt in monochrome than in the presence of colour, which by its profusion and exaggeration in many of his pictures disturbed the quiet enjoyment of light and atmosphere which was so apparent in these reproductions.

Mr. Wall referred to Ruskin's estimate of Turner's paintings, his statement that Turner had originated new ideas of the power of colour.

After some conversational discussion

Mr. Howard remarked that although, doubtless, the reproductions under attention were very fine, he must confess he should have liked better to have seen copies of the works of such men as Webster and other popular painters of a similar class.

After some further consideration

Mr. G. Wharton Simpson observed, that when Turner painted studies for educational purposes he painted in monochrome, his *Liber Studiorum* series consisting of sepia drawings. These photographic reproductions, therefore, just did for his larger works what he had done for himself in the *Liber Studiorum*. In regard to the criticisms of Ruskin upon Turner it should not be forgotten that, able and instructive as they were, Turner himself had repudiated some of them, and stated that Ruskin discovered meanings in his work that he never dreamt of.

Mr. Martin asked what was the effect of the preparation of hydrochloric acid and red oxide of lead, which Mr. Wall had recommended for improving discoloured engravings?

Mr. Wall said its peculiarity was, that it not merely restored the purity of the whites, but seemed to deepen and give crispness and vigour to the blacks.

After some further conversation the Chairman asked Mr. Wall to which of the modes of preparing collodion he gave the preference, judging from the results?

Mr. Wall had not arrived at any decided conclusion on the subject. Each would, probably, have its advantages under given circumstances.

Mr. G. Wharton Simpson, in answer to a question from the Chairman, said that Mr. Thurston Thompson had never, he believed, published his method of manipulating, it might, however, reasonably be inferred that it was not widely different from that adopted by other operators, who had obtained equally successful results. Mr. Simpson further stated, in compliance with a request from Mr. Fitch, that his experience in that department of photography was not so extensive as that of professional photographers, who devoted themselves to that branch of the art: he could, however, recommend with confidence the use of bromo-iodized collodion in reproducing any dark oil painting, or anything else with vivid contrasts. He (Mr. Simpson) had that morning made an experiment to verify one which he had made some years ago, and had found bromide of silver alone very much less sensitive to light than iodide alone, and that a combination of bromides and iodides was more sensitive than either. With an exposure of four minutes in full aperture of a portrait lens he had not obtained a trace of an oil painting with a collodion containing 4 grains of bromide alone, but with one grain of bromide and four grains of iodide he had a good negative.

Mr. Sebastian Davis remembered having some conversation with Mr. Thurston Thompson at the time when Mr. Hardwich's collodion was before the society. Mr. Thompson then informed him that he found he had obtained the best collodion from some French pyroxyline which he imported direct. He could not obtain any so good in England, he stated. He sensitized with a mixture of iodides and bromides, using somewhere about equal parts, but varying according to circumstances. For his own part he liked an old red, bromo-iodized collodion for copying purposes, as it allowed slow development, to obtain detail and intensity without danger of fogging.

Mr. Valentine Blanchard said, as the result of somewhat extensive experience in copying oil paintings, he would offer one or two suggestions as to what he conceived would be Mr. Thompson's mode of lighting those pictures for copying. He conceived that the light would be thrown on the picture to be copied in the direction, and at about the same angle as that in which it was painted by the artist. This might easily be seen by examining the pictures, as the heavy impasting on Turner's paintings would be found to give definite cast shadows. The very fact of this heavy loading of the picture with colour, although at first sight it appeared to create a photographic difficulty, really was the salvation of the photographs, redeeming them from flatness, and filling them with atmosphere. The light caught the rough surface and without altering the drawing gaining innumerable points of pure light, which at once gave brilliancy to the photograph. It was well to let the light strike the picture at a long angle to get the best effect in copying. Another point of great importance was to have everything darkened around and in front of the picture, so as not to be reflected by the surface of the picture. Regarding bromides he believed they produced a great increase of sensitiveness, but he believed it was to all rays, and not to certain coloured rays in particular. Their especial value in reproductions consisted in the fact that they so materially lessened contrasts, and produced harmony. He himself generally used as much bromide as iodide in his collodion. Direct sunshine was most important. Himself and parties had recently had to copy a very old painting, believed by some to be an original Tintoretto, of great value. Several persons had tried to copy it and failed. They found it impossible to do anything with it in a room, but on taking it into the open air and direct sunshine, they got a very successful negative. He had no doubt whatever but that these copies of Turner had been taken in full sunshine by Mr. Thompson.

Mr. Simspon referred, in corroboration of the opinion expressed by Mr. Blanchard, to the copying to the Raphael's Cartoons at Hampton Court by Mr. Thompson, who had them placed in the open air. He (Mr. Simpson) felt somewhat unwilling, however, to admit that the only pyroxyline suitable for the purpose was obtainable in Paris, as Mr. Thompson seemed to think. It was, however, somewhat singular, that in a recent conversation on the collodion used in producing instantaneous pictures, Mr. England had stated that he obtained his pyroxyline from a certain Paris house, and that none which he obtained in this country was so satisfactory. After some further conversation,

Mr. Davis, referring to the lenses most suitable for copying, remarked, that he believed that no lens was so suitable to this kind of work as Dallmeyer's Triple. It covered better, gave a flatter field, and straighter lines than any other lens, and was in every way best for reproductions. The orthographic, he considered, was inferior, and it should be borne in mind that the copies before them, stated to be produced by it, were no test of the value of a lens for copying purposes, as there were no straight lines to be produced without distortion.

Mr. Wall said he had recently received a letter from Mr. Maddison, of Huntingdon, who had considerable experience in reproductions, and he gave similar testimony to Mr. Davis as to the superiority of Dallmeyer's Triple for copying purposes.

Mr. Howard remarked that he remembered some very fine copies at one of the Society's exhibitions some years ago, before triplets were made.

Mr. Davis remarked that those were, he believed taken with a portrait lens with Waterhouse diaphragm, which would answer for copies very well, but the triplet was better.

Some conversation ensued on the samples of the results of different collodion exhibited, and also on the best mode of using the bleaching agency of chlorine in restoring the pure whites of discoloured engravings. The use of chlorate of potash and of chloride of lime was recommended.

Mr. Simpson stated that owing to the very bad printing weather, Mr. Robinson had not been able to supply the copies of the presentation print; but he hoped that they would be ready in the course of the next month, and before next meeting.

Mr. Davis wished to call the attention of members to the alleged accelerating influence of hot developers on dry plates, a subject which the Experimental Committee were about to investigate. Trustworthy information on the subject would possess high value; and he invited all members who had opportunity, to experiment and communicate results to the Experimental Committee.

The Chairman asked if any preparation had been made by photographers to give a reception to foreign photographers who might be attending the International Exhibition? Other trades and professions were taking such steps, and he thought it very desirable that photographers should do so. Doubtless, the parent Society ought to initiate any movement of the kind.

Mr. Wall thought something of the kind was most desirable, and it should be by the combined action of all photographic societies.

A paper "On the Use of Bromides in Collodion," by Mr. Blanchard, was promised for the next meeting, and the proceedings terminated.

## Correspondence.

### FOREIGN SCIENCE.

[From our Special Correspondent.]

*Paris, 15th April, 1862.*

By the aid of the electric light, M. Nadar has succeeded in obtaining a large number of views in the Catacombs of Paris, which form, certainly, one of the most singular contributions to science that has ever been made by the photographic art. They will, doubtless, find a place in your Universal Exhibition. These views must now possess a greater interest than ever, as, owing to the insecure condition of the roof of the excavations forming the Catacombs, the public are no longer admitted to them in order to gratify their curiosity.

M. Alphonse suggests a method of obtaining vignette portraits without the aid of the vignette glasses usually employed for that object. Reviewing the experiments generally adopted for vignetting, such as the introduction of cotton wool, swans down, screens, &c., none of which appear to completely satisfy the wants of the artist; the coloured glasses have the objection of being rather costly, and are frequently broken in the printing frame, consequently their use is greatly restricted. The method proposed to be substituted is as follows:—Trace on a piece of white cardboard an oval of the size required, shading off from a deep black centre to the edges, by means of a stump. From this drawing, as many negatives as required may be taken, and of different sizes, if desirable, by varying the distance between the lens and the cardboard. The negatives are developed and fixed in the usual manner, intensified with bichloride of mercury, and then varnished. If the drawing be properly executed, a very good substitute for the coloured glass, may be obtained. By a little forethought and management, the place on the glass may be fixed with the nicest accuracy, so that no difficulty in placing the head in the centre of the oval, need be experienced.

M. de La Blanchere has published a treatise on the stereoscope. It contains a history of the discovery, and various improvements in this magical little instrument, an excellent summary of the various theories of binocular vision; and a description of the materials necessary in the production of stereoscopic pictures, the methods by which negatives and positives, both on glass and on paper, are obtained or working with dry collodion, and an account of the various apparatus to which the stereoscope has been applied. Although little more than a compilation, the book will be found to possess a certain usefulness to those who are interested in this branch of the photographic art.

M. Berthelot has succeeded in a most interesting chemical experiment, resulting in nothing less than the direct combination of hydrogen and carbon. Having for a long time been convinced that by placing hydrogen in contact with carbon, at an extremely elevated temperature, they would combine with each other, he tried the experiment at all temperatures, but, at first, without obtaining the desired result. Finally, the extremely simple and happy idea occurred to him of making a current of hydrogen pass between the two carbon points of the electric light excited by Bunsen's battery of 60 elements, and then his efforts were crowned with success. At this extreme temperature the hydrogen combines with the carbon, and the product of the combination is carbide of hydrogen, discovered some years ago by M. Berthelot, to which he gave the name of acetilene. He has been able to collect sufficient of the product to submit it to numerous experiments, and discover that it possesses all the properties of acetylene derived from organic sources. M. Berthelot has previously succeeded in —firstly, forming by means of mineral compounds, and by a purely chemical method, the principal carbides of hydrogen; secondly, in transforming these carbides into alcoholic compounds; but this was neither a carbide nor an alcohol resulting from the direct combination of two mineral principles—from carbon and hydrogen. This, however, is only a *philosophical* production of alcohol, not yet available for manufacturing purposes: though, as a scientific fact, it is both curious and important.

M. Froment has invented a new chronograph, which promises very remarkable results. The apparatus measures seconds, the duration of which is only one five hundredth part of a second: it consists, mainly, 1st, of drum about 40 inches in circumference, silvered on its surface, which is covered with lamp-black at the beginning of an experiment, and to which clockwork imparts a motion of three turns in a second. 2nd, Of a diapason giving 500 vibrations per second, perfectly controlled, by comparison during several whole days with a regulator, which is both electrical and astronomical. 3rd, Of a fixed point in the diapason, which traces a sinuous curve upon the cylinder covered with lamp-black. 4th, Of a little electrical apparatus, intended to mark, by a point proceeding from the spark of induction, the beginning and the end of each phenomenon.

What distinguishes this chronograph from all others which have preceded it, is the very great length by which a phenomenon of infinitely short duration is represented on the blackened cylinder, and the facility with which this length may be subdivided by a microscope. It is stated that in recent experiments the time occupied by a ball in passing through a space of some inches, after being projected from a rifle, was accurately measured.

---

## PHOTOGRAPHIC CONTRACT IN THE INTERNATIONAL EXHIBITION.

*"Semper stultus."*

Dear Sir.—The extraordinary document which has emanated from the Commissioners of the Great Exhibition, inviting "tenders" for the sole privilege of operating in the building; is to my mind, one of the the most glaring evidences of official blundering, that these profound and talented gentlemen have yet been guilty of, and in saying this, I make a bold assertion.

In the appointment of Captain Fowke, who may however be an excellent engineer officer, but whose design for the Exhibition building, has caused him to become celebrated as the most original architectural bungler of the day; instead of obtaining a gentleman whose abilities would, at least, have been of such an order, that he would have been competent to have erected a temple of industry and art, which might bear a favourable comparison with an arcade market or a railway station, which it is an acknowledged fact that "the house that Fowke built," either in point of symmetry, elegance, or architectural beauty does not. In classing art photographs with patent grubbers, liquid manure distributors, and other products of mechanical dexterity, as though a picture which embraces in itself the highest efforts of scientific skill and artistic ability, was produced by a process similar to grinding "Dixey's land" upon one of those anacreontic abominations yclept a barrel organ, they displayed a deep seated, and no doubt laboriously acquired, ignorance of art and architecture, which might scarcely be anticipated from a New Zealander. Such being the case it ought not to be surprising that they indulge us with a taste of their leading propensity, when they invite tenders for the privilege of operating in the building, by constructing a code of rules for intending "tenderers" which, I think, will have the effect of deterring any but those who may have friends at court from making an offer for the monopoly. In the first place, they do not bind themselves to accept the highest, or, in fact, any tender. Now this appears to me to be a very "tender" subject. Though a gentleman may stand at the summit of his profession, his taste and skill beyond question, and his offer considerably in advance of other competitors, his tender may be but so much waste paper, unless he posess a friend amongst the Commissioners. This is unjust to the profession, and makes tendering a mockery and a delusion. Now the fairest system would be to have tender completely open, taking care, however, that only operators of proven ability be allowed to manipulate.

Again, in the event of any dispute, the Commissioners form the only tribunal of judgment, and from whom there is no appeal. Now as the unlucky photographer will, in all human probability, have more rows with the Commissioners than any other individuals, I scarcely think that the court could be considered an equitable one, when the judges are parties to the action and will allow of no appeal from their fiats. They rouse a never slumbering suspicion in my breast, of either their total ignorance of the theory and practice of the art of photography, or else their prejudice against it, and their desire to injure it in the eyes of the public, by decreeing that no operating will be allowed after 10 a.m., or if I read the rule right, before that hour, unless upon conditions that are not detailed: and, as a culminating point to a tissue of eccentricities, which would be laughable, were they not unfair to the public, and unjust to the profession, they will not allow any space within the building for either sensitizing or developing, nor yet will they allow those two indispensable formulas of the wet collodion process to be carried on in the building. This rule, if carried out, will totally prevent the application of what is universally allowed to be the best and safest system now known to science, and will compel the artist to use dry plates against his judgment and experience, besides entailing on him double labour, and poorer results.

Now Mr. Editor, I would call upon the profession to protest to a man, against what all must look upon as either an evidence of the densest stupidity, or a strong desire to lower photography in the eyes of the public, to minister to the vanity of a clique of painters who arrogate to themselves alone, the privilege of being called legitimate artists I would also advise the non sending of tenders, till the specifications are modified. I am yours, &c.,

Thomas D. Bell.

## Talk in the Studio.

Photography and Astronomy.—Mr. Warren De la Rue delivered the Bakerian lecture, at the Royal Institution, on Thursday evening last, in which he described his photographic operations in Spain, in connection with the great eclipse. After the lecture the Astronomer Royal made some interesting remarks on the immense value attaching to photography as a recorder of such phenomena, its superiority consisting in the absolute certainty of its testimony, whilst that of any individual was apt, under such circumstances, to be warped, coloured, or disordered by the intense excitement of the moment, arising even out of honest interest in the subject. Photography was subject to no such sources of error, and hence the great value of its record.

Photographic Washing Trough and Well Baths.—We have received from Messrs. Bland and Co., some earthenware vessels, manufactured by Mr. G. Elliot, for photographic purposes, which supply a want and are well worthy of attention. The first is intended for washing prints, and is a large earthenware circular pan, something like a foot-bath about 15 inches in diameter and a foot deep. At the bottom is an aperture which communicates with a syphon moulded in the earthenware and forming part of the pan. This principle, as our readers know, as been suggested and used before in washing prints, but we have never seen it so neatly carried out. The bath being placed beneath a tap the flow of which is properly regulated, will, as soon as it is full, commence to empty itself, and so keep up a steady flow of water: whilst the solution of hypo being of greater specific gravity than water, will sink to the bottom of the vessel and be carried off first all the way. If the mouth of the pipe giving the suppy be turned a little to one side so that the stream enter the pan at an angle, a rotary motion will be communicated to the prints, which will aid the completeness of the operation. The other vessel is a very convenient form of the horizontal well bath, which will be very useful for exciting large plates with a very small quantity of solution. Instead of being formed like the ordinary horizontal baths, quite flat, the well, or portion where the solution is held, is placed at an angle with the portion in which the plate is laid. When the solution is in the well that part rest flat on the table, the other portion in which the plate is laid being elevated at about an angle of 45°: when this is quickly lowered into a horizontal position, the solution flows evenly over the plate. For experiments, traveling, and other purposes, this will be found very useful.

Photographic Albums.—We have received from M. Bourquin an album for photographic portraits, which has some points of novelty in ornamentation. In addition to an elegant binding of morocco, studded with bosses of gilt metal, it is adorned with an imitation of Tunbridge ware, or inlaid wood. The pattern is printed in oil on a veneer of light wood, and then French polished. The imitation is perfect, and the ornamental effect very good. The interior of the book isalso of a very superior character, the mounts being of fine card, with a delicate tint, which gives an excellent effect to the photograph. A correspondent of a daily paper remarks on this notice :—" Is it for the sake of the postal revenue, or from a desire of the authorities to patronise obsence art—or do they lack the legal power to destroy such pernicious things? Her Majesty's customs at once seize and destroy all obscene prints and the like productions, whether imported with merchandise or in passengers' baggage, and occasionally the police and the Society for the Suppression of Vice shew activity in prosecuting the miscreants who, for gain, pander to the morbid passions and sensual vice. Your readers may blush for their country when they read such a public official notice, if the Postmaster-General does not; and, I hope that the notice may be withdrawn for a more stringent one.

Obscene Photographs, &c., in Book Packets.—A notice has been issued by the Post Office authorities, stating that on the 1st of May next, and thenceforward, all photographs, drawings, prints, or other things, which may be obviously and unquestionably of an obscene character, will be excluded from the privileges of the book post, and must not be sent in open covers to any place in the United Kingdom, or to the Colonies, or to any foreign part. It is added that it will be the duty of postmasters to send forward in envelopes, as unpaid letters, any packet which may seem to them clearly to fall within the meaning of this prohibition.

## To Correspondents.

South London Photographic Exhibition.—Notice to Exhibitors.—Wo are desired to announce that a modification has been made in Rule 7. Exhibitors, instead of sending untouched duplicates in the same frame as coloured pictures, are requested to send them in separate frames.

T. R. Heaton.—We believe the rules are reprinting. We will Inquire, and if any are in existence send you a copy. If not we will do so as soon as they are reprinted.

N. B., Newbury.—We can only recommend you to read the various articles and communications on the subject of mealiness which have appeared durIng the last few months in our pages. Do you take care to let the toning bath stand a few hours before use? We believe that several causes induce mealiness; but it is only the printer who can tell the probable cause on examining his own operations, carefully comparing them with the possible or probable causes of this defect.

Wellwisher.—An optician will make you the mounting, or get it made for you.

Annesley Free.—The best mode of removing either black or white varnish from a plate, must depend entirely upon the solvent originally used in the varnish. Almost all black varnishes may be dissolved by means of turpentine or benzole. The white varnish may be dissolved by benzole or chloroform if it were of the class applied cold. If it be a spirit varnish it will be more difficult, but strong alcohol may remove it. Any method of toning and fixing together is uncertain as regards permanency. You had better be content to secure this quality even at the cost of a little trouble. We are obliged by your kind intentions.

N. sends us some defective prints and observes: "The progress of civilization in photography is productive of new diseases—as elsewise. I have never had such results as these in former days, before the introduction of the acetates and phosphates into the toning bath. Have my prints 'measles?' examine them by transmitted light. I have ascertained the cause of failure. *I used too much of the acetate (and phosphate of), soda with the chloride of gold*, and it attacked the albumen of the paper. It is *not* a case of under-fixing, or of imperfect washing. The only question I ask is, have these prints the 'measles?' The disease is new to me, and I desire to be able to recognise it." The specimens sent are very decided and malignant cases of "measles;" and with all deference to our correspondent's judgment and ability, we should unhesitatingly pronounce the cause imperfect fixation The mottled dirty yellow effect is due to decomposed hyposulphite of silver, which is in the body of the paper, and underneath the albumen, as may easily be ascertained by splitting away the albumen with a penknife. The cause of the imperfect fixation is not so clear, but may proceed from hypo too weak, or too old; or from too short immersion. Or it may be from impure hyposulphite of soda.

Francis B.—You will find Information on the Solar Camera on pp. 247 and 253 (Nos. 142 and 143), of our fifth volume; and on p. 110 (No. 96), of our fourth volume.

North Briton.—The information on the subject of bees, regarding which you inquire, is in the letter of our Paris correspondent, on p. 222 (No. 105), of our fourth volume.

O. K. Walker.—Your vignette head is very good. The other is just a little hard. With practice and care you will succeed.

F. M. S.—If you had been a careful reader of our pages, you would have ascertained that there is no especial secret in what is called producing negatives by the positive process. The phrase simply means that a positive collodion and iron development are used, and the amount of printing vigour required, obtained by intensifying. If your positive collodion give a somewhat vigorous image, you may use it as It is; if not, add a little of some intense negative collodion. If your positive bath be freely acidified with nitric acid, it will be scarcely suitable for the purpose, as the bath should be nearly neutral. Expose a little longer than for a positive. Omit all nitric acid from the developer; use about 15 grains of protosulphate of iron, and 15 minims of glacial acetic acid in an ounce of water. In developing, do not stop short so soon as for a positive, but continue the development as long as any additional detail can be obtained; taking care however not to continue it until there is a foggy deposit on the shadows. Now wash, and then pour on to the plate a solution made as follows:—pyrogallic acid, 2 grains; citric acid, 1 grain; distilled water, 1 ounce. When this flows freely without greasy lines, return it to the developing cup, add about ten drops of a 20-grain solution of silver kept for the purpose, and again pour on the plate; keep them moving, and when the desired intensity is obtained, wash and fix. Sometimes the intensity is not readily secured: if the pyro and silver decompose and become discoloured before the negative is sufficiently Intense, wash it off and repeat the operation. This is a very brief description of the operations; but we cannot enter Into them more fully here. See articles on Iron Negatives, and on Modes of Intensifying, in the Photographic News Almanac, where you will obtain all the information you require. Good results depend more on intelligence, skill, and care than on secret processes. Use the alkaline toning by all means; do not commence the old system.

Pyroxyline.—We generally prepare our own soluble cotton. We regret to say that we do not know of any house that supplies a trustworthy article. We have repeatedly tried samples from different photographic chemists, and have unwillingly come to the conclusion that they have been portions of waste batches, which were unfit for the manufacture of collodion for sale. We have recently been favoured by Mr. England with a sample of the pyroxyline he uses, and which he gets direct from Paris, but we have not yet had an opportunity of trying it.

An Amateur Subscriber.—Mr. England's dark slide and instantaneous shutter were made, he informs us, by Mr. John England, manufacturer of photographic apparatus, 56, Upper Charles Street, Fitzroy Square.

Teesdale.—A lens intended to cover a plate 10 by 8, will, of course, cover a plate 9 by 7 still better; but you must bear in mind In using a lens of longer focus, and covering a plate larger than you intend to use, you include a less angle in the picture; that is, everything will be on a larger scale, and there will be less subject in the picture than if a lens of shorter focus were used. You will however gain the advantage of better definition and less perceptible distortion, by practically cutting off the margins. In using cyanide to reduce the density of an over intensified negative, there is great danger of the half tones being attacked first, and the picture being injured; great care should be exercised in its use. We have handed your order to the publisher.

Several correspondents in our next.

Vol. VI. No. 190.—April 25, 1862.

## THE PHOTOGRAPHIC DEPARTMENT OF THE INTERNATIONAL EXHIBITION.

So far as we are able to judge at the present moment, there will be no startling novelty in the English Photographic department at South Kensington. A respectable display of good photography, such as may usually be seen at the annual exhibition of the Society, will unquestionably be presented; but nothing more. Already, without the guidance of a catalogue, we recognise without difficulty the presence of many old favourites, in whose productions wet collodion and dry plates divide the honours. In the latter, as might be anticipated, the Manchester men take high rank; and we recognise with pleasure, already well hung, the magnificent results obtained on collodio-albumen plates, by such men as Mudd, Sidebotham, and Wardley. In wet collodion, nothing we have yet seen hung, surpasses the landscapes of Mr. Vernon Heath. Leiut.-Col. Stuart Wortley has some exquisite instantaneous views of the Bay of Naples, and Vesuvius in eruption, very similar in delicacy of style to Mr. Vernon Heath's pictures. Mr. Dixon Piper exhibits some very perfect large pictures, amongst which are some very fine atmospheric effects. In portraiture the fine studies of Mr. D. O. Hill, will attract much attention, as will also the subject pieces and *genré* pictures of Rejlander and Robinson. So far as we can judge at present the contributions of life-size pictures are not so numerous as might have been anticipated; as the hanging was but slightly advanced, however, on our last visit, it is impossible to speak with certainty.

In the classification and arrangement on the walls, every care possible under the circumstances, is taken to give the best pictures the best positions, but as every foot of hanging space must be made available, it follows that some pictures must hang far above the line, and others below, whilst others must be used as they will best fit in or fill up. A staff of efficient and active operatives, accustomed to hanging, are engaged upon the work, under the superintendence of the Committee, who attend from eight in the morning to six in the evening, working with more than the energy of paid labourers.

Since our last, some modification in the arrangements as regards jurors in this department has been made. Of those we before mentioned as appointed to that duty, two remain —Dr. Diamond and M. Claudet. To these are added the names of Professor Tyndall, Mr. Thurston Thompson, and Lord H. G. Lennox. Sir David Brewster now takes office in another department. Regarding the additional names we have little comment to make. No name stands higher in science, or will command more confidence and respect, than that of Professor Tyndall. Mr. Thurston Thompson is one of the most accomplished photographers of the day, and although a professional photographer, is not engaged in any competitive relation to the majority of other professional photographers; nevertheless, as he is a contributor to the Exhibition, we cannot but think there is some lack of propriety in the appointment. Of Lord Lennox's photographic accomplishments we know nothing beyond the fact that he was a pupil of Mr. Thurston Thompson. A jury of five, however constituted, is necessarily more likely to give satisfaction than one of three; and although we cannot but think some men in whom photographers would have had more confidence might have been appointed, we trust that, on the whole, justice will be done.

The contract for photography in the building has been undertaken by the London Stereoscopic Company. We hope that some modification of the original conditions has been obtained.

## MR. SUTTON ON RAPID DRY PROCESSES.

Mr. Sutton has recently been giving considerable attention to the maturing of a rapid dry process; the principle upon which he is working being somewhat similar to that announced by M. Roman last summer, in which a certain amount of free nitrate of silver was to be left in the film of a collodio-albumen plate. Unlike M. Roman, however, Mr. Sutton discards hot development. He says:—"Whilst others have been varying the preservative, or using dry collodion without a preservative, or availing themselves of the assistance of heat in development, we have been endeavouring to apply the principle of retaining some free nitrate in the film without allowing it to produce stains, or eat away the iodide, and the result is that our experiments have been crowned with success; and we have prepared rapid dry plates which have yielded excellent negatives with the same exposure as the best wet collodion." As to the quality of the negatives he further desires to place on record that—

"We have succeeded in preparing rapid dry plates as sensitive as the best wet collodion,—that these plates yield excellent printing negatives, having clean lights and red blacks—that the film will bear the ordinary rough treatment of washing without being protected by varnished edges; that it does not wrinkle or produce blisters; that the picture is quickly developed by means of a cold developer, consisting of pyrogallic acid with acetic acid and a few drops of nitrate of silver added; and that the principle on which these plates have been prepared consists in using a suitable iodized collodion, in washing the excited film thoroughly from the silver bath in order to prevent stains, and in restoring the sensitiveness by means of fresh silver added to a suitable preservative, which never becomes absolutely dry and hard."

The only point upon which Mr. Sutton expresses any doubt is the keeping qualities of the plates, but bases a conviction that they will keep, upon the fact that the plates of Dr. Hill Norris keep well, and that they contain free nitrate of silver. This, however, Dr. Hill Norris denies of his recent rapid dry plates. Nearly twelve months ago, Dr. Norris informed us that he had succeeded in eliminating all free nitrate, and that the quality of the plates was improved. We may state, however, in reference to the keeping properties of dry plates containing free nitrate, that Dr. Diamond informed us the other day, that he had just opened a packet of dry plates which had been prepared by Messrs. Bland and Co. four or five years ago, and were found to be perfectly good. Mr. Bland has subsequently informed us, when speaking of the fact, that the plates in question received no washing at all; but were coated with the preservative solution, consisting of gelatine with citric acid, direct from the nitrate bath.

Without offering further comment, we proceed to make some extracts from recent numbers of the *Notes*, in which Mr. Sutton develops his ideas of the correct principle upon which rapidity in dry processes should be based, and explains the details of formulæ and manipulations:—

"The principle which we have followed in preparing these rapid dry plates, is that of a double coating, similar in character to albumenized collodion, but differing in some important points. For instance, in the process of Dr. Taupenot you are obliged to use a very thin collodion, greatly reduced by the addition of ether, or your plate will be covered, during the development, with a multitude of blisters about the size of a pin's head, which spoil the negative. Now the use of this kind of collodion greatly reduces the sensitiveness of the plate because sensitiveness depends, in great measure, upon the state of the excited collodion film. In our new process this objection does not occur, because we commence with the most sensitive and creamy cadmium collodion, and yet avoid all chances of blistering by using a suitable second film. In the next place in the Taupenot process, the second nitrate bath is strongly acidified with acetic acid, which is added in about the same proportion as the silver. This renders the second film insensitive. But in our process the second nitrate bath contains very little acetic acid, and it is not impossible that even that little may be omitted altogether. If, therefore, our process resembles that of Dr. Taupenot in having a double film, and a double excitation, it still differs from it in two very important points. In a word, we have taken the Taupenot process as a basis, and have modified it in those particulars in which it was evident that sensitiveness was sacrificed, through mistaken notions of what was right and necessary."

The details of the process follow, but as they are modified in a subsequent number, we shall quote them from the latter, in which also some further affirmation of the principle is given :—

"Before giving minute directions, we will endeavour to explain the principle upon which we believe the rapidity of a dry plate to consist. It is in the retention by the film of a certain small quantity of free nitrate of silver, this small quantity of nitrate being entangled or combined with a coating of organic preservative applied to the iodized collodion film. Our experiments do not permit us to believe in the possibility of employing any other principle in the production of a rapid dry plate, and we cannot endorse the opinion expressed by Mr. Bartholomew, in a communication which we have copied from the News into the present number, or encourage our readers in the hope that they will obtain any good result in that way. If you take an excited collodion plate from the nitrate bath, and wash it thoroughly in distilled water, it is notorious that you reduce the sensitiveness immensely, and it is equally certain that the lost sensitiveness cannot be restored by the application of any of the known preservatives to the film. At the same time it is not necessary for the preservation of the original sensitiveness that the nitrate of silver which remains upon the plate should be of the same strength as the nitrate bath. If the excited plate is removed from the 30-grain nitrate bath in which it was excited, and immersed in another of only one-third the strength, the sensitiveness will remain about the same, and it will only become necessary perhaps, in some cases, to add a little silver to the developer to give the necessary intensity to the blacks.

"Assuming then the truth of the above principle, our object has been to ascertain the best means of allowing a sensitive plate to dry with a little free nitrate of silver in it, and yet to keep well for a few days, and give clean, good negatives.

"There are three ways of accomplishing this object :—

"1st. You may apply a very thick coating of iodized collodion to the plate—excite it thoroughly by a prolonged immersion in the nitrate bath—then dip it into a 10-grain bath of nitrate of silver, slightly acidified with acetic acid (say one drop to the ounce of bath), and then pour a preservative over it and let it dry. A plate prepared in this way would closely resemble in its appearance and properties one of Dr. Norris's rapid dry plates; that is to say, if freshly prepared it would be as rapid as wet collodion, and would give a bluish-black picture, with a slight tendency to greyness in the lights, if the development is pushed too far. In this process the drop of acid to the ounce in the second bath is for the purpose of making the plate keep better; and the use of the preservative is to combine with or entangle the free nitrate, so as to prevent it from attacking the iodide of silver in the film. A mixture of honey and gum arabic, dissolved in water, seems to be a good preservative for this process. A thick film of iodized collodion is recommended in preference to a thin one, because it will hold more material, and is always more sensitive. The way to get a thick film is to use collodion containing a great deal of pyroxyline, made at a high temperature, and very soluble; or to coat the plate twice with collodion.

"2nd. Coat the plate with iodized collodion in the usual way, that is, so as to get a film of the common appearance, and not a thick one. Excite the plate, and wash it thoroughly with water. Pour over it an iodized preservative, and let it dry. It is now insensitive to light, and may be put away ready for use at any time. In order to excite it a second time, dry it well before the fire, and then pour over it iodized collodion as before, and excite it in a 30-grain nitrate bath, containing one drop to the ounce of acetic acid. Wash, as in the first process, in a 10-grain nitrate bath, let it dry, and it is ready for use.

"A plate prepared in this way, with a double coating of collodion, looks just as creamy and solid as a piece of opal glass, and the flame of a candle looks dull and red through it. The object of the preservative intervening between the two films is to prevent the second coating of collodion from attacking and dissolving the first. It also entangles the free nitrate. Iodized gelatine solution may be used for the preservative. Say 4 grains of gelatine and 2 grains of iodide of potassium to the ounce of water, which is quite strong enough.

"3rd. This is simply a modification of the Taupenot process. Coat the plate with collodion of the usual density, and excite in the usual way. Wash thoroughly, and pour over the plate the following preservative :—

| | | |
|---|---|---|
| Albumen ... ... ... ... | 3 | ozs. |
| Water ... ... ... ... ... | $1\frac{1}{2}$ | ,, |
| Honey ... ... ... ... ... | 10 | grs. |
| Gum arabic ... ... ... ... | 10 | ,, |
| Iodide of potassium ... ... ... | 20 | ,, |

"Dissolve the three last substances in the water made hot, then strain the solution into the albumen, and beat all up to a stiff froth. When settled it is ready for use. The object of adding the honey and gum arabic to the albumen is to prevent blistering of the film, and the proportions given above are nearly the same as those used by Mr. Macpherson, of Rome, in his albumen process. The plate is now insensitive, and may be put away for use as required.

"In order to excite it, dry it first before a hot fire, and dip it into a 20-grain nitrate bath for half a minute, and afterwards into a 10-grain bath, both baths being being slightly acidified with about one drop of acetic acid to the ounce, as before. Then put the plate away to dry, and it is ready for use.

"Whichever of these three methods is employed, the plate is as sensitive as an ordinary wet collodion one, and instantaneous views of breaking waves, &c. may be taken upon it when dry, and after it has been prepared some hours or days, according to the season.

"The mode of development may either be that recommended by Dr. Hill Norris, viz., by first moistening the plate, and then pouring over it the pyrogallic developer, with a few drops of nitrate of silver added, or it may be developed thus :—

"Without first moistening the plate, put it into a dish containing some very weak pyrogallic acid with very little acetic acid, and no nitrate of silver. Let it remain in this until all the details are faintly visible, and then intensify in the usual way. Citric acid is perhaps less liable than acetic to obliterate the image produced by light, and one grain of citric acid to a pint of weak developer might be enough to use. The image is at first brought out by means of the free nitrate which is retained by the film. If the plate had been *thoroughly* washed it would be absolutely necessary to add nitrate to the developer, or no image would appear. Fix with saturated hypo, and finish in the usual way.

"The first and second of these three methods are rather more rapid than the last, and give softer negatives, but they are more liable to become veiled in the development. The last process gives cleaner pictures.

"In working with process No. 3, the tourist would take with him a lot of plates in the first stage of preparation, and also a nitrate bath for the second excitation and washing. Some of his plates he would prepare as rapids, in the manner described, and the others as slow ones, by giving them a thorough washing. This he would do from time time as he wanted them, and in the meantime the rapid plates would keep two or three days, and the others as many weeks. The plan would be a great gain upon wet collodion, and the subjects would be better selected, and the negatives quite equal in quality, if not better. The time is not far distant when wet collodion will be altogether given up for out-of-door work, whether the exposure be long or instantaneous. Let us all strive to hasten the arrival of that good time, and give a new impetus to photography, and render it a tenfold more attractive pursuit to the amateur than it is at present."

## REMARKS UPON SOME OF THE APPARATUS EMPLOYED IN PHOTOGRAPHY.*

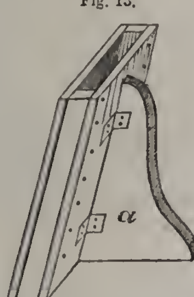
BY F. R. WINDOW.

Baths and Dippers (*continued*).

India-rubber, slate, and wooden baths, have not, I believe, been manufactured for sale, or been much used by photographers generally. I will confine myself to describing the last mentioned, which may perhaps prove useful to some of my readers, should they ever find themselves beyond the pale of photographic civilization, with a broken bath, and no shop within a hundred miles or so, where another can be procured. It is convenient in such a case to be able to obtain an effective substitute, by simply applying to the village carpenter and at the oilman's; also a wooden bath is so exceedingly cheap, so easy to make, and so perfectly efficient when properly made, that *the recipe* may be useful to many a country photographer for his ordinary daily use.

The best material is dry soft pine, as this wood imbibes more readily the resinous cement: common deal will do very well. Pieces should be selected without knots. The two larger sides, which I will term the *back* and *front*, may be made for baths up to 12 by 10 inches, of ¼-inch stuff; and the bottom must be of ½-inch stuff. Having cut the several pieces to the required size, they are to be planed on both surfaces. It will be seen by referring to fig. 13 that the sides and bottom fit in between the back and front pieces, and therefore the breadth of these former determine the breadth of the opening of the bath, which must be settled according to the particular idea of the maker. I think in most cases that three-quarters] of an inch is sufficient. On to the back is fixed a foot ($a$), for the bath to rest

Fig. 13.



upon when in use, and if it be intended for field work this must be fastened with hinges, to enable it, to be folded up.

Having prepared all the pieces, and screwed on the foot, a line must be drawn upon the inside of the back and front pieces, half an inch from the edges of the sides and bottom of each, to mark where the side-pieces and bottom will join on to them. They are then laid on a table face upwards, and thoroughly coated on that side with rosin cement, by means of a coarse brush, to within about an eighth of an inch of the line. The cement must be laid on thinly at first, very hot, and rubbed well into the pores of the wood, and several subsequent coats must be given, until there is a thickness of at least $\frac{1}{32}$-inch, evenly spread over the whole surface. If any difficulty be experienced in getting finally a nice smooth surface, a hot iron, such as a shovel, held at a little distance above it, without touching, will be found an easy remedy. When the inner faces of both back and front are well coated, and the cement perfectly set, the trough is then put together firmly with screws, wood to wood; no glue being used. Except for the question of appearance, it is not necessary that the joints be a very perfect fit. A sufficient quantity of cement is now made hot in a pipkin or ladle, and poured into the bath, being run down one of the sides, which is tilted downwards for that purpose. This coats that side piece, and also runs into and fills up the joint. The bath is next held upright, that the hot cement may flow over the bottom and into the joints round it, and finally tilted in the reverse direction, that the surplus may run off over the other side. If on inspection it appears necessary, this operation must be repeated. The bath is thus thoroughly protected on the inside with a material quite neutral to nitrate of silver, it is perfectly water-tight; and a good coat of cement upon the top, and a thin layer all over the outside, makes it complete.

I should observe that care must be taken when using a bath of this description to avoid rubbing the dipper or plate hard up against the sides, as by doing so small particles of the cement may be ground off, and they may settle upon the plate. A little caution will avoid this.

The cement for lining wooden baths, or for coating any parts of photographic apparatus that require protection against the action of nitrate of silver, is composed of

| | |
|---|---|
| Yellow beeswax ... ... ... | 3 parts |
| Rosin ... ... ... ... ... | 4 „ |
| Fine grit ... ... ... ... | 3 „ |

The above proportion of wax and rosin cannot always be strictly adhered to, owing to the varying quality of commercial samples of these substances. If, upon experiment, the compound is found too brittle, more wax must be added; and on the other hand, too great softness must be corrected by the addition of more rosin.

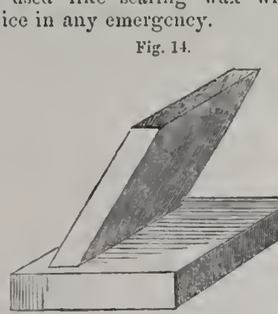
The grit may be either red tile, red brick, bath brick, slate, tobacco pipe, or any such material, reduced to a fine powder in a mortar. It will give its colour to the compound, according to the substance selected.

To make the cement: first boil some water in a pipkin over a bright fire, to make certain that there is no flaw in it, and that it will stand heat properly. Then dry it well inside, and place it on the hob near (not on) the fire with the rosin and wax in it. When these are melted, add the grit, and stir it to mix all the ingredients thoroughly. Whenever it is being used, it must be constantly stirred before each brushful is taken, otherwise the grit will sink to the bottom. Before using it for the first time, a trial must be made, to see if it be of a proper consistency. My practice is to let a drop about the size of a shilling fall upon a piece of glass, and place it in the air until thoroughly cold and set. I then chop at it with the blade of a table knife, which should chop out little pieces only in close vicinity to the point struck. If large pieces are chipped off, leaving the glass bare in places, more wax must be added; if an impression of the knife be only made, and nothing chipped off at all, more rosin is wanted.

It must be borne in mind that the ingredients of the cement are of a very inflammable nature; and every precaution must be taken to avoid accident from their becoming ignited. If a pipkin be not at hand, an iron ladle will do.

This cement will also be found useful for repairing photographic glass and porcelain dishes, measures, baths, &c., as well as for sundry minor purposes, and the amateur especially will find it a very useful article to have always handy in his laboratory. I generally keep some by me in sticks that may be used like sealing wax with a candle at a moment's notice in any emergency.

Fig. 14.

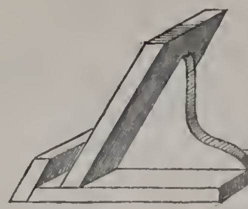


The simplest foot for a dipping bath is a block of wood with a mortice cut in it of a proper size to receive the bath; but this is a rather clumsy affair, because the wood must be of

* Continued from page 184.

some considerable thickness to take proper hold of the bath, and it must project, as shown in fig. 14, a good way behind the bath, to prevent the whole being top heavy. This arrangement also necessitates a separate foot for each different sized bath. The universal foot (fig. 15) is far more

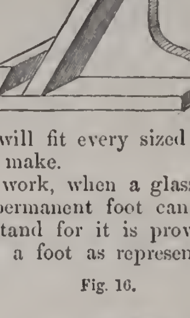
Fig. 15.



convenient, as it will fit every sized bath, and it is also simple and easy to make.

For out-of-door work, when a glass or porcelain bath is used, to which a permanent foot cannot be attached, and when no special stand for it is provided in the arrangements of the tent, a foot as represented in fig. 16 will be

Fig. 16.



found very convenient. Both the front and back being provided with hinges, it folds up into little compass, and may be made of slight materials; therefore it is very portable. When in use, to prevent the bath from slipping off the bottom ledge, which is made without any beading upon it, so that it may fit all baths, an india-rubber band is passed round foot and bath, to keep them securely together.

A foot should never be made so as to hold the bath in a vertical position: it must always be a little inclined backwards (figs. 14, 15, and 16), to prevent the plate from falling off the dipper.

All dipping baths of whatever kind or material should be provided with a cover for the double purposes of keeping out dust, and of protecting the plate from the light during sensitizing, so that the door of the laboratory may be opened without danger while a plate is in the bath. This cover for opaque baths need only fit loosely over the opening of the bath like the lid of a pill box, and may be made of wood, cardboard, or any convenient material. The cover of a transparent glass bath should fit over the whole bath, and rest upon the foot, so that all parts may be entirely shielded from light; or it is still better to enclose the glass bath in a wooden case, and fit the cover on to this latter. The bath must not be fastened in the case, but should fit easily into it, so that it may be taken out whenever it is necessary to clean it.

Some baths intended for use in the field are fitted with water-tight covers, by means of which the photographer is enabled to dispense with a bottle for the bath liquid, which can by this means be carried safely in the bath itself, and his baggage is so much lighter and less bulky. All kinds of baths can have such water-tight covers fitted on to them, but those made of gutta-percha are generally preferred, both from their greater cheapness, and especially from their non-liability to fracture, which is a valuable quality in such an article for field work. The water-tight cover consists of a wooden lid, lined with gutta-percha or india-rubber, which is pressed firmly upon the opening of the bath by means of screws working in a frame-work, adjusted on to the bath itself, or on to the box which contains it. There are several designs used for pressing the cover upon the bath, which are all of them perfectly efficient. Gutta-percha is the best material for the packing of the cover. It has just sufficient spring to answer the purpose. Pure india-rubber would be superior to gutta-percha in warm weather, but in the cold it becomes hard and useless. Vulcanized india-rubber should be avoided for this purpose, as any combination of sulphur, especially such in which free sulphur exists, is dangerous to be used in direct contact with silver solutions; by boiling vulcanized india-rubber first in a strong solution of caustic potash, to eliminate the free sulphur, it might possibly be rendered harmless to the bath liquid, but I think it is safer to reject the material entirely.

(*To be continued.*)

## M. FOUCAULT'S HELIOSTAT.

The Heliostat, as hitherto constructed for scientific purposes, acts usefully only on a luminous ray of 2½ to 3 inches in diameter: besides, we do not require the reflected ray to maintain an absolutely fixed direction, and provided that the deviation remain within the limits of the solar angle, the experiments proceed regularly. Now-a-days, for illustration of lectures, and for various applications of astronomy and photography, it has become indispensably necessary to operate with a larger quantity of light, to collect more rays, and to fix them as long as possible in a given direction.

Of all the heliostats known, the easiest to place in position, and the one which resolves the problem in the most elegant and general manner, is unquestionably the heliostat of M. Silbermann. By placing his mirror in the centre of motion, and by taking the points of support upon two exterior and concentric arcs, M. Silbermann has given to his heliostat the property of assuming positions unattainable in all other instruments of the same kind. But these advantages, universally acknowledged, have not reconciled experimentalists to the necessity of supporting and moving a heavy mirror. It was necessary, therefore, to contrive some other arrangement.

In the instrument invented by M. Leon Foucault, the metallic mirror, which is not less than thirteen inches long by six and a half inches wide, is supported by a vertical column, upon which it rests by means of a disc which resembles in every particular the circular mirror of S'Gravesande's heliostat. This disc is in fact suspended by two pinions diametrically opposed to each other, and put in motion by the action of a horary index upon a normal axis fixed on its back. The mirror attached to this disc, which surrounds it on all sides, can be made to turn in its own place around a common centre; and as it is important that at every moment its greatest dimensions coincide with the plane of reflection, this condition is met by prolonging the directing index behind, and by engaging its second extremity in a groove fixed on the back of the mirror, in the direction of its greatest length. The directing index, the normal tail of the disc, and the groove of the mirror, thus form a rectangular triangle, constantly comprised in the plane of reflection, and the hypothenuse of which has an invariable length. The directing index represents the incident ray, and the reflected ray is figured both by the line which passes the point of intersection of the index with the horary axis, and by the centre of the disc; this line is equal to the two halves of the needle, and divides the rectangular triangle into two equal isoceles triangles.

The principal centre of the instrument is the point where the conducting needle of the mirror crosses the horary axis which gives it motion. To dispose at will of the direction of the reflected ray, it is sufficient to move spherically the centre of the disc around this central point. To this end we take as a fixed centre of all the motions another point situated lower down in the vertical projection of the principal centre, and attach to this point the base of the column of the mirror by a crank of invariable length: then, by virtue of the parallelogram thus formed, we can turn the column in every direction, and by this means direct the reflected ray without altering the distance of the centres.

The rest of the instrument presents nothing special; the horary axis is put in motion by clockwork. Its inclination fixed upon, is adapted beforehand to a given locality; following in this respect the custom of constructors of astronomical instruments. The directing needle of the mirror is placed at the declination of the day by means of a graduated half circle, furnished with an index, and mounted upon a true centre.

To put the instrument in operation the course to be followed is precisely that which has been recommended for M. Silbermann's heliostat. Of the four conditions to be fulfilled, which consist in putting the instrument in the meridian in the latitude of the place at the hour and the declination of the day, it is sufficient that any two be primarily satisfied in order, generally, to fulfil the others, with the aid of the index mounted parallel with the directing needle.

Thus it will be seen that the new instrument is characterized by two peculiarities, which in heliostats previously known, exist only by one excluding the other. In the first place the mirror is set *a plomb* upon the inflexible vertical column, capable of supporting a considerable weight; in the second place the mirror of elongated form, orients itself spontaneously, following the plane of reflection, so as to project the reflected ray in the most favourable direction.

## REMARKS ON THE PREPARATION OF PHOTOGRAPHIC PYROXYLINE.

BY M. M'A. GAUDIN.

It has become a habit to continue to call by the names of gun-cotton, fulmi-cotton, pyroxyline, fulminating-cotton—the cotton soluble in a mixture of alcohol and ether, employed in photography. But, in fact, photographic cotton cannot be usefully employed with fire-arms: when ignited it generally melts, leaving behind a considerable residue of an aqueous nature.

Everyone who has prepared photographic cotton must have remarked how variable the nature of this product is, according to the circumstances under which it is prepared; hence it is exceedingly difficult to constantly obtain an identical product. As the product varies according to the circumstances under which it is prepared, in order always to obtain the same product, it is necessary to realize at each operation conditions which shall be perfectly identical; but instead of so doing the operations are performed, first with one acid and then with another; with a cold mixture or with a hot; with cotton, or paper, or rags; hence the dissimilarity of the products which must necessarily result from the various formulæ acted upon for the production of a very delicate molecular reaction, which includes an entire series of bodies readily transformed into each other.

The composition of the various pyroxyles is still but imperfectly known; it was at first supposed that the fulminating compound resulted from a sort of combination of lignine with nitric acid, and this is doubtless true; but what is most important to ascertain is, in what photographic cotton differs from true fulmi-cotton, in order to have clear ideas upon its mode of preparation.

Until recently I had always thought that to act well upon the lignine, the nitric acid ought to be entire; and, with many others, I believed that any appearance of nitrous compound in the acid was a bad precedent. I had many times seen my cotton inflame, disengage reddish fumes, and become converted into a viscous and burnt substance; but there is a great difference between the existence of nitrous gas during the preparation, and its appearance during the destruction of the fulmi-cotton. Then this gas is the *result* of decomposition, not its *cause;* and, doubtless, analagous reasoning had led M. Rivot to adopt a rational process, which always gives an excellent product.

According to M. Rivot, the nitrous gas in the nitric acid far from being injurious in the preparation of photographic cotton, is, on the contrary, the best element in its production, so much so, that, according to him, photographic cotton will be, so to speak, the result of the displacement of water by deutoxide of nitrogen $N_2O_4$, while in fulmi-cotton this water is replaced by nitric acid $N_2O_5$, as admitted in principle.

Abandoning all theory, the utility, I may even say the aptitude, of the nitrous gas to produce photographic cotton, is demonstrated by the process discovered by M. Rivot, and which he has always practised with complete success. He has obligingly communicated to me the following as his recipe:—

Commence by saturating nitric acid with binoxide of nitrogen, by passing through it a current of this gas, which is easily obtained by the action of nitric acid (cold), diluted with its volume of water upon turnings of red copper. This apparatus is mounted upon a mattrass closed by a cork, pierced with one end of a glass tube, connected with a disengaging tube of vulcanized india-rubber. The disengagement is continued until the acid has acquired a density of 1° 31.

We then add to 50 parts of this acid, saturated with binoxide of nitrogen, 60 parts of fuming nitric acid of commerce, marking 1° 47. The mixture should mark 1° 40 of the densimeter.

Eighteen fluid drachms, weighing 25 drachms, are poured into a porcelain capsule, and perfectly covered with a plate of glass; then 15 fluid drachms of concentrated commercial sulphuric acid; weighing 27 drachms, are added; when perfectly mixed, raise the glass cover, and add, one at a time, pieces of white filtering paper, cut round to the diameter of the capsule, until 3 drachms are added. The reaction is allowed to take place for a quarter of an hour at the least, then the paper is withdrawn from the acid, and washed in abundance of water.

This washing is easily performed, but to cause the last traces of acid to disappear, it appears necessary to submit the paper to the action of boiling water for a time.

I have received some information upon the solubility of photographic cotton in alcohol alone. I had been told that cotton of this nature, which readily dissolves in a mixture of ether and alcohol without residue, was generally soluble in absolute alcohol, and that the collodion made in this manner was employed for the negatives of reduced geographical charts. This process, therefore, does not appear to me to be new, but the publicity given to it at the present time, with the means of making suitable photographic cotton with certainty, is a good thing.

Some time ago I attempted to produce photographic cotton by *steam;* that is, by submitting rags to the vapours of fuming nitric acid; that, however, did not succeed, but as nitrous acid appears to be so efficacious in producing the reaction required, it is very probable that in exposing the lignine under the form of cotton, filtering paper, rags, &c. and a sustained current of nitrous acid gas, a very marked result may be obtained, which cannot be determined beforehand; but the experiment which may very easily be performed, deserves to be made, as it may lead to a very good process.

## PHOTOGRAPHIC CHEMICALS:

### Their Manufacture, Adulterations, and Analysis.

*Sulphides* (continued).—*Sulphide of Silver.*—Most unfortunately for photographers, sulphur is an element for which silver seems to exercise an especial predeliction; and as sulphuretted compounds are almost constantly present in some degree in the atmosphere, and are always liable to find their way into that great receptacle for gaseous emanations, photographic processes, in large towns at all events, are carried on under certain disadvantages; whilst the preservation of the finished photograph from the fatal attacks of this insidious enemy, sulphur, always forms a subject for anxious deliberation for the artist who wishes his productions to be handed down to, and admired by, succeeding generations. Not only may sulphur obtain access to the print from atmospheric agencies, but it may exist in the pores of the paper itself, owing to a variety of causes; the print may have been insufficiently washed from the hyposulphite of soda, and this salt by the gradual absorption of atmospheric oxygen, will then become converted into sulphate of soda with deposition of half its sulphur, according to the following equation:—

$$NaO.S_2O_2+O=NaO.SO_3+S.$$

But, supposing all the free hyposulphite of soda or of silver has been removed in the washing process, sulphur may still find access to the delicate silver film forming the picture. Very frequently the paper on which the picture is printed contains this element in the free state to start with. Hyposulphite of soda is now almost exclusively used by papermakers as an *antichlor*, and by the action of acids upon it the extra equivalent of sulphur is deposited in the pores of the paper, where it sometimes exists in such considerable quantities as to be detected by chemical tests. Another source of sulphur may be the sulphates which the paper or the washing water naturally contains. It is well known that a soluble sulphate in the presence of organic matter, favoured by *damp and darkness*—those well-known enemies to the keeping qualities of photographs—are gradually deoxidised by the hydrogen or the carbon of the organic matter, with formation of a sulphide, thus:—

$$NaO.SO_3+4H=NaS+4HO, \text{ or}$$
$$NaO.SO_3+2C=NaS+2CO_2.$$

The danger to which the print is thus exposed is very great: the silver, even in the darkest parts of the photograph, is present in extremely small quantities (it probably owes its peculiarly intense colour more to the molecular condition in which it exists than to any other cause), and when the metal is changed into sulphide, either by contact with sulphur or an alkaline sulphide, it loses its tinctorial properties, and assumes the pale, yellow colour belonging to a very attenuated film of sulphide of silver, and the appearance of which is probably well known to all our readers. The chemistry of sulphide of silver, therefore, possesses an interest to the photographer on more than one point, as a knowledge of it would frequently tell him that he was about to place his pictures in conditions of danger, where a more ignorant artist would see no harm. The photographers' silver residues are likewise most frequently collected from spent fixing baths in the form of sulphide of silver; a knowledge, therefore, of the chemical reactions of this salt are necessary for its conversion into the metallic state. We will, therefore, briefly give the most important chemical facts connected with this body.

Sulphide of silver occurs native, and is formed when silver and sulphur come together; thus the yellow, and afterwards brown, film with which silver vessels become tarnished when exposed to the atmosphere, to the sulphurous exhalations from sewers, &c. consists of sulphide of silver. When a soluble sulphide, or sulphuretted hydrogen gas comes in contact with a solution of silver, this sulphide is precipitated in black-brown flakes. When heated in the air it is resolved into metallic silver, and sulphur, which burns into sulphurous acid; at a gentle heat some sulphate of silver is also formed. Fused with iron, it yields sulphate of iron and metallic silver; and when lead is used the products are sulphide of lead, and an alloy of lead and silver. When heated to redness in hydrogen, it is also reduced to the metallic state; but with aqueous vapour the decomposition is only partial. Chlorine does not act upon it at all in the cold, and very slowly when heated. Sulphide of silver is insoluble in solution of ammonia, except when it has been precipitated in company with chloride of silver, when it partly dissolves together with the latter.

The reduction of sulphide of silver to the metallic state is a point of some interest to the photographer who finds his residues of silver accumulating, as the greater portion of them are most likely to be in this condition. The most successful process, as well as the one most readily adopted for this purpose, is that of Mr. Spiller. The hyposulphite fixing bath, after repeated employment, will, if set aside, gradually let fall the greater part of its silver in the state of the insoluble black sulphide, which usually forms an adherent crust on the bottom and sides of the vessel. The portion of metal remaining dissolved may also be completely precipitated, by the addition of sulphide of sodium or ammonium, and thus the entire quantity of the silver may be collected together on a filter as sulphide. Mr. Spiller recommends that this should be dried, and triturated with about an equal weight of carbonate of soda, and added by successive portions to fused nitre contained in a crucible, and employed in tolerable excess. The process is known to be finished when the contents of the crucible no longer show any trace of the black particles of sulphide; and, according to the temperature of the furnace, the silver will either be found as a melted button or in the condition of a honey-combed, partially fused mass; in which latter case it is convenient to pour off the flux while yet fluid, so that the produce may afterwards be more readily washed from the alkaline salts by a stream of water. The silver recovered by this process is not likely to contain any other impurity than a small quantity of gold originally derived from the toning bath; and this will be left behind as a purple or brown powder on dissolving the metal in nitric acid. Furthermore, Mr. Spiller states that he has repeatedly tested the flux for silver, but without finding any, unless the precaution of adding carbonate of soda had been omitted.

Before mixing the precipitated sulphide of silver with the carbonate of soda, it may be advisable to *roast* it, in order to drive off the free sulphur which it contains. This precaution is unnecessary when pure sulphide of silver is employed, but as this body is always contaminated with sulphur when it is obtained from spent hyposulphite of soda fixing baths, it saves some expense in nitre to get rid of this excess of sulphur. This is readily done. The dried sulphide is to be placed in a shallow crucible, and submitted to a temperature which must on no account exceed a dull red heat. The sulphur will be seen to take fire, and the mass should be well stirred with an iron spoon, until the blue flame has disappeared from its surface. The black mass which remains is pure sulphide of silver. If the heat has been properly regulated, the sulphide will be in the form of a powder; but if the temperature has much exceeded a dull redness, the sulphide of silver will have become fused, and will then be difficult to deal with, owing to the slight malleability of the fused sulphide, which renders it difficult to mix with carbonate of soda and nitre. In such a case as this the best plan will be to throw some iron nails (in excess) into the crucible, and then to cover them with a mixture of carbonate of soda and borax, and expose to a bright red or white heat for an hour, stirring the contents of the crucible at intervals with an iron rod. The sulphide of silver will be decomposed by the iron with formation of sulphide of iron, and metallic silver which collects together at the bottom of the crucible.

## The International Exhibition.

### THE BUILDING.

Before the issue of another number of the Photographic News the International Exhibition at South Kensington will have been opened. As we shall from time to time have to invite the attention of our readers to its lessons in connection with our own and the cognate arts, it may be interesting at the outset to give a brief abstract of an official description of the building. In common with every one else who has seen the erection, we regret to say that it is irredeemably ugly. Various similes have been used to convey an idea of its utter lack of architectural beauty; it has been compared to a barrack, to a railway station, or rather a goods station, and to a horse repository. It is a huge squat square brick building, mean looking in spite of its vast proportions, and still meaner in its detail. The two large domes, surmounting nothing in particular, seem only to add to the grotesque effect instead of conferring either beauty or grandeur. It is beside our purpose here, however, to enter into architectural criticisms; we merely wish to give completeness to future accounts of its photographic and scientific departments, by first supplying a brief description of the design and character of the erection.

The site of the principal portion of the buildings adjoins the Royal Horticultural Gardens at South Kensington. It lies between Prince Albert's Road on the west, Exhibition Road on the east, and Cromwell Road on the south. The ground belongs to the Commissioners for the Exhibition of 1851, and was purchased by them out of the surplus funds of that exhibition.

The character of the structures, unlike the uniform glass building in 1851, is varied, the different purposes for which the buildings are destined having been kept in view in designing them by their engineer and architect, Captain Fowke, R. E. The buildings provide on a large scale for four objects:—I. *Picture Galleries*, which require to be solid structures, secure from all accidents of weather, extremely well ventilated, and lighted at the top; II. Ample spaces of different forms, and lighted in different ways, for the *Exhibition of Works of Industry*, arranged in courts and galleries; III. Platforms and wide passages, for *Ceremonials and Processions*; and, IV. Accomodation for *Refreshments*.

The picture galleries occupy three sides of a quadrangle. The largest gallery is in Cromwell Road; this is 1,150 feet long, 50 feet wide, and 50 feet high above the ground floor; being about as long as the gallery at the Louvre, at Paris.

The passage from end to end of this great picture gallery is uninterrupted, although the entrance is in the centre of it. The construction is of substantial brickwork. The piers at the entrance are 14 feet wide, and 7 feet thick; and the foundations throughout are of concrete, 5 feet thick. The walls will be lined with wood, and pictures may be hung, if desired, to a height of 30 feet. The lighting will be on the principle so successfully demonstrated in the Sheepshanks Gallery, which was the first *public* gallery perfectly lighted by day and gas light. These principles require that the quantity of light should be as great as possible, be subject to control, and obtained from above; and that the rays from the skylight incident on the pictures should in no case be reflected by their varnished surfaces, so as to strike the eye of a spectator while standing at a convenient distance for examining the pictures. The inflexibility of these principles, and the necessity for perfect ventilation, have regulated the architectural treatment of the present structure: as the light *must* come from the top, and the pictures *must* hang on the walls, there could therefore be no fenestral treatment in the upper walls. The greatest damage has been done to pictures by want of proper ventilation; the miasma from crowds is most injurious if not effectually removed. In this gallery ample provision has been made for ventilation in the only right and effective places. Not to waste valuable space, a floor has been provided beneath the picture galleries, and this must be lighted from the sides.

The entrance to the principal picture gallery in Cromwell Road will be through three noble recessed arcades. They are each 20 feet wide, and 50 feet high, and will look as imposing in their quantities as the principal façade of St. John Lateran, at Rome, and other Renaissance porticoes of Italy. The visitor enters a vestibule and hall, 150 feet long, and together 110 feet wide, which leads to the industrial halls and galleries; whilst two flights of steps, 20 feet wide, lead on either side up to the picture galleries.

The auxiliary picture galleries are in Prince Albert's and Exhibition Roads. They are 25 feet wide, and about 30 feet high, and jointly 1,200 feet long, and are, of course, lighted and ventilated on the same principles as already described. They will receive the smaller-sized oil-paintings, the water-colour paintings, architectural drawings, designs, and engravings.

The industrial buildings will be constructed chiefly of iron, timber, and glass. They consist of the following parts:—Two duodecagonal domes, which are 160 feet in diameter and 250 feet high, and are the largest of ancient and modern times. The dome of the Pantheon is 142 feet in diameter and 70 feet high; the dome in the Baths of Caracalla was 111 feet; Bruneleschi's, at Florence, is 139 feet in diameter and 133 feet high; the dome of St. Peter's is 158 feet in diameter and 263 feet high from the external plinth; the dome of St. Paul's Cathedral is 112 feet in diameter and 215 feet high. The domes will be of glass, with an outer and inner gallery. It has been proposed to erect one of Messrs. Chance's dioptric lights at the top of one of them and to illuminate it at night. The vista from dome to dome, through the nave, is 1,070 feet. Each of the domes springs from the intersections of the nave with the two transepts. The nave and transepts are 100 feet high and 85 feet wide; the nave is 800 feet long, and the transepts are each about 635 feet long, including the domes. They are lighted on both sides by clerestory windows upwards of 25 feet high, and would reach a mile if extended. The roof will thus be water-tight, which a glass roof can hardly be made. The building will be much cooler in summer and warmer in winter than a merely glass building. The nave, which runs east and west, will thus have a north light, undimmed by blinds. At 25 feet from the ground a gallery runs at each side of the nave and transepts. The level of the ground is five feet below that of the surrounding roads. Instead of descending into the building upon entering, the visitor ascends two steps to a great platform or dais under each dome, and then may descend into the nave and transepts by three noble flights of steps, each 80 feet wide, which lend themselves to most decorative arrangements, or he may ascend into the galleries. The entrance is therefore made on a mezzanine, as it were, of the building. There is more than a mile and a half of upper galleries, some 50 feet and some 25 feet wide; two courts, each 250 feet by 86 feet; two courts, each 250 feet by 200 feet; two central courts—that at the north 150 feet by 86, that at the south 150 feet by 150 feet. All these glass courts are 50 feet high, and lighted from above. These courts will be the only portions which at all resemble the Crystal Palace.

The entrances to the industrial buildings are in Prince Albert's and in Exhibition Roads. Each entrance is 55 feet wide. As many exits from the building will be provided as public convenience may require.

The refreshment halls and arcades will be permanent buildings. They overlook, with a north aspect, the whole of the Royal Horticultural Gardens, with its cascades, fountains, &c. They will be cool, but with a sunny view. The halls will be 300 feet long and 75 feet wide; the two arcades will have about 1,500 feet in length and 25 feet in width. All kinds of refreshments, both light and solid, will be supplied. The visitor will be able to obtain—in the morning, a *déjeuner à la fourchette*; at luncheon, Neapolitan ices or Bass's ale, and bread and cheese; at dinner, English roast beef and plum pudding, or the latest inventions in cookery from Paris, with samples of the wines of all nations.

The machinery galleries are the only portions which are obviously of a temporary character. They extend along the west side of the Royal Horticultural Gardens for about 1,000 feet in length by 200 feet wide, in four spans of 50 feet wide each. They are constructed of timber, and offer a very useful suggestion for the cheapest kind of agricultural buildings. These are all of framed work, without any joinery.

A bed of gravel underlies the whole ground. The foundations have been excavated to the gravel, and a base of concrete put in, on which brick piers, with York stone slabs, have been placed to receive the iron columns. The slabs for the columns of the great domes weigh upwards of a ton.

The iron castings comprise 166 round columns for the nave and transepts, 12 inches in diameter, connected with a like number of square pilasters; 312 eight-inch round columns, and 149 twelve-inch square columns, for the galleries; 138 eight-inch square clerestory columns, and 160 ten-inch square columns, supporting the floors of the picture galleries; 62 round columns for supporting the roofs of the glass courts; (put all the columns end to end, and they would extend from the Exhibition building, either eastward as far as the London Docks, or westward as far as Kew, or northward as far as Hampstead, or southward to the Sydenham Crystal Palace;) 1,165 girders throughout, 11,600 feet of pipes, 15,000 feet of gutters, 14,000 feet of railings, 1,000 brackets, 700 trusses and girders, 1,400 shoes, &c.: the whole is estimated to weigh nearly 4,000 tons. The wrought iron is estimated to weigh about 1,200 tons.

It is estimated that about 17,000 loads of timber will be consumed. For the windows below the picture galleries there are 32 window-frames 16 feet by 13 feet, and 68 window-frames 16 feet by 7 feet. For the top lighting of the galleries, 45,000 feet superficial of frames and glass are in preparation. For the clerestory lights of the nave and transepts, nearly a mile length of frames, 25 feet high, is preparing; and for the courts, upwards of 30 miles of sash-bars and glass.

The roofs will be covered with slates for the great picture galleries, and elsewhere with felt, except in parts, to show how ornamental roofing may be hereafter applied.

The contract for the whole works was let to Messrs. Kelk and Charles and Thomas Lucas, Brothers, whose tender was the lowest. The whole responsibility for the nature and execution of the works rests with the contractors. Mr. Meeson, C.E., prepares the working drawings for them. All proceedings are submitted to Captain Fowke, R.E., who acts for Her Majesty's Commissioners. He confers with a Building Committee, consisting of the Earl of Shelburne, Mr. W. Fairbairn, and Mr. W. Baker; and Her Majesty's Commissioners reserve to themselves the final approval of everything. Captain Fowke is assisted by Captain Philpotts and Lieutenant Brooke, and certain non-commissioned officers of the Royal Engineers. Mr. Clemence is the contractors' foreman of works. No clerk of works is employed. The contract is of a threefold character: for the use and waste of the buildings a sum of £200,000 is to be paid absolutely; if the receipts exceed £400,000, then the contractors are to take up to a further sum of £100,000; and if this sum is fully paid, then the centre acre of the great picture galleries is to be left as the property of the Society of Arts. Lastly, the contractors are bound to sell absolutely the remaining rights over the buildings for the further sum of £130,000, which may be paid by the surplus receipts of the Exhibition, if the success be great, of which there is a good prospect.

Regarding the Photographic Department, which is not referred to in the document of which we have given an abstract, we may state that it is high up in the Central Tower, and is reached by flights of not less than seventy steps. The amount of space we have repeatedly described; apart from its remote and inconvenient position, and the limited proportion, the room is well enough, being lofty and well lighted.

## DR. HENRY DRAPER'S HOT-WATER PROCESS.

BY E. BORDA.*

Your remarks respecting the rapidity of tannin plates, developed by Dr. Draper's hot-water process, suggests a point which it is of great importance to ascertain.

Is a tannin plate, developed by that process, quicker or even as quick as a wet plate? I am of opinion that it is far from having yet been proved conclusively; it is a complex problem to solve. The difficulty arises from one singular fact which every practical tannin worker cannot fail to have discovered; the rule so often given, that the exposure required by a collodion worked with tannin is a constant multiple of the time required by the same collodion used wet, is not confirmed by experience; it may appear so with a slow collodion, the margin of exposure of a tannin plate developed cold being so wide, but with quick collodion it does not hold out. A collodion rapid wet, is not proportionally as rapid with tannin, compared with a slow collodion.

I have found collodion which was very rapid wet, to be fully as slow with tannin as some collodion which would have required, if wet, many times the exposure of the former to give a similar result. Tannin appears to equalize the length of exposure, and the merit as to rapidity of a collodion used with tannin, is to be found on a different basis from the same quality being possessed when used wet. How far this property may be extended to other dry processes I am not prepared to state, but I have fully tested it with tannin. It is not to be inferred from this that a collodion may not be found which, while very rapid wet, will be equally so with tannin; as a general rule, however, it is a mistake, and, therefore, the photographer must not rely too much on the rapidity of a collodion used wet to govern the exposure of his tannin plate prepared with it.

After making a first attempt to develop some tannin plates by Dr. Draper's process, and meeting with no success, I repeated the experiment, and it resulted most encouragingly, with an exposure shorter than, under the same circumstances, the same collodion would have required wet at the time the plate (four months old when exposed) was prepared. This would naturally lead me to the conclusion that Dr. Draper's process is quicker than wet collodion, if the fact above mentioned had not been well known to me. Here is a new and vast field open to the experimenter. As to loss of sensitiveness by time, it is so slow that in four months I have been unable to detect any.

My complete failure at my first attempt to develop by Dr. Draper's process, arose from several causes; I used the water too hot, the developer too cold, too much silver, and proportionally too little citric acid. These are all important points, which, while they add to the difficulty of developing a tannin plate successfully without some practice, becomes with skill and judgment elements enabling the operator to control the best result with more certainty. I have, in a former communication, stated how the exposure could be carried much further than was strictly necessary to obtain a well-defined negative without injury, provided the development was regulated accordingly. Dr. Draper's process increases the margin in the opposite direction. It seems as if almost any exposure within reasonable limits, either very short or very long, could, by judicious development, give a good negative with a tannin plate.

The temperature of the water in which the plate is soaked before development is a new element, and a never-failing indication enables us to regulate it. The same developer gives a different tint to the negative according to the exposure, which tint alters from bluish-black to bright purple-red, and is the more red that the plate has been more over-exposed. This same sensitive indication applies to the hot-water process, a proper tint being soon ascertained with a constant developer, and too high a temperature having the same effect as too much exposure, so that if the image appears too red the temperature is too high. Really almost every day reveals, in the beautiful tannin process, the most useful and interesting features.

I thought that the enemy after abandoning his Munson Hill and wooden guns would be satisfied with the "madness" of his pursuers and abandon the field; but he introduces two redoubtable champions, which Siccus is perfectly willing to meet, with as many more as he or they wish to enlist, on fair ground. Sellers tells us that Mr. R. Shriver has come to the conclusion that *nothing but the wet collodion* can give the superb delicacy of shades the wet always gives. This is rather sweeping. If Mr. Shriver has given a fair trial to dry processes, and to the tannin in particular, his opinion is the more worth quoting, that he is an excellent photographer, and his stereographs among the best I have ever seen; but if he has not, his conclusion has no weight. The same applies to Mr. T. R. Peale, who *assumes* the wet to be the most perfect condition of the collodion film. I would forever regret that the ephemeral condition of collodion, wet, should prove the most perfect—but, an assumption may do to discuss abstract questions, it becomes an axiom when self-evident, in the present instance it amounts to nothing.

The relative value of the different processes must be established by a comparison of the results they give. Two years ago, a committee being appointed to decide for a prize photograph amongst the many productions at the Manchester Exhibition, a print by Mr. Mudd, from a Fothergill negative, was decided to be the best. Repeatedly, prints from dry plates, albumen, collodio-albumen, tannin, &c., are mentioned in the accounts of the different exhibitions through Great Britain as deserving the palm. The albumen transparencies of Messrs. Ferrier and Soulier, from albumen negatives, have not been surpassed. Nor are dry processes a "*madness*" or

* *American Journal of Photography.*

a "*fashion*," they are older than the wet, and used far more extensively for field work. Therefore, I would conclude by stating, what no one can deny, that the relative merits of negatives obtained, wet and dry, are at least an open question, and to be decided by time and careful comparison, and not by mere assertions.

## WET AND DRY COLLODION.

BY COLEMAN SELLERS.

The readers of the various photographic journals must have noticed that there is being more and more written about various dry processes, and that some perfect process of that kind (equal or superior to the wet in skilful hands) is to be considered the goal towards which all enthusiastic amateurs are to hasten, and the attainment of which is to leave nothing to be desired. Thus, what a host of advocates for the dry are giving their testimony in its favour, while hardly one is the champion of the wet in the field. They all seem to agree that time is no object, that for views without animated objects it matters little whether the exposure required is five seconds or five minutes, so far as the result is concerned, and some even think the long exposure an advantage, making the result more controllable.

Now, too, Mr. E. Borda is added to the list, and I tremble lest he should make me throw away all the various little conveniences I have arranged with care for the wet work in the field, and convince me that I must be a "Siccus" against my will. As he says in a recent letter, "What a triumph it will be to convert the would-be 'Jamin and glycerine' into a 'Dry Harrison.'"

Almost daily too, do letters come with the oft-repeated question, "Can you advise me what dry process to try?" And only yesterday, a (for a long time) correspondent, who has had all kinds of trouble with the wet, writes me, in his joy, that his first tannin plate "is developed, and is on the stove drying," the best negative he had ever made. There must be some reason for all this. Some who have never been successful with the wet, are doing charming work with the dry; and even successful amateurs are throwing aside their dark tents, and working tannin. All admit that portraits and pictures of moving objects can only be taken with wet collodion, but many prefer to avoid such subjects and take pictures only of still life.

It has occurred to me, since reading Mr. Borda's article in the last number of this Journal, (and right glad I am to see him in print,) to answer the general enquiry of "What dry process shall I try?"—through the pages of the *American Journal*, and referring my correspondents to it, save much needless writing. Having tried most of the formulæ proposed, and been successful with many of them, I may be considered as a disinterested party—and give my opinion in favour of Major Russell's tannin process—more from observing the general success of others who work it, than any fondness of my own for it; and let not friend Borda think that my conversion is complete, when I advise all who have had trouble with the wet to select some reliable dry process, and persevere with it until they are perfect; and of the processes now in vogue, Major Russell's is the best.

The reason I have come to this conclusion is from the fact that success in the wet is more dependent on the collodion than on any of the other chemicals used; an amateur buys his stock of chemicals, and among them a bottle of collodion from some reliable maker; his picture will be very good for a beginner, and all seems clear before him; soon, however, comes the cry, "I can get no intensity;" the same chemicals will not give the same result. The bath is doctored, and all sorts of expedients are resorted to, to produce intensity, while the fault in reality may be the deterioration of his collodion from age. Taking for example my own experience when I had a great many 14×18 plates of machinery to take, I used pound after pound of collodion, it never got old on my hands, and a uniform degree of intensity was obtained. But when I had taught another to do my work, and had thus limited my experience to the *semi-occasional* work of an amateur with no time to operate, then these troubles came to me; but knowing the cause, I could throw aside my old collodion, make fresh in small quantities, and thus avoid all trouble. All, however, cannot do thus, few are willing to do the dirty work of making gun cotton, and prefer to purchase collodion ready made.

Having tried all the various sensitising salts, my own choice has been the iodide and bromide of ammonium. Collodion prepared with these is quick when new, but no matter how well the cotton has been washed, it will redden work slower as it gets old. Now with the tannin process, all kinds of collodion seem to do well, some better than others it is true; but samples good for nothing wet, have been first-rate dry. This I know from having given many kinds of collodion to those who work the tannin, and have seen the result. See, too, Borda's account of his wet picture with new collodion, how very quick it was. That collodion was from cotton I have been working for some times past, but it will not always be so quick; as it gets older it gets slower, and must be thrown aside, or used for dry plates. In the case of an amateur who can only find time to work, say once a week, every pound of collodion bought, if it is new and quick when purchased, will yield only a few days' good work before it gets old.

There is a way, however, of managing collodion, recommended by Hardwich and others, which I am now trying, and time will show if it will get over all the trouble or not; it is as follows:—Take of cotton (such as will dissolve ten grains to the ounce in equal quantities of ether and alcohol) eighty grains, wet it with four ounces of absolute alcohol, shake it well, then pour off two ounces, leaving two ounces in the cotton. Throw away the portion poured off; add then 4 ounces of ether, which will dissolve the cotton and make a plain collodion with only half the quantity of alcohol necessary to make up bulk. Mark this plain collodion with the date of its mixture. Next, in two ounces of alcohol dissolve sixteen grains bromide of ammonium, and forty grains of iodide of ammonium; this, filter with care, and mark sensitizer, with its date of mixture. When about to use any collodion, take, say one ounce of the plain collodion, and add to it one third of an ounce of the sensitiser, shake up and use immediately.—*American Journal of Photography.*

## DIFFICULTIES IN PRACTICAL PHOTOGRAPHY.

BY S. R. DIVINE.

The difficulties and discouragements that beset the professional photographer in his daily work, do not require to be told to those who have had much experience; but there are those who think that other practitioners in the sun-painting art are not troubled with the obstacles that spring up in their own path, and that if they could only get this man's or that man's process, they would be able to produce fine works uniformly, and escape all their own peculiar cares and difficulties. If you, my aspiring photographic friend, have any such idea, banish it at once. Take our word for it, that every artist has his heart-rending discouragements, and the beautiful works that your neighbour produces are the results of his constant care and never-failing patience. His knowledge of photographic mysteries is perhaps not greater than yours, but he may exercise more care in the details of manipulation.

Every photographer has his chemicals out of order occasionally, and must go to work to rectify them. The bath may work splendidly in the morning, but exhibit obstinate freaks in the afternoon. The collodion which gave so fine intensity yesterday is worthless to-day, and so it goes. When everything is in perfect order for making pictures we must not expect such a state of things to last, but must be always on the alert to discover the least symptoms of derangement, and apply the remedies.

A journeyman photographer once made application to us for work, and, being in want of help, we proceeded to ascertain something of his capabilities by asking questions as to the methods he pursued in obviating the difficulties that occur with the nitrate bath for negatives. He replied that he never had any difficulty with his bath, when we promptly informed him that we did not require his services, for he either told an untruth, or else he had no experience in the management of chemicals.

The great source of difficulty in making pictures is the bath, and it might be well perhaps to mention the means we employ to rectify it when out of order. If our bath fogs, we first ascertain whether it contains acid or whether it gives an alkaline reaction. An alkaline bath will always fog, and in case alkalinity is the sole cause, it is remedied very speedily by the addition of a small quantity of acid. But a negative bath must possess only a very slight degree of acidity. If acid does not cure a fog, the probability is that the bath is foul with organic matter, which may be removed in several ways. A good method is to evaporate the bath to half its bulk, by pouring it into a suitable earthen dish, and applying heat. Most of the organic matter will precipitate, rendering the solution black and dirty, and, after adding pure water to make up the original quantity, it is ready for use, after filtering. Another method is to set the bath in the sun till the foul matter separates. It will be some time before the black matter completely precipitates, and if sufficient time is not given, the solution will fog worse than before. Still another method is to add a substance that will cause a precipitate, which in settling carries down the organic matter with it, by a mechanical action. A few drops of a solution of common salt is very good, which, by addition to the bath, forms an insoluble chloride of silver which settles slowly to the bottom, and takes some of the impurities with it. Solution of cyanide of potassium is also very good for the purpose, as it forms a nearly insoluble precipitate.

But the method we employ more than any other is precipitation with bicarbonate of soda, and re-solution with nitric acid. A bath can be cleansed in a very short time by this method, and most thoroughly.

Collodion may produce fogging even when the bath is in proper condition. It generally results from an alkaline state, and may be cured in that case by adding a small quantity of hydrobromic or glacial acetic. It does not require much practice to be able to take a picture when all the chemicals are in working order; but to know the cause and cure of all the difficulties that occur in practical photography requires years of experience.—*Humphrey's Journal.*

## Proceedings of Societies.

### North London Photographic Association.

The monthly meeting of this Society was held at the Myddelton Hall, on Wednesday evening, April 15, G. Dawson, Esq., Lecturer on Photography at King's College, in the chair.

The minutes of the previous meeting having been read and confirmed, Mr. R. W. H. Stuart, of Chiswick, was elected a member of the Society.

The Chairman then called upon Mr. Bockett to read his paper on "Photographic Micrography."

The paper was illustrated by some very good enlargements of animal tissues, sections of wood, coal, &c., mounted on cards of the size now so fashionable for albums.

The apparatus employed was also placed upon the table for inspection.

At the conclusion of the paper, the Chairman, calling attention to the apparatus exhibited, wished to know if Mr. Bockett proposed making any experiment for the enlightenment of the members.

Mr. Bockett said in answer that he had not come prepared to take any negatives.

Mr. Shadbolt in opening the discussion felt that like a bather his great difficulty lay in making the first plunge. He would observe, by way of commencement, that he would have liked to have seen some results produced by the apparatus, had it been possible. He thought there were some objections to the focussing glass, and begged to recall to the remembrance of the members some experiments made by Claudet on the ground glass of the focussing screen. He thought Ramsden's eye-piece a more desirable instrument to employ, as it would then be impossible to focus beyond the plane. He could not understand Mr. Bockett's objection to sunlight. It struck him also that the exposure mentioned in the paper, viz. five minutes, was simply enormous. Mr. Wenham, followed by Mr. Delves and others, had produced micrographic subjects instantaneously.

Mr. Bockett begged to remind him that while they used sunlight, he simply employed diffused light.

Mr. Shadbolt in continuation said, that in making the pictures instantaneously, the exposure could be easily managed by the insertion of a cardboard between the object and the light. He thought that the animal tissues were scarcely ever well rendered. The palates, particularly that of the slug, were decided successes; but he begged to call the attention of the members to the tip of the blow-fly's tongue, which, though not out of focus, had that appearance, owing to the want of detail. This was caused by the non-actinic character of the membrane. He thought the suggestion made by some to throw actinic light on a non-actinic body a mistake; his plan would be to retard the light on the actinic portions of the subject. One of the chief difficulties to be encountered was want of sharpness, for the 200th part of an inch was quite appreciable in the microscope. In reference to polarized light, he thought its principal use was in the delineation of non-actinic subjects.

The Chairman called upon Mr. Ross for some remarks.

Mr. Ross said that his knowledge of the microscope was limited.

The Chairman thought the narrow tube of the apparatus before him objectionable, as it was calculated to cut off some of the rays.

Mr. Burr: A large body would be an improvement, as it would prevent any reflection from the sides which would tend to destroy the vigour of the image.

Mr. Shadbolt employed a paper tube covered with black velvet, which effectually absorbed all the stray light.

The Chairman thought a conical tube desirable.

Mr. Ross thought the dividing of the tube in half would meet the case. A series of joints, after the principle of the telescope, would produce the requisite widening at the end attached to the camera.

Mr. Shadbolt thought it desirable to adjust the object glass instead of the image for the correction of the visual and chemical rays. An object with a certain amount of thickness would enable the operator to determine with very little trouble the amount of difference.

Mr. Burr asked the use of a secondary magnifier?

Mr. Shadbolt could not see any advantage.

Mr. Bockett had tried, but had not succeeded in getting the itch insect.

The Chairman recommended him to go down to his country (Scotland), and he would have no doubt of his success.

Mr. Shadbolt handed round for inspection a micrographic enlargement of a section of one of the palm species. It was produced by Mr. Hodson, on a Daguerreotype plate, as far back as 1841. He employed in its production a small ¼-plate camera arranged vertically. As moveable ground glass was employed for focussing, which was removed, and the sensitive daguerreotype plate was dropped in its place.

The Chairman, referring to the date, said the exposure must have been extremely long, as it was before the introduction of bromide.

Mr. Martin thought there was evidence of bromine in the picture.

After a discussion on Kingsley's condenser, and Ramsden's eye-piece, in which Mr. Ross, Mr. Shadbolt, Mr. Bockett, and other gentlemen took part,

The Chairman, referring to the collodion mentioned by Mr. Bockett, viz., Thomas and Ramsden's, objected to both, as containing a considerable amount of structure. The collodion most desirable for micrographical experiments would be one, the pyroxyline of which was made in acids at a temperature not below 160°. Such a pyroxyline, dissolved in alcohol, nearly absolute 5 parts, ether 3 parts, would carry a large amount of iodizing solution even when considerably diluted. It would also bear any amount of washing, and could be intensified with perfect ease. He admitted the pyroxyline he had described would be expensive to prepare commercially, as so much would be lost in the acids.

Mr. Seely thought such a collodion would be admirably suited for instantaneous pictures in the magic lantern.

Mr. Shadbolt thought it a question of manipulation, as structure could be avoided with care. The two causes of failure was water in the ether or alcohol. Absolute alcohol was very greedy of water, and would drink it from the atmosphere. The great remedy was to keep the plate a long time out of the bath.

The Chairman still thought the structure depended more upon the cotton.

No further discussion ensuing upon the paper, a vote of thanks was proposed to Mr. Bockett.

The Chairman announced that three photographs were presented to the society's portfolio by Mr. Moens. The subjects were: "The Aqueduct at Carthage," "The Caves at Balaclava," and "Whippingham Church."

Mr. Bockett announced, in answer to the Chairman, that his micrographic results were quite at the service of the meeting.

Mr. Shadbolt called the attention of the meeting to a photograph by Mr. Edwards, said to be 10 by 8, but which was imperfectly covered at the top edges. By the segment at the top he was enabled to get at the diameter, which he found to be 11 inches. He had no desire to run down lenses, but he did desire to establish facts.

The Chairman: What is the square?

Mr. Shadbolt: Barely 9 by 6¼.

Some discussion followed relative to the determining the size of different oblongs to be obtained out of a given circle.

Mr. Shadbolt handed round for inspection two beautiful *cartes de visite* pictures by Robinson, of Leamington, as illustrations of what can be produced by the introduction of artistic arrangements into photographic portraiture.

There being no other business before the members, the meeting terminated.

## Correspondence.

### PHOTOGRAPHIC DEPARTMENT OF THE INTERNATIONAL EXHIBITION.

Dear Sir,—You are doubtless familiar with the final arrangements made by the Commissioners for British photography, and may possibly have visited the *camera obscura* devoted to its reception, but as I have just returned from my first visit, and as my blood in consequence is at very little little below 212° Fah., I have dared to pour the *boiling* thoughts that burst their channels, into print: that is if you will insert them.

I had heard of the conciliatory spirit of the Commissioners, and that in spite of the misunderstanding between them and the photographic body, they were desirous of doing all honour to photography, that though its claims to rank as a fine art had not been legally indorsed, it should have a fair field, with every opportunity to distinguish itself; that it should have a room to itself, without the portals of the fine arts, it is true, but not beyond their benign influence. With a contented mind therefore, and a feeling of self congratulation that I had been one of the fortunate ones chosen, from the many unchosen, I attached the official printed label to my package, and mounted it and myself on the roof of an omnibus, bound for the Exhibition. So full was I of eager anticipation of the busy sight that would soon meet my eye, that I had made myself unusually attractive, until my neighbour on the roof suggested that the big label in front of me announcing me as class 14, addressed to Her Majesty's Commissioners, wanted "this side up, with care," to make it complete. On arriving at door C, a policeman barred further progress until I had wasted full five minutes in convincing him of what he knew already, that I had a right to enter. After smearing the package with some mysterious hieroglyphics in paint, a porter who wore an official bandage on his arm, seized the package, and bade me follow him. On we trudged down a long corridor, through the opening of which a constant whirr, hum, and bustle streamed in, vaguely indicating what an immense beehive it was. We had now reached the centre part of the building, but had no time to take in anything but the most confused impressions, for I was following the nimble-footed porter rapidly up a broad staircase, which brought us to the entrance of the fine-art galleries. Through an open door I saw grand old pictures, hung in a magnificent gallery, and lit by a mellow subdued light, which came from above. I felt that if photography had found a home anywhere adjacent to these galleries, it had at length recieved full and complete justice. These thoughts, however, were the very vanity of vanities, for the porter was already half way up a narrower and meaner staircase, the walls of which are brick, washed with red colouring, and I reluctantly followed. A landing is reached, and then another flight; now another landing and another flight, and still another, and we are in the Photographic Department.

Here I paused to take breath, and gulp down the bitter disappointment which was almost choking me. Truly the Commissioners, if they have proven themselves anything but men of business, as the many cases of mismanagement, and something worse, which have come to light, go to show, have, at any rate, shown themselves good hands at a practical joke. This last joke, at the expense of poor photography, is worthy a place in *Punch*. Their acts say plainly enough this new-fangled would-be art, that is scarcely out of swaddling clothes, and yet has the presumption to try and swell itself out into the majestic proportions of the arts, old as the Parthenon or the Capitol, like the frog in the fable, truly it shall receive a lesson not easily forgotten. Photography would be a fine art, indeed! Its desire for elevation shall be fulfilled, for it shall be the highest art in the building, an art so high, that those who would behold its productions shall take a lesson in gymnastics before they can do so.

Unfortunately, poor education bears the biggest half of the burden of this joke, for it occupies the largest portion of the room. It appears the Commissioners think that, as the object of education is to elevate, therefore the instruments employed should be placed so high as to be beyond the gaze of nine-tenths of the people who will visit the building. Truly there is no royal road to knowledge and photography, the path is a steep and uninteresting one of 72 steps.

An Exhibitor.

### PHOTOGRAPHIC JURORS IN THE EXHIBITION.

Sir,—In your last number after having alluded to my appointment as a juror of class 14, in terms which cannot but be most gratifying to me, you have expressed some doubts as to the fitness of a professional photographer for the office, because other professional photographers may naturally feel that they would rather not have been judged by one with whom they are in business competition.

I am happy to be able to dispel your fears. My fellow photographers have already proved what is their feeling on this question, for they have themselves demanded that I should be one of their jurors. The special Commissioner for the department of jurors in the International Exhibition of 1862, in apprising me of my appointment, stated in his letter that it was in consequence of my having been recommended by a considerable number of exhibitors, to be juror in class 14 (photography and photographic apparatus).

If the appointment had been conferred by Her Majesty's Commissioners, without their having consulted the exhibitors, I might have felt some delicacy in accepting the office; but I could not hesitate one moment in considering that the exhibitors, having acted themselves *as jurors in my case*, had wished that I should be honoured with their confidence.

Owing the highest distinction an exhibitor can desire to a most honourable and brotherly feeling of my fellow labourers and competitors, I have accepted it with pride and gratitude, and I assure you the remembrance of it will be for me an everlasting source of gratification.—I am, dear sir, yours very truly,

A. Claudet.

[We have much pleasure in giving record to the grounds of M. Claudet's appointment as a juror. Our remarks were written under a conviction, based upon what we believe are good grounds, that the Commissioners had given but little heed to the nominations of exhibitors.—Ed.]

## Talk in the Studio.

Royal Patronage.—It will interest many of our readers, who are familiar with the name of Mr. Jabez Hughes, in connection with frequent communications at the metropolitan photographic meetings and in photographic journals, to learn that he is at present executing a series of commissions for Her Majesty. Mr. Hughes has recently fixed his residence at Ryde, having purchased the business of the late Mr. Lacy, of whom he will be a worthy successor. It is somewhat singular that the first picture Mr. Hughes took in the Isle of Wight was a portrait of Prince Leopold. This was so satisfactory that it was succeeded by commissions to execute photographs of various works of art in the palace at Osborne, and of various views of the exterior and interior of Wippingham Church, which has been recently rebuilt by Her Majesty. Several of the views already successfully executed, we have seen; and may mention amongst them one or two of a marvellous extent of angle, having been taken on plates 10 by 8 with a No. 1 triple achromatic lens of about 8 inches equivalent focus, with a large stop. The prints when trimmed were upwards of 9 by 7, with sufficient pictorial definition to the edges. We are glad to record, in the commission of Mr. Hughes, another of the many graceful tributes to the art on the part of Her Majesty, in the employment by turns of almost all photographers of reputation or ability.

Mason v. Heath.—This case came on again in the Court of Common Pleas, on Thursday week, before Lord Chief Justice Erle and Justices Willes, Byles, and Keating, sitting in Banco. Mr. Montague Smith, Q.C., said the action was brought by the plaintiff, who was the publisher of *The Photographic Portrait Gallery*, against Mr. Vernon Heath, the photographer, of Piccadilly, to recover two negatives of the late Prince Consort. At the trial, last sitting, the plaintiff stated that he had written to, and obtained the permission of his Royal Highness to publish his portrait in the *Gallery*; and that he then made an agreement with Mr. Heath to take two negatives for the sum of five guineas. The defendant alleged that there was no agreement of the kind, and refused to give the plaintiff one negative without the payment of fifteen guineas. The jury found that there was no agreement for two negatives, but considered that the plaintiff should have one negative upon the payment of five guineas. His lordship then directed a verdict to be entered for the defendant, with leave to the plaintiff to move to enter the verdict for him according to the finding of the jury. The learned counsel then moved pursuant to leave reserved. The Court granted a rule nisi.

The Photographic Contract at the Exhibition.—The long-pending question of the right to photograph the Exhibition was settled on Tuesday evening, when the secretary announced that the tender of the London Stereoscopic Company had been accepted. Several of the most eminent photographic firms were eagerly competing for this privilege, and the keenness of the contest was enhanced by its being rumoured that Messrs. Day and Sons were also striving for it, as the most valuable auxiliary they could obtain for the production of an illustrated work on the chief contents of the Exhibition. It is much better, however, that the choice has fallen on professional photographers, and from the high character of the London Stereoscopic Company they are likely to do the work admirably well. A very high price was paid to the Commissioners for the privilege, and a still higher sum must be expended by the firm to perform the contract well. No photographs are to be sold in the building; no views to be taken after 10 a.m., and none at all without the consent of the exhibitors themselves. The latter, however, is a merely formal clause, as, of course, the main source of profit will arise from the desire of the exhibitors to have their stalls and cases represented in stereoscopic views.—*The Times.*

Patent Ozone Light.—"This latest improvement in the combustion of air for illuminating purposes," says the *Manchester Courier*, "has just been tried at the Victoria Station. The invention is patented by Messrs. Trachsel and Clayton, engineers, Ardwick. A first-class carriage was darkened and then lightened with the brilliancy of gas by the new flame, which burned in the usual lamp; its advantages are—that it cannot explode, and shows colours as in daylight. The light is very mild and steady, even when the carriage is in motion; it is evolved from air passing through certain chemicals; is not dearer than gas, and is much more portable."

## To Correspondents.

William Vaughan.—It is impossible to state with certainty what amount of glass should be in any part of a glass house, without a precise knowledge of all details, only to be obtained by personal inspection. Seven feet of top light, with plenty of side light, would in many circumstances be sufficient. Take care, however, to have those seven feet well forward, and not immediately over the head of the sitter. 2. The lenses called half-plate, in either Dallmeyer's or Ross's catalogue, will cover a whole plate better than many whole-plate French lenses.

A. B. C.—The simplest and least expensive instantaneous shutter consists in the use of a piece of wood held in the hand. If you require something inexpensive for occasional use, this, or a hat or cap—anything in short which will cover the lens—may be employed with a little care and dexterity. 2. The card picture is a little hard, from slight under-exposure. The lens is not quite equal to the work; and the background is not quite free from stains. The printing is pretty good and free from mealiness. 3. If a proper collodion be used, and the plates properly prepared, there is no reason why the result should not be good, a day or a week after preparation.

H. V. C.—The small white houses on the shore at the foot of Mount Orgueil, are at all times inimical to the effect of a picture, in which, as in the scene itself, they have a spotty effect. In the specimen sent, the result would have been better if the plate had received longer exposure and less development, or if less silver had been used in the development. By giving sufficient exposure to bring out all detail, without forcing the development, you will generally obtain skies which will print slightly through, just giving a tint instead of white paper. To secure clouds, the best plan if the exposure be not instantaneous, is to shade the sky, either by using a Dallmeyer's shutter, or holding a piece of blackened card or board horizontally above the lens, so as to cut off the rays from the sky until the foreground is properly exposed, and then give an instantaneous exposure for the clouds. We have not had personal experience in the processes recently recommended by Mr. Bartholomew, and cannot, therefore, give much information beyond what is supplied in his various communications. No apology whatever is needed for your queries, which we always take pleasure in answering, and giving the best information in our possession.

Achromatic Lens.—It is the custom of all opticians, of any reputation, to engrave their names on the mounts of their lenses. We can form no idea of the maker of the lens you mention from the initials given. Probably it is from some French house which manufactures for "the trade."

J. G. L.—Ebonite will stand with impunity a very strong solution of nitric acid. The mode we adopt with such baths is first to wash with a solution of soda, then with a solution of nitric acid, and finally rinse thoroughly.

W. R. D.—We cannot devote the amount of space in this column necessary to instruct you how to take a good negative, and then how to print from it. The information you require is scattered over our pages; but perhaps your simplest plan would be to get any good elementary manual expressly intended to meet such wants as yours. Try that of Mr. Hughes.

Photo.—The person you name was at one time a photographic dealer in New Oxford Street, but has not been in the business we believe for the last two years. We are sorry for your victimization, and would willingly prevent others from sharing the same fate; but we cannot, unfortunately, insert the letter of warning, as the law of libel is apt to put awkward constructions on such matters. We can only recommend our readers to deal only with houses of known respectability, of which our advertisement pages present a goodly list, all of whom have "a local habitation and a name."

An Amateur Subscriber.—In speaking of portrait lenses of 3½ in., 4½ in., and 5½ in., Mr. England referred to the distance from the back lens. Waterhouse diaphragms are always placed between the front and back lenses; but they are not necessarily central. The exact position depends on the relative power of the lenses in the combination; and if the lenses are made by an optician who understands his business, the position selected is that which will give the least distortion and the flattest field, consistent with rapid action. By placing the stop nearer the front lens, the field is flattened, but the amount of light is diminished. We should imagine a stereo picture would be covered by the lens you refer to sufficiently well for most subjects with a stop of ⅜ in. diameter, and that on occasion a much larger stop might do. Probably the maker himself can give you exact information of what ought to be done with the lens.

H. G. B.—Your remarks on the article in the *Saturday Review* are very true. M. Claudet remarked to us the other day in a conversation on the subject, that it might be accepted as a certain rule in reference to the writers of such articles, that they were personally *ugly*, and had received from photography uncompromising justice! Hence the spleen.

R. G.—If an iron negative be very full of detail but thin, use the pyro solution of moderate strength, and add plenty of silver: take care, however, to have sufficient acid to prevent reduction on the shadows.

New Light.—We are obliged for the extract, which as you see we insert. We will examine the specification, and if it afford any useful information, our readers shall be put in possession of it.

A New Subscriber.—In using a focussing glass, take care that the ground glass be very fine, otherwise its texture will be so much magnified that you can scarcely distinguish a sharp image on it. Your focussing glass should be adjusted to your sight by screwing the end in or out, and when once adjusted may be screwed tight and kept so. For use it is placed with the open end flat against the ground glass. Unless your sight be bad, it is rarely necessary to use magnifying power in focussing.

Puzzler states that for some time past he has been unable to obtain a rich creamy-looking film: on taking the plate from the nitrate bath it looks blue and thin; but after exposure in the camera it becomes quite dense and creamy. This is a somewhat puzzling circumstance at first sight, but it is not due to the action of light. If the plate had merely stood in the dark during the time it was in the dark slide, the result would have been the same. It simply proves that the whole of the iodide in the film was not converted into iodide of silver before the plate left the bath: and some free nitrate remaining on the film, the process of double decomposition—whereby the iodide of silver is formed—continued whilst the plate was in the dark slide. You must allow the plate to remain longer in the bath. Probably the collodion you are using gives a somewhat repellant film, or it may contain a larger proportion than usual of pyroxyline and iodides; in either case a little longer immersion than usual in the bath will meet the difficulty.

G. C. is thanked. Nitrate, T. P. E., E. T., X. P. R., J. F., J. M., and several other correspondents in our next.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 191.—*May* 2, 1862.

## THE OPENING OF THE INTERNATIONAL EXHIBITION.

The grand exposition of the world's industry and art is now open. The spectacle, and the music, and the worship by which it was inaugurated are over; and, according to the programme, the Exhibition is, with a flourish of trumpets, declared open. Writing, as we do, immediately upon leaving the building, with the mind possessed by almost bewildering echoes of glorious music, by confused and fragmentary visions of, perhaps, the most magnificent collection of paintings ever assembled in one place, the choicest array of the world's industry, and, as the Laureate phrases it—

> " Shades and hues of Art divine,
> All of beauty, all of use,
> That one fair planet can produce,
> Brought from under every star,
> Blown from over every main,"

With all these, and a thousand nameless and indescribable associations, it will readily be conceived we are not prepared now to enter into any detailed description, even if we had time, before going to press.

The general arrangements for the opening many of our readers have doubtless learnt from other sources. The building was crowded at an early hour by a gaily-clad assembly, and the reserved seats, or rather such of them as were desirable, were soon filled. At about one o'clock the bands outside the building proclaimed the arrival of the procession, consisting of the various officers connected with the different departments of the undertaking, and with the Horticultural Society and the Society of Arts, Chairmen of Juries, Acting Commissioners of the Colonies and Foreign States, Civic Authorities, the Commissioners of the Exhibition of 1851, and those of the present Exhibition, the Bishop of London and some other clergymen, Her Majesty's Ministers, and finally the special Commissioners appointed by Her Majesty to represent herself in conducting the opening ceremony, and their Royal Highnesses the Crown Prince of Prussia and the Prince Oscar of Sweden. These slowly proceeded to the Western Dome, where was placed the throne and chair of state. The National Anthem was then sung by the choir in the Eastern Dome with magnificent effect; after which Earl Granville addressed the special Commissioners, briefly describing the origin, progress, and intention of the Exhibition. After a few words of response from the Duke of Cambridge, the procession again formed, and proceeded to the Eastern Dome.

The special music composed for the occasion now commenced. Meyerbeer's grand overture, consisting of a triumphal march, a sacred march, and a quick march embodying the national air "Rule Britannia" was in every way worthy of the occasion, and was given with magnificent effect. This was followed by the ode composed by the Poet Laureate for the occasion, sung to Dr. Sterndale Bennett's music by a chorus of 2,000 voices, accompanied by an orchestra of not less than 400 instruments. If the words were not altogether worthy of Tennyson, the music was in every way satisfactory; solemn, lofty, and at the same time simple and melodious; it was a noble specimen of choral music. More instrumental music, and a prayer by the Bishop of London; this was succeeded by the Hallelujah Chorus, and the National Anthem. The Duke of Cambridge now proclaims the Exhibition open; a flourish of trumpets, and the reverberating plaudits of those close at hand, taken up by those beyond, announce throughout the building to the assembled thousands, that the ceremony is concluded. The barriers which had guarded all but the main avenues are removed, and the visitors are soon swarming in every nook and corner of the Exhibition.

Nevertheless, the interior is far from being completed. Many of the departments, the French especially, are a simple chaos, and are surrounded by a cordon to preserve them from inspection at present. A few weeks will certainly elapse before anything like completion is attained. In most of the departments something remains to be done; but the very best had been made, within the last twenty-four hours, of the interior. To those who visited it a day or two before, it seemed impossible that it should be even accessible to the public on the first of May. At ten o'clock on Wednesday morning the building was cleared of contributors and their assistants, and the work of cleansing and putting in order commenced. The result obtained in the few hours that followed was as amazing as satisfactory.

It is impossible to form any definite or comparative estimate of the Exhibition at present. Our own coviction, from the hurried glance amid the excitement of the opening day, and former inspection during the course of progress, is, that as a display of art and industry it has not been rivalled. The sense is almost overwhelmed in attempting to comprehend so much of beauty. The picture galleries alone contain a collection of all that is excellent in modern art, such as the world never before saw. Regarding photography we cannot say much at present. The English photographic department was not opened, a barrier being placed across the doorway. Effecting a breach, however, we passed up the steps piled with dirt and rubbish into the deserted room. A glance at the contents made us hopeful: the pictures are all hung, and comprise some excellent photography. The display of apparatus was not complete, and we shall not at present pass any comment upon it. We may remark, that we were glad to see that Mr. Breese has contributed two tables of stereoscopes, containing his exquisite instantaneous transparencies, and one or two moonlight pictures. Those interested in the discussion which our notice of some of these pictures aroused, will have an opportunity now of forming their own conclusions.

The display of photography in the French department will be very fine, especially in solar camera pictures. In these we fear that our own department will be surpassed, whilst we shall excel in landscape. In figure photography generally, we conceive our own photographers will learn something from their French neighbours. Italy contributes some very fine, large architectural photographs. We must leave this subject, however, for further attention.

The photographic arrangements of the London Stereoscopic Company were, we believe, very complete. Small towers were erected in five different places, commanding views of different parts of the ceremony. These were under the charge of Mr. England, Mr. Russell Sedgefield, Mr. Stephen Thompson, Mr. Taylor and others, and we understand that a variety of fine negatives, instantaneous and otherwise, stereoscopic and ten by eight, were secured, prints from which will be in the hands of Her Majesty probably by the time these pages have reached the reader.

The prices of admission will not reach their minimum until the end of the present month, after which the admission on the first four days of each week will be a shilling. It will be gratifying to those of our readers whom it may concern, to know that if they wait for this period, the arrangements will by that time be just about complete, so that the loss is not great in doing so. The admission on the 2nd and 3rd of May is £1 each person; from the 5th to the 17th, 5s. each; from the 19th to the 31st, 2s. 6d. each. So that those who wait the cheapest period will find the Exhibition in the most perfect and complete state.

## THE CONTRACT FOR PHOTOGRAPHY IN THE INTERNATIONAL EXHIBITION.

We briefly intimated last week that the London Stereoscopic Company had secured the permission to photograph within the International Exhibition during the time it may remain open, and we expressed a hope that for their own sakes they had secured some modification in the conditions originally announced in the form of tender issued by Her Majesty's Commissioners. Since then we have obtained some additional information on the subject, from which we ascertain that the weakness and incompetency on the one hand, or the unfairness and disregard of good faith on the other, which have characterized many of the acts of the Commissioners, have been strikingly illustrated here.

Let us guard ourselves against being misunderstood at the outset. We regard with complete satisfaction the fact that the contract has fallen into the hands of a house pre-eminently well qualified to execute it, and on terms, which whilst very heavy, the well-known enterprise and unlimited facilities possessed by the firm, may render remunerative. Perhaps there is no establishment in London, in which the art is conducted as a commercial enterprise, that has issued so much thoroughly good photography, or that will be better able to do justice to the mass of art-treasures which, in spite of mismanagement, will be brought together at South Kensington. We feel satisfied that the art, the exhibitors, and the public, will, so far as the Stereoscopic Company is concerned, receive entire justice. Nor do we conceive that a shadow of blame can attach to that company, because, rightly appreciating the weak and vacillating character of the Commissioners, their ignorance of the conditions they ought to impose, and their uncertainty of what they really intended to enforce, a tender was sent in, which practically pooh-poohed the regulations proposed, or boldly ignored their existence, in effect saying: "this is really all nonsense; these conditions are impossible; we tender, therefore, on conditions which are tenable, and on none other."

Well qualified to execute the contract worthily, as the Stereoscopic Company undoubtedly is, shrewdly and wisely as it has undoubtedly acted in disregarding ridiculous conditions, the Commissioners are not the less guilty of a gross injustice to photographers generally. When they announce that no preparation or development of plates is to be permitted inside the building; that the hours during which photography shall be allowed will be limited to a period which shall be regulated by their pleasure, or caprice; and that no sale of photographs will be permitted within the building, photographers not familiar with the character of the men with whom they are dealing, naturally conclude that the conditions are binding; that dry plate photography, during limited morning hours, when much of the Exhibition would be in a state of dishabille, is all upon which they can calculate; and as the amount and value of the work which can be done will be limited at best, and its value curtailed still more by the fact, that they cannot sell their productions inside the building, they, of course, limited the amount of their tenders accordingly. Our readers will be somewhat surprised, however, to hear that in the tender accepted all these conditions are set aside; that wet-plate photography, with all proper facilities for the preparation and development of plates in the building, is to be permitted; that the operators are not to be confined to the hours before ten in the morning, but on all legitimate occasions; and finally, that the pictures produced *are* to be sold within the building. All these changes are perfectly right, and such as common sense would dictate; but before they were made, common justice demanded that the persons whom they concerned should have been informed of them. Not a word of such changed intention, however, was published, not a word of it reached those who were tendering. The fact that changes so natural and reasonable were made at all seems to have been simply due to the good sense and business ability of the firm who secured the contract, who were strong enough to quietly over-ride the fatuous decisions of the Commissioners.

Of course there was a reason for this concession. The reason was a golden one: the Stereoscopic Company offered a most handsome sum, and made a most tempting proposal. Their tender for the privilege of photographing in the building, unfettered by foolish conditions, was a sum of fifteen hundred guineas down, together with a certain share of the profits of photographs to be sold in the building. The prospect of "going snacks" was too much for the virtue of the Commissioners: the published conditions were waived, and the tender was accepted; and the Company have secured the right to photograph, and to sell their productions in the building without let or hindrance. Next in amount to the tender of the Stereoscopic Company was that of Messrs. Day and Son, lithographers, who sought the photographic contract for the aid it would afford them in delineating by their own art the contents of the building. Messrs. Negretti and Zambra, also, we believe, ran somewhat closely in the race for the contract.

The management of the photography in the building has been placed by the Company, we understand, under the superintendence of Mr. England, whose instantaneous and other views of America and Paris have won a world-wide celebrity. Arrangements are, at the time we write, in course of progress for securing negatives from different points of view of the opening ceremonial, copies of which will at once be forwarded to Her Majesty. We have no doubt but that the results will be in the hands of the Company, and their skilful representative, completely successful in a photographic sense; we trust they may not be less so commercially.

## THE SOIREE OF THE PHOTOGRAPHIC SOCIETY.

The Annual Soiree of the Photographic Society was held in the large hall of King's College on Friday evening last, the 25th ultimo, and was, as usual, satisfactory and successful. Although the attendance was not so crowded as to constitute the inconvenient crush experienced at some scientific evening receptions, it was large—numbering about five hundred persons, and comprising many names famous in science, art, and letters. It would be out of place to individualise here, but we may remark that the presence of some of the oldest photographic experimentalists and discoverers, such men as Mr. Fox Talbot and the Rev. J. B. Reade, were not amongst the least pleasant associations of the evening.

Although the Society had held no exhibition this year, and was consequently without the facilities which the exhibition has formerly presented, for decorating the room with photographs, the hall was, notwithstanding—thanks to the influence and exertions of Dr. Diamond in beating up contributors—well supplied with choice illustrations of the art. M. Claudet was a large contributor, and exhibited specimens of all kinds, from the life-size portrait of Faraday, coloured in oil, to enamels for lockets and brooches, executed, we believe, by the process of Camarsac. Amongst M. Claudet's contributions which attracted most attention were several enlargements by the solar camera from *carte* negatives, the prints being about 21 by 17. Many of these were very fine and had received but little aid from the pencil, being simply, as M. Claudet happily phrases it, "corrected." Conspicuous in quantity, and in many instances in quality also, were the prints of the Amateur Photographic Association, which excited a good deal of attention. Messrs. Caldesi and Co. contributed a series of very fine and large photographs of the Elgin Marbles, and other antique art treasures. A number of the exquisite vignette heads, in the style which at once identifies them as the productions of Mr. T. R. Williams, were much admired, as were also several coloured portraits of the same gentleman. Some of these struck us as amongst the very finest oil-coloured photographs we have seen. A portrait of Mrs. Windham, who recently enjoyed a temporary celebrity and "bad eminence," was a marvel of fine colouring; exceedingly brilliant, it was at the same time soft, delicate, and harmonious in the highest degree.

A series of large reproductions from Turner's pictures, by Mr. Thurston Thompson, to which we have before referred, excited much attention and admiration. The attempt to reproduce by photography the paintings of Turner might have been conceived a hopeless task, but in Mr. Thompson's hands it has become a successful fact. Many of the pictures, even in the monochrome, are rich in the peculiar excellencies exhibited by Turner's pictures generally, the unmistakeable presence of atmosphere, the rare distances, the perfect composition. The celebrated "Carthage" is one of this class, which scarcely seems to need the charms of colour to render it a perfect picture. Some few which depend, in the originals almost entirely upon colour for their value, are not so successful; but, as a whole, the series will worthily find a place in the portfolio of the amateur and connoisseur, as well as amongst the choice studies of the painter.

Mr. Rejlander was not extensively represented, nevertheless he had contributed some very fine pictures, of which one—a glass positive of a beautiful model in the garb of a nun—excited especial attention and admiration; and, because it possessed so much of art, many observers, after examining it, exclaimed, "Oh, a copy of an engraving!"

Mr. Robinson had contributed "Lady of Shalott," "Elaine with the Shield of Launcelot," "Early Spring," and various other pictures, all of which were much admired. Mr. Wilson had a frame of charming instantaneous and other pictures, 7×5. Mr. Heath, Mr. Mudd, Mr. Stephen Thompson, Mr. Mayall, the London Stereoscopic Company, McLean and Melhuish, and others, had sent some excellent pictures.

Several stands of stereoscopic transparencies were contributed by Messrs. Murray and Heath and others. Messrs. Horne and Thornthwaite exhibited some novelties in apparatus, a table of microscopes, and some very choice specimens of chemicals, which attracted much admiration. Mr. Solomon had also a table containing some excellent apparatus. Mr. Ross sent a complete set of panoramic apparatus, of large size.

A series of vases ornamented with photographs were exhibited, but without label or anything indicating the mode by which the photographic ornamentation was effected: we presume they were by a process recently patented for photographing on uneven surfaces.

Mr. Durham had sent a few sculptured sketches in clay: a pair, consisting of boys engaged in cricket, were charming little studies.

There were doubtless many other pictures, works of art, and notable inventions, which we have not noticed, as the crowded state of the room with charming living pictures rendered it a matter of some difficulty to give undivided attention to matters simply photographic. The assemblage generally seemed highly delighted with the occasion, if the animated countenances and the constant hum of pleasant voices were a fair indication. Refreshments were served in the library of the college. Taken as a whole, the soiree was decidedly successful.

## Scientific Gossip.

Improvements in the Oxy-hydrogen Light—The Magnesia Light—Arborescent Crystallization on Photographic Plates—New and Important Spectrum Discoveries—Examination of Coloured Glass in the Spectroscope.

Some improvements have recently been made in the oxy-hydrogen light, which cannot fail to be of value to photographers. One objection to the employment of this light for photographic purposes, is the very feeble amount of chemical rays which it emits when evolved by the ordinary means. The earth lime is universally employed as the body which is to be rendered incandescent by the heat, and this is about one of the worst agents for actinic purposes which could be employed. Mr. Fryer has lately been making a series of experiments with this light, with a view to determine what substance, when made incandescent, produces the greatest amount of light. He has operated on various salts of calcium, magnesium, strontium, barium, and also upon some other substances. The best results were obtained from magnesium compounds. The sulphate of magnesia, when baked, was found to yield a bright light, but was decomposed by the heat; and the sulphurous acid escaping, was very unpleasant. Calcined magnesia succeeded the best of all; but when the powder was used, the gases blew it away. When the powder was mixed with water and afterwards dried, the cake was friable; and when the dry powder was pressed into a mould, by means of hydraulic pressure, the cake split up into laminæ when subjected to the current of ignited gases. After many experiments with the materials in different proportions, it was found that sulphate of lime one part, and calcined magnesia two parts, mixed with water and modelled into a cake and dried, produced the best results. This, however, is not all that could be desired, as in time the cake becomes cracked and fissured by the gas. The illuminating power is exactly double that of lime, the ratio being, pressure and volume of gas being equal, as 54 is to 27. The experiments were conducted with oxygen, and the coal gas supplied to Manchester. The jet used was a form supplied by Mr. Dancer, a jet of oxygen being surrounded by an annular jet of the coal-gas. Mr. Dancer has further improved the jet by allowing the oxygen pipe to project beyond the hydrogen, and by not contracting the aperture of the hydrogen, or coal-gas pipe. At the last meeting of the Manchester Literary and Philosophical Society, Mr. Fryer exhibited this light; its effect is said to have been very striking.

Some remarkable appearances of crystallization have been noticed by Mr. Petschler in the preparation of glass plates with bichromate of potash and gelatine, for photographic purposes. The striking peculiarity is, that the inorganic salt in contact with the organic matter produces vegetable forms; specimens on glass plates representing mosses, ferns, and algæ in beautiful ramifications, which vary in many ways, dependent upon the strength of the solution, temperature, state of the atmosphere, and other causes. The plates were prepared in different ways. Some were first coated with collodion, on the surface of which a hot mixture of gelatine and bichromate of potash was poured, and then allowed to cool and dry spontaneously. In a few hours the crystals began to form and ramify themselves over the plate. The gelatine mixture was composed of three parts of gelatine and water, twenty grains to the ounce, to one part of a saturated solution of bichromate of potash. Several other plates were prepared in which the order of application of the ingredients was varied, or some of them omitted, all of which gave beautiful, tree-like crystalline forms. The great variety and beauty of these vegetations must be seen to be appreciated, as they can with difficulty be represented by drawings. Mr. Petschler believes that no chemical combination takes place between the salt and the gelatine, but that the latter acts simply as a medium. The gelatine, when firm, retains a certain quantity of water; but when the moisture is driven off by heat, the crystallization is suspended. There is great similarity in appearance, and there is, possibly, some connection in cause between these arborescent crystallizations and the ramified form in which the salts of some metals are found naturally in agate, slate, and even trap rock, where the oxide of manganese is frequently found to have assumed similar forms. Mr. Mosley has suggested that the arborescent appearances might, perhaps, arise from the density of the solution, from the resistance of the gelatine to allow of crystallization in the usual rhombic form, and possibly to the subtle electrical or galvanic action supposed to be excited during crystallization. He has stated that some years ago he obtained from a solution of bichromate of potash, tree-like forms with spreading branches and pendent rhomboids, which, under the polariscope, appeared like a tree with gems of rich colours for fruit.

An important discovery has been made in spectrum analysis. It has hitherto been thought that the luminous bands and lines characteristic of a metal were always invariable, whatever the temperature of the incandescent vapour which evolved the light. Now, however, it has been found that this is not the case. Professors Roscoe and Clifton have made the discovery that certain broad luminous bands in the spectra of calcium, strontium and barium, and which are usually considered to be characteristic of the metal, entirely disappear at the high temperature of the intense electric spark, and are replaced by fine lines. The new lines which supply the place of the broad bands, are generally not coincident with any part of the band, sometimes being less, and sometimes more refrangible. Thus the broad band in the flame spectrum of calcium, named Ca $\beta$, is replaced in the spectrum of the intense calcium spark, by five fine green lines, all of which are less refrangible than any part of the band Ca $\beta$; whilst in place of the red or orange band Ca $\alpha$, three more refrangible red or orange lines are seen. The total disappearance in the spark of a well-defined yellow band seen in the calcium spectrum at the lower temperature, is strikingly evident. The Professors have also assured themselves by repeated observations that in like manner the broad bands produced in the flame spectra of strontium and barium compounds, especially Sr $\alpha$, Sr $\beta$, Sr $\gamma$, Ba $\alpha$, Ba $\beta$, Ba $\gamma$, Ba $\delta$, Ba $\epsilon$, Ba $\eta$, dissappear entirely in the spectra of the intense spark, and that new bright non-coincident lines appear. The blue Sr $\delta$ line does not alter in intensity, or in position, with the alterations of temperature thus effected, but, as has already been stated by the authors, four new violet lines appear in the spectrum of strontium at the higher temperature. This most interesting branch of scientific enquiry is at present almost too incomplete to enable them to do more than suggest a possible cause for such phenomena as the disappearance of the broad bands, and the production of the bright lines. They, however, venture upon the supposition that at the lower temperature of the flame, or weak spark, the spectrum observed is produced by the glowing vapour of some *compound*, probably the oxide, of the difficultly reducible metal; whereas, at the enormously high temperature of the intense electric spark these compounds are split up, and thus the true spectrum of the metal is obtained. The professors have observed that in none of the spectra of the more easily-reducible alkaline metals (potassium, sodium, or lithium) can any deviation or disappearance of the maxima of light be noticed on change of temperature.

A specimen of glass has been forwarded us by "F. R. W." for examination in the spectroscope; it is one of the deep orange kind, with that peculiar mottled appearance which is characteristic of a silver coloured, flashed glass. In the spectroscope it is seen to cut off in the most perfect manner all the chemically active rays, even those affecting bromide of silver. The glass is one of the most perfect we have ever seen, and could with safety be used for glazing a window with any aspect, as even the direct rays of the sun would be almost entirely shorn of their chemical activity by passing through this glass.

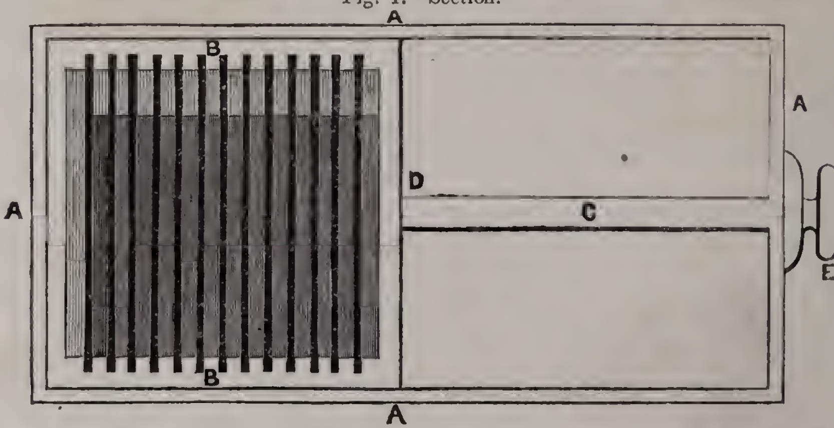
## A TOURIST'S CAMERA.

### To Expose Twelve Dry Plates without Extra Backs.

Dear Sir,—I will endeavour to describe the apparatus for taking stereoscopic views on dry plates, which I had the pleasure to show to you, and I hope with the aid of drawings to make it intelligible to your readers.

I shall begin with the plate-box, which I believe to possess some originality. It consists of a box of ¼-inch mahogany, 11½ inches long, 8¼ wide, 5¾ high, A (fig. 1), in which slides a sideless box B, made of rather stouter

Fig. 1. Section.

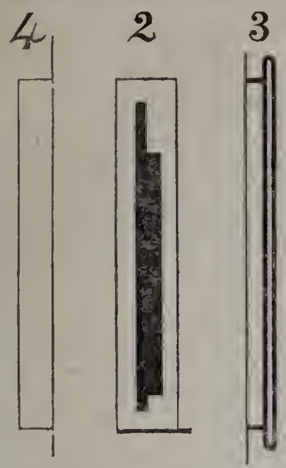


wood, especially the top and bottom, which should be about ½ inch thick having thirteen corresponding groves cut in them, in which the slides are placed, one for focussing, and twelve for the dry plates; midway at D, on both sides of the outer box, and exactly opposite, portions should be cut out, say ½ inch wide, and pieces of wood pierced, as in fig. 2, and ¾ inch wide, should be fastened on, so that a kind of shutter of wood, or, what would be better, tin, and shaped like the plate slide to be hereafter described, can be pushed through against one of the slides brought opposite to it by the bar C taking the place of the slide when it is pushed into the camera, and preventing any light touching the plate behind it.

The shutter should project about an inch from the plate-box; when occupying the place of the slide, the piece of wood where it enters, should project about ⅜ of an inch from the side of the outer box, with a flange, as in fig. 3, so that a black silk bag, lined with yellow, in which the shutter is placed, may be fastened to it by an elastic band; the opposite piece of wood, through which the slide passes *out*, should project about ⅜ths of an inch (fig. 4), and fits into a corresponding opening cut in the side of the camera, the centre of which opening is 4½ inches from the front.

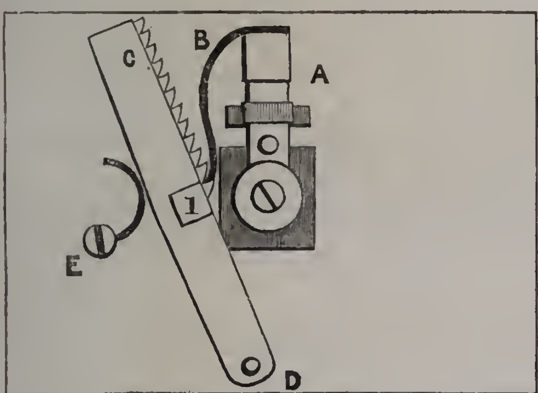
The bar which slides the inner box (C, fig. 1) should enter the outer box at the front, and have a wooden knob E to draw it out; each slide in succession, beginning with the focussing-glass, shaded dark in fig. 1, should be drawn out opposite to the openings on each side of the outer box, and when the shutter passes freely through, pushing out the slide, a notch should be made in the bar C when the bolt of wood A (fig. 5) comes down, and numbered 0 for the ground-glass, 1 to 12 for the plates.

In pushing down this bolt, after each plate has been passed into the camera, a register of the number of the plate



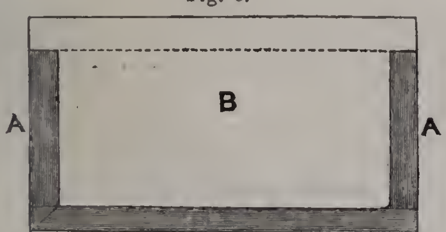
*last* exposed is made by the contrivance shown in fig. 5. To the top of the wooden bolt A is attached a piece of metal, B; a piece of wood C (hollowed out for a piece of metal to slide rather tightly, having teeth cut in it), is attached by a screw on which it can move as a pivot at D, and is kept up to B by the spring at E. It has a small square cut out to show the numbers, which are marked on the toothed piece of metal, 1 to 12, on card or paper fastened to it. It follows

Fig. 5



that when the bolt A is pulled up from the bar, the piece of metal, B, passes into the next tooth, and when the bolt is pushed down again it registers the next number; of course the bolt must never be pushed down until the next plate has passed into the camera. The plate-slide (fig. 6), for a plate $6\frac{3}{4}$ by $3\frac{1}{4}$, is made of stout card, and pieces of wood A, to confine the plates, are glued on; the side pieces

Fig. 6.



are partly cut away at an angle to allow the plate B to slide in, so as to keep it close to the back and resting on the bottom piece, beyond which a small portion of the card projects to slide into the grooves cut in the inner box. The outer edges should be slightly rounded to prevent catching the sides of the opening in passing in and out of the box, the inside edge of the openings should also be rounded. I think *tin* would perhaps answer better than card for the slides, and would be more durable.

The slides, as well as every part of the interior, both of the camera and plate-box, should be blackened with lamp-black stirred into a hot solution of gelatine, and the slides should be numbered.

Sufficient of the back of the slide in which the ground-glass is placed should be cut out to allow of focussing.

A piece of wood, shaped as in fig. 7, must be made to fit into the camera from the back (with a groove A at bottom and top) to correspond with the grooves in the plate-box, so that when the plate-slide is pushed out by the shutter, it may pass smoothly into the camera, and after exposing the plate and putting on the caps of the lenses, the slide is returned back into the plate-box by a stout piece of wire, B, which passes through a hole in the camera and in the piece of wood (7). It should *not* be drawn quite out of the camera when in use, but should be attached to the plate-box by a piece of elastic band, and when not in use is secured through loops on the top of the box.

Pieces of metal should be screwed to each side of that part of fig. 7 where the pin passes through at C C, and a portion of the wood cut away and the cavity filled with cotton wool, which answers as a stuffing. A piece of card or tin slides in at the front of the camera, and goes into two

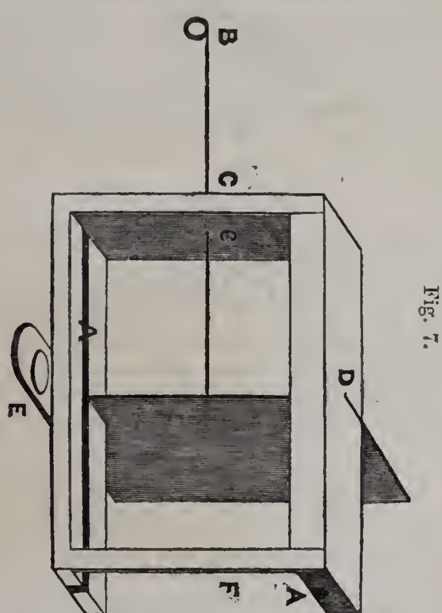


Fig. 7.

notches as at D to separate the lenses; a screw at E passes through the camera and screws into the table, and the side F is cut out for the projection in the plate-box.

The *table* is *hinged* to fold up to the side of the plate-box when the camera is removed. It has a rim of wood round it, and when the camera and plate-box are attached they should fit exactly as regards width, and in the plate-box in length also. The table is made rigid by the camera being screwed down, and by a piece of wood underneath, which moves on a screw from one side of the division, and is screwed down to the other side.

The tripod legs are attached to iron eyes fastened on the table, two of the eyes being on the piece of wood just described. The camera is a folding one, 9 inches long, 8 wide, $6\frac{1}{2}$ high, and is adapted for taking larger pictures by having another front for a view lens and double dark slides.

When in use for stereoscopic pictures a black bag is fastened on to the back with elastic, and draws close with double strings. This serves for a focussing-cloth, and in the event of any hitch of the slides within the camera, the hand can be introduced through a piece of elastic which is passed over the opening.

In packing, the camera is folded up, and the table turned up to the side of the plate-box and put into a case (the front upwards), made either of leather or of the glazed stuff used for umbrella covers, lined. The case should have a foundation of thin wood.

The camera and the front for the twin lenses pack against the top of the plate-box. The piece of wood (fig. 7), and focussing-cloth *on the front*, now *uppermost*, over all is put a square of the same glazed material as the case, large enough to cover the whole of the apparatus, *and the lenses* when in use, and two leather straps, enable the package to be carried either by a handle of wood, as a knapsack. The straps should be buckled over the covering when the apparatus is set up as they prevent its being blown away, and by taking off the tripod legs, the whole can be conveniently carried short distances.

The size of the package is about 12 inches high, 10 by 8½, and weight about 11 lbs., exclusive of the lenses which may be carried separately.—Your truly, THOMAS BARRETT.

P.S.—I should recommend the plates to be packed in numbered dozens, in the following manner:—Cut two pieces of card the size of the plates, and fasten to the ends pieces of paper folded in and out, so that a double piece about ⅛-th inch broad may separate each plate. The last plate must face the next, and may be always No. 12. A description of the view taken may be entered in a memorandum-book, as 1, 2, &c. of No. 1 dozen, &c.; and if they are put into the plate slides as they are arranged in the packet, and returned in the same order, there can be no mistake as regards the number.

*Red Hill, Reigate, April*, 1862.

## THE NEW PICTURE GALLERIES.

BY A. CLAUDET, ESQ., F.R.S.

[WE have recently been favoured with an eloquent and able letter from M. Claudet, in which he administers an effective rebuke to the writer of an impertinent article which recently appeared in the *London Review*, entitled the "New Picture Galleries," a portion of which was reprinted into our pages, and commented upon at the time. The following are some extracts] :—

If the writer of the article on "the Picture Galleries" had been content to criticize the unsuccessful attempts of inapt practitioners, he might have found ample ground for exercising his wit, and would have been perfectly justified in endeavouring to deter incapacity from meddling with photography. In doing so, he might have rendered a signal service to the art. But he has generalized his remarks, striking, not the failures, but the art itself and its principles, accusing it of all the miserable productions of those who are incapable of understanding it; and he has arrived at this strange and absurd conclusion, *that no true likeness can be taken in this way.*

Does this conclusion agree with the remarkable fact, that every one has his likeness taken by photography in preference to any other process? For, notwithstanding its supposed defects, it is the surest way to obtain likenesses perfectly true and characteristic, and in this respect more satisfactory than those which are embellished by the portrait-painter, which, according to our critic, are "*the result of study and generalization, qualities lacking in an ordinary photograph.*"

Still, there is a class of persons who instinctively hate photography as heartily as socialists hate aristocracy—those whose features are either common, ugly, or unmeaning, and those of both sexes who recollect, naturally not without regret, the time when they did not wear a wig or dye their hair. We may well imagine what their feelings are when they look at themselves in their toilet-glass; and, surely, if these fragile manufactures were a new invention, they would be likely to receive more destructive blows than praises for their catoptrical performances. It is, indeed, for this numerous class that portrait-painting is *more true than photography*, and that *photographic likenesses are nothing but caricatures.*

If so many have obvious reasons for being dissatisfied with their lot in the dispensation of the graces of nature, it is not surprising that they should generally complain of their appearance in a "*carte de visite.*"

We find that our photograph is ugly, therefore we have been disfigured by the artist, or rather by his camera. To convince ourselves that it must be so, we look at the likenesses of our friends; and as we have a great number of friends who, like ourselves, are exceedingly plain, we exclaim, in delight, "Oh! it's no use to deny it, photography can only produce *caricatures.*" Of course, if we have been ill-treated, it is the fate of every one and the fault of photography. Decidedly this art is detestable; let us turn it into ridicule!

Our task will be very easy. We have only to stop at certain shops in Regent Street, where are exhibited for sale the most heterogeneous assemblage of "*cartes de visite*" of emperors and empresses, kings and queens, princes and princesses, the Pope and his cardinals, bishops, generals, ambassadors, ministers, orators, philosophers, preachers, actors, dancers, acrobats, pugilists, and gorillas, all in a row of perfect "*égalité, fraternité.*" Are not the greater number of them miserable specimens of photography, printed in a horrid gingerbread tint, "*some out of focus, the generality badly posed, and standing or sitting in the centre of perfect chaos. Panels of walls, doors, jars of conservatory flowers, tables, and other articles of furniture, lean, roll, and tumble about the apartment, as if spirit-rapping was going on, in every position out of the perpendicular. The central figure may be in focus and straight; but even if she escape with no distortion, such as a monster hand or foot, or a cheek that seems afflicted with the mumps, all her 'entourage' is reeling about her, as if she had been taken in the saloon of the big ship during the great storm.*"

I suppose that this lively and most picturesque description is perfectly correct, and I have no doubt that the critic of the *London Review* has seen such hideous photographs, and has not exaggerated their defects for the mere pleasure of appearing witty; but what has all that to do with photography? Is it absolutely necessary or unavoidable that the camera should produce pictures *distorted and out of focus; that the persons should be badly posed, and standing or sitting in the centre of perfect chaos, and surrounded with pieces of furniture, leaning, rolling, and tumbling about the apartment, &c.?*

If these defects are the result of bad instruments, and of the ignorance and stupid management of clumsy photographers, it is perfectly ridiculous to accuse the art of being their cause. Nevertheless, such a theme has been thought a subject fit for a serious paper, and an intelligent man has not found it an ungenial task to disparage an art so beautiful and so perfect as photography, for the poor satisfaction of running down what is generally admired. At all events, it was unworthy of the *London Review* to have permitted the publication of such diatribes against the greatest feat of modern philosophy and ingenuity, and one of the most marvellous discoveries of our age.

In stopping before the shops exhibiting photographic "*cartes de visite,*" you have seen nothing but *caricatures*. Be it so. But is it owing to the ugliness of the photographs, or to the ugliness of the persons represented? It may be either, or it may be both; but whatever it is, that has nothing to do with photography.

If, after a walk along Regent Street, you had chosen to describe the strange diversity of the perambulating multitude, would you have found much to say in praise of the refined expression of countenance of every one you had met—of the beauty of form of every individual, male and female—of the distinction of their bearing, the elegance of their manners, and the taste of their dress? I rather think that you would have returned home very little charmed with your physiological study.

Among those who had passed before your eyes, judging only from their external appearance, might you not perchance have mistaken a nobleman for a farmer, a legislator for a publican, a bishop for a schoolmaster, a clergyman for a waiter, a Russian prince for a commercial traveller, a banker for a tea-dealer, an eminent writer for a toast-master? But if, instead of the reality, you had seen only the photographs of these persons, with their distinguished names written at the foot of their "*cartes de visite,*" would you not exclaim, "Oh! these cannot but be *caricatures*; it is just what might be expected from photography?"

In plain truth, photography caricatures because it represents too faithfully the individuality, and because too many individualities are nothing but caricatures of mankind. No doubt a clever painter might be able to represent the same individuals in such a manner that they would all appear gifted with the mien appropriate to their mind, rank, and station: the nobleman aristocratic in his bearing, the legislator exhibiting the mind of a Solon, the bishop venerable and dignified, the clergyman evangelical and modest, the Russian prince noble and elegant, the banker important and grand, the writer full of thought and inspiration.

Photography represents people as they are; and painting, as they ought to be, or as they would like to be. The last may be more agreeable to the persons represented; but the first is more satisfactory to those who want the truth, and do not care for the fiction of poetical treatment. In description there is nothing like good, plain, and intelligible prose. For truth there is nothing like a mirror: and is there anything more resembling a mirror than the camera of the photographer?

Ask a mother, whose son is travelling in distant lands and seas, which likeness she prefers—the "*carte de visite*," or the painted portrait of her dear boy? She may be proud of the latter in its splendid frame, and in showing it to her friends she may exclaim, "Don't he look handsome! what an agreeable and distinguished expression!" But depend upon it, when alone, that mother, with tears in her eyes, will be thinking of her son: she will look for him, not on the wall of the drawing-room, but in *that elegantly bound album containing some thirty or forty "so-called likenesses*," and, in her case, very justly so called, for among them she finds the real and truthful image of her absent son. With what rapture at the end of twelve mouths will she open a letter from the young man containing another "*carte de visite*" taken at Calcutta, Hong Kong, or New Westminster, showing him with a grown beard, in his new garb adapted to the country, looking full of health and spirits! Imagine, on the other hand, the pleasure of the son when, in return, his beloved mother has enclosed him in a letter her own "*carte de visite*," and, perhaps, that of an equally dear sister. I can guess what will be the first and irresistible impulse of his heart: in transport he will press these precious "*cartes de visite*" to his lips! And thou, cold sarcastic critic, hast no other name for photography than *caricature?* "*Mais vous n'êtes donc qu'un barbare!*"

Have you ever understood what is photography? Have you studied the beautiful and unerring principles upon which it is based? If you had, the most imperfect photographic production would be a source of admiration to you. The great Newton himself would have been in ecstasy had he had the good fortune to witness such an unexpected result of some magic property unknown to him of that light he had profoundly investigated during his life, and the principles of which he had so successfully unfolded.

We see the forms of all the works of creation by the light they reflect. The rays being refracted through a lens that nature has placed in front of that wonderful instrument called the eye, form on the delicate membrane of the retina the image of all external objects. The eye, in reality, is a camera obscura, and photography is nothing else; the only difference between the two is, that in the eye each separate ray communicates on the retina the particular colour belonging to it, while in the photographic camera only one ray, called the actinic, can act upon the photographic surface; consequently, the retinal image has all the colours of nature, and the photographic image has no colour, being only like a mezzotint engraving. In every other respect the result is the same, the forms, proportion, and perspective in the camera being as perfect as those depicted on the retina.

Now the science of optics teaches us how to construct lenses producing an image as perfect as that formed by the lens of the eye. If so, why should a photographic picture be distorted more than the natural one? Therefore, let the photographer procure a perfect lens, and, if he knows how to use it, he will produce a representation of objects in their exact forms. With such a lens, and operating upon a very highly sensitive preparation, he will be able to take a portrait in a few seconds, and, in truth, even instantaneously, catching the fleeting expression of the moment. Therefore, if he has the skill and taste to light his model artistically, to place it in a natural and becoming position, waiting only for a suitable and pleasing expression of the countenance, he will produce, not a caricature, but the most satisfactory portrait, and by careful management, I have no hesitation in asserting, a flattered likeness of every one.

Notwithstanding the remarks of our critic, the features of women can be photographed as successfully as those of men. Of course, in bad photographs, out of focus and improperly lighted, the strongly marked and hard outlines of men may, without losing all their character, bear a greater amount of defects than the delicate forms of youth and gracefulness. But the apparatus, chemical manipulation, and artistic arrangement which are capable of producing a perfect photograph of men, will do ample justice to the most refined and beautiful features which may grace the other sex. In fact, photography, which can represent the cylindrical curve of a marble column, or the roundness of an ivory ball, only by means of an almost imperceptible gradation of tint, can also by the same means delineate the softness of youth and grace with a perfection which no painter is able to approach by the most delicate touches of his brush.

We have to consider photography as any other art—in its capabilities of perfection, and not as the performance of those who do not understand it. Would it not be the height of absurdity to condemn music because all the day long we hear shrieking songs and the horrid whistling of ragamuffins, as to condemn photography because at every corner we see disgusting photographs? Music out of tune is as intolerable as photographs out of focus. But we must submit to the annoyance to which we are exposed, not only in our walks, but in the drawing-room, where, after having been treated with the sight of the elegantly bound album of "*cartes de visite*," we are invited to listen in silence to the screaming song of the young lady of the house with an accompaniment upon her piano out of tune. If so many desire to be musicians, why not as many desire to be photographers, when to be so they have only to buy any instrument?

If we wish to hear good music, we go to the opera and the concert-room; and if we want to have and to see good photographs, let us go to some respectable gallery, and not to the "dusky abode" of some miserable charlatan. Probably there are in London photographic establishments fit to receive good company, where the art is practised with skill and taste, and where correct and pleasing portraits are exhibited.

Our critic has adopted another course, if we may judge from the following description he has given of his photographic trip:—"*Which of us is so fortunate as not to be able to recall sufferings in the inferno of some eminent photographer?—to recollect how, while waiting our turn to pass into the dusky abodes beyond, we surveyed, in all the misery of protracted anticipation, the shadowy forms of those who had before passed under the operation, searching, like bereaved relatives in a Mosque, for the disfigured appearance of a friend.*"

Certainly the writer must be pitied; but has he not richly deserved his fate, if, wishing to have his portrait enshrined in his friend's album, he has selected for the operation such a strange place as the *inferno* of a photographer?

How can we explain his bad fortune? except by supposing that, having only the Sunday for leisure time, he has been obliged to choose, among the numerous suburban anti-sabbatarian "artists," *an eminent photographer* of Wapping, *to portray his features by his painful process, and while waiting for his turn in his dusky abode*, he has seen *the portraits of some fair creatures as vulgar as clowns at Bartlemy fair!—almost all having a cast in the eye, others having an unmeaning grin, or a silly smile, or a surly frown; one of the young ladies looking saucy, another melancholy, and another having that dangerous look that Petruchio himself would not dare to marry her.*

Perhaps, after all, if the critic has got a bad photograph, he has been a most fortunate man, and may be congratulated about his Sunday photographic trip. I am sure he did not leave his heart in the dusky abode of Wapping, in looking at the portraits of the fair creatures exhibited in the "saloon" of the artist. At the same time, wishing a lucky chance to all "fair creatures," we warn them, if they wish to be married, never to risk themselves in any dusky abode, or to visit the *inferno* of the eminent photographer in which our critic had to endure such dreadful sufferings.

107, *Regent Street, 25th March*, 1862.

## FESTIVAL AT M. VOIGTLANDER AND SON'S ESTABLISHMENT.

We extract the following interesting account of a festival at the establishment of M. Voigtlander and Son, from the *Deutche Reichs Zeitung* of February 26th:—

In the large hall of the "Odeon," we had occasion to witness a festival on the 22nd of February, which, as to its importance to German art and industry, may worthily be placed side by side with the celebration which Mr. Borsig, of Berlin, gave to his workmen on the occasion of the completion of the 1000th locomotive engine. In the optical institution of Messrs. Voigtlander and Son, the 10,000th photographic instrument had been completed already towards the end of the past year, and in celebration of this event, the head of the firm, M. Voigtlander, regaled his workmen with a splendid supper, followed by a grand ball, which was kept up till a very late hour, and was in all a very happy affair. The 10,000th instrument had been retained for the occasion, and stood finely decorated in the hall, surrounded by Austrian and Brunswick flags, transparencies, &c., headed by a portrait of M. Voigtlander. At supper, a large silver cup was presented to M. Voigtlander by the oldest workman, and an appropriate address made by M. Rossing, also one of the oldest men. After the ball, M. and Madame Voigtlander were serenaded at their residence.

As we spoke of the importance of this celebration, we owe, perhaps, a proof of it, which will be the more welcome as nearly everybody is greatly interested in photography. When Daguerre made his famous invention, he was confined to take lifeless objects, for, as is universally known, at that time only lenses with weak power of light were used; but when Voigtlander came out with his double lenses, made according to the calculations of Professor Petzval, it was possible to take portraits. The grand achievement was then universally applauded, and the inventor rewarded by a medal, struck expressly for this purpose in Paris. It is natural that owing to the great success of Voigtlander, many manufactories of such lenses were opened in all countries; but up to the present day the lenses of Voigtlander have preserved their old fame, the least proof of which is the 10,000th lens, and the fact that they are found in all the first establishments in the world. The manufactory of Messrs. Voigtlander and Son has recently been vastly enlarged, and yet it is impossible to satisfy the daily increasing demands; and they count on making 2000 lenses this year, whilst the 10,000 have been produced in twenty years, an average of 500 a year. Besides these lenses, the institution produces also a very large number of opera glasses, which they also made first with achromatic lenses. These are principally bought in England, where they are universally known by the name "Voigtlander," and at races will be found in the possession of every gentleman. It would occupy too much space to enumerate all the different branches of the establishment, and we will only mention, that even twenty-five years ago, M. Voigtlander produced telescopes, which, according to the judgment of Gauss, Schumacher, and others, were found equal, and even in some respects superior, to the renowned Frauenhofer telescopes. The present proprietor of the establishment, which was founded one hundred years ago by his grandfather, was always on the alert to extend the business as much as possible, and succeeded in doing this principally by his connections with other countries. Thus we meet here with the rare combinations of artistic efforts and commercial enterprise. We conclude this report, which we felt ourselves bound to make, with a hearty wish that we may soon be able to congratulate M. Voigtlander on the completion of the next 10,000 lenses.

## CARD PROCESS FOR ALBUMENIZED PAPER.

BY A. SINCLAIR.

*Silvering Solution.*

| | |
|---|---|
| Nitrate of silver ... ... ... | 800 grains |
| Water .. ... ... ... | 10 ounces. |

Dissolve the silver in the water, then take two ounces of the solution, add aqua ammonia fortis (not concentrated) until the precipitate is just redissolved; then add nitric acid, until it is just *neutral;* mix this with the rest of the solution, the six ounces plain silver, and filter: float the paper three to four minutes.

The paper should be white and fine. I have, with thin negative paper, succeeded well with a sixty grain solution, but for ordinary paper I think eighty grains more reliable.

Print deep. Wash clean from free silver, first in clean water, and then in a solution of one ounce of salt to one quart of water; rinse in clean water and tone.

*Toning Solution.*

| | |
|---|---|
| Chloride of gold ... ... ... | 15 grains |
| Carbonate of soda... ... ... | 150 ,, |
| Water ... ... ... ... | 15 ounces. |

Dissolve the gold in one half of the water, and the soda in the other, and keep in separate bottles in the developing room.

To use it, take one ounce of the gold solution, and add it to four ounces of water and one of the soda solution, then add the other four ounces of water, and mix all together, making ten ounces of toning bath. Use tepid, and tone a little deeper than the colour required, as it will come back a little in the fixing bath. A little practice is necessary to obtain the correct tint, which may be varied from a rich chocolate brown to a deep blue black.

Rinse in clean water, and fix in—

| | |
|---|---|
| Hyposulphite of soda ... ... | 1 ounce |
| Water ... ... ... ... | 6 ounces. |

A strong solution of soda destroys the tone entirely.

Great care must be taken to keep the fingers perfectly free from soda, as the least grain of it getting into the toning solution would entirely spoil it. If the toning solution grows weak while using, add more gold and soda. This bath can only be used once, but the fixing solution may be used as long as it remains clear, and works in twenty to thirty minutes.

This is the cheapest toning process I know of, as two grains of gold make ten ounces of the toning solution, sufficient to tone five or six dozen cards.

*Rochester, January 18th,* 1861.

[We should think it advisable in the above silvering solution to add alcohol (some find ether good), to secure a more perfect coagulation of the albumen; a preliminary heating of the paper would probably effect the same purpose. Mr. Sinclair and his pupils, however, have had excellent success.]—Ed. *American Journal of Photography.*

## TO HOLD THE MIRROR UP TO NATURE.

Mr. Edward L. Porter communicates to the editors of *The Scientific American* of March 22nd, the following:—

"Suggestion to Photographers.—A radical defect in nearly all likenesses taken by the new method now in use, arises from the fact that the sitter being in a novel situation, unconsciously assumes a constrained and unnatural expression of countenance, and having no means of correcting this, it is of course repeated in the picture. Hence, so few sitters are entirely satisfied with their photographs. The improvement we suggest, is designed to obviate this defect, by attaching to the camera an ordinary plane mirror, so adjusted that the sitter, instead of staring into blank space with a feeling of what a ridiculous part he is playing, shall look at his own reflection in this glass during the entire operation. He will thus be enabled at once to assume and retain his ordinary expression of countenance, or take any other that best pleases himself. The picture will be an exact reproduction of the image in the mirror, and cannot fail of being perfect in every respect."

Our correspondent, Mr. E. K. Hough, informs us that he used a mirror in the manner above proposed, in North Carolina, about two years since. The practical effect was that the sitter put forth extraordinary exertions to look handsome and wise; the picture was the exact reproduction of the image in the mirror, and did not fail of being an exceedingly comical caricature. Mr. Hough's experience will be fully endorsed by almost every practical photographer. The great and very difficult art of the operator at the camera, is to distract the mind of the sitter from thoughts of "how do I look?" and "I must have a smiling countenance," &c.

Most of the awkwardness and unnaturalness of photographic portraits, come from these silly attempts of people to assist or improve nature: the human face never assumes a more ridiculous expression than when the mind is filled with vanity and affectation of beauty and smartness. Very few photographic portraits, indeed, are wholly free from this kind of blemish. Fortunately, the evil is diminishing, for people are getting used to sitting for their pictures, or more careless, or know better how to avoid awkwardness of expression.—ED *American Journal.*

## AMMONIA-NITRATE FOR ALBUMENISED PAPER.

PHOTOGRAPHERS generally seem to be persuaded that there are peculiar virtues in the ammonia-nitrate of silver, for photographic printing. The use of ammonia-nitrate for plain paper has become universal, and now when the albumenised is rapidly superseding the plain paper, all are anxious that means may be devised for reinstating our favourite sensitizing solution. Most of the methods to accomplish this end, which have come partially into practice, are the more or less objectionable and chiefly on the ground that the-so called ammonia-nitrate solutions contain little or no ammonia-nitrate at all. The two following processes, however, employ the genuine and unadulterated article.

*First process.*—Soak the salted albumenised paper in ninety-five per cent. alcohol, in order to coagulate the albumen, and then, after thoroughly drying the paper, silver with ammonia-nitrate by any of the known methods. I have tested the process in only a few experiments, and in these the ammonia-nitrate was ninety grains to the ounce, and the solution was poured on, and spread with a glass rod.

*Second process.*—Silver the paper in the usual way with plain silver. When the paper is dry, or nearly so, expose it to the fumes of concentrated ammonia. In the experiments the ammonia was poured on some cotton placed at the bottom of a half-gallon wide-mouthed bottle. Above the cotton the silvered paper was hung, the bottle worked up, and all left so for about five minutes. After removal from the bottle the paper was exposed to a current of air till the odor of ammonia was removed.

*Remarks.*—Comparative tests by the ordinary process were made by printing at the same time and from different parts of the same negative on pieces of paper prepared with plain silver. Thus, a peice of paper silvered with plain paper, was cut in two, and one half exposed to the ammonia fumes, and both were then printed and toned in the same manner. These tests showed plainly, that the ammonia-nitrate paper was more sensitive, and was toned with greater facility.

Probably, when ammonia-nitrate is used, the quantity of salting and of silver may be materially reduced. I believe that one or two grains of salt for the ounce of albumen, and a forty-grain strength of silver will be found to answer. The paper I used was salted with ten to twenty grains, and thus acquired a strong silver solution.

The alcohol to be used in the first process should itself be salted, if the salting of the albumen is weak.

The above processes are founded on suggestions first published in this Journal. The use of alcohol was first recommended by the editor, and the ammonia fumes by Mr. Campbell of Jersey City. Mr. Campbell's article was published in July, 1858, and had in view only the plain paper. For ammoniating the paper a whole size daguerreotype coating box was recommended.

In using the second process great care must be taken that the ammonia fumes do not reach the collodion room.—*American Journal of Photography*

# Proceedings of Societies.

## AMERICAN PHOTOGRAPHIC SOCIETY.

THE regular meeting of the American Photographic Society was held at the New York University, April 14th, 1862. Vice-president RUTHERFORD in the chair.

After some minor business, and the election of six new members, the subject of hot-water development was called up by the Chairman.

Col. PIKE found it worked well with all dry plates. He seldom used more than 80° of heat, however. He found that very hot water blurred the lines of the negative.Four seconds was the longest exposure he gave his plates. He had used a sherry-coloured solution of caramel in place of tannin, and taken quite good instantaneous pictures by using a drop in the exposure. He avoided the use of a new collodion, as it had a hard surface, and was not so easily impressed in the camera as a film that is powdery when examined under a microscope. He considered collodion as unfit for use if less than 6 months old. He used a sample of waste collodion from a gallery where it had stood a year.

The CHAIRMAN thought a neutral bath was not the best for tannin plates and hot water development. His had occasioned many failures.

Mr. THOMPSON kept a very acid bath for tannin plates expressly, and found no trouble with it.

Mr. HULL, by request, gave his formula for collodion :—

| | | |
|---|---|---|
| Collodion. | Alcohol ... .. ... | 4 oz. 95°. |
| | Ether ... ... ... | 4 oz. |

Dissolve it in 56 grs. gun cotton.

| | | |
|---|---|---|
| Iodizer. | Iodide Potass. ... ... | 36 grs. |
| | Bromide Potass. ... ... | 12 grs. |
| | Iodide Cadmium ... ... | 12 grs. |
| | Water, enough to just dissolve. | |

Add this solution to 4 oz. *absolute* alcohol.

Mix above together, making in all 12 oz. of finished collodion, and add *tincture of iodine* till it is sherry-coloured. Instantaneous pictures of waves, vessels in motion, &c. &c., had been taken on tannin plates with the above collodion. He never poured his tannin solution over his washed plates, but always used a dip bath, using the same tannin over and over again. He did not recollect when the solution was made up.

Mr. THOMPSON used six vertical baths; the first containing the silver bath; the second, third, fourth, and fifth, water; and the sixth, tannin solution. He placed his plates in each successive bath, and found they were sufficiently washed before they reached the tannin bath. He usually prepared one dozen stereos per hour in this apparatus, and then changed the water, saving of course the silver by precipitating.

Mr. HULL found that his savings in this way by computation paid for his pyrogallic acid.

Dr. LEEDS showed some prints on gallate of iron, and explained his process:—Immerse the paper eight minutes in bichromate of potass, saturated solution, and dry. Expose two and a-half minutes under the negative to bright sun-light. Wash in the dark room for half an hour. Immerse in solution of sulphate of iron, 1 oz. to 24 of water. Wash thoroughly, and immerse in saturated solution of gallic acid. Wash and dry.

Mr. CAMPBELL said the addition of gelatine to the bichromate of potass. would preserve the whites, and add brilliancy to the prints.

Professor SEELY showed some samples of buff-coloured cotton from Central America, supposed to be a species of Nankeen cotton. He would make pyroxyline of some of it, and report. He also spoke of surgical photography. A patient without any nose was photographed to-day, and then a piece of flesh taken from his arm, and put into shape as a nose; when healed, another picture will be taken, and the two exhibited to this Society.

Mr. RUTHERFORD called attention to the fact that Emerson's Stereoscope, as manufactured by E. Anthony, entirely corrected all distortion in viewing geometrical figures, by closing or separating the lenses. He showed the effect on a picture of the moon, which could be made to seem concave, flat, or correctly round.

Mr. JOHNSON exhibited some very beautiful experiments with various gas-burners, so arrayed as to have circular or other motions by the force of gas. By means of four revolving burners, throwing illuminated figures on a ground-glass screen the figures all had motion, and the effect was very beautiful.

On motion, adjourned.

F. F. Thompson, Secretary.

## Correspondence.

### NEUTRALIZING THE SILVER BATH WITH CARBONATE OF SODA.

Dear Sir,—Allow me to make a few observations on Mr. Blanchard's statement respecting the negative bath.

When carbonate of soda is added to a bath containing acid, it does not make it alkaline, on the contrary, the bath remains *acid*, carbonic acid being substituted for the acetic or nitric, as the case may be: The carbonic acid gas only being thoroughly expelled at a boiling heat, this done, the bath is then *neutral*. I have always prepared my bath by adding carbonate of soda to it after iodizing—when simply filtered, it is then in first rate condition for negatives; but for a positive bath a *trace* of acetic, or preferably nitric acid should be added. With the bath so prepared for negatives the addition of the $\frac{1}{10}$ part of a drop of ammonia will cause a reduction all over the plate thus showing that the solution was either faintly acid or neutral, as so small a quantity of alkali is sufficient to make it alkaline and useless, whilst in that state, I am convinced that it is impossible to obtain a negative by iron development in an *alkaline* bath, test paper may fail to show acid, but there must be a *trace* of acid, however weak, to obtain brilliancy in the shadows; a chemically *neutral* bath showing a slight trace of fog. I make these observations with all deference to Mr. Blanchard's opinion but they are the result of numerous experiments.

I can quite confirm the statement of Mr. England as to the value of a large proportion of bromide in collodion. About 3 years ago I was engaged somewhat extensively in the manufacture of collodion. Many of the persons who tried it were astonished at the quickness, cleanliness, and keeping qualities it possessed. The iodizer was compounded as follows:—

| | |
|---|---|
| Alcohol ... ... ... ... | 500 parts |
| Iod. ammon. ... ... ... | 25 „ |
| Brom. cadmium ... ... ... | 25 „ |

Add 60 parts to 500 of the plain collodion. I am, respectfully yours, H. C. Jennings, Jun.

### TO ASCERTAIN THE EQUIVALENT FOCUS OF A LENS.

Sir,—As you lately published an article on finding the focal length of a compound lens, will you permit me to describe another method, which is better adapted to ordinary cameras, and lessens the amount of error in computation.

Mark off two inches on the ground glass of the camera by a pencil line; cut a strip of printed paper exactly to the length of 15¾ inches; cause the picture of the strip of paper to fall on the focussing glass. If the picture is longer than the space marked off, move the paper away from the camera; if smaller, bring it nearer, until the length of a sharp picture of the piece of paper is exactly two inches. Measure the distance between the paper and the ground glass of the camera: the tenth part of that distance is the focal length of the combination. I am, yours, &c., X. P. R.

### AN EFFICIENT DRY PROCESS.

Sir,—If you think the following formulæ, for a good dry process, quick, simple, certain, and very satisfactory, worth a place in your journal, it is much at your service.

Wash the sensitized collodion film well in good common, spring, or pump water (hard), if from the chalk it may be *too* hard perhaps, without previous boiling, but from lime stone and most other sources I prefer it to rain or soft water, on account of its alkaline reaction on the sensitized film, or otherwise soda must be used to produce this effect. Give a *last* washing by pouring fresh water over the plate from a jug; the *first* washings from the sensitizing bath may be all in the same water in a hand basin. Drain for a minute from one corner, and pour on a drachm or two of the warmed gelatine solution, two or three times off and on, and drain from the same corner, on a piece of blotting paper, to dry for use.

The gelatine solution is made as follows:—

| | |
|---|---|
| Gelatine ... ... ... ... | 20 grains |
| Gallic Acid ... ... ... | 20 „ |
| Water ... ... ... ... | 4 ounces |

Dissolve in a hot-water bath, and strain for use. A piece of camphor in this will keep it good, and it is better than spirits of wine, which is apt to leave some irregular markings in the skies, &c.

Exposure in the camera from half-a-minute to four or five minutes (*extremes*) according to light and subject.

To develop, pour over the film hot water enough to moisten it completely, particularly at the edges. Then pour on the developing solution of plain pyrogallic acid, without any acid, two or three times off and on, when a red picture shows itself very quickly. Now add a few drops of an acid nitrate of silver solution to the pyro, to bring out the picture thoroughly and completely.

The pyrogallic solution is made with 20 grains of pyrogallic acid, dissolved in 1 ounce of spirits of wine, three or four drops of this are added to each drachm of water necessary, according to the size of the plate. The nitrate of silver solution consists of 30 grains of nitrate of silver, dissolved in 1 ounce of Beaufoy's acetic acid. Fix with cyanide of potash and wash, &c.

These pictures are very clean all over with good skies, and dense enough for all good printing effects. With all the conveniences and advantages of a dry, over a wet collodion process, this is only deficient in two of the essentials of the latter, in not being instantaneous, and in not giving a visible certainty on the spot, of a good negative being made; gelatinized films never move under the developing, fixing, and washing of them. If the picture is thought to be not dense enough after fixing, &c., it may be made quite sufficiently so by a little more pyro and silver. I can say nothing yet of the keeping qualities of these prepared plates, beyond a few weeks this spring, when they were not deteriorated in that time.—Believe me to be very truly yours,

*East Lothian, Scotland, April 21st*, 1862. E. T.

### RAPID DRY PROCESSES.

Sir,—It is curious to notice the opinions formed from experiments in photography; two persons in search of particular results may arrive at opposite conclusions. Mr. Sutton seeking a rapid dry process, lays down as a *sine qua non* of extra sensitiveness in dry plates, that there must be free nitrate of silver retained in the film, and there being none in my process, (not having seen the *Notes*, I do not know if it is the alkaline gelatine, or the morphine process, or both, to which he alludes), "he cannot encourage any hope of good results" from them, now my experience with them leads me to marvellously opposite opinions, and I have received testimony of their efficiency from correspondents. A sentence such as the above, from Mr. Sutton's pen, is received as coming from a standard photographer, and carries weight with it, nevertheless, the fact is undisturbed, viz., that the sensitiveness in both formulæ is so great, after the removal of all free nitrate, that the plates will bear instantaneous exposure, and I have negatives of landscapes taken by them with the usual wet process exposure, prints from which will be shown at the Sydenham exhibition taken on wet unwashed collodion, on wet washed collodion, and on washed and dried collodion (morphine process), more convincing than all the argument possible, and as there are no special precautions in their preparation, nor complex solutions required, it is in the power of all to succeed with them as easily as myself. If Mr. Sutton has tried the formulæ, I cannot imagine how such an expert chemist and photographer failed; if he has not done so, and states his opinion from theory, I hope he will do me the justice of testing them. I am sir. yours respectfully, WILLIAM BARTHOLOMEW.

[The most sensitive dry plates known commercially, are those of Dr. Hill Norris, described as extra sensitive, and these he states to have no free nitrate. ED.]

## INTENSIFYING DRY PLATES.

SIR,—Can you or any of your readers supply me with a good formula for intensifying dry plates? I find that the several strengthening solutions recommended for plates by the wet process, will not all answer for the dry, and that the attempt to gain intensity by their use has lost me several negatives, which were good in all other respects. I find also that negatives obtained from Fothergill and malt plates require different intensifying agents to those prepared by other processes. At first I employed Mr. Blanchard's method, by pouring over the wetted film a solution of 4 grains iodide potassium, and 2 grains iodine, to the ounce of water, and when the image was converted into yellow iodide, poured off, washed, and treated with citro-pyrogallic and silver. This last operation was wholly ineffective, as the colour of the film remained unchanged. Several plates were treated in this way, and to test one of them, a saturated solution of hypo was poured on after redevelopment, when the film was immediately dissolved. In no one case have I found this method successful with dry plates.

Having been compelled to abandon Mr. Blanchard's formula, I adopted the one given by you at vol. iv. p. 13, and dissolved 20 grains of bi-chloride of mercury in an ounce of water, to which I added iodide of potassium until the red precipitate became dissolved. Half of this and half of water acted admirably upon plates prepared like Fothergill's, with the exception that the albumen coating was *not* washed off; and after treatment with citro-pyrogallic and silver, satisfied me in every respect. But with ordinary Fothergill plates, as with those by the malt process, I found myself no better off than with Mr. Blanchard's solution. The film became converted into yellow iodide, and resisted all subsequent attacks from the redeveloper. In one case, indeed, there was slight blackening, and in one stereo plate, part intensified while the rest would not. When the image came out as a positive—as several of the plates did—I was in every instance obliged to abandon the attempt to intensify as hopeless.

This morning, as a last resource, I prepared the solution so strongly recommended by Mr. Brothers, of Manchester, PHOTOGRAPHIC NEWS, vol. v. p. 167, by dissolving 30 grains of mercury and 30 grains of chloride of ammonium in 10 drachms of water, and a second solution of 1 drachm of liquor ammonia to 10 of water. On treating a plate with the former of these, the film did not assume "a rich cream colour," but blackened very unequally, without further change. At the end of one minute the solution was poured off, the film washed, and the ammonia solution applied, when the image at once vanished, leaving me to the unpleasant conviction that I had been completely "sold."

I should state that all the plates referred to were exposed, developed, and fixed last autumn, and that never having before obtained a negative from a dry plate that required intensifying, I have had no experience in the matter until within the last fortnight. The strengthening solutions I have mentioned may succeed well enough with their iron negatives by the wet process, but they seem to me to be unsuited to dry plates. I shall be glad to find that some more reliable means can be suggested than those which have proved so unsatisfactory in my hands, and that if I have committed any error in the manipulation, you will kindly point it out.—Yours very respectfully, AMATEUR.

[The fact that want of density or vigour is not a common characteristic of dry plates, has rendered unnecessary much attention to the best modes of intensifying them, and the conditions are consequently not well understood. It is quite certain that those processes of intensifying which are successful with wet plates, are by no means necessarily so with dry plates, the presence of organic matter in the latter materially modifying the result. The best mode of dealing with dry plates, which show tendency to thinness, is to continue the intensifying with pyro and silver whilst the plate is still wet after fixing. Any plate, by either wet or dry process, is difficult to intensify a few months after development, irregular patches almost invariably occurring. If bichloride of mercury be used, it should be much weaker, and remain on the plate a shorter time than for wet plates, or the image will be actually weakened. If the solution of iodine, to be followed by pyro and silver be used, the result will be better if it be removed, and the plate well washed before the image has been coverted into the yellow iodide of silver; on first applying the solution, the film assumes a dark greyish colour: wash the plate at this stage, and then use pyro and silver. It should be borne in mind that the application of hypo or cyanide to the plate at any stage after it has been treated with iodine is dangerous, as much of the image which consisted of reduced silver, having been again converted into iodide of silver, is easily soluble. Possibly sulphide of potassium would be found useful in intensifying dry plates: it is much in use amongst American operators for wet plates, and it appears likely that it might be more applicable to dry plates than many intensifying agents. Perhaps, if any of our readers have had occasion to experiment in obtaining additional vigour in dry plates, they will give us the benefit of their experience.—ED.]

## Photographic Notes and Queries.

### REMOVING VARNISH FROM PLATES; MEALINESS, &c.

SIR,—In the last number of the PHOTOGRAPHIC NEWS, a correspondent wishes to know a method whereby he can clean glasses that have been varnished. I have always found that benzine will take the black varnish, and that for white spirit varnish, nothing is so good as pure wood spirit (naphtha).

Some time since, having some varnished glasses, I tried many things to clean them; amongst others, soaking them in strong alcohol, with no effect, until I tried the naphtha, and that answers admirably. I merely apply the spirit the same as though I was coating with collodion, and let it rest on the plate about half a minute, and then return it to the bottle, afterwards rubbing the plate with cotton wool; when the collodion is all off, I wash in two or three waters.

A great deal has been said and written about mealiness in toning. My strong impression is, that we must look to the albumenizing for the trouble; for let anyone now troubled with it prepare a sample of paper with albumen, simply using albumen, water, and chloride of ammonium, and sensitize upon a 60-grain silver bath, without the addition of acid or any other substance, and I am sure they would no longer meet with the difficulty; for I always prepared my own paper. until the rage for cartes de visite compelled me to buy it, owing to not having the time to prepare my own, when I got mealiness in its worst form. I tried many samples, sometimes without and sometimes with it, always using the same silver bath (60 grains), and the same toning (carbonate of soda 5 grains, chloride of gold 1 grain, water 6 ounces). If I got a paper free from it, I could not get the tone I desired.

I now use Marion's Highly Albumenized, and am very well satisfied with it, although I would rather have my own preparation; and even all of Marion's is not good, for I have had some very bad.

A sample of paper I obtained from one house smelt very strongly of acetic acid; this I could do nothing with; the pictures were smothered with mealiness.—I am, sir, very respectfully yours, K.

*April 24th*, 1862.

## Talk in the Studio.

Photograph of the Eye.—At the meeting of the American Photographic Society in February, Dr. Henry D. Noyos exhibited a negative showing the optic nerve and interior of a rabbit's eye. The impression was obtained by a newly invented instrument devised by himself and Mr. Grunow, a practical optician. Such a photograph had never been obtained before in America, although it is said to have been done in France. The interior of the eye, namely the retina and optic nerve, has been disclosed to observation in the living person, by an instrument invented in Germany, called the opthalmoscope. This has been in use for ten years, but it is only now that the interior of the eye has been photographed. Dr. Noyes explained the working and principles of the new opthalmoscope, by the aid of diagrams and the presentation of the instrument itself. Through it diseases of the eye can be studied with greater facility, and scientific records of them kept. The instrument displayed, in its elegant and finished workmanship, the highest mechanical skill. The discourse of the doctor was listened to with close attention, and the audience expressed their approbation by applause.

Mayall *v.* Higby.—This case was again heard at the Court of Exchequer on April 24, before the Lord Chief Baron, and Barons Martin and Wilde, sitting in Banco. Mr. M. Smith said the action was brought by Mr. Mayall, the photographic artist in Regent-street, against the defendant, who also pursued a similar calling. Mr. Mayall entrusted to Mr. Tallis, the publisher of the *Illustrated News of the World*, a considerable number of photographic portraits of eminent men, with a view to engravings from them, issued in connection with that journal. Mr. Tallis became a bankrupt in April last year, and these photographs were sold by the authority of his assignees at 5s. each to the defendant, who took copies of them in a reduced size, and sold them to the public. Mr. Mayall then brought his action. The first count of the declaration stated that the defendant wrongfully and unlawfully kept possession of the plaintiff's goods while they continued to be the property of the plaintiff, and raised the question whether there was any copyright in photographs; the second count was for the detention of the goods. Upon the first, the jury found a verdict with 1s. damages for the plaintiff; and on the second also a verdict for the plaintiff, with £20 damages. By leave of the learned judge, the learned counsel now moved to enter a verdict for the defendant on the first count. Rule nisi granted.

Colour of Water.—A long memoir has been lately published by Wittstein, on the colour of water. He establishes—1. That pure water is not colourless, but blue. 2. That the mineral matters which a water may contain, do not affect the colour. 3. That the variety of colour in water depends more on the organic matter in solution. 4. The organic matter is held in solution by an alkali. 5. The amount of organic matter in solution depends solely on the amount of alkali. 6. The smaller the amount of organic matter, the less is the colour removed from blue: as the organic matter increases, the colour goes from blue to green, and eventually to brown. 7. Periodical changes in the colour of the same water do not depend on changes in the organic constituents, but on rest and atmospheric appearances. 8. It may be universally accepted as a rule, that the browner a water is, the softer it is; and the nearer the colour approaches blue, the harder it is. The difference does not depend so much on the amount of organic ingredient as on the amount of alkali. There is nothing very new in this. Experienced water testers have for some time judged or guessed the amount of organic matter from the colour of the water.

## To Correspondents.

J. Garnett.—The proper colour for "touching" prints must entirely depend upon the tone of the picture. A mixture will generally be required; the following colours in different proportions, or some of them, will generally answer: warm sepia, madder brown, English ink, or Indian ink, neutral tint, and sometimes a little burnt carmine. If the print be on albumenized paper, a little gum should be added to the colour to prevent the touched parts showing dull on the albumenized surface. For touching out spots in negatives we know of nothing which answers the purpose so well as cadmium yellow.

A. Gun.—You will generally obtain intensity sufficient in copying engravings by using an old red sample of collodion. Or by the use of a more sensitive collodion, and a nitrate bath containing acetate of silver. A bromo-iodized collodion is not necessary for this purpose. If you obtain some of the collodion of the maker you name, "with usual iodizer," and add to that you are using, you will probably obtain intensity enough without difficulty.

X. Y. Z.—Your questions are put somewhat indefinitely. You ask what is the use of tincture of iodine in albumen, and of a chloride in albumen, without saying anything about the purpose to which the albumen is applied, whether for the dry albumen process, preparing paper, or for the collodio-albumen process. We presume you mean for the latter. We do not recommend either of these additions to the albumen, but they have been recommended by some operators for especial objects. The addition of tincture of iodine had been suggested to prevent any tendency to fogging, and would be equivalent to adding a trace of acid, nitric acid being liberated on the contact of iodine with nitrate of silver. The addition of a chloride is supposed by some to aid the double purpose of producing cleanness and sensitiveness. The formula which in our hands is most successful, is that of Mr. Mudd. Exemption from blisters depends on the use of a suitable collodion in the first instance, and in drying the semi-prepared plate thoroughly before the final sensitizing.

J. B.—The negative arrived smashed to pieces, so that we can form very little idea of it. From examination of some of the fragments it appears much under-exposed.

W. A. Y.—We should imagine from your specimens, some of which have very good qualities, that you would have very little difficulty in obtaining a situation in London. 2. The salaries of operators in London vary, and depend entirely upon the standing of the establishment, and the ability of the operator. We should say the amounts vary from 30s. to two or three times that sum, and upwards. 3. There are no facilities for exhibiting the specimens of advertizers at our office. 4 Demand and supply are about equal as regards photographic assistants; perhaps at the present moment the demand for first-rate men exceeds the supply.

A Tyro.—The paper to which you refer is a highly albumenized *Rive* paper, and will not tone so easily as some samples; but there can be no reason why it should refuse to tone at all if all your operations are properly performed. It sometimes happens than rain water which has stood some time is unsuitable for making a toning bath. Try the use of distilled water, that will probably remove your difficulty. A toning bath is generally best a day or two after it is mixed.

J. M.—Your friend is right in characterizing your picture as under-exposed and over developed; the use of more sensitive and less intense collodion would have answered the same purpose. The collodion you are using appears somewhat too intense, and is probably the cause of the defect you describe in your glass positives. Less light over head, more side light, and longer exposure, will improve your results. The difference in the exposure necessary between single and double combinations, will entirely depend on the respective foci and apertures. We cannot advise you as to the best mode of adding to the height of your room. A stop of about an inch and a quarter will enable you to get sufficient definition in a standing figure with the lens you name.

J. F.—If you wish to separate your two lenses which are now connected and focussed by means of one pinion, the simplest plan will be to cut the rod, and be content afterwards to focus them separately. Any method of coupling them by a loose piece would be likely to get out of order and work imperfectly. 2. We are uncertain as to the conduct of the Custom House officers on the Continent in reference to prepared dry plates. The safest plan would be to have a box with an inner covering of orange glass, which would permit the plates to be seen without exposing them to light. 3. A landscape camera intended for use with one lens, or lenses of the same focus, may be rigid, if the lens have means of adjustment. The advantage of sliding or bellows bodies is that they permit of the use of lenses of different focal lengths. 4. Crown or sheet glass may be used with propriety for small sized negatives, but it is a wise precaution to try each plate first by screwing it down in the pressure frame, so as to make sure of not subsequently destroying a good negative by breakage in printing.

T. G.—The toning process used by the late Mr. Lacy was not one of mixed hypo and gold, but one of the alkaline gold formulæ. We shall be glad at any time to hear from you.

Nitrate.—So far as we can judge by the sample sent, the decomposition in your ammonio-nitrate bath has simply arisen from contact with organic matter, as you have probably floated your albumenized paper on it. If there be any trace of free ammonia, decomposition would be apt to ensue.

J. T.—We are at all times anxious to assist our readers, but the general question of the best mode of building a glass house is too indefinite to enable us to give any information or advice of value, as everthing must depend upon the requirements and means of each individual. If you have space and means, you will find the following dimensions give good results: 30 ft. long, 12 ft. wide, 15 ft. high at the loftiest part, and 8 or 10 ft. at the lowest part. 7 or 8 ft. dark overhead, and the rest of the roof glass; as much side light as you can get, and no front light. Let the sitter face north, and take especial care to have the roof watertight.

H. Schaw.—We are obliged by the paper, which shall have our early attention.

Private Letters.—We receive from time to time letters to which answers by post are requested. Our time is generally so closely occupied with pressing duties that we have not time for more private correspondence than absolutely belongs to such duties. Where we can, however, we do occasionally write; but can only do so at convenient times. We have at the present moment an accumulation of such letters, waiting for a leisure day or two in which they may receive attention. Correspondents who shape their questions so that they can be answered in the News will generally receive the earliest information, as a specific time is devoted every week to answering such communications. We hope those of our readers who can, will take the hint.

Several correspondents in our next.

Erratum.—We are requested to state that in our report of the last meeting of the North London Photographic Society, a slight injustice is done to Mr. Ross, who, in answer to a question from the Chairman, is made to say that he did not know much about the microscope. As the firm of which Mr. Ross is the principal enjoys a well-earned celebrity for the manufacture of microscopes, as well as all optical instruments, this remark will not mislead many of our readers. It may be desirable to state, however, that his remark was rather intended to apply to the practical details of microscopic photography than to the microscope itself.

# THE PHOTOGRAPHIC NEWS.

Vol. VI, No. 192.—*May* 9, 1862.

## HOT DEVELOPMENT FOR DRY PLATES.

A singular discrepancy appears to exist in the experience of different photographers as to the value of hot developers, especially in their application to tannin plates. For years past, heat has been used by Mr. Mudd and some others with collodio-albumen plates; but in the hands of the majority of photographers using other processes, it has not been universally, or even, we believe, generally successful. In our hands, with collodio-albumen plates, it has been completely satisfactory, as it has in all cases of which we have any definite information; but have no reason to believe that it has been largely adopted.

The announcement of its amazing effect on tannin plates in America has given a fresh impetus to experiments in that direction, and the results, as we have stated, present considerable discrepancy. Mr. Sutton recently tried hot development with tannin plates, and states that the films split up, entirely spoiling the negative. Mr. England, some weeks ago, stated a similar result as attending his efforts with hot development. More recently he informs us that, getting over that difficulty, heat in his hands always produces fog. Amongst the American operators there are some who state at their meetings that they have utterly failed in obtaining the results described, whilst the majority, however, have been entirely successful. There can be no doubt that for these discrepant results there is a cause, and the conditions have varied in some way at present unexplained. We have been during the last few weeks experimenting at intervals with hot development, and have arrived at some conclusions which may be of service to our readers in their own operations.

We may remark at the outset, that we have been somewhat disappointed in the results. We have found unquestionably that the time of exposure may be considerably reduced when hot developers are used, but there are other difficulties which go far to nullify the advantages. The splitting of the film we have found no difficulty in obviating by the use of suitable collodion; but we have found in all cases that where great heat is used, and free nitrate of silver is present, that there is considerable tendency to fog or surface reduction, and that in the conditions in which we have worked, this difficulty was sufficient to nullify the value, in other respects, of heat. This is a difficulty which we have no doubt can be met, but a little care and further experiment will be necessary to settle the precise conditions.

The first plates on which we operated in our recent experiments were prepared with caramel, and forwarded to us by a correspondent some months ago. We obtained with them fully detailed pictures with a very short exposure; but in all cases there was a certain amount of red fog, which appeared chiefly at the edge where the plate had drained. We concluded that some traces of free silver had been left at this edge, and that as the plates had been kept about five months, decomposition had set in. We have since been led to the conclusion that this result was considerably aided, if not entirely caused, by the effect of heat.

We have since then tried hot development on simply washed plates; plates treated with gallic acid; plates treated with gallic acid and honey; and plates treated with tannin and honey. In each of these cases heat has proved a decided accelerator, but it has also, unfortunately, produced more or less of fogging, or general surface reduction. The fog thus produced may easily be removed, it is true, by means of a camel-hair pencil, as it lies loosely on the surface of the picture; but this is a makeshift which ought not to be needed. We have a full conviction, however, that this is to be avoided entirely without losing the advantages of hot development, a conviction which we hope to verify shortly by further experiments.

We may just briefly hint here, what appears to us to be the source of the discrepancy between the successful and unsuccessful experiments in this direction. In the various incidental allusions of the successful operators in America to the conditions under which they work, we find that very old collodion, with plenty of free iodine, and an acid silver bath are used. These, as we know, are very potent agents in preventing fog. In our own experiments we have used a variety of collodions, some new and colourless, some a few months old, and one two years old; but all sensitive and not containing more free iodine than is indicated by a lemon tint: and the silver bath has been nearly neutral, having only the faintest trace of acetic acid. Mr. England's operations are, we believe, conducted with chemicals in similar condition. He, moreover, redips the plate in a silver bath before development, and the application of a hot developer under such circumstances, is almost certain to produce at once the surface reduction to which we allude, and when that is commenced, development rarely progresses favourably. It is probable, that in the use of an old collodion and an acid silver bath, the conditions will be found which admit of the successful application of hot developers.

## THE HONEY AND TANNIN PROCESS.

Some experiments we have recently made with tannin and honey have been most successful and gratifying, both as regards the quality of negative, and the sensitiveness and certainty of the process. In sunlight, an exposure of seven seconds, with a lens of six inches focus and half-inch aperture, has produced a good negative of buildings and foliage. The negatives are of very fine quality, and the prepared plates, notwithstanding the use of honey, quite dry and free from stickiness. In the preparation of the plates we followed Mr. England's instructions, but tried a variety of different collodions, the results of which we will briefly state.

We first made a collodion of the pyroxyline used by Mr. England, a sample of which he had favoured us with. It is evidently made at a low temperature, three grains giving a collodion of quite sufficient body, which yields a tough, skinny film, easily removed from the plate without tearing. This was iodized with three grains of iodide of ammonium, and three grains of bromide of cadmium. The plate became in the silver bath very creamy, and worked exceedingly well at once in the wet state, giving a clean, brilliant, dense negative with very short exposure. When prepared with the honey and tannin, it yielded good negatives with an exposure of about eight or ten seconds in sunlight. The film had a tendency to loosen, but with care was not lost.

We next tried a sample of commercial collodion of high repute for the wet process, which is generally believed to be iodized with cadmium, and to possess no bromide. This gave a clean, good quality of negative, but was much slower; with an exposure of twelve seconds it was not more than half done.

A sample of collodion prepared by Mr. Sebastian Davis, according to the formula he recently described at a meeting of the South London Society. This gave exceedingly satisfactory results in every way, and was scarcely inferior in sensitiveness to the first mentioned

We next tried some plates with a sample of collodion made by ourselves about two years ago; the pyroxyline was made by a formula we have often described; it contained equal portions of the iodides of potassium and cadmium, about two grains of each, one grain of bromide of cadmium. This yielded the best result, giving a good negative with seven seconds exposure. It adhered well to the glass, and behaved well in every way, allowing, moreover, of the use of slightly exalted temperature in development without fogging.

The silver bath, as we have stated, contained only the faintest trace of acetic acid. The plates received no preliminary coating. In some cases there was a tendency to leave the glass, but this was easily obviated, even when heat was used, by running an edging of black varnish around with a camel-hair pencil. The washing was effected by placing the excited plate in a dipping-bath of distilled water, containing a little acetic acid; it remained there until another plate was coated and immersed in the silver bath, and was then washed with from a pint to a quart of common water, poured slowly from a jug. The honey and tannin, fifteen grains of each dissolved in an ounce of water and filtered, was then poured over the plate, the first quantity drained off, and the plate again covered, and set to dry spontaneously. The development was tried in various ways; but the following was found best:—the plate was moistened with water at a temperature of about 80°; a solution of pyrogallic acid, containing about one grain in five ounces of water, was then applied, and in a minute or two a faint image appeared. The plate was again washed, and a two-grain solution of pyrogallic acid, containing half a grain of citric acid, twenty or thirty minims of acetic acid, and a few drops of a thirty-grain silver solution, applied until the negative was fully developed.

Whether the honey plays a chemical or mechanical part in the operation, we cannot say; but it certainly seems to be an important auxiliary, and it is somewhat singular that simultaneously with Mr. England's announcement of his use of the mixture here, Col. Pike announced at the American Photographic Society that he always added sugar or rock-candy to his tannin solution. The result is, we think, certainly an improvement on tannin alone. The plates develop nearly as rapidly as wet collodion, and they are very clean, and very brilliant.

Mr. H. P. Robinson, of Leamington, observes to us in a recent private letter,—"I have been trying Mr. England's tannin and honey process, on fifteen-inch plates, with wonderful results. Exposure a trifle more than for wet plates; results as good or better than wet." Mr. England is making some further modifications, by which he states a still further augmentation of sensitiveness is attained, so nearly, indeed, is the exposure to instantaneity, that he contemplates competing for the Marseilles prize; in which case he will scarcely be at liberty, to communicate further on the subject at present. Major Russell has, we understand, made some further improvements in the tannin process proper, which will doubtless appear in a new edition of his work. In the meantime we recommend strongly to our readers a trial of tannin and honey.

## THE PHOTOGRAPHIC GARRET.

We have tried hard to feel satisfied with the position assigned to photography by the Commissioners in the International Exhibition. We have tried to believe that probably photographers generally, in common with ourselves, attached an importance to our art which it did not possess in the eyes of the world, and that we were a little over-exacting in our estimate of its claims: that men of far-reaching vision, of large experience in the world, in science, and in art, probably saw photography, and all pertaining to it, in their just proportions, and would assuredly assign the art its right position. We received personal assurance from one high in authority, that Her Majesty's Commissioners never intended any slight to the art, but were desirous of doing it all honour; that finding it in a doubtful position, they resolved to give it a fair field on which to win its spurs, and that a separate department would be devoted to it: we accepted the assurance with all thankfulness, and hastened to announce the glad tidings.

Every visit to the building increases our mortification, however, and our conviction that British photographers have ground of bitter complaint. A separate department, indeed, they have obtained; separated with a vengeance, from all probability of attention or interest on the part of visitors. We venture to state that nine-tenths of the persons who visit the Exhibition will never see the department at all, and that the majority of them, if they think at all about it, will come to the conclusion that British photography is not represented. The first day, as we have before stated, the department was closed. The second day we found it open, and the rubbish partially cleared away: two solitary individuals had found their way there. A melancholy-looking foreigner and a boy. Let the Commissioners look out, or suicides will be committed there! The solitude of the place is a temptation.

The small, uninviting doorway, or opening in the wall at the right hand, immediately before entering the British Picture Gallery, has not, at present, even any announcement that it leads to the photographic gallery, and might readily be supposed, by any one not better informed, to be a private entrance to a clock tower, or ventilating department. The adventurous person who, passing through the doorway, begins to ascend, will not have his conviction altered by the shabby appearance of the winding flights of steps; and it is only on reaching the top that he will find that he is in the British photographic department, where, as a daily journalist has recently euphemistically phrased it, photography "is allowed to hover over the confines of art, more as an attendant than as a companion."

If all the photography in the Exhibition were in the same position the matter would be more tolerable. If the photography of the world had been gathered into one vast apartment, however remote its position, we could have been content. A large portion of the public would have enquired for it, and sought it out, however toilsome the journey. But the photography of other countries is placed in the most accessible and prominent positions; in the main aisles or avenues, in the courts leading out of the nave, in the main galleries. Let the visitor turn where he will, even in the most listless general examination, he meets time after time with displays of foreign photographs. Amongst the first things to catch the eye in the main body of the building, are the large architectural photographs in the Roman Court. Amongst the most noticeable things in the main gallery are the large French photographs. And so, wandering through the building, we find photographic contributions from Canada and India, from all parts of Continental Europe, and from Africa, all hung in more or less accessible positions. Photographs from Jersey, even, find a place in the main body of the building. Is it probable, then, that the general visitor will ever think he has missed *the* photographic department?

England is the birthplace of photography as now practised: it is the birthplace of photography on paper and collodion. It has the largest amateur photographic population, we venture to assert, of any country in the world. Photography in this country is not only under the immediate patronage of royalty, but is practised by royal hands. England invites the world to a friendly tournay of science, art, and industry; and having done this, thrusts photography into a garret or attic. Whether their productions be considered the offspring of science, fine art, or industrial art, British photographers, we repeat it, have bitter reason to complain of their treatment.

## DECOMPOSITION IN COLLODION.

BY AUG. TESTELIN.

Photographic collodion is a mixture of many substances which readily react upon each other, giving rise to spontaneous decompositions which effect great changes in the composition of this valuable photographic agent.

The principal elements of collodion are ether and alcohol; the former, especially, constituting the greater portion of it. Ether being a very unstable compound, it is easily decomposed by the action of the air, hence it follows that collodion is also altered under similar circumstances.

On the other hand, prepared photographic collodion contains salts, with bases almost always alkaline, whose presence singularly hastens this alteration; moreover, these bases are combined with a metalloid (iodine), which also exercises, in another direction, and under the influence of light, a decomposing action upon ether and alcohol. Lastly, the products resulting from these successive decompositions act injuriously upon the pyroxyline, which forms the most delicate part of collodion. It is this series of complex reactions which are the primary causes of the variability of photographic processes, where the solution of the pyroxyline serves as a basis, and as the medium of the sensitive agent, that we propose to study in this present article.

We now proceed to carefully analyse the changes that take place through the contact of air with these various substances, and the reactions which these latter exercise upon each other.

1. The presence of air in the bottles in which ether is kept, changes it partly into water and acetic acid; this latter combines slowly with another portion of the ether, not yet decomposed, and forms acetic ether, but under the influence of light the action is much more vivid and complex.

When the ether is in contact with an oxydisable metal, such as zinc, cadmium, lead, iron, &c., the alteration is more profound, the absorption of the oxygen proceeds more rapidly, and in this case a metallic acetate is produced, and then the reaction is always accompanied by the producton of formyle, which immediately produces a formiate of oxide of ethyl, and a metallic formiate.

2. The anhydrous salts with alkaline bases are for a time without action upon pure ether at ordinary temperature; but when moist air has access, the ether appears reddish brown by transmitted light, and after the lapse of a certain time, acetates and formiates of the same bases are found.

When the alkaline salts are not anhydrous, as is the case in collodion, this reaction always takes place, and in a much more evident manner when the ether is in presence of alcohol, which furnishes water in a state quite favourable to the reactions, either by decomposition, if it is anhydrous, or in ceding its water of hydration if it be less concentrated.

The brown tint which the ether then assumes is not remarked in the collodion, the iodides of which have alkaline bases, because it is concealed by other simultaneous reactions, which also give rise to a more intense colouring. Besides this brown tint, due to the decomposition of aldehyde, evolved in these several cases, cannot be very apparent in collodion where the alkaline substances exist only in very small quantities.

3. When the ether contains an iodide or a bromide in solution, and it is in this condition that we must always regard the ether of the collodion, the spontaneous changes developed are always more numerous; and if a slight decomposition has already commenced by the absorption of oxygen, the reactions proceed rapidly, although they take place nevertheless with an ether at first very pure.

Besides most of the iodides and bromides, as well as some chlorides, by dissolving in ether, are partially decomposed, disengaging according to the nature of the salt, iodine, bromine, or chlorine, the contact of which, with ether, always determines the decomposition of this latter, by producing corresponding acids, which themselves act upon the ether to form other products (acetic acid, formic acid, for nitrate of oxide of ethyl, aldehydic acid, &c.).

Under the influence of light the iodine and bromine of the iodides and bromides dissolve, the contact of hydrogenous organic substances (ether and alcohol) partially decomposed these matters by removing their hydrogen, with which the iodine and bromine have a great tendency to combine, there is formed on the one hand an oxide of the base as first united to these metalloids, and this oxide combines with the acetic acid, which, in the first place, existed in the ether, and which is also produced in a quantity proportionate to the oxygen disengaged during this reaction, there results then an acetate, while, on the other hand, the iodine or bromine, removing the hydrogen from it, produce hydriodic or hydrobromic acid, which, in the nascent state, is in its turn decomposed by the ether, forming water and hydriodic and hydrobromic ether.

Iodine or bromine, added directly to the ether, produce hydriodic and hydrobromic ether (corresponding, we might say, with formic acid), iodized or bromodized compounds, formyle, a body resembling heavy chloric ether, and lastly, a product analogous to chloral. In distilling the liquid by a gentle and gradual heat, we obtain all these products in succession, with the exception of the periodide of formyle, and liquids analogous to chloral, which remain in the retort, mixed with a variable quantity of heavy bromic ether.

4. Iodine dissolves in alcohol, absolute or diluted with water, and colours it of a very deep red; but it does not appear to cause any very evident reaction; nevertheless, if we add to this liquid some hydrate of potassa, or of soda, the colour completely disappears when the liquid is warmed, and quicker in proportion as the solutions are more concentrated. Here is, then, produced some iodide of potassium or of sodium, according to the base added, some formic acid, formiates of the same bases, and periodide of formyle, if the potassa or soda does not remain in excess. This reaction is produced in the same manner, and almost as quickly, with the oxides of most other metals. Fragments of zinc, cadmium, iron, lead, &c., produce the same effect, and in every case where we deprive an alcoholic solution of iodine of its colour, by introducing slips of metal, there is formed, among other products, a certain quantity of iodide of formyle. The greater part of this iodide is deposited, on straining, in an extremely light granular form, which disengages a very pungent odour when isolated from the mixture.

Upon gently evaporating the liquid, in proportion as the alcohol becomes volatilized, crystals of iodide of formyle are deposited, which a slight washing with pure water separates from the metallic iodide and the formiates which have appeared during the reaction.

5. When we leave to itself a mixture of alcohol, ether, iodine, and monohydrated nitric acid, in a bottle that is not quite full, or slightly corked, beside the formation of all the bodies we have instanced, we remark, at the expiration of a certain time, a deposit of yellowish white needle-shaped crystals. Sometimes it happens that this deposit consists of a heavy oily liquid, but the latter is produced when the mixture is prepared with bromine instead of iodine. The composition of this substance is unknown to us; its instability, even when kept under water, only admits of our ascertaining that the influence of light colours it brown, and appears to decompose it into iodine and a gaseous substance, the odour of which is similar to that of chloral.

If we mention these facts, which, perhaps, may appear foreign to the question, it is, on the contrary, because we find their application in all the reactions which take place during the different phases of the alteration which photographic collodion undergoes.

For, in studying, for example, the reactions to which a mixture of iodine, alcohol, ether, and nitric acid give rise, we shall succeed in accounting for, in a manner as precise as circumstances permit, the changes which take place in the composition of a collodion prepared with acid pyroxiline, either on account of insufficient washing, or on account of the decomposition it undergoes, in certain cases even after its solution.

Thus, a simple collodion to which we have added iodine, with the intention of changing the latter into an iodide by means of slips of metal, becomes altered in the course of a few months, so that it disengages nitrous fumes, and manifests a very acid reaction, and the sides of the bottle become covered with a quantity of small red crystals.

Having had occasion to observe the simultaneous changes produced by time in alcoholic and ethereal solutions of iodine and nitric acid, we have only been able to refer the cause of this singular effect to the decomposition of the pyroxyline, the only body which can furnish the oxygen elements of the nitrogen.

However, we have never observed similar results in nitric cotton; but the facts which Mr. Hardwich recently published on the decomposition of this body, confirm us in our first supposition.

## REMARKS UPON SOME OF THE APPARATUS EMPLOYED IN PHOTOGRAPHY.*

BY F. R. WINDOW.

Baths and Dippers (*continued*).

*Dippers for Vertical Baths.*—Dippers are so essentially part of the vertical baths they are exclusively used with, that I will first say a few words respecting them before turning to the subject of horizontal baths.

It seems to be generally admitted that the question of dippers is rather a sore point, and on turning over the leaves of this journal or other publications devoted to photography, we see frequently repeated complaints of the caprices and misdemeanors of these instruments, as well as many suggestions of devices to correct their shortcomings. I am rather inclined to think, however, that they scarcely deserve all the ill that has been said of them, and that many mischances have been laid at their door which could be more appropriately attributed to other sources, and oftener than not, I fancy, to the photographer himself.

A dipper is intended to hold the glass plate when it is plunged into the vertical bath, and to draw it out again. It must clearly be of such a form that no part of it can touch the front of the plate upon which is spread the delicate collodion film. For this reason they are made like a flat hook, the plate being allowed to rest against the back and on the bottom only.

Dippers are made of plate glass, glass rod, silver wire, porcelain, and gutta-percha.

Plate glass dippers are probably more used than any of the others. They are formed by cementing a small slip of thick plate glass on to the bottom of another strip of plate glass of the same width a trifle longer than the depth of the bath. The small slip of glass forms the lip or hook upon which the plate rests: it should, therefore, be thicker than any of the plates that are likely to be used, and before being cemented on to the dipper, the edge of the lip should be ground on a stone so as to form an acute angle with the back piece, (fig. 17); this forms a groove which offers the plate a firm seat, and if the lip be formed of sufficiently thick glass there is no danger of the plate slipping off. The great vice of this kind of dipper appears from the complaints of several photographers to be the tendency of the cemented lip to come off, and as this naturally always happens at critical moments when the plates are being placed in the bath or taken out, it would be sufficient to condemn the instrument entirely, if the charge were, well founded, or the fault without remedy. Such an accident has not happened to me since the early days of collodion photography, when the proper way of making the various instruments was not

Fig. 17.

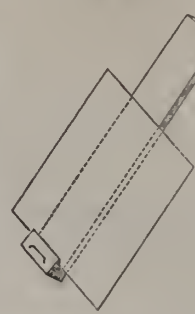

Fig. 18.

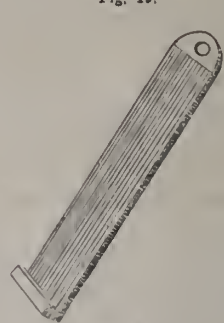
Fig. 19.



at all decided by experience, and unsuitable cement was often used for this purpose, but now I think they may generally be relied on. Still it would, no doubt, be better to increase the security by the addition of a silver rivet such as are employed to repair broken china, &c., which would render a disaster of this nature impossible except in the case of breakage.

It would be well if this kind of dipper were made a little wider than is usual, that the plates may have a more substantial support, and also the lip is seldom made of sufficiently thick glass to form a deep groove in which the bottom edge of the plate can lie securely, so that it can only rest *on* the lip, and a little cause is sufficient to make it fall off. Want of a proper attention to this detail is the principal cause of the glasses getting off the dipper in the bath, which necessitates one of the most disagreeable kinds of fishing that I am acquainted with; if the dipper be properly made in this respect, and the bath slightly inclined from the perpendicular, as mentioned above, no fear need ever be entertained of such a misfortune.

If from the flatness of the surfaces the dipper is found to adhere inconveniently to the inside of the bath or to the back of the plate, one large drop of cement upon each side of it will remedy this entirely, as it will prevent the dipper from lying perfectly flat against either of the surfaces.

Another objection to glass dippers has been made, that they are apt to break the bath by striking with violence against the bottom. I do not think any remark is necessary on this point, except to recommend more careful manipulation to those photographers to whom such an event has occurred, as it can only be the result of a want of ordinary attention.

Porcelain dippers are, in my opinion, preferable to those constructed of plate glass, as last described; they are made all in one piece, therefore the lip can never give way unless by breaking, and it can be made of a more convenient form. When of the same thickness they are, I think, equally strong, and equally cleanly. It would be an advantage if they were made wider than is usual, especially those intended for large-sized plates. Another improvement would be to make them corrugated, or slightly grooved on both sides nearly to the top; this would add to their strength and also prevent all

* Continued from page 196.

chance of their adhering either to the bath or to the plate (fig. 19).

Some glass dippers have lately been made for sale in one piece, like the porcelain dippers, the lip being turned up instead of stuck on. These are better in principle than those which are of two pieces cemented together, but the specimens I have seen of them were not of a satisfactory form, the top of the lip being turned inwards, which would inevitably touch and tear the collodion film.

Metal dippers are made of a loop of silver wire, or an iron wire coated with gutta percha, bent into the form shewn in fig. 18; they are useful for large plates which might be too heavy to trust upon a dipper of glass or porcelain, but their cost is too great for them ever to come into general use for ordinary work.

Dippers are sometimes constructed of glass rod bent into the same shape as the above, but they are not to be depended on, and should only be used with very small plates except on an emergency.

Gutta-percha dippers are made like porcelain dippers, but these also should only be used for small plates. When a dipper is made of such a flexible material as gutta-percha it is apt to bend under the weight of a heavy plate, and force it off the lip.

A dipper intended for carrying about in a portable bath should always be made specially for it, with the head cut into a diamond shape, (fig. 20) so that it may lie diagonally inside the bath when the water-tight cover is screwed on; and

Fig. 20

if this be well devised the soft gutta-percha cover will press lightly upon it and keep it from shaking about and getting broken. The top of the dipper will of course get wetted with the nitrate of silver splashing on it when carried in this manner, and must be wiped with a piece of filtering paper or rag, before being used.

Generally speaking, the vertical baths and dippers are very convenient for plates of moderate size, and present no difficulties in practice; but for large plates their use is not unattended with risk from the fragile nature of the dipper, and the excessive, as well as rather awkward handling a plate has to undergo. Also, the great quantity of bath liquid such baths require, when very large plates have to be sensitized, is a serious consideration for amateurs especially; and in my opinion it will be found more suitable for such purposes to have recourse to a horizontal dipping bath, the construction of which I propose next to examine.

(*To be continued.*)

## PHOTOGRAPHIC CHEMICALS:

### THEIR MANUFACTURE, ADULTERATIONS, AND ANALYSIS.

*Sulphides* (concluded).—Few of the other sulphides possess any interest to the photographer. Sulphide of gold is obtained from the toning baths, either mixed with, or free from silver, according to the kind of solution employed, and, therefore, a brief account of its properties may not be out of place. Formed by precipitation, it is a heavy black powder which very readily decomposes with separation of metallic gold. At a gentle heat the sulphur goes off, and if left in contact with the atmosphere in a moist state the gold is likewise separated with formation of sulphuric acid; the oxygen being absorbed from the atmosphere. Ignition, either *per se*, or with the usual mixture of carbonate of soda and nitre used for decomposing the sulphide of silver, at once reduces it to the metallic state.

Platinum is sometimes used for toning pictures, instead of gold; it is a valuable metal, and would also be recovered in the form of sulphide. Sulphide of platinum is a black, heavy powder, decomposed by heat and fusion with nitre, but not so readily as sulphide of gold. When exposed to the air in the moist state it becomes oxidised, and then contains a quantity of free sulphuric acid, along with platinum-black. When this compound is heated in contact with the air, it takes fire and burns with a hissing noise and violet flame, continuing to glow with evolution of sulphuric acid.

*Nitrites.*—A brief account may here be made of some of these salts. Nitrite of silver, along with nitrate of silver in the sensitising bath, communicates several curious properties to the collodion plate, which deserve further investigation.

In order to facilitate this promising branch of research, if any of our readers feel inclined to pursue it further, we will briefly describe one or two of the most important nitrites.

*Nitrite of Potash.*—This salt is formed in the following way:—Heat nitrate of potash in a crucible, and keep it at a red heat for a long time. The extra equivalents of oxygen in the nitric acid gradually go off, and there remains nitrite of potash, mixed, however, with a considerable excess of undecomposed nitrate. Dissolve the mass in boiling water, and allow to crystallise by cooling. The undecomposed nitrate of potash crystallises out first. On concentrating the mother-liquor, neutralising it with acetic acid, and then mixing it with twice its volume of strong alcohol, crystals of the nitrite are deposited, which must be collected on a filter, washed with alcohol and rapidly dried. It forms a white crystalline deliquescent salt, without alkaline reaction.

*Nitrite of Soda* is prepared from nitrate of soda in exactly the same manner as the potassium salt. The only reason for its being referred to here is, that it is not deliquescent (according to Gmelin), and is, therefore, a much better salt to work with than the potash nitrite, which is generally used.

*Nitrite of Silver.*—This is the most important of the nitrites for photographic purposes. It may be prepared in several ways. If an aqueous solution of nitrate of silver is boiled for several hours with finely divided silver, the metal is dissolved with formation of a light yellow liquid, which, when evaporated down to a density of more than 2·4, solidifies after some time, on agitation. If this mass is extracted with water, a basic salt remains undissolved, in the form of a yellow powder. Cold water or alcohol, likewise throws down this powder from the yellow solution. Some time ago, we remember mention having been made of some valuable properties which were communicated to a nitrate of silver bath, by boiling it with finely-divided silver for a few hours. We are not aware that the subject has been pursued further, but it is evident from the above that this process would give rise to a certain quantity of basic nitrite of silver in the bath to which the properties would be due. Nitrite of silver, in the basic form, blackens when exposed to the light: it dissolves readily in ammonia, but only sparingly and partially so in water, flakes remaining behind.

A monobasic nitrite of silver may also be prepared, by mixing together aqueous solutions of crude nitrite of potash or soda with nitrate of silver. The precipitate is filtered, washed, and then dissolved in boiling water, filtered from the precipitated oxide, and allowed to cool. The salt thus prepared forms long and slender needle-shaped prisms, having a wavy lustre; they are colourless when immersed in the liquid, but acquire a slight sea-green tint when taken out. It requires three hundred times its weight of cold water to dissolve it, but is more soluble in hot water; it is insoluble in alcohol.

According to Proust, the yellow liquid obtained by boiling finely-divided silver with an aqueous solution of nitrate of silver, contains both the above nitrites of silver. The liquid has the following properties:—When boiled down by itself it gives off a small quantity of nitric oxide gas, then fuses and yields a yellow sublimate. The mass treated with water, when cold, yields nitrate of silver, and leaves a mixture of metallic silver and a yellow powder. The yellow solution oxidises when exposed to the air, and deposits crystals of nitrate; the same result is produced by heating it with nitric acid, the liquid being then decolorised, and giving off nitric oxide gas. Hydrochloric acid added to the liquid, throws down white chloride of silver. Ammonia precipitates black pulverulent silver, and retains oxide of silver in solution. Potash forms a brown precipitate of suboxide of silver, which is converted into the protoxide on exposure to the air, but if immediately dissolved in cold dilute nitric acid, again gives a black precipitate with ammonia. Cold water added to the yellow liquid throws down the yellow basic nitrite; but on dropping the yellow liquid into boiling water, the precipitate changes colour from yellow to red, and is then converted into black metallic silver, which forms a specular deposit on the sides of the vessel. So long as the precipitate remains yellow or red, it disappears on the addition of nitric acid; but after it has become black, nitric acid no longer dissolves it. Alcohol, likewise, throws down the yellow powder, and the liquid filtered from it leaves on evaporation a residue of nitrate of silver and metallic silver. Tincture of sulphate of indigo is decolorised by the yellow liquid with precipitation of silver.

Nitrite of silver is also formed when nitrate of silver is heated for some time above its fusing point: it is certain that some of this salt is formed when nitrate of silver is fused in the ordinary process of preparing the fused nitrate; and it is probable that the increased intensity noticed when fused nitrate is used in preference to the crystallised salt, is due to the presence of a small quantity of nitrite.

If the presence of any nitrite be suspected in the nitrate of silver, and it be desired to be got rid of, the best plan is to boil an aqueous solution of the fused salt with a little pure nitric acid, and then evaporate down on a water bath. The nitrous acid is driven off by the nitric acid, and the slight excess of the latter remaining with the dry nitrate after evaporating down, may be removed by heating it just short of its fusing point.

Nitrite of silver is capable of forming a double salt with potash and soda. The potash salt is obtained by adding nitrite of potash in excess to nitrite of silver, and evaporating over sulphuric acid. It forms yellowish rhombic crystals, which are permanent in the air.

## The International Exhibition.

### PHOTOGRAPHY.

The contributions to Class XIV., "Photographic Apparatus and Photography," are, so far as we can glean from the present incomplete arrangements, scattered over something like five-and-twenty different places in the building. The number of contributors, so far as we can gather from the not very perfect official catalogue, is nearly four hundred. Of the number of pictures contributed, it is still more difficult to form an estimate, as the catalogue affords no indication whatever, all the contributions of each person being included under one number, without any intimation whether that number embraces one or twenty pictures. From a roughly-made calculation, we judge there are not less than two thousand frames, some of these including many pictures.

In the British department there are about one hundred and fifty-six contributors, and of these about thirty-six exhibit apparatus and chemicals, leaving one hundred and twenty as exhibitors of pictures. It is somewhat singular that this is just the number of exhibitors at the last exhibition of the Photographic Society. The number of pictures now exhibited, or, rather, frames of pictures, is between eight and nine hundred: the number at the last exhibition of the Society was six hundred and twenty-two. On the quality of the pictures now exhibited it would be unfair at present to make any remark, as the glasses are for the most part covered with a thick coat of dust, which renders any correct judgment impossible. The department is indeed, at present, incomplete; and workmen are still engaged in connection with it. An awning has to be erected over the glass roof, but not in immediate contact with it: this will lessen the glare of heat and light, and with some ventilating arrangements, will, we trust, make the apartment more tolerable. Cases of apparatus, &c., and stands of stereoscopes, which are at present enveloped in linen covers, will then be displayed, and the apartment being put in order, fair description and criticism will be possible. Already, as we anticipated, Mr. Breese's moonlight pictures are exciting much discussion, and a bet of fifty pounds to a farthing was recently offered, on the question of their genuineness. We have reason to believe that the question will engage the careful attention of the jurors in this department, and will, we doubt not, issue in confirming our convictions, expressed nearly twelve months ago, of Mr. Breese's perfect good faith in using the term, "photographs by moonlight."

As we have stated, the catalogues give no information as to the number of pictures forwarded by each contributor, and, as necessarily follows, no clue to the subject, and little guidance as to the process; and as the various pictures of the same contributor are not all hung together—the exigencies of the space demanding that they should be arranged so as to fit—the task of examining and comparing the pictures will require care and attention. We intend, as far as possible, when everything is in order, to make our description and criticisms serve to some extent as a hand-book to the various photographic collections.

In the French department, which is not yet, however, completed, the catalogue gives a list of about one hundred and eighteen exhibitors, of which twenty-eight contribute apparatus and chemicals. The pictures, or frames of pictures already hung, are between four and five hundred. The number of contributors at the last French Exhibition, in Paris, were upwards of one hundred and sixty, sending upwards of one thousand three hundred pictures. The space devoted to photography in the French department is, so far as we can judge without actual measurement, about twice as large as the especial room devoted to British photography, and much more conveniently arranged, being a long gallery, admitting of a series of small transverse screens, each of which are, in many instances, devoted to a single contributor. Life-size pictures, by the solar camera, and as described in some instances, taken direct, form an important feature in this department, from their number and excellence. Some carbon prints and some enamels, by Carmarsac, are especially good. Some exquisite photographs on white silk, with ample margin, showing as well by transmitted as by reflected light, are curious and beautiful. Amongst the finest landscapes in the French department are those of our countryman, F. Maxwell Lyte, who figures in the catalogue as "Maxwell, L." Some large instantaneous pictures of shipping, water and clouds, by M. Varnod, of Havre, are unsurpassed, if equalled, by anything we have seen.

Canada sends some very good pictures: the once United States none, so far as we can ascertain. Rome sends very fine large architectural subjects. Spain nothing. Of other contributors in Continental Europe, we may mention Belgium, Denmark, Austria, Bavaria, Prussia, Saxony, Greece, Italy, Norway, Portugal, Russia, Sweden, Switzerland, &c.; amongst British colonies, and other foreign countries, we may mention India, New South Wales, Tasmania, Jersey, Natal, Brazil, &c. Some of these are not yet hung, and none we believe, quite completed; we will, however, give each detailed attention in due course.

We may mention another noticeable feature in connection with photography in the Exhibition, that in many instances it occupies a conspicuous and creditable position in illustrating manufactures and art designs. In one instance, half a dozen excellent photographs fill panels in one of the erections in the nave, somewhat unmeaningly called "trophies." These six pictures are about 18 by 15, and exhibit the interiors of workshops and tan-yards, with groups of workmen engaged upon the various processes in connection with tanning, currying, and leather-dressing, as conducted in the establishment of Messrs. Bevingtons, of Worcester. These are good as photographs, and capital as illustrations of the operations. The depth of definition is surprising. They were produced, we understand, with the full aperture of a triple lens, by a son of one of the partners.

## MAYALL *v.* HIGBY.

This case, which was tried before the Lord Chief Baron at Guildhall, when a verdict was found for the plaintiff, leave being reserved to the defendant to move, was finally heard on Tuesday, before the Lord Chief Baron, Mr. Baron Martin, Mr. Baron Bramwell, and Mr. Baron Wilde, sitting in Banco.

The declaration alleged that the defendant had wrongfully taken and kept possession of certain photographic portraits of eminent persons belonging to the plaintiff, and copied them and sold them, and thereby depreciated the value to the plaintiff of the originals, and the declaration also claimed an injunction to restrain the defendant. The second count was in detenue.

The plaintiff and defendant are photographic artists. The former some time past lent to Mr. Tallis, late proprietor of the *Illustrated News of the World*, a considerable number of photographic portraits of the celebrities of the day, for the purpose of having them engraved and published with that paper. Tallis became bankrupt, and the messenger of the Court sold the photographs to the defendant, who took reduced copies of them and sold them.

Mr. M. Smith, Q.C., moved for, in pursuance of leave reserved and obtained, a rule to set aside the verdict and enter it for the defendant, on the ground that the right alleged, and the right to the injunction were not proved.

Mr. V. Williams, in showing cause against the rule, said, No question of copyright, either at common law or by statute, arises here. The plaintiff complains that his right of property in the photographs has been interfered with without his consent. That right has been defined to be *jus utendi et fruendi.* The defendant, getting possession of the portraits wrongfully as against the plaintiff, had multiplied copies of them in a reduced form, and afterwards sold them. He had obtained from a Mr. Bennett £100 for some, and it was quite clear that the plaintiff's property is depreciated in value in exact proportion to the profit made by the defendant. Those persons who had purchased copies from the defendant were not likely to purchase from the plaintiff. The latter is, therefore, entitled to substantial damages, although he has been content to take a verdict for nominal damages as sufficient to sustain the injunction granted by Baron Bramwell at chambers. Baron Parke, in "Boosey *v.* Jeffreys," the great case on copyright, 4, *House of Lords Cases*, said, "The author of a literary composition has an undoubted right at common law to the piece of paper on which his composition is written, and to the copies which he chooses to make of it for himself or for others. If he lends a copy to another his right is not gone; if he lends it to another under an implied undertaking that he is not to part with it, or publish it, he has a right to enforce that undertaking." And Lord Chief Justice Erle in the same case says, "The author has remedies for the wrongful abstraction of copies; he may prevent publication, he may acquire back the copies wrongfully made, he may sue for damages if any are sustained." In these passages (continued Mr. V. Williams), pictures may be substituted for literary compositions, as is shown by the case of "Prince Albert *v.* Strange," 18 L. J., in which Lord Cottenham applied the same principles to the case where copies of the Queen's and Prince Albert's etchings were surreptitiously obtained, and the publication of them advertised.

Baron Bramwell: Suppose, Mr. Williams, a man discovered some inscriptions upon stones and brought them home, could another take casts of them without his consent and publish them? By so doing the value of the stones would be greatly depreciated.

The Court then called upon

Mr. M. Smith, who argued that the plaintiff was not entitled to damages on the first count, or to an injunction, and that the plaintiff had not shown that he had the exclusive right of publishing copies of the portraits. He had lent them to Tallis for the purpose of their being engraved, and after that any one could copy and publish them.

Mr. Aspland followed on the same side, contending that the plaintiff was not entitled to an injunction to the extent prayed, as it would prevent the defendant from selling negatives which were his own property, and because the plaintiff had recovered damages in respect of that very matter.

The Court decided that, although the negatives continued the defendant's property, the selling of them would be an act of injury to the plaintiff, and therefore, apart from any question of copyright, the sale of them would be actionable; therefore, the injunction might issue under the 79th section of the Common Law Procedure Act, 1859. The Court also said that it might have been otherwise if the plaintiff had received full damages in respect of the sale of all the negatives, but the actual damages were nominal only in respect of the right.—Rule discharged, and injunction to go.

# Proceedings of Societies.

## London Photographic Society.

The usual monthly meeting of this Photographic Society was held in King's College, on the evening of Tuesday last the 6th of May. Peter Le Neve Foster, Esq., in the chair.

The minutes of the previous meeting having been read and confirmed, the following gentlemen were elected members of the society:—Messrs. W. H. Warner, of Ross, A. B. Brown, of Gibraltar, L. Caldesi, of Pall Mall, Hanson, of Leeds, and J. B. Brown, of Birmingham.

A large number of the prints of the Amateur Photographic Association were laid on the table, and received considerable attention.

Mr. Glaisher called the attention of the meeting to some curious photographs in colours, which had been produced by Dr. Diamond. One was taken in the year 1851, and gave a very decided approximation to the natural colour of the objects depicted. The sky was blue, the roof of a house a reddish brown, an outhouse a similar colour, a little lighter in tint, the tree was green; each object was in short in its proper colour. No explanation could be given of the cause. All Dr. Diamond could state on the subject was, that it was produced in the course of some experiments, and was not at that time an uncommon circumstance. The collodion it appeared, contained, in addition to the usual iodides, arseniate of quinine, and the developer formic acid. Another picture was on a stereoscopic plate, and was recently produced with an ordinary collodion and iron developer. In one half of the picture the lights were red, and in the other half blue. He took the opportunity of expressing his pleasure that the hint he had thrown out at the last meeting, as to bringing specimens, had been taken, and the noble array of the Amateur Photographic Society, now before the members, would well repay examination.

Mr. Vernon Heath asked the indulgence of the meeting whilst he gave a verbal description of his method of operating in enlargement, a press of unexpected engagements having prevented him from preparing a paper. He had during the last three months taken not less than 250 positives, and 300 negatives with a view to satisfactory enlargement. He would very briefly and simply state his experience, with a view to aid others in achieving what he had been attempting. He believed that the future of photography would lie very much in this direction—the production of very small pictures, and by subsequent enlargements producing absolutely better results with less trouble than were now obtained with large apparatus. Those who had experience in landscape photography by the wet process, knew well the trouble and anxiety caused by the enormous bulk of materials and apparatus they had to carry into the field. Last year, in going to Scotland, he had to pay for 330 lbs. excess of luggage. He now believed that with a good lens and good manipulation, results might be obtained which, by skilful enlargement, would render this excess of field apparatus entirely unnecessary. In his first connection with the wretched case "Mason *v.* Heath," he had been asked to try if the negative could be reproduced. He said he had no doubt that by a little practice it might be done nearly equal to the original. His first experiments disappointed him much. He found there was much to learn in the matter. Photographers would readily comprehend when they examined the circumstances; when they remembered that in enlargement, owing to the length of focus and small aperture necessary to be used, an exposure of ten minutes would be required, and the result of such an exposure totally differed in character and intensity from that produced by a short exposure. In reference to the negative of which he had just been speaking, two of his operators had been engaged upon it, and they made not less than 200 positives, not one of which in his estimation came up to the mark. The proper character of positive he had found, was one without intensity, but possessing every trace of detail, such as he now exhibited to the meeting. He would now explain his method. He did not use the solar camera, but copied in the ordinary camera, taking first a transparent positive from his original negative, and from the positive another negative. He used a lens made for him by Mr. Dallmeyer, to whom he must in justice say, that he had taken great interest in the matter, and had furnished him with the exact equivalent focus of the lens. This lens was attached to an extending bellows camera. To this also was attached a scale, divided into 10ths of an inch, the zero of which corresponded with the equivalent focus of the lens. By the aid of this he was enabled to dispense entirely with focussing; he simply calculated the distance the camera required to be extended on one side of the lens, and the box or camera holding the picture to be copied on the other side. Notwithstanding that he did not focus, he invited attention to the pictures he exhibited, which would be found to possess the most perfect definition. He thought he had succeeded in producing the proper character of positive, but he was not quite sure that he had produced yet the best possible character of negative, and he now invited gentlemen present, of experience and ability, to give their aid and carry the matter further. In his manipulation, he used any good bromo-iodized collodion; he had tried several which answered very well, but he thought he gave the preference to that with which he produced his landscape negatives. He developed with five grains of iron, and a large proportion of acetic acid. With the positives he did nothing more. With the negatives he proceeded in the same manner, but it then required some amount of intensifying, and he was not quite sure as yet which was the best method. At present he used bichloride of mercury after fixing; but he was not quite satisfied with the amount of intensity. He believed that if photographers generally, and amateur photographers especially, were to confine their attention to the production of small pictures, and either get them enlarged, or do it themselves at their leisure, they would save themselves much trouble, and obtain better results. He would conclude by showing some specimens which had been sent to him by Mr. Warner, of Ross, who enlarged by the same process which he had just described. In reference to them, he might observe that Mr. Warner had stated that he had been using hitherto a lens which had not quite satisfied him, but that he had procured one from Mr. Dallmeyer, with which he was much better pleased.

Mr. Heath exhibited his apparatus and a variety of transparent positives, negatives, and enlarged prints, in the course of his remarks. An enlarged head of the late Prince Consort, amplified between two and three times, was much admired, and considered by many as superior to the original.

M. Claudet asked Mr. Heath how he lighted his picture?

Mr. Heath said invariably from the north: he never used direct sunlight. The apparatus was placed at an angle of 45° to the northern sky.

M. Claudet asked what exposure was necessary to produce an image the same size as the original?

Mr. Heath said, using a small diaphragm about 45 seconds. Mr. Warner had informed him that he used direct sunlight, placing a piece of ground glass a foot in advance of the negative. He then gave a long exposure so as to avoid anything like chalkiness.

Dr. Diamond exhibited a negative of fine intensity having a blackish tone. This he said was originally a somewhat thin positive: the only mode of intensifying used was to leave it for about twelve hours in an old hypo bath, which, by sulphuretting the image, produced the amount of intensity now seen.

M. Claudet asked Mr. Heath how he found the equivalent focus of his lens?

Mr. Heath said Mr. Dallmeyer, who had made the lens for him, had given him the equivalent focus, and he found in practice it was absolutely correctly stated. He had consequently only to measure by means of his scale for any amount of enlargement, and the result, without any focussing, was always correct. Suppose, for instance, the lens to possess an equivalent focus of eight inches, if he wished to produce an image the same size, he simply extended the camera and the negative 16 inches at each side of the lens.

M. Claudet asked from what point he regulated the equivalent focus?

M. Dallmeyer said, he might perhaps explain that the lens was one of his triple achromatic lenses. He had calculated the exact equivalent focus, and upon the lens he had marked the places from which to measure, from which, as a centre, Mr. Heath calculated the necessary extension on either side. The amount of extension necessary was regulated by the ordinary law of conjugate foci.

After some discussion as to the exact application of this law, in which M. Claudet, Mr. Shadbolt, and Mr. Dallmeyer took part.

Mr. Shadbolt asked Mr. Heath for the results of his experience in the use of parallel or converging rays for enlarging.

Mr. Heath would mention some of his earliest experiments. He had at one time made an aperture in the roof for his negative, and having fixed his lens, and a table for the paper beneath, attempted, with such light as he could get, to print the image on to albumenized paper. This he found hopelessly long. His conviction was, that the north light was best.

M. Claudet asked if the direct light of the sun was not better?

Mr. Heath thought not.

A conversation followed, in which M. Claudet expressed a conviction that the direct light of the sun and the use of a condenser, as in the solar camera, would give better results, as in that case only the centre of the lens, on which the image of the sun was brought to a focus, was used, and thus much aberration avoided.

Mr. Shadbolt objected to the solar camera, because of the dispersion suffered by the rays falling obliquely on the negative, and because a chromatic condensing lens could never produce an achromatic image.

M. Claudet said the image was not produced by the condensing lens. He thought, however, that an achromatic condenser would be an improvement.

Mr. Shadbolt said that would only palliate, not cure, the evil. It would not get rid of the dispersion.

Mr. Dallmeyer agreed with Mr. Shadbolt, and entirely differed from M. Claudet. The dispersion and confusion alluded to, or, more correctly, perhaps the diffusion, appeared to him to produce in all the solar-camera pictures he had seen a certain fuzziness. Mr. Heath's productions were, he thought, free from this, and possessed the perfect definition and sharpness of the originals. In reference to the long exposure to which Mr. Heath had referred, he had been engaged for some time in making a lens expressly for enlarging, which would possess much greater intensity than the triple. Mr. Williams had been trying it, and one of the results was on the table for the inspection of members. There were also two or three specimens at the International Exhibition. In this country, where direct sunlight was so uncertain, he thought the solar camera could not be worked with advantage.

M. Claudet said that the solar camera would produce the results now referred to without sunlight.

Mr. Dallmeyer said he might observe that Mr. Warren De la Rue had found, in enlarging his astronomical photographs, the northern light was most satisfactory.

Some further conversation resulted in a challenge from Mr. Heath, in which he offered, if M. Claudet would bring an untouched print enlarged four times by the solar camera, he would bring one enlarged four times by the process he had described. This challenge was accepted, and it was agreed that each should bring a specimen enlarged from the same card negative.

Mr. Fry said his experience entirely corroborated that of Mr. Heath. He was in the constant practice of enlarging in the way described, using one of Mr. Dallmeyer's triplets, and with the most complete success. Some specimens he had so enlarged were now in the International Exhibition.

The Chairman said he did not remember Mr. Fry's name as an exhibitor.

Mr. Fry explained that they were exhibited by Mr. Swan, as illustrations of an improved stereoscope in which one small and one large picture was used.

Mr. Heath wished to remind the meeting that all the specimens he had brought where in their rough untouched state, and results of experiments in a bad season of the year. He thought it would be very interesting to have some statistics as to how many days of the year the solar camera could be used, the percentage of successes and failures it produced, and the expenses of working it.

M. Claudet asked if Mr. Heath had tried the solar camera?

Mr. Heath: No; but I have seen your results.

Mr. Claudet: I have tried both, and I think the solar camera best.

After some further conversation, in which Mr. Heath stipulated that the specimens for comparison at the next meeting should be untouched, the discussion terminated.

The Chairman, in proposing a vote of thanks to Mr. Heath, said that the subject had elicited much interesting discussion, and he trusted that the friendly challenge which had arisen out of it would prove conclusive and satisfactory. The thanks of the meeting were accorded by acclamation.

A paper on subjects arising out of the discussion, by Mr. Claudet, was announced for the next meeting, and the proceedings terminated.

## THE CARTE DE VISITE.*

[There is so much that is true, mixed with a few misconceptions, in the following article, that we have pleasure in presenting it as a contrast to some of the would-be clever articles which have recently appeared in journals devoted to miscellaneous literature.—Ed.]

There are probably few pairs of eyes turned towards this page which have not been directed before now to some nob, or moulding, or keyhole, or door-handle in a photographic studio, and so have remained fixed in a delirious stare till the *carte de visite* was an accomplished fact. It is commonly a very heavy blow when one first sees the result of that operation which we have so many of us gone through. We explain ourselves in our different ways when we have the first interview with our own portraits after they come from the photographer's. If we are of a demonstrative nature, and besides have not been bred at the Court of St. James's, we exclaim "Lor!" when we first see ourselves. Some again will utter a mere unintelligible exclamation of surprise or grief; others will bless themselves; and truculent and hot-livered persons will invoke upon the head of the artist that which is not a benediction. There remains yet a class of well-bred and undemonstrative individuals who confine themselves to a speechless examination of the newly-arrived cards, merely expressing their agony by an eloquent silence, by twisting the work of art first this way and then that, holding it now at a distance, and now near, and anon upside-down.

We get accustomed to the portrait after a time, are able to face it, to see it on our drawing-room table in a small frame, or in an album, or even in the books of our dear friends and acquaintances. If we are public characters (and it is astonishing how many of us now find that we are so), we are actually obliged at last to get accustomed to the sight of ourselves in the shop-windows of this great metropolis. Our shepherd's-plaid trousers, our favourite walking-stick, our meerschaum pipe, meet our gaze turn where we will.

We do not all come out of the photographic studio alike unhappy. There are those to whom the process does justice, as well as those to whom it does injustice; nay, there are some on whom it confers actual benefits, and who show to greater advantage on the *carte de visite* than in their own proper persons. I have myself sat on two occasions for one of these portraits. On the first I was simply occupied in keeping still and presenting a tolerably favourably view of my features and limbs to the fatal lens; but the result was so tame and unimposing a picture that I determined on the next occasion to throw more intellect into the thing, and finding a richly gilded curtain-tassel convenient to my gaze, I gave it a look of such piercing scrutiny, and so withered and blasted it with the energy of my regard, that I almost wonder it did not sink beneath the trial. That look has, I am happy to say, been reproduced faithfully, and no one could see the portrait without giving its original credit for immense penetration, great energy and strength of character, and a keen and piercing wit. It is difficult to lay down rules of general application, but it may be safely said that the people who come out of the photographic struggle the best, and who are least injured in the engagement, are people of ordinary appearance, from whom we do not expect much. It is common to hear some lady who is generally acknowledged to be pretty, urged by her friends to sit for a *carte de visite.* "You really *ought* to have it done," they say; "you would make such a charming portrait." The portrait is taken, and is, after all, not charming. On the contrary, it is sufficiently the reverse to make the dearest of the victim's female friends happy.

Those to whom this process does the greatest justice are people the proportion of whose faces are well balanced, whose features rather err on the side of smallness than largeness, and who are not generally considered to be beautiful. It is possible to have symmetrical features and a well-proportioned face, and yet to fall very far short of beauty; and it is equally possible for a countenance to be wrong in some of its proportions, and yet leave an impression of beauty on our minds. But any one in this last case will be a great sufferer in going through the photographic process. As the two likenesses appear side by side in the album they will astonish all who look at them. They thought the one was such a much plainer person than she here appears, and the other so much prettier.

There are many beauties of colour and expression which cannot be rendered by the agency of the camera. Colour of of hair, colour of the complexion generally, of the lips, the cheeks, the eyes, all these go for nothing; and as to expression, the most expressive countenances suffer most invariably: a little happy touch of expression is a phenomenon one hardly ever remembers to have seen caught in a photographic portrait. If the face be left to take its chance—so to speak—a heavy or mournful look is the usual result, and if any particular expression be attempted, it is almost sure to look like a grimace; a truth of which we constantly see illustrations in the portraits of those engaged in the theatrical profession, when some special expression has been attempted. People of mediocre abilities, as people of mediocre beauty, will come off best in sitting for their photographs. They will astonish us by looking so clever, as the others by looking so pretty. Real genius and real beauty will often astonish us the other way. It is as difficult to give a man's outside, with all we know of it in a portrait, as to produce a fair representation of his mind in a biography.

There are, however, very many motives which all work in consonance to make us patronise this very thriving business of photography. First of all there is the appeal to our vanity. You yourself are the subject of your own especial consideration and that of one or two others for some considerable space of time. What a delightful thing that is. Whether you are good-looking or ugly you like that, depend on it. Then, the portrait done, you have the opportunity of distributing yourself among your friends, and letting them see you in your favourite attitude, and with your favourite expression. And then you get into those wonderful books which everybody possesses, and strangers see you there in good society, and ask who that very striking-looking person is?

Those albums are fast taking the place and doing the work of the long cherished card-basket. That institution has had a long swing of it. It was a good thing to leave on the table that your morning-caller while waiting in the drawing-room till you were presentable, might see what distinguished company you kept, and what very unexceptionable people were in the habit of coming to call on you. But the card-basket was not comparable to the album as an advertisement of your claims to gentility. The card of Mrs. Brown of Peckham would well to the surface at times from the depths to which you had consigned it, and overlay that of your favourite countess or millionaire. Besides, you could not in so many words call attention to your card-basket as you can to the album. You place it in your friend's hands, saying, "This only contains my special favourites, mind," and there is her ladyship staring them in the face the next moment. "Who is this sweet person?" says the visitor. "Oh, that is dear Lady Puddicombe," you reply carelessly. Delicious moment!

Yet, sitting for one's photograph is, after all, not a pleasant performance to go through. Of course it is a mere nothing to what one used to endure in sitting for a regular portrait in a gloomy apartment in Newman or Berners Street. Many of us

* From *All the Year Round.*

remember that operation vividly enough, and some even of the new generation can call to mind what they have suffered as children in the artists' quarter just named. They remember the dismal house with the curious window on the first-floor cut up so as to encroach on the second. They remember the dirty servant of all work who opened the door, and who ushered the victims into that dingy dining-room which was too suggestive of dentistry to be pleasant. As in the dental dining-room, so in this of the artist, there was a wonderful impossibility of identifying the apartment with eating and drinking. It would be impossible for anybody to enjoy either food or wine within its precincts. A few very old periodicals, a very fat and dirty volume of the Every-day Book of Hone, and some one or two books of amateur poetry, were on the central table, and as to works of art these abounded at the dentist's as at the painter's, but with this difference: at the first they would be engravings by different hands, and bearing affecting inscriptions in pencil, that made one's grinders shake in their sockets. "To Mr. Lipscrush, with the artist's *grateful* remembrances," or, "from a grateful patient," or, "in commemoration of many professional *favours* conferred on the artist." In the Berners Street dining-room the works of art were without such inscriptions. The pictures which hung round the artistic dining-room—and many of which had no frames—were ordinarily of elevated subjects: Titania with Bottom wearing the ass's head, Ophelia hovering over the book, Ugolino gaunt with starvation, Virginius sacrificing his daughter, and other exhilarating companions to the dinner table. There they hung, a perpetual monument to the want of taste of the British public, and there hung some of the portraits which the artist had been driven to paint, when he found that high art left his dining-table with nothing more eatable upon it, than an army list or a number of Blackwood. Among these latter works would be included "Portrait of the Artist," painted evidently at the Ugolino period, glaring round at society out of hollow, sunken eyes. The artist's father, his mother, and a general officer, who bore a strong resemblance to the artist himself in a Nathanic red coat and epaulets.

What wonder that one should go up from such a dining-room expecting to hear in a soothing voice the words "Open, a little wider," with an accompaniment of rattling instruments in a drawer? And what a place was the Studio itself when you reached it. That window observed from outside as encroaching on the second-floor was blocked up as to the lower half, so that there was no chance of seeing anything of the street unless it was the garret-window and the parapet of the house opposite, with an old flower-pot, a dangling fragment of clothes-line, and a row of hideous distorted chimneys, showing their gnarled and twisted arms against the dull grey sky. To spend an afternoon looking at such a prospect was not hilarious. Nor was the interior of the room much better. The half-finished pictures leaning against the wall, the studies from nature or copies of the old masters—old enough to have grown up into misters one would think by this time—the plaster casts of nude arms doubling themselves up so as to bring out the muscles in a very unnecessary manner, for nobody ever said they were *not* muscular, the antique heads, with noses on which the blacks and dust had gathered loweringly; their hollow parts and sunken lines protected by the nobbier portions, relieving with a white and brilliant glare the bits of old tapestry, frouzy costume, and improbable armour—all these matters made up an interior which if it was picturesque (which it wasn't) was infinitely dismal and disheartening.

You were seated on a throne, too, which to persons not of the regal class was in itself disconcerting. Some question of perspective, or points of view, rendered it needful that you should be raised on high, and so you were perched up on a green-baize throne. You sat on a cut-velvet old-fashioned chair, whose timbers creaked responsive every time you sighed, and more old-fashioned chairs were placed about the room, which might have reminded one of ancient times, if they had not been so much more suggestive of Auction Marts and nosey brokers.

What an afternoon's entertainment! If the artist talked, you felt he was not minding his business; if he worked, he was apt to be silent; while, if he tried to connect labour and conversation, his talk would be characterized by the Remark unconnected and the Reply inappropriate, and the afternoon's labour would very likely result in that disastrous phenomenon, an unrecognizable likeness.

Now what is the photographic ordeal after this? Nothing. Absolutely nothing.

But, just as the sufferings which we are called on to undergo have in this age been reduced, so also, alas! have the powers of endurance, and so the same human being, who once bore a journey of three days and nights by coach, grumbles at a two hour's whirl by railway; and he who has known the horrors of a month or so of sittings, finds that to wait an hour or so in a photographer's gallery, going right through all the portraits on the wall and table, exhausts his patience. When at last he is released from the waiting-saloon and mounts to the operating-room above, that he is in the worst possible cue for the performance in which he is to take a part. He feels at once dazzled and oppressed by that glare of light above his head. It makes him blink, it closes up his eyes, it gives him a sense of having been up all night. The properties about the room, too, are bewildering. There are all sorts of things appropriate to all the different professions which different sitters may be expected to follow. There is a piece of complicated wheel-work for a mechanician, a pair of globes for a geographer, a nautical compass for the mariner, and a pair of compasses for the civil engineer. There, too, is a palette and an easel for the artist, a book for the divine, an empty brief for the lawyer, an hour-glass for the philospher, and an inkstand and a pen with a tremendous feather in it for the author. Lastly, there is a wretched painted scene which is intended to take the public in as a landscape-background, but the honest instrument will never fall into the scheme, and hating the landscape always proclaims it for the sham which it is. The background is intended for private and non-professional persons, and there is also a pillar and a curtain—but who are those for? What is the profession of that unhappy and misguided wretch who is supposed to pass his life in a perpetual environment of pillar and curtain? There may have been persons so situated once, but now we turn our pillars into letter boxes, and the curtain draperies into ladies' cloaks rich in festoons of crimson.

The thirty seconds which the light requires to take a likeness are so utterly exhausting, that if there were one more necessary I believe no human being could go through with the thing. The horrible necessity of keeping motionless is an incentive, of almost irresistible force, to violent action. Terrific are the temptations of those thirty seconds. You feel that you must make a face, yell, spring up, and cut a frantic caper. You say to yourself: "Suppose I were to sneeze, to choke; suppose I were to burst out into a rude guffaw? I will, I must! Suppose I were to squint; I think I *am* squinting. The brass knob on which I am told to fix my eyes is getting muzzy; it is huge in size; it revolves; I can't see it. My hands are tingling, swelling, bursting. All is dizzy before me—I shall explode!"

(*To be continued.*)

## Correspondence.

### KEEPING DRY PLATES AFTER EXPOSURE.

Dear Sir,—I have long had a suspicion that plates prepared by the tannin process, and its modifications, though the keeping qualities before exposure seem almost unlimited, should be developed in a moderate time after exposure, in order to secure the best results.

My experience has shown me that plates kept only a few days after exposure have lost much of their strength and vigour, coming out slowly as grey and weak negatives. This suggested to me the necessity of making an experiment to decide the question beyond a doubt, and I carried it out in the following manner:—

I prepared a tannin plate with a collodion containing bromide; in fact, an old mixture I am now working for this process; exposed to a good light in a bi-lens camera, cut the plate in half, developed one half the same day, and kept the other before developing for 15 days.

The difference between the two halves is, as you will see from the print enclosed, so great that one might be supposed to have been taken at mid-day, the other at midnight.

As I have seen assertions that tannin plates have been developed weeks after exposure, an interesting question arises. By what change is the image removed, and under what circumstances is it possible to keep plates without injury for a reasonable time after exposure?

Perhaps you or some of your correspondents can give the desired information; at any rate, the above fact may be useful to some of your readers in guarding them from one source of failure.—Yours truly, G. S. Penny.

*Cheltenham, May 3rd*, 1862.

[The specimen received is an interesting illustration of the experiment described. One half of the picture is brilliant and well detailed; the other ono universal grey, sky and foreground alike, without detail, and the barest iudications of objects as seen through a dense fog. It would suggest a plate which had not received a twentieth of the proper exposure, which had by pushing development given some traces of an image, and then become buried and veiled in general reduction, in which, however, there was no density. Dr. Hill Norris states that his plates if kept too long after exposure, before development, gradually lose the image, and in time return to their original sensitiveness. He also states that the acetic acid or its vapours will remove the latent image impressed by light. In order correctly to investigate the subject, we are brought again to the interesting but ill-understood question of the exact operation of light in producing the latent image. Dr. Norris believes it to be what he terms an excitation, an action set up in the molecules, which, if not continued by the action of a developer, gradually subsides, and the *status quo* is restored. Apart from the question of theory, however, the fact described is an important one, which our readers will do well to mark.—Ed.]

## INTENSIFYING DRY PLATES.

Sir,—I am much obliged to you for your observations on my communication in last week's News. You have hit the right nail on the head. The best mode of dealing with dry plates which show a thin image is to re-develop immediately after fixing. Since I wrote to you, I found I had two plates which had not been fixed. Having cleared these and washed well, I applied a 20-grain solution of nitrate of silver to the film, and proceeded to gain intensity with citro-pyrogallic in the usual way. The result was satisfactory, no further treatment being requisite. I can also confirm what you state as to the expediency of employing a weak solution of iodine, or of iodide of mercury. If the solution be too strong, or be kept too long on the film, the image becomes almost obliterated. This was the case with a stereo plate, one of the first I had endeavoured to strengthen; the iodide of mercury having entirely buried one of the pictures, and left but a faint trace of the other. Three days ago I took this plate to the dark room, moistened the film, poured over it a 20-grain silver solution, and finally redeveloped with citro-pyrogallic. The picture, of which a faint trace only was discernible, quickly came out very strongly, but the other did not reappear at all. The former was much too dense, the half tones being destroyed, and the plate rendered utterly worthless for printing. The experiment, however, is instructive as to the results to be anticipated from the employment of too strong a solution of the mercurial iodide.

The great point to be observed in all plates which require intensifying with bichloride of mercury or solutions of iodine, is that the image to be intensified contains a sufficient amount of silver; for if this is not the case, the result can scarcely be other than unsatisfactory. For this reason, redevelopment with pyro and silver should invariably follow the fixing operation; and where that course has been omitted, it should be resorted to prior to the employment of any other means of obtaining intensity. After this, should greater density be requisite, the mercurial iodide will confer it; care being taken that the solution be weak, and that it be poured off the film immediately the blackening of the image has taken place. Should too strong a solution be used, and the film become converted into yellow iodide, the remedy seems to be thorough washing, then pouring a solution of nitrate of silver over the film, and finally redeveloping with citro-pyrogallic. After this, any iodide still remaining on the plate may be removed by hypo, without danger to the image.

I regret having overlooked Mr. Hannaford's method of intensifying, given in vol. v. p. 336 of the News. Had I seen it before I determined to write to you, I should probably not have intruded on your space. On reference to the last edition of Hardwich, p. 345, I find he has detailed the process of strengthening with sulphide of potassium, to which you allude. But my strong impression is that for dry plates, there is nothing preferable to citro-pyrogallic and silver for the purpose, and that the iodine and mercury solutions should only be resorted to when this method fails, as it sometimes will, to bring up the density to the required poiut.

In the present state of dry plate photography, the subject on which I have ventured to occupy your attention is, or will be, one of great importance. If the experience of this year's summer and autumn should prove that dry plates can be so prepared as to be as sensitive as wet, and that they may also be rendered available for all purposes of instantaneous exposure, then the best mode of strengthening them must form an indispensable chapter in future treatises on photography, and the sooner the subject is ventilated and thoroughly investigated, the better will it be for the interests of the art.—I remain, sir, yours respectfully, Amateur.

[We are glad to receive from such an intelligent photographer as we know "Amateur" to be, confirmation of our suggestions on this subject. He rightly observes that it is likely to become a very important one, especially if simply washed collodion plates take the position which some anticipate for them.—Ed.]

Dear Sir,—In reply to the letter of an "Amateur," in which my name is mentioned, I beg to say that the solution I use for strengthening negatives, can be used for dry as well as for wet plates, if carefully applied. Instead of *one minute* being sufficient to produce the "cream colour," it would probably take from half an hour to three hours, depending on temperature and various other circumstances. I would advise your correspondent to exercise a little moro patience in conducting his experiments, he would then perhaps, succeed better, and not hastily condemn processes, which in other hands, produce the best results. In contrast to what an "Amateur" says, allow me to quote the following from the letter of a professional photographer, recently received. He says, referring to other processes he had tried, "So I have come to the conclusion, after much *time* and *trouble*, that there is uone so valuable for its certain results and its artistical qualities as your own; with it I can *always* get any amount of density or delicacy, and by auy of the others I could uot."

I do not claim any originality, as the process is merely a modification of oue used by the late Mr. Archer.—Yours very truly, A. Brothers.

Benzine.—This fluid reaches the point of ebullition at a lower temperature than turpentine, and necessarily at a much lower heat than linseed oil, which in varnish making is combined with it. It volatilizes at a very gentle heat, and forms an explosive gas, in connection with the air, scarcely less dangerous than gunpowder. In the present instance the room was nearly air-tight, and the force of the explosion was equivalent to that of a gunpowder magazine.

Growing of Plants by the Electric Light.—M. Hervé Mangou, of Paris, France, has succeeded in growing the seeds of rye under the influence of the electric light alone. The plants assumed their green tint rapidly and vigorously, and showed no perceptible difference from those grown in ordinary daylight.

## Talk in the Studio.

THE STEREOSCOPIC COMPANY IN THE EXHIBITION.—We understand that the Stereoscopic Company have been very successful so far in the International Exhibition, several fine large pictures as well as stereographs having been secured of different incidents in the opening ceremony. The following day Prince Frederick William, seated on the throne, and his suite, were successfully taken. The *Daily Telegraph*, in its account of the opening day, had some amusing remarks on the arrangements and operations of the company, which we quote:—"Close to the dais, and near that unlucky plaster cast of Lady Godiva, stood a tall, strange-looking parallelopipedon, covered with crimson baize, and having in its eastern face two square apertures. One of those apertures was partially veiled by a yellow curtain; within the frame of the other a human hand was seen from time to time stealthily moving. This curious machine was at first surmised to be either a Fantoccini show or the cognate temple dedicated to the performances of Mr. Punch; but on closer inspection certain lateral placards became visible, setting forth that the London Stereoscopic Company had obtained from the Royal Commissioners—and at a prodigious outlay too—the exclusive privilege of taking views within the Exhibition building. The tall parallelopipedon was, in fact, the monster camera of the London Stereoscopic Company, and the hand belonged to the ingenious operator, making arrangements for taking those photographs of the ceremony of which the very earliest proofs were forwarded, per Queen's messenger, to Her Majesty. We may add that the London Stereoscopic Company, finding themselves somewhat pressed for the proper means for taking the required pictures, had placed at their disposal the whole of the magnificent collection of photographic lenses exhibited by the world-famous opticians, Voigtländer of Vienna. This ready act of international courtesy emanated from Messrs. Voigtländer's agent, Mr. Callaghan, of New Bond-street." That the small temporary erections built for operating chambers, which our contemporary, oblivious of his geometrical studies, styles "parallelopipedons," should be "monster cameras" is funny enough; but that in order to secure stereoscopic and 10 by 8 pictures from half-a-dozen points of view, the "magnificent collection of photographic lenses" in question should be required by the firm who has undertaken this contract is a superlative joke. The same amusing writer says:—"We don't know whether any discreet employé of the London Stereoscopic Company was despatched to the dais, with instructions to whisper a police inspector to whisper an aide-de-camp, who in his turn was to murmur a word of entreaty and advice in the ears of the illustrious party on the throne and in the [illegible]; but it is certain that during the convenient period afforded by the performance of the special music, the distinguished group kept themselves in admirable positions, and under every condition of immobility favourable to having their portraits photographed. The Duke, it is true, had once crossed his legs in a somewhat unpicturesque manner; but he suddenly remembered that unseen monitor within the crimson parallelopipedon, and assumed a more artistic pose. Prince Frederick William of Prussia scarcely moved a muscle for ten minutes together. The Archbishop of Canterbury, in his flowing white canonicals, looked tranquilly venerable. Lord Westbury and Mr. Denison looked as placid, statuesque, and dignified as it seems the privilege of all Lord Chancellors and Speakers of the House of Commons to look. Prince Oscar of Sweden, a remarkably handsome man, of almost gigantic stature, and so exceedingly swarthy as to disappoint some ladies who imagined that all Scandinavians must be fair, till they were told that the Royal Swede was the descendant of the southern Frenchman Bernadotte—the dark Prince never stirred, and seemed as if it would take a blow from Thor's hammer to move him. The only exception to the rule was Lord Palmerston, who was gossiping now with the Bishop of London and now with the Chancellor, and seemed so heartily to appreciate Auber's music as at one time to be disposed to dance to it. Let us not forget among the immobiles the Earl of Derby, who looked every inch the fourteenth Earl, and who, we fancy, regarded the members of the Japanese Embassy, who sat directly facing him, with an expression of haughty disdain, as though he deemed them creatures of an inferior race; and Lord Sydney, who looked so very respectable and so very quiet, that we shall be disappointed if we do not see his benignant countenance and his white staff as Chamberlain developed in the minutest degree in the forthcoming photographs."

## To Correspondents.

A SUBSCRIBER.—We published Mr. England's modification of the tannin process as he gave it. The amount of sensitiveness he describes as equalling that of wet collodion simply iodized and developed with pyro: the lens, aperture, &c., he did not state. The bath, we presume, is not so strongly acid as recommended by Major Russell. See articles on "Hot Development," and on "Tannin and Honey Process" in present number.

REGNAULT.—1. We believe Keene's collodion does contain a bromide, but you can add more if you wish. The bromide of cadmium will answer best. 2. The amount of iodide to complete the saturation of the nitrate bath depends on its strength. A strong nitrate bath will dissolve more iodide than a weak one. One or two grains of iodide of potassium will generally be sufficient for an ounce of silver. Any slight excess of iodide of silver must be filtered out. 3. It entirely depends on the object to be attained whether a solution of gallic acid be made with hot or cold water, and whether or not alcohol be added. An ordinary saturated solution will be made with cold water, and contain four or five grains to the ounce. Some samples are still more soluble. 4. We have seen the best approximation to the dark sepia tone you describe produced by Le Gray's formula, containing chloride of gold and chloride of lime. See PHOTOGRAPHIC NEWS ALMANAC. 5. The reproduction of engravings when exposed in sunlight generally requires a very short exposure.

AMATEUR.—Articles on the tannin process appeared in our last volume: we may especially refer to articles on pp. 121, 135, 198, 217, and 271; and also in the present and several other numbers of the current volume.

H. B.—The general plan of your glass room appears to be very good; but we should have preferred to have it two or three feet wider. Beyond that we do not see any especial need of suggestions. We believe "Early Spring" is ready.

ASPIRANS.—A portrait lens and a single lens both having the same equivalent focus, would not conveniently be worked together in a camera focussed from the back, as the position of the compound lens would require altering at different distances.

A.—The only case of similar spots to those in the prints sent which we have met with, were caused by some citric acid coming in contact with the picture, before the hypo was entirely removed. Has anything of that kind possibly happened with your prints?

C.—The best material with which to stipple your glass roof with, so as to exclude direct sunlight, is white lead and turpentine. The proportions will be easily determined by experiment, but we cannot state them precisely.

R. G.—The sky in the print you forward is of a very good tint indeed, and infinitely preferable to a sky of white paper.

X.—Your negatives are a little too hard at present. Observe carefully the best photographs you see issued by good operators, and strive to equal them. Care and practice will do much.

W. & D. DOWNEY.—We do not know of any first-rate operator at present who is out of an engagement. Should we hear of any we will let you know. Operators of really good ability are much in demand just now; several of our friends in London are in need of such assistance at present.

E. B.—A rack and pinion is chiefly useful in portraiture, but the practice of focussing by means of the body of the camera is now much used, and is more convenient, especially where two lenses are used in the same camera.

ENQUIRER.—When your alkaline toning bath of carbonate of soda and gold is exhausted, do not add more gold solution to it, but use a fresh bath entirely. 2. Double the quantity of solution will tone double the number of prints.

F. B.—A developing solution containing acetate of iron will give a more intense negative than the ordinary developer of sulphate of iron. In our hands, however, we have found it less manageable, and it does not keep well.

ALBUM.—Photographs on albumenized paper may be tinted in powder colours, but only when they are going to be put in a case, or framed, so that the surface may be protected by glass, otherwise the colour would rub off.

G. F. L.—It is generally desirable to print a little deeper than is desired for the finished proof, to allow for loss in toning and fixing. The exact depth must be decreased largely by the quality of the paper, as some samples require more overprinting than others. 2. Card portraits look best with a margin of about one-eighth of an inch at the top and sides, and about three-eighths or half-an-inch at the bottom. 3. Mount with freshly made starch, or good French glue. 4. We cannot offer any opinion as to the question of price. The tendency in photography at the present day seems to be in the direction of producing a large quantity at a low price.

B. F. LEWIS.—It is not desirable in portraiture to work with a stop any smaller than is sufficient to produce sufficient definition over every part of the picture. Rapidity is a great object in portraiture, and that can rarely be secured with a very small stop. Moreover, the picture is rounder and bolder with a large aperture.

R. G.—We see no reason to suppose the failure to be the fault of the shutter, but of the manipulation. You have only partially lifted the shutter, and so exposed only part of the sky. If after shading the sky during part of the exposure you finally lift the shutter entirely, the whole sky may be exposed for the time you require. You may very easily ascertain the exact working by watching the ground glass as you place the shutter in different positions.

STEREO.—Understand thoroughly that good light is necessary to instantaneous photography. With the best lens, the purest chemicals, and the most rapid process, you can scarcely hope for instantaneous pictures in a dull light. Sunlight is best, but there are some very good actinic days without apparent sunlight.

F. L.—Your prints are, to our taste, much overtoned and very inky. With a warmer tone they would have been better pictures. Be more careful to attain perfectly manipulation. Without care there can be no good photography.

L. R. R.—Allow your film to set better before immersion in the nitrate bath: that will frequently remove a tendency to leave the plate. If your bath is very acid it will aid in causing the evil. Dirty or damp plates will sometimes cause it. A new and very collodion is more apt to give a film which leaves the glass than a more porous sample. Care in manipulating will often prove a remedy. 2. When a solution of pyrogallic acid is old and dark coloured it is useless as a developer, and must be thrown away. 3. We prefer hypo for fixing negatives.

M. P.—See Mr. Wall's "Manual of Colouring." A few lessons from Mr. Wall would probably aid you considerably.

Several correspondents in our next.

# THE PHOTOGRAPHIC NEWS.

Vol. VI. No. 193.—*May* 16, 1862.

## THE EFFECT OF BROMIDES IN COLLODION.

In a recent article on this subject, we endeavoured to show that, whilst, with some theorists and experimentalists, the accelerating influence of a bromide in collodion was still a moot point, its value had received universal recognition by all practical men whose results depended on extreme sensitiveness. We then mentioned the fact, somewhat inexplicable to us, that Mr. Sutton, whose skill and judgment as a practical photographer we generally hold in the highest esteem, had recently been recommending a return to the use of simply iodized collodion and pyrogallic acid development, as giving greater sensitiveness, and producing better results.

Mr. Sutton has recently devoted another article to the subject, detailing some experiments, and enforcing his former position by arguments, which, to us, are inconclusive, and, in some instances, scarcely fair. As the subject is one of the first importance to photographers, and as we have the profoundest conviction of the beneficial action of bromides, as giving rapidity, delicacy, and cleanliness to the negative, we shall quote the experiments and remarks referred to at some length, and offer a few observations, pointing out where we conceive they are fallacious. Mr. Sutton says:—

"The first experiments were made with collodion containing only bromide of cadmium, and no iodide of any kind; and it was used with a new bath of Baily's pure neutral nitrate of silver, of the ordinary strength. The quantity of bromide dissolved in the collodion was eight grains to the ounce. More than this can easily be dissolved, but the collodion must not then give an even film.

"Eight grains of bromide of cadmium contain about 4⅔ grs. of bromine; while 4 grs. of iodide of cadmium (the usual quantity added to an ounce of collodion) contain about 2⅔ grs. of iodine. The bromized collodion used in our experiments would therefore give as much bromide of silver in the film as is contained in very highly iodized collodion, and much more than in common iodized collodion.

"When the bromized collodion film is immersed in the nitrate bath, it assumes at first a pale blue colour, and this very slowly passes to a pale whitish yellow. In order to acquire the maximum degree of creaminess or opacity, and to lose the blue tint, the plate must remain *several hours* in the bath, and even then the film is not so creamy as a common iodized film which has been left a few *minutes* only in the bath. On using a bromized collodion containing only half the above stated quantity of bromide, the film was at first paler and thinner than before, and never became what is called creamy, but always thin and poor.

"In this first experiment we perceive a marked difference between bromized and iodized collodion; for whereas the iodide of silver is quickly formed in the one film, the bromide of silver is very slowly formed in the other. It becomes evident, therefore, that those operators who use a large quantity of bromide in their collodion, and only allow the plate the usual time in the nitrate bath, must expose it with a considerable quantity of unconverted bromide still contained in it, and how that can conduce to the exalted sensitiveness of which these gentlemen speak, we must leave it to them to explain. If collodion containing, say 5 grs. of bromide of cadmium to the ounce, requires a couple of hours in the bath to convert the whole of the cadmium bromide into bromide of silver, the film, after a sojourn of only five minutes in the bath, and while it is still blue and thin, must surely contain some free bromide of cadmium, and if that conduces to sensitiveness it is a new and remarkable fact, which we hand over to those who recommend a large quantity of bromide in collodion to explain."

We may observe here that all Mr. Sutton's experiments are made with a bromide only. Now, no one knows better than he, that in chemistry, the combined action of any two bodies is not necessarily just the sum of the separate action of each; and that the action of an iodide alone, or a bromide alone, is no necessary criterion of their result, when in combination. We may add also, that whilst we are prepared to admit that the complete conversion of the bromide in collodion into bromide of silver, is a slower process than the conversion of iodide into iodide of silver, bromine having less affinity for silver than iodine, we cannot indorse Mr. Sutton's opinion that several hours are required for the process. A plate coated with bromized collodion and immersed in the nitrate bath, and withdrawn in two or three minutes, presents a thin, opalescent appearance; but if allowed to remain five or six minutes it becomes, not creamy certainly, but opaque and white, and we have not observed any further change, if left for an hour. That it should not acquire the same creamy effect which the iodized collodion does is very natural, seeing that the colour of bromide of silver is white, whilst that of iodide of silver is yellow. Let our readers try a very simple experiment: take a solution of nitrate of silver, and add a little bromide of potassium, either in solution or in small particles, and observe whether the process of double decomposition take place at once, or very tardily, they will find, in truth, that it is almost as rapid as when an iodide is used; in a very few minutes if sufficient of any bromide be added the whole of the silver is precipitated in the form of a bromide of silver, which is of a milk-white colour. If, for the purpose of comparing the rapidity of the process, the silver be thrown down in a similar manner with an iodide, the precipitate will be found, as is well known, of a primrose tint, and the difference between the two will readily account for the fact, that the iodized collodion gives a more creamy film than the bromized sample. If, then, as seems probable, the extremely tardy formation of bromide of silver, which Mr. Sutton describes, be the result of some unnoted circumstance, or abnormal condition, and not a well-ascertained general fact, any deduction from it does not affect the question at issue.

Mr. Sutton then further proceeds:—

"Having thus formed upon glass a film of collodio-bromide of silver, thick or thin as the case may be, the next point to determine is the action of the nitrate bath upon it. Is it eaten away, as iodide of silver is, by the bath, or does it remain, like a film of collodio-chloride of silver, apparently unacted on by the bath? Experiment shows that the latter is the case. A fresh 30-grain nitrate bath will dissolve a certain small quantity of bromide of silver, but not enough to affect the appearance of the film after twenty-four hours' immersion in it. The bath does not exercise anything like the same energetic action upon bromide as it does upon iodide of silver. If you coat the two halves of a stereoscopic plate, one with iodized, the other with bromized collodion, and leave the plate twenty-four hours in the bath, the iodized film will be eaten away and reduced to clear glass, while the bromized film will appear to be unaffected. We see here a resemblance between bromide and chloride of silver in the property of resisting the action of the nitrate bath. But it is still certain that the bath does, when fresh, dissolve a *small* quantity of bromide of silver, because we have seen small particles which have been detached from an over-bromized plate disappear in it. Besides which, the constant use of bromized collodion gradually puts a good bath out of order, and causes it to give grey, fogged, and insensitive negatives, as we shall show bye-and-bye.

"The next point to determine is the effect of light upon bromide of silver.

"When the plate is removed from the bath, in any state (that is, either when the film is blue after a few minutes' immersion, or pale yellow after an hour or more), and exposed to direct light, it quickly changes colour and assumes a deeper blue, or slaty tint; its original blue tint becoming deeper in one case, and its yellow tint becoming lead colour in the other. Moreover, the longer you expose it to light, the darker the colour becomes, so that if a negative were laid upon the film, a strong positive could be printed upon it in a few minutes. Few photographers, we believe, are aware of this property of bromide of silver, and it will be interesting to try it in direct positive printing, because it appears to be highly sensitive to direct light, and to blacken rather more rapidly than chloride of silver. But how different is this from the action of light upon iodide of silver. If you expose to light a film of sensitive collodio-iodide of silver it changes colour instantly to a very pale brown, but the change proceeds no further, and the film gets no darker by prolonged exposure. Here, again, the bromide of silver bears a strong resemblance to the chloride, but none to the iodide. Observe, also, that bromide of silver will darken when exposed to light, even with bromide of cadmium in excess, just as chloride of silver will darken with chloride of sodium in excess; but iodide of silver will *not* darken with iodide of potassium in excess, as the insensitive iodized Talbotype paper sufficiently proves.

"If you expose to light a film of collodio-chloride of silver, and then pour over it some pyrogallic developer, you produce a magnificent deep ruby-red deposit, when viewed by transmitted light. If you treat in the same way a film of collodio-bromide of silver you produce a thin olive-coloured deposit, with no richness or density. A film of collodio-iodide of silver treated in the same way yields, like the chloride, a deposit of a rich ruby-red colour. Our readers will already foresee what we shall tell them bye-and-bye of the way in which the admixture of bromide with iodide of silver reduces and enfeebles the fine rich colour of the deposit produced by the developer upon the iodide when used alone.

"It only now remains to compare the sensitiveness of bromide with iodide of silver by exposure in the camera, and development with pyrogallic acid, or with iron.

"In order to treat the bromide fairly, and give it every chance against its rival, we must first expose it in its blue state, and afterwards repeat the experiment when it has become yellow and fully formed. In the first case you simply apply bromized collodion to one half of a stereoscopic plate, and iodized collodion to the other half, excite in a pure nitrate bath, expose both together, and develop either with pyro or iron. The result is a fully exposed negative upon the iodized film, and only a thin, faint grey trace of the sky and highest lights upon the bromized film. In the other case you try an entire plate with a fully formed film of bromide against another with iodide alone, and the result turns out exactly the same as before. Bromide of silver alone is, therefore, proved to be extremely insensitive in the camera. And so, having convinced yourself of this fact, you put away your good bath, and let no more bromide go into it, because a dozen such experiments would ruin it beyond recovery."

We have quoted these observations at length, because they contain much that is interesting and important; but, as regards the question in hand, we entirely deny their relevancy. Bromide of silver alone, we admit to be less sensitive than iodide of silver in its best conditions; but we deny, as we have done before, that any legitimate argument is thence derivable as to the effect of combining the two: each might be easily quite insensitive alone, and yet the two in combination be highly sensitive. Let those of our readers who have the opportunity, try the experiments for themselves; let those who have not time, carefully note the results of the experiments recently tried by Mr. Blanchard, and produced before the South London Photographic Society, the report of which we give in the present number; experiments which, we may add, we have ourselves repeatedly tried before, and with similar results. As regards the influence upon the nitrate bath, let our readers be at ease, we have at this moment a nitrate bath in excellent condition, which has had some thousands of bromo-iodized plates excited in it. Mr. Sutton then proceeds to refer to our own articles on this subject:—

"Our friend Simpson has frequently insisted upon the accelerating effect of a bromide when added *in very small quantity* to iodized collodion. We regret that we cannot follow him in these refined experiments. It has given us frequently so much trouble to establish even the broad leading facts of photography, such as those described in this paper, that we are compelled to accept with hesitation the statements of others on very nice points, which can only be established by long and close observation. Mr. Simpson has also arrayed against us the names of some mighty men in photography, such as Williams, Blanchard, England, and Wilson, who all, he says, agree with him in using bromo-iodized collodion, and find it more sensitive than the other. But we know something of the doings of these gentlemen as well as our worthy friend. About this time last year we had many long country walks and talks with Mr. Williams, and he showed us some of his admirable negatives, but complained that his bromo-iodized collodion was decidedly slow. Mr. Blanchard, in his letter to the *Notes*, complains of the patience required by a photographer, and hints at the many failures and difficulties encountered in his mode of working, Mr. Wilson, in a recent letter to the *Notes*, warns our readers that instantaneous photography requires a peculiarly fine condition of light. Remember, too, that the instantaneous stereograms which we have lately reviewed in this Journal have all been taken in broad summer sun, never in diffused light. Many of the negatives, particularly those by Mr. England, are very thin and flat, and appear to have been taken by twilight or moonlight, rather than by 'the gay beams of lightsome day.' Mr. Williams's negatives were thin, and required intensifying with bichloride of mercury and iodine. Some of Mr. Wilson's, which we saw, were covered with the thick veil of grey fog, peculiar to iron development upon bromo-iodized collodion, and although these were failures, yet they indicated the tendency of the process to produce this sort of failure. There is no evidence, therefore, that any of the instantaneous views to which we have alluded have been taken with a good and rapid collodion, but on the contrary, great reason to believe that the collodion used was decidedly slow."

Now we utterly protest against all this, and we put it to our friend Sutton's sense of fair play if it be not too bad to the gentlemen he names. He has seen some of Mr. Wilson's failures, and he argues thence that the character of the process by which he obtains successes is to give fog, when the truth is, that Mr. Wilson's pictures are generally very brilliant. Mr. Blanchard states that much patience is required in the practice of instantaneous photography, referring to the watching and waiting necessary to secure fine effects of light and atmosphere, and Mr. Sutton argues thence that this is the result of using bromo-iodized collodion. Mr. England's negatives are characterized, unseen, as thin and flat, when the truth is they are very brilliant, although soft, as those who have seen them can testify. Mr. Williams had met with a sample of slow bromo-iodized collodion, but that did not lead him to discard bromides, for he still continues their use.

As to our own refined experiments we cannot help smiling. We have on occasion, we believe, recommended as little as a third of a grain of bromide to an ounce of collodion, and we know that a much less proportion will produce a decided effect. The other day we asked a well-known practical photographer, who has experimented largely in this direction, how small a quantity of bromide he had ever found to be of value; he stated that he had on some occasions found that one-sixteenth of a grain to the ounce produced a marked improvement in the picture. In our own practice we have found that from half a grain to a grain in an ounce of collodion was the best proportion for portraiture, and a little more for landscapes. This gives stability, softness, rapidity, and cleanness. We have tested the matter hundreds of times, in every possible way, and the results have been invariably confirmatory of our convictions.

Mr. Sutton states that he can take instantaneous pictures of waves, &c., with simply iodized collodion and pyrogallic acid development, using a lens of five inches focus, and half-inch stop, in diffused light. We do not doubt it for a moment. We have seen instantaneous pictures of similar subjects taken with a lens of eight inches focus, and a three-eighths stop, with bromo-iodized collodion and iron development. But it must be remembered that these are not the subjects to tax rapidity. The pure light of Jersey is not that of smoky cities. M. Soulier, in a conversation we had with him recently, insisted emphatically on this fact, that street scenes are the real tests of instantaneity. Mr. England's successes have been in the streets of Paris, and some of Mr. Blanchard's in the streets of London, and it is here they test the value of bromides. Mr. England informs us that he has spent many months in experimenting on this subject, and his conviction is that, *cæteris paribus*, bromo-iodized collodion with iron development is three times as rapid as simply iodized collodion with pyrogallic acid development.

Our own experience has led us to believe that there are certain conditions occasionally attainable in which simply iodized collodion and pyrogallic acid development will give as good and rapid results as it is possible to desire; but these conditions are difficult to attain and impossible to preserve; whilst with bromo-iodized collodion and iron development there is no difficulty. Mr. Sutton is a skilful manipulator, he manufactures his own collodion, which is as good as can be made, and he works in a Jersey light: we can understand how it may happen, as we know it does, that he is pre-eminently successful with the iodide alone. As regards the influence of bromides generally, we think he is in error, and we have the universal practice of American photographers, Continental photographers, and the most eminent photographers in this country in favour of our position.

## REMARKS UPON SOME OF THE APPARATUS EMPLOYED IN PHOTOGRAPHY.*

BY F. R. WINDOW.

### Baths and Dippers (*continued*).

*The Horizontal Dipping Bath.*—The vertical bath which I have just described is so universally used in this country, that I do not think horizontal baths, intended for sensitizing collodion, or other plates, were even manufactured for sale in this country until within a few weeks of the present time; and yet, although they are inferior in some few points, which I will presently investigate, for general business purposes, they have so much to recommend them, especially to the amateur, that it is a matter of surprise to me that their use has been hitherto so neglected.

There are two kinds of horizontal baths. Those in which the plate is placed collodion side upwards, and those in which the plate lies with the collodion side downwards. The description which follows refers solely to the last. The first-named baths, or those in which the collodionised plate is laid film upwards, are convenient, and, I think, to be preferred to the vertical bath, especially for large plates, on account of the small quantity of exciting fluid required with them, but in practice they are found to be inferior to the other kind of horizontal bath, and I shall, therefore, confine my remarks to these latter. I should mention, however, that the first are extensively used on the Continent, for all purposes.

A plate is sensitized in a vertical bath by plunging it *into* a vessel containing the exciting silver solution. In a horizontal bath, on the contrary, it is laid, face downwards, *on* the silver solution, in the same manner as positive paper.

A horizontal bath is a tray about a quarter of an inch larger each way than the plates that are to be sensitized in it, deeper at one end than the other; at the deep end the corners are filled up to the same level as the bottom of the shallow end, so that a plate laid in it may rest horizontally, one extremity upon the bottom of the bath at the shallow end, and the other upon the two corners of the deep end. Sufficient liquid is used just to cover the bottom of the shallow end, and the two corner pieces. Fig. 21 gives the plan of such a bath, and fig. 22 a section of it; the dotted line in fig. 22 showing the level of the bath liquid.

Fig. 21.

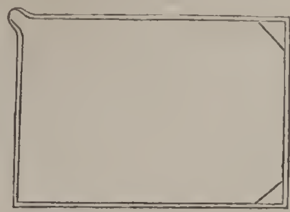


Fig. 22.

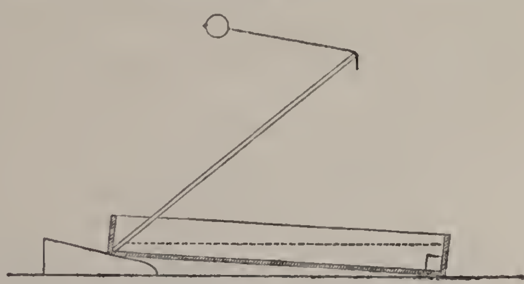
A horizontal bath may also be made with the bottom parallel to the edges, but curved, or hollowed out, in the sense of the length, so that a plate, when lying in it, may rest only on the edges of its sides. Practice has, however, convinced me that this is less effective than the one I have just described, as the film has more intimate contact with the bottom of the bath, and has a greater risk of being disturbed than when it merely touches the corners at two unimportant points.

The handy photographer can make a horizontal bath for himself, or, in default of tools, he can have one made by a carpenter in the following manner:—Take a piece of plate glass a quarter of an inch larger each way than the proposed bath, and set it in a wooden frame a quarter of an inch broad and an inch deep, like a boy's slate; only, instead of making the grooves, which are to hold the glass in the side pieces, parallel to the edges, let them be cut so as to give the required inclination to the bottom of the bath (fig. 23).

Fig. 24.



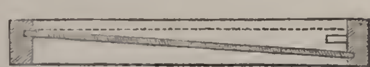


Fig. 23.

These grooves should be about an eighth of an inch in depth. The corners are then to be filled up with a piece of wood fastened in with cement, or, what is better, a silver wire may be fixed across them at the proper level. Lastly, all the woodwork inside and out must be thoroughly well coated, and the joints well stopped with hot rosin cement. Such a bath will cost about one-sixth of a porcelain vertical dipping bath, and is equally efficient.

A temporary horizontal dipping bath may be made with an ordinary washing tray, whether of glass, porcelain, or gutta-percha, by filling up the corners at one end with some substance inactive to nitrate of silver—a piece of sealing-wax is always handy and is easy to fix by heat—and tilting up the other end, by placing a wedge under it (fig. 24).

To use a horizontal dipping bath sufficient silver solution,

* Continued from page 221.

as I have mentioned before, is poured into it just to cover the shallowest part of the bottom and the corners at the deep end. The collodionized plate is placed upright at the extreme shallow end, standing on the bottom of the bath and against the angle, with the collodion side towards the other end, and by means of a silver or horn hook it is gently lowered with one movement to a horizontal position, when the other end of it will rest upon the corners (see fig. 24), the face of the plate being immersed in the liquid.

There is clearly no *necessity* for regulating the quantity of bath solution with extreme accuracy, as an excess would only have the effect of wetting the back of the plate as in a vertical dipping bath; but as the advantage is offered by this kind of bath of only wetting the face, which economises the bath liquid, by the quantity that would adhere to the back if wholly immersed, and also frequently saves it from much impurity off the backs of dirty glasses, it is as well to take the benefit of it.

The objection to a horizontal bath for professional persons who are constantly working with many different sized plates in the course of the day is, that each sized plate requires its particular bath, and it would be in many cases inconvenient to change frequently from one to another, when their vertical dipping bath will take all sizes alike. This drawback does not equally apply to amateurs who generally confine their operation to one particular size for each purpose, and to them it offers many advantages, which I think would amply justify their introducing it into their laboratories.

It is cheaper than any other kind of bath in the same material, whether it is bought or home made.

From its form it is easy to clean, and to ascertain when it is clean; and consequently one made of that most useful material, gutta-percha, is just as good as a more expensive one made of glass.

The quantity of bath liquid required is reduced by at least three quarters. A stereoscopic plate in most vertical baths, requires from 8 to 12 ounces of liquid; in a horizontal bath 2 ounces are sufficient. It is needless to observe that with large plates the economy on this point is very great.

There is no fear of the plate getting off the dipper, whether through breakage or carelessness.

There is no danger of the dipper breaking, as a metal hook is used.

In taking a plate out of a vertical bath it collects on its surface any particles that may be floating on or near the top of the liquid, but from the mode in which a plate is raised in a horizontal bath, all floating impurities are chased down to the extreme end, and are carried off with the first few drips; therefore from this cause the plates are free from spots; also the surface only of the liquid is disturbed by placing the plate in it, consequently all sediment or heavy impurities will remain at the bottom, instead of being stirred up every time as is the case in a vertical bath. This is another important advantage. However long the bath has been standing unused and unfiltered, even when a large quantity of sediment is at the bottom, by passing a strip of filtering paper over the surface, to clear away floating particles or scum, this kind of bath is always ready for immediate use and will produce clean pictures.

For large plates the manipulation is infinitely easier, and they are in consequence less liable to damage from handling. With a vertical bath when a plate is taken out it has to be lifted with one hand, while the dipper is held in the other, and it requires much expertness not to injure the film. With a horizontal bath, the plate is raised with the hook in one hand to a vertical position, and held so until sufficiently drained; it is then inclined further backward, being supported by the other hand touching the back, when the hook being laid aside both hands are free to convey it to the slide, or washing dish, according to the process, without even touching the edges. Small plates are taken between the finger and thumb, the same as from a vertical bath.

Ten minutes' practice will convince a practical photographer, that this kind of horizontal bath is really much *more* easy to use than the vertical dipping bath, for all sized plates above quarter-plate, and that it is also quite *as* convenient for the small sizes. Ever since I first used one from necessity a few years ago, I have adopted them exclusively for all sizes, and the favourable experience I have had of them, induces me to call the attention of photographers to their many advantages, as I am convinced that their being so little known, is the only cause that they are not in more general use.

If manufacturers in porcelain and gutta percha, would produce an article of this kind, like figs. 21 and 22, in the sizes mostly used by amateur photographers; say ¼-plate stereoscope, and 10×8. I believe they would find a ready market directly the public were aware that such a thing was on sale.

The dipper or hook that is used with a horizontal dipping bath, may be made of horn, tortoise-shell, silver &c. The hooked portion should be about ⅜in. long, bent at right angles to the haft. They can be bought in silver ready made, for half a crown. They can be made out of an old comb with very little trouble. The plate must always be held in the angle of the dipper, (see fig. 24), care being taken to avoid touching it with the point,

A horizontal bath will be found eminently suited for several other purposes, besides sensitizing collodion or albumen plates. Among these I may specify more particularly, the facility they offer for developing plates with gallic acid; the film being placed face downwards, and, at the top of the developing liquid, there is less tendency to deposit sediment upon the picture, than when it is laid, as is usual, face upwards, at the bottom of the gallic acid solution.

Also a horizontal bath affords probably the most convenient, as well as the most economical manner of applying the hyposulphite solution to the developed plates; economical, because the solution can in this manner be used without trouble to complete exhaustion, and without waste from spilling by pouring it on and off in the usual manner; and particularly convenient, because hyposulphite residues can thus be kept by themselves, and reduced separately by liver of sulphur, leaving the developing, washing and draining silver residues in a form that can be cheaply reduced to chloride by hydrochloric acid. The mixture of hyposulphite with the other washings, is a very frequent cause of considerable waste, as many photographers, not well aware perhaps, of the large percentage of silver lost by their neglect, throw away the compound residue, rather than take the trouble to reduce it to a marketable form.

## Scientific Gossip.

New Process for Preparing Iodide of Potassium—Comparison with Old Processes—Non-existence of the Periodide of Iron.

The progress of chemical science has caused numerous improvements to have been made of late years in the manufacture of photographic chemicals. Nitrate of silver has frequently formed the subject of notice in these columns, and we now propose to devote some consideration to the preparation of the almost equally important salt—iodide of potassium. The manufacture of this body has lately been considerably improved by Baron Liebig, who has devised a beautiful process for preparing it with readiness in considerable purity. His mode of proceeding is the following:—One part, by weight, of phosphorus is placed in a porcelain basin, rather deep, and about forty parts of hot water poured over it. When all the phosphorus is melted, twenty parts, by weight, of pure iodine are very carefully stirred in, a few grains at a time, the action being allowed to entirely cease before adding a fresh quantity of iodine. Combination takes place with violence. A great portion of the phosphorus passes into the amorphous variety: this, however, in no way interferes with the process, as the amorphous phosphorus acts upon the iodine just as well, although not quite so fast: this may, therefore, be an advantage, rather than otherwise, inasmuch as there will not be so much danger of the violence of combination exceeding due bounds. When the whole of the iodine has been added, and the action has stopped, the liquid will be colourless, and will consist of a solution of phosphoric and hydriodic acids, formed from the ingredients acting upon the elements of water, according to the following equation :—

$$P+5I+5HO=PO_5+5HI.$$

There will also be a trifling excess of phosphorus at the bottom, which will be in the form of dirty reddish-brown flakes. These may be filtered off, and the clear, colourless liquid must be mixed with milk of lime until the mixture, tested with red litmus paper, has an alkaline reaction. (The milk of lime is prepared by slaking good quick lime, and then mixing some of the white hydrate of lime with distilled water, until it has a milky appearance.) The lime will unite with both the acids, forming insoluble phosphate of lime, and soluble iodide of calcium: the whole must be filtered (through a linen filter, as it would be a tedious operation to filter it through paper), the precipitate well washed, and the clear filtrate, consisting of solution of iodide of calcium, boiled down with twelve parts, by weight, of pure sulphate of potash in powder. This decomposes the iodide of calcium, with formation of sulphate of lime and iodide of potassium. When the liquid has been evaporated down to about one-half its original bulk, the whole is allowed to cool and to remain at rest for six hours; the mixture is then filtered, and the precipitate well washed, as before. The solution will now consist principally of iodide of potassium, but it will also contain a little iodide of calcium (owing to the twelve parts of sulphate of potash added, not being quite sufficient to decompose the whole of the iodide of calcium,) and sulphate of lime (from the trifling solubility of this salt in water). The lime is now to be separated by adding a small quantity of *pure* carbonate of potash to the filtrate, and the solution, upon being filtered and evaporated, yields crystals of pure iodide of potassium. This mode of preparation has been found to yield, according to Pettenkofer, almost the theoretical quantity of iodide of potassium from a given weight of iodine. By modifications of this process, we may prepare the iodides of sodium, lithium, barium, strontium, calcium, magnesium, manganese, ammonium, &c.

Dr. W. S. Squire, who has recently brought forward the results of his experience in using this process on the large scale, states that he finds the iodides prepared in this way, very easily acquire a pinkish hue, and that it is very difficult to get them to crystallize properly; what the cause of this is, is not very evident, but the objection has been completely removed, by fusing the salt before crystallization; the iodides after this treatment crystallizing beautifully, and retaining their colour remarkably well. A specimen of iodide of ammonium was prepared in this way from a sample of fused iodide of barium, and it was found to be superior to everything else as an iodizer for photographic purposes; this is perhaps the best test of its purity. With this slight modification, Dr. Squire, considers that the process of Baron Liebig is one of the best ever proposed for the manufacture of iodide of potassium; the potassium salt used is at once the cheapest and best, and the only other item of cost in the materials, is the phosphorus; however, as one ounce of this body is sufficient for the production of one pound and a half of iodide of potassium, the expense of this element amounts only to about one penny for every pound of iodide of potassium manufactured by this process.

It may be of interest as well as use, if we compare this beautiful process with others which have been employed in the manufacture of iodide of potassium. Of the numerous plans proposed, only three have been found practicable. 1. A solution of iodide of iron or zinc, (formed by the direct union of the elements under water), is decomposed by a solution of carbonate of potash. 2. Iodine is added to a warm solution of caustic potash; the colour disappears with formation of iodide of potassium and iodate of potash: the solution is then evaporated to dryness, and heated with charcoal, which reduces the iodate to iodide. 3. Iodine is added to a solution of sulphide of barium; in this case sulphur is precipitated and iodide of barium formed. The solution is then boiled with powdered sulphate of potash; this produces the insoluble sulphate of baryta, which may be separated by filtration, the iodide of barium remaining in solution. According to the first and second plan, purified pearlashes are used instead of pure carbonate of potash, which is too expensive for the purpose. In this way the various impurities of the potashes find their way into the iodide of potassium, or else they must be eliminated by rejecting the mother liquors, and recovering the iodine from them. This is, however, far from being an economical plan. The third process has the great disadvantage that the product is rarely, if ever, free from sulphur compounds, which of course render it in the highest degree injurious when attempted to be employed in any photographic process: it is also rather inclined to blacken when heated. With these exceptions it is a tolerably pure preparation, and is very free from sulphates, chlorides, and other impurities generally found in iodide of potassium.

It has long been a moot point, according to the handbooks of chemistry, whether there exists such a compound as the periodide of iron. Mr. Squire has recently decided this point in a very satisfactory way in the following manner:— A quantity of iodine was divided into three-parts, two of these were combined with iron so as to form a pale-green liquid; the third portion was then added, and the whole boiled so as to promote combination. After the dark-brown solution had cooled, it was shaken up with about three times its volume of ether. In a little time the ether was found floating upon the water, when it was found to have carried with it the whole of the third portion of iodine, leaving the remaining iodide of iron dissolved in the water, from which carbonate of ammonia threw down the white carbonate of iron. This experiment pretty conclusively proves what was asserted by the President of the Pharmaceutical Society, in the *Philosophical Magazine*, in 1836, viz.: that the periodide of iron had no existence, and that the brown solution, obtained by exposing a solution of iodide of iron to the air, was nothing more than a solution of iodide of iron, with some free iodine.

## PHOTOGRAPHY IN AMERICA.

*2, Wall Street, New York, April* 28, 1862.

Dear Sir,—I notice that development of wet plates with protosulphate of iron, seems to be yet in its infancy in England, as the use of pyrogallic acid is here. Most certainly, when properly used, iron is the best developer *to a certain limit*, but when the development is pushed with the same treatment, a flat negative, void of vigour, is the result.

Our most successful workmen in portraiture, take the plate wet from the camera, and flow it with the protosulphate of iron developer, allowing it to remain on the plate until the details are fully out, but no longer. Wash off the solution, and then continue the development with the usual pyrogallic acid developer, adding to each dose two or three drops of a forty-grain nitrate of silver solution: the iron development being to bring out the most perfect detail, and the pyro and silver to give the requisite intensity. This treatment takes time, and herein lies the fault of our professionals. The American characteristic is "hurry up," and everything is done on the lightning-express principle. Our gallery operator in the dark room sees the detail come out in his negative most beautifully, but the iron developer does not give intensity, he thinks of the two or three customers in the waiting room, he "hurries up" the job by flooding the beautiful negative with sulphide of potassium; (or as a friend of mine lables: "stinker odorum,") gives it the requisite *blackness*, and spoils all the delicacy and softness of his resulting prints.

In printing and toning albumen paper, however, we are on the ascendant. The old gold and hypo bath is no more heard of; in fact I do not know a single instance where it is used in a first-class gallery, nor do I know a single amateur who adheres to it. That process is among the things of the past. The printing process now most in vogue is to use thin albumenized paper, not heavily salted: sensitize it by floating one minute only, on a seventy-grain solution of nitrate of silver, made quite alkaline with ammonia, *i. e.*, just alkaline enough to keep itself clear from colour. If floated longer than one minute, the albumen will lose its gloss, and the print sink into the pores of the paper. The silver solution as above will need to be filtered occasionally, and can be strengthened by adding silver when necessary. After first ammoniating it, as long as it keeps clear it will need no more alkali. The toning most used is the ordinary bi-carbonate of soda and chloride of gold bath, to which some salt, 1 grain to the ounce, has been added. We always clear our prints from free nitrate before toning, by washing and then immersing ten minutes in salt water. Fix with fresh hypo, as usual, and wash in an automatic washing trough. Many advertisements in our papers read: "by the *new albumen process*." This simply means that our artists use albumenized paper in place of the old plain ammonio-nitrate process. Its usage is compartively new with us. Mr. Anthony tells us he uses in his paper factory several large barrels of fresh eggs per week, and never has a sheet on hand more than two days old.

A word about the so called "hot water accelerator" for tannin plates. The term "*hot*" water is incorrect, for if the plate is heated above 100° the edges are very liable to turn red, and the development is seldom equal all over the negative. The most certain method of working is to expose the plate the same as for wet collodion, and then put it in a vertical glass bath, containing water at about 90° heat; allow it to remain there until thoroughly soaked, say seven minutes. Take it out and pour on the developer at the usual temperature, the plate being yet warm. The developer is kept best in three stock bottles, as follows:—At least I give my own method not knowing how others do.

*First bottle.*

| | |
|---|---|
| Pyrogallic acid ... ... ... | 24 grains |
| Acetic acid, No. 8 ... ... | 4 drachms |
| Filtered rain-water ... ... | 8 ounces. |

Keep well filtered.

*Second bottle.*

| | |
|---|---|
| Nitrate of silver ... ... ... | 80 grains |
| Filtered rain-water ... ... | 4 ounces. |

*Third bottle.*

| | |
|---|---|
| Citric acid ... ... ... | 320 grains |
| Filtered rain-water ... ... | 4 ounces. |

When ready to develop a lot of plates, I mix in a chemist's dropping-bottle half an ounce each of the 2nd and 3rd solutions. This is my dropping silver solution. If the 2nd and 3rd are mixed together and kept in one bottle for any time, citrate of silver will be precipitated, and great waste incurred; therefore, it is best to mix fresh every day as above.

I then pour into a developing glass enough of No. 1 to cover my plate by flowing, and add one drop only of the silver drops. Flow it quickly on and off the warm plate, keeping it in constant motion. As quick as the solution discolors, throw it away and apply a fresh dose. The picture should flash out quickly, and care must be taken that the development be stopped before it fogs, as it is apt to do. When all the details are well out, wash off the pyrogallic acid and fix with hyposulphite of sodium. After which the negative can be intensified to any degree by a cold application of pyrogallic and silver.

From repeated experiments I learn by experience that for this process an old collodion, very porous and rotten and red with free iodide, is far more sensitive than a new sample. The usual experience of the wet plates is here reversed. The warm water has no other effect on the plate than to thoroughly open all these pores and render the film instantly permeable to the developer. My conviction of this is confirmed by the fact that the picture is *in* the film, and not on the surface when I use old collodion, and they are on the surface when I have tried new samples which worked very well wet. Those on the former are very vigorous and bold with a very short exposure, while the latter develops weak and slow.

A subject which engrosses our apparatus manufacturers now is the best changing box for dry plates in the field. The system of carrying a separate lot of double backs for the camera, each containing two plates, is very good, but exceedingly tiresome to one who, like myself, is addicted to long solitary pedestrian excursions. Some of our New York houses have been getting up changing boxes for stereoscopic plates, but they are all clumsy compared with a little box of British make I have used for two years. It measures eight inches long and five inches high and wide. The box constitutes the camera, and a changing box, carrying one dozen plates, fits inside of it; a leather handle on the top secures the whole. The entire concern, with a pair of Ross's short focus lens, weighs five pounds when filled with prepared plates, and I have repeatedly carried it in one hand during a day's walk of fifteen or twenty miles, scarcely feeling the weight. It has no name of maker on it, so I have no means of telling who deserves the great credit due for its ingenious construction. In my next I will enclose a few samples of the work it does, and will also give in full my method of preparing dry plates at the rate of fourteen per hour.

I intend starting to-morrow for two weeks' driving among the mountains of New Jersey and Pennsylvania, and may have some experience to relate on my return. Until then, farewell! which, photographically speaking, means, may the weather keep clear and well fixed, without fog.—Yours respectfully, F. F. Thompson.

## COPYRIGHT IN PHOTOGRAPHS.

A few weeks back we mentioned the fact of Mr. Mayall having obtained a verdict in an action he had brought for the recovery of certain prints from some of his photographs, which prints he had *lent* for the purposes of engraving. These prints having been erroneously sold, were copied by means of fresh negatives being taken from them by the purchaser of the prints so lent by Mr. Mayall. We likewise pointed out that the result of that verdict did not in any way establish the existence of *Copyright* in photographs. A rule *nisi* having been granted by the Court of Exchequer, calling upon the plaintiff to show cause why the verdict he had obtained upon one of the counts of his declaration should not be altered, it was at first expected that the question of copyright would come under discussion; but the Court afterwards expressly stated that copyright was not the point for consideration, and was quite beside the question at issue between the parties. As, however, it seems to be erroneously supposed by some persons that a copyright exists in photographs, either by the common law or under the Engraving Acts, it may be useful to point out how the matter stands. If any such right is claimable in a photograph *after its publication*, it can only be by analogy to copyright in books, which the House of Lords has, upon more than one occasion, decided does not exist by the common law, but only by statute. These cases were argued in the presence of the common law Judges. Upon the last occasion the Lord Chief Baron Pollock was present, and he expressed a very decided opinion against the existence of copyright by the common law. He said, "I think common law cannot create new rights, and limit and define them, because in the opinion of those who administer the common law such rights ought to exist according to their notions of what is just, right, and proper. Weighing all the arguments on both sides, and looking to the authorities up to the present time, the conclusion I have arrived at is, that copyright is altogether an artificial right, not naturally and necessarily arising out of the social rules that ought to prevail among mankind assembled in communities, but is a creature of the municipal law of each country, to be enjoyed for such time and under such regulations as the law of each State may direct, *and has no existence by the common law of England*. It would follow from this that copyright in this country depends altogether on the statutes which have been passed on this subject." Again, in a recent case in Ireland, which arose out of a photograph having been made from recollection of an oil picture, "*The Death of Chatterton*," the Master of the Rolls in Ireland said, "I apprehend it is clear that by the common law copyright or protection exists in favour of works of literature, *art*, or science, to this limited extent only, that while they remain unpublished no person can print them, but that *after publication* they are by common law unprotected." It is therefore quite certain that the common law affords the author of a photograph no protection in the shape of copyright after it has been published. The question then arises whether any statute affords him such a protection? Unfortunately, in the present defective state of our laws of artistic copyright, there is no authority for saying that any such protection exists: on the contrary, "The Copyright (Works of Art) Bill," which has passed the House of Commons, and is now in the Lords, expressly recites as a fact, "that by law, as now established, the authors of paintings, drawings, and *photographs* have no copyright in such their works." We trust that such an injustice will now be speedily remedied by the Bill being passed in such an amended form as is requisite for the protection of all parties whose interests it affects.—*Athenæum.*

## MASON *v.* HEATH.

THIS case came before the Court of Common Pleas again on the 8th inst.

The plaintiff's counsel had obtained a rule *nisi*, according to the leave reserved at the trial of the case, when the verdict was given for the defendant, and the jury appended to their verdict a recommendation that Mr. Mason should receive one negative on payment of five guineas.

Mr. Hawkins, Q.C., and Mr. Gray showed cause against the rule, on behalf of Mr. Heath; Mr. Montagu Smith, Q.C., and Mr. Maude supported the rule.

Mr. Hawkins informed the Court that Mr. Heath had, immediately after the trial, complied with the recommendation of the jury, and had delivered the negative to Mr. Mason, on payment of five guineas. He then called the attention of the Court to the fact, that Mr. Mason's claim had always been for two negatives, for which he had tendered five guineas, considering that in excess of the sum which Mr. Heath was entitled to receive, which he estimated at a guinea for each negative. He said that it had never been a question of price on the part of Mr. Heath at all, as he would, at any time, have been but too glad to have got rid of the plaintiff, by giving him the negative, if he had been content with the one which the Prince had permitted him to have, but that Mr. Heath had been compelled to defend the action at great expense, owing to Mr. Mason insisting upon his claim to the second negative, the only second negative in existence being that taken expressly for another purpose by the Prince Consort's order. He also called attention to the fact of Mr. Heath's having, at all times, been anxious to refer the matters in dispute, and to Mr. Mason's persistent refusal to refer them, even after Mr. Justice Willes's strong expression of opinion that it was a case which ought to be referred.

Mr. Hawkins was proceeding to comment upon the evidence, when he was stopped by the Court, who called upon Mr. Montagu Smith to state in what manner he considered the Court could give effect to the rule.

Mr. Montagu Smith, in an elaborate argument, contended that the property in the negative passed to Mr. Mason, so soon as the Prince had given directions that that particular negative should be the one delivered to Mr. Mason, and he further contended that Mr. Heath, not having stated the price at which he would deliver the negative, had dispensed with the necessity of the plaintiff tendering any other sum before commencing his action.

Mr. Maude followed on the same side.

Lord Chief Justice Erle said, that, notwithstanding the ingenuity shown by Mr. Montagu Smith and Mr. Maude in their arguments, he could not hold that any property whatever passed in the negative, so as to found an action for trover, and that Mr. Mason's remedy must rest upon breach of contract only. The jury had found distinctly that no such contract as that set out in the declaration had been made at all, and although words had been put into their mouth at his own suggestion, raising the question as to a contract for a single negative, yet that the Court could not amend the record, even if they had desired to do so, so as to enable Mr. Mason to claim a verdict in respect of any such contract. The tender, as proved at the trial, and relied upon, was a tender for two only, and before any effect could be given to the recommendation of the jury, even treated as a finding that the same sum should be paid for one negative, it would be necessary that the jury should find a tender of that sum for one negative, or a distinct dispensation with the tender on the part of the defendant. No such questions, however, had been put to the jury at all, or suggested by the plaintiff's counsel at any part of the case. The rule must therefore be discharged, and verdict for the defendant stand.

## THE CARTE DE VISITE.*

There is, in truth, much that will always be adverse to the production of an agreeable photographic likeness; but at the same time, it is quite as true that a very great deal might be done by a little more knowledge, thought, and painstaking, to render such portraits infinitely more pleasant than they are generally found to be.

People who are considered good-looking, and those even who are beautiful, have a hundred different aspects, and to seize the best one and reproduce it is a function of Genius and not of Chemicals. If you have had a friend whom you have wished to show off to another friend, have you not often been disappointed that the first was "in such bad looks" as really not to look even pretty? The person who was expected to be struck with admiration has wondered at your taste, and you have been obliged to own that there was matter for disappointment. Even in nature, out-of-door nature, this is so. The view which you saw from the hills above the old French town, with the evening sun lighting up the rich plain, making the mountains in the distance amethysts, and the river a line of gold, while the one cloud shadow lay over the old cathedral tower and blackened it, so that all the rest sparkled the more—what is that very same scene when the sky is grey, and the mountains grey too, and plain and river and cathedral are all of one monotonous slate-colour!

But though it may take a Reynolds to do justice to the beauty of the living creature, and a Turner to reproduce that of the mountain and the plain, there is much to be got out of the photographic lens—which it would be wickedness to disparage—infinitely more than it is ordinarily made to convey to us. There are one or two simple matters which might be borne in mind by photographers with immense advantage to their sitters and to their own reputations as well. They do not yet quite understand their trade.

The two great main considerations which should occupy the mind of every photographer are these: What is the best view he can take of his sitter, and what the effect of light and shade which will be most becoming to that sitter's countenance. On these two considerations the success of the portrait entirely depends.

Now as to the question of view there is some tolerable amount of understanding manifested by the great body of photographers. The sitter is generally so placed that the most favourable aspect of his face may come before the lens, and so that the rapid perspective to which he is subjected shall distort him as little as may be. It is pretty well known that if his legs are nearer the machine than his body the first will be disproportionately large for the last; that if his hand is stretched out towards the artist, it will be twice the size it ought to be, and that even the fact of his nose being nearer the camera than the rest of the face will give to that central feature a large and swollen aspect.

Such general rules as these applying equally to all sitters, are then pretty well understood. But this is not enough. The photographic artist who would wish to produce a really successful portrait, should study the special defects and special beauties of the individual before him, and consider in what the faults of such a physignomy will assert themselves least strongly, and the merits show the most. This is the function of an artist, of a man of considerable natural abilities, and immense experience. It is exercised by some of the best French photo-

* Concluded from p. 226.

graphers in an eminent degree, by one—M. Camillo Silvy—who has set up his studio here in England.

M. Silvy—and almost he alone in this country—seems to understand the immense importance of *shadow* as an ingredient in a successful portrait. This is his great stronghold, more even than the taste which he shows in his choice of view, costume, and accessory. These last are great elements in M. Silvy's portraits, but the distinguishing merit of them is the well-chosen light and shade. It is perfectly surprising that this has not been more considered by all photographers. Their process is a thing simply of light and shade. It is the light that makes the portrait come into existence at all. The patches of shade, more or less dark, alone prevent a carte de visite from being a sheet of blank paper. Surely the shapes of those patches of shade are all-important. It is little known—and when it *is* known we have prettier photographs—that a light coming from above the head of the sitter is the most unbecoming thing in the world, and that a face so lighted cannot by any possibility show to advantage. Now, the ordinary photographer's glass-room has a diffused light all over it, but mainly coming from above, so that the eyes show in two dark caverns of shadow, while a black patch appears under the nose, throwing the termination of that feature up to the skies, and making it show as an isolated nob, the full size of which is—and few of us can bear this—done the amplest justice to. This top-light, moreover, scores out relentlessly those baggy marks which many of us have too well developed under the eyes, and which are not characteristics of the human beau-ideal, while—in the case of ladies—a kind of trough on each side of the mouth is joined to the chin-shadow after the fashion of a Vandyke beard.

In ladies' portraits, the elimination of beauty, and not so much of character as in men, is the thing to be borne in mind. Now, the most becoming light is one level with the face, or even, perhaps, somewhat beneath it—it being a great mistake to suppose that the foot-lights on the stage are unbecoming. Such a light as that described above would make any face in the world ugly, and yet it is just such a light which is to be found in most photographer's rooms.

As much as possible, as much as may consist with the action of the photographic process, the light from above should be got rid of in taking these portraits, and a light from the side brought into use. This seems to be understood in a rare manner by M. Silvy. His portraits are very popular, but, perhaps, many of the people who like them are ignorant of the reason which causes their preference. The reason lies, to a large extent, in the softness and size of the shadows which lie in such agreeable masses on the faces which came within the range of this photographer's skill. He has discovered the simple truth, that in an affair in which it is a question altogether of shadows, the distribution of those shadows is a thing of vital importance. Of every face in this town there is a view to be taken, and a light and shade to be selected, which will show it to advantage or disadvantage. To subject all to the same glaring light, descending on all alike, and to all unbecoming, is scarcely the way to produce agreeable results. Yet we have known a photographer standing under his own light, and most hideously distorted by that circumstance alone—without the additional help of his instrument—to argue with us, the wretched sitter, that we were none the worse for his light!

It is difficult to speak strongly enough about this question of shadows and their value. Queen Elizabeth, in her ignorance, thought shadows unbecoming to the glory of her majesty, and wished to be painted without any at all: and, doubtless, there are people who now-a-days think shade a smudgy dirty thing, the less of which comes upon their countenances the better. But light cannot be thrown out in its full brilliancy, nor forms shown in their variety, without its aid. Why, one of the main differences between a fine day and a dull one lies in the shadows which proclaim the first, and are wanting in the other. On a wet, dull day, as you stand in the grey sickly light, you may look all round about in vain for your shadow; it is not to be found. A cheerless, monotonous glare is over all things. The sun comes out, and the first thing it does is to cast your shadow dark and clear and sharp upon the ground—your shadow and that of the trees, the buildings, and all things else that come within reach of its rays. How different everything looks then; how solid, how bright, how finished! Those shadows are larger in the early morning and again as the day declines, and it is one reason of our admiration of those two seasons that then the rising or sinking sun catches but one side of every object, and leaves so large a portion of the scene lost in a mysterious and softened shade.

## INVENTORS AND THE INTERNATIONAL EXHIBITION.

Provision has just been made for the protection of inventors exhibiting at the International Exhibition by the passing of an Act for the Protection of Inventions and Designs exhibited at the International Exhibiton of Industry and Art for the year One thousand eight hundred and sixty-two. 29th April, 1862.

Whereas it is expedient that such Protection as is hereinafter mentioned should be afforded to Persons desirous of exhibiting new Inventions or new Designs at the International Exhibition of Industry and Art to be held in the present Year, under the Direction of "The Commissioners for the Exhibition of 1862:" Be it enacted by the Queen's most Excellent Majesty, by and with the Advice and Consent of the Lords Spiritual and Temporal, and Commons, in this present Parliament assembled, and by the Authority of the same as follows:—

1. This Act may be cited for all Purposes as "The Protection of Invention and Designs Amendment Act, 1862."

*Protection of New Inventions.*

2. The Exhibition of any new Invention at the said International Exhibition shall not, nor shall the Publication, during the Period of the holding of such Exhibition, of any Description of such Invention, nor shall the User of such Invention, under the Direction of the said Commissioners, prejudice the Right of any Person to register provisionally such Invention, or invalidate any Letters Patent that may be granted for such Invention.

*Protection of Designs.*

3. The Exhibition at the International Exhibition of any new Design capable of being registered provisionally under the Designs Act, 1850, or of any Article to which such Design is applied, shall not, nor shall the Publication during the Period of the holding of such Exhibition of any Description of such Design, prejudice the Right of any Person to register provisionally or otherwise such Design, or invalidate any Provisional or other Registration that may be granted for such Design.

## Proceedings of Societies.

### South London Photographic Society.

The usual monthly meeting of the South London Photographic Society was held in the City of London College, on the evening of Thursday, May 8th. Mr. Sebastian Davis in the chair.

The minute-book not having arrived in time, the routine proceedings were delayed until the close of the meeting.

Mr. Howard, as Treasurer, and Mr. Wall, as Secretary, intimated their wish to retire from those duties at the Annual Meeting to be held next month.

Mr. Wharton Simpson hoped this intimation was not to be regarded as a formal tender of the resignation of these gentlemen, the loss of whose services would be deeply felt by the Society. He trusted they would reconsider the question, and suggested that as Mr. Wall's increasing professional duties left him very little time for the discharge of the secretaryship, an assistant should be appointed to share the labour.

After some remarks from the Chairman, and conversation on business matters,

The Chairman called upon Mr. Blanchard for his paper on "The Influence of Bromides in Collodion."

Mr. Valentine Blanchard said that he was compelled to come before the meeting with an apology. He had prepared no paper. But he thought that when he told them that in going into the subject of bromides, he had found in the course of his experiments, that in order to treat of the subject fully it would require more time than he could then give it, that some of the experiments demanded a more complete investigation before he could give a positive opinion upon them, and he was especially anxious to arrive at definite conclusions on some points recently raised by Mr. Sutton in the *Photographic*

*Notes* they would hold him as legitimately excused. They would allow him now, he hoped to exhibit the results he had brought with him, and make some comments thereon, for the subject would necessarily produce an animated discussion, and he would then, with their permission, take up the subject after the recess, when he hoped to bring before them a more complete paper than he could possibly have done had he written one for the present meeting. There had always been a great deal of conflicting evidence as to the increased sensibility imparted to collodion by the introduction of bromides, and many men, standing high in the profession, had recorded their opinion that there was nothing gained by their introduction. One thing was, however, certain, that bromides had produced such a uniformity of action in collodion, that, even if they were to admit that, under the most favourable circumstances, a simply iodized collodion could be made to give results as rapid as one containing a bromide, still all must admit that their introduction had tended in no small degree to improve the productions of photography, for, whereas, an iodized collodion giving good results a few days after iodizing, would, at the end of a few weeks, be comparatively useless for rapid purposes, the introduction of a bromide would render it as useful at the end of as many months. He would now pass round the results of his experiments as far as he had gone, and he thought the value of bromides would be found very evident.

His *first experiment* was with two samples of collodion on one plate. Both were prepared about six months ago. One half of a plate was coated with collodion iodized with iodides of cadmium and ammonium, 3½ grains to the ounce. The other half with iodide of ammonium 4½ grains, bromide of cadmium 1 grain. It would be seen that the bromo-iodized half was clean and full of detail, whilst the simply iodized half was dirty and under-exposed. This experiment was made in a bath quite new, and nearly neutral, giving, with the collodion he usually employed, instantaneous results. There was no colour to indicate the liberation of free iodine in the simply iodized sample.

*Experiment* II.—One half of a plate was coated with a collodion bromo-iodized as follows:—Iodides of cadmium and ammonium 4½ grains, bromide of cadmium 2 grains. The other half with collodion iodized with iodide of potassium 3½ grains newly iodized. The bromo-iodized half was perfectly clear and brilliant, whilst on the iodized half there was the ghost of an image covered by fog. The experiment did not quite satisfy him, for the iodized collodion was altogether only 24 hours old, and, therefore, could not be in its best condition.

In *Experiment* III, he took the same iodized collodion as in the last for one half of the plate, and introduced 1¼ grains of bromide of cadmium into a portion of the same collodion for the other half of the plate. This was sensitized in an old bath. Both halves indicated under-exposure, but the bromo-iodized half was much the best.

*Experiment* IV was a repetition of the last, but instead of using the instantaneous shutter employed for all the other, experiments he gave about 2 seconds. The bromo-iodized half was quite clear with the exposure about right, whilst the iodized half was partly fogged, but indicated under-exposure.

*Experiment* V was with iodide of ammonium 2½ grains, bromide of cadmium, 5 grains, for one half of the plate: bromide of cadmium, 5 grains, for the other half. It would be seen that where bromide was employed alone, there was but a faint picture, and that the introduction of 2½ grains of iodide had wonderfully improved the results.

It appeared, however, that where the bromide was present in large quantities, a corresponding amount of iodide was necessary for the best results, for it seemed that the excess of bromide had a tendency to rob the iodide of a portion of its creaminess. The point he wished to determine in his experiments was, how much bromide to use with the greatest advantage; he hoped to have more to say on this point when he resumed the subject after the recess. All the preceding results were produced by iron development; iron, 30 grains, with a very small quantity of acetic acid, not more than 10 minims to the ounce.

His next experiment was made with collodion iodized with iodide of potassium, 3½ grains, for one half of the plate; iodide of potassium, 3½ grains; bromide of cadmium, 1¼ grains, for the other half; but developed with pyrogallic acid, 2 grains; acetic acid 10 minims, to 1 ounce of water. The bromo-iodized half gave a thin picture with plenty of half tone, whilst the iodized half had a complete reduction of silver all over of ruby red colour, which would indicate an alkaline condition of bath or over-exposure. Unfortunately, he had not this result with him, for on washing it after fixing, the whole film washed off. He was unprepared for this, for in all the other results with iron development he had taken no care whatever in the washing. It appeared, however, that the pyro exercised some influence upon the film, which made it unable to bear rough treatment. He thanked them for their patient attention to his imperfect remarks, and he hoped to go more completely into the question next season.

Mr. Harmer remarked that he had often observed a much greater tendency in the film to leave the glass when developed with pyro, than when developed with iron, and especially that it would not bear treatment with bi-chloride of mercury after development with pyro.

Mr. Wall had met with similar experience.
