In Britain, though dyeing has been carried on for many years with great ſucceſs, very little progreſs was made in inveſtigating the theory of the art. The Royal Society, indeed, ſoon after its inſtitution, recommended it to ſome of its members; but as no treatiſe made its appearance in conſequence of this, it ſeems very ſoon to have loſt their attention. Lewis, many years after, publiſhed ſome very important remarks on dyeing; but they were confined to a few proceſſes. The Britiſh dyers ſatisfied themſelves with a tranſlation of Hellot. Such was the ſtate of the art when the article DYEING in the *Encyclopædia* was drawn up. It conſiſts chiefly of an abſtract of Hellot's treatiſe. But within the laſt 30 years, the attention of men of ſcience has been very much turned to [illegible] complicated art. In Sweden has appeared the treatiſe of Scheffer, and Bergman's notes on it; in Germany, the experiments of Beckmann, Poerner, and Vogler, and the diſſertation of Francheville; in France, the treatiſes of D'Ambournay, D'Apligny, Hauſſmann, Chaptal, and, above all, of Berthollet; in this country, the ingenious remarks of Delaval, of Henry, and the valuable treatiſe of Dr Bancroft; beſides many other important eſſays. Theſe, together with the progreſs of the ſcience of chemiſtry, on which the theory of dyeing depends, have thrown ſo much new light upon the art, that we find ourſelves under the neceſſity of tracing the whole over again. We ſhall paſs over, however, very ſlightly thoſe parts of the art which have been ſufficiently explained in the article DYEING, *Encycl.*

To underſtand the art of *dyeing*, we muſt be acquainted with the *ſubſtances* on which it is practiſed, with the nature of *colour*, and with the method of permanently changing the colour of bodies. Theſe three things we ſhall conſider in the three following chapters. In the firſt, we ſhall give an account of the ſubſtances of which garments are uſually made, with which alone the art of dyeing is concerned; in the ſecond, we ſhall inquire into the nature of colour; and in the third, explain the theory of dyeing, as far as it is at preſent underſtood. In ſome ſubſequent chapters, we ſhall give a general view of the proceſſes by which the different colours are given to ſtuffs.

CHAP. I. OF THE SUBSTANCES USED FOR CLOTHING.

381 Clothing

THE ſubſtances commonly employed for clothing may be reduced to four; namely *wool*, *ſilk*, *cotton*, *linen*. As there is no name in the Engliſh language which includes all theſe ſubſtances, we ſhall take the liberty, in the remainder of this article, to uſe the word *cloth* for that purpoſe. They are all made into *cloth*, of ſome kind or other, before they can be uſeful as articles of *clothing*.

382 Conſiſts of wool,

1. WOOL, as is well known, is the hair which covers the bodies of ſheep; it differs from common *hair* merely in fineneſs and ſoftneſs. Its filaments poſſeſs a conſiderable degree of elaſticity; they may be drawn out beyond their uſual length, and afterwards recover their form when the external force is removed. The ſurface of wool and hair is by no means ſmooth: No inequality, indeed, can be perceived by a microſcope; nor is any reſiſtance felt when a hair is laid hold of in one hand, and drawn between the fingers of the other, from the *root* towards the *point*; but if it be drawn from the *point* towards the *root*, a reſiſtance is felt which did not take place before, a tremulous motion is perceived, and a noiſe may be diſtinguiſhed by the ear. If, after laying hold of a hair between the thumb and fore finger, we rub them againſt each other in the longitudinal direction of the hair, it acquires a progreſſive motion *towards the root*; the *point* gradually approaches the fingers, while the *root* recedes from them; ſo that the whole hair very ſoon paſſes through between the fingers.

Theſe obſervations, firſt made by Mr Monge, demonſtrate that the ſurface of hair and wool is compoſed, either of ſmall laminæ, placed over each other in a ſlanting direction from the root towards the point, like the ſcales of a fiſh—or of zones, placed one above another, as takes place in the horns of animals *.

On this ſtructure of the filaments of hair and wool depend the effects of *felting* and *fulling*. In both of theſe operations, the filaments are made, by an external force, to rub againſt each other; the poſition of their aſperities prevents them from moving, except in one direction: they are mutually entangled, and obliged to approach nearer each other. Hence the thickneſs which cloth acquires in the fulling mill. The filaments have undergone a certain degree of felting, and are interwoven like the fibres of a hat. The cloth is contracted both in length and breadth: it may be cut without being ſubject to ravel; nor is there any neceſſity for hemming the different pieces employed to make a garment. See FELTING and FULLING, in this *Suppl.*

Wool is naturally covered with a kind of greaſe, which preſerves it from moths. This is always removed before the wool is dyed; becauſe its preſence is very prejudicial to the ſucceſs of that operation. The aſperities of the ſurface of woolly fibres would impede the converting of it into thread by ſpinning; but they are in a great meaſure covered, previous to that operation, by ſoaking the wool with oil. The oil muſt alſo be removed before the wool be dyed. This proceſs is called SCOURING, which ſee in this *Suppl.*

We have already, in the ſecond part of this article, given an account of what is at preſent known concerning the compoſition of wool and hair. It would be foreign to the ſubject of this chapter, to deſcribe the method of *ſpinning* and *weaving* wool.

Wool is of different colours; but that which is white is preferred for making cloth; becauſe it anſwers better for the purpoſes of dying than any other kind.

383 Silk,

2. SILK is a ſubſtance ſpun in fine threads by the *ſilk worm*. Its fibres are not ſcaly like thoſe of wool; neither have they the ſame elaſticity: but ſilk, in its natural ſtate, before it has undergone any preparation, has a conſiderable degree of ſtiffneſs and elaſticity. In this ſtate it is known by the name of *raw ſilk*. It is covered with a kind of gummy varniſh, which may be removed by ſcouring with ſoap. The ſcouring deprives it of its ſtiffneſs and elaſticity. Raw ſilk is of a yellow colour, owing to yellow reſinous matter with which it is naturally combined. We have given the method of ſeparating this matter, and alſo the gum, in the article BLEACHING, *Supplement*.

Silk, before it is dyed, is always freed from its gum, and generally alſo from its reſin. It may be dyed without

---

* *Ann. de Chim.* vi. 300.

out the application of heat ; which is not the caſe with wool.

3. COTTON is a fine downy ſubſtance, contained in the pods of different ſpecies of goſſypium. The ſpecies from which the greater part of the cotton brought to this country is taken is the *herbaceum*. The quantity imported annually into Britain is very great ; in 1786 it amounted to 20 millions of pounds ‡. Cotton varies greatly, according to the plant on which it grows, and the climate where it is cultivated. The chief differences are in colour, and in the length, fineneſs, and ſtrength of the filaments.

No aſperities can be diſcovered on the ſurface of theſe filaments ; but Lewenhoeck obſerved, by means of a microſcope, that they are triangular, and have three ſharp edges. This is probably the reaſon of a well known fact, that cotton cloth, when applied by way of dreſſing, always irritates a ſore.

Some cottons are naturally white ; others a fine light yellow, as thoſe of which nankeen is made ; but moſt commonly cotton is of a dirty browniſh yellow colour, which muſt be removed before the ſtuff can be dyed. This is done by the proceſs of *bleaching*. The fibres of cotton, even after being bleached, retain almoſt always ſome lime and oxyd of iron, which muſt be removed before we attempt to dye the cotton ; becauſe their preſence would ſpoil the colour. This is done by ſteeping the cotton for ſome time in water acidulated with ſulphuric acid.

Cotton, like ſilk, may be dyed without the aſſiſtance of heat. It is not nearly ſo eaſy to dye cotton any particular colour as it is to dye wool or ſilk. If wool and cotton be put into the ſame dyeing veſſel, the wool frequently acquires the wiſhed-for colour before the cotton has loſt any of its original whiteneſs.

4. LINT, from which *linen* is made, is the inner bark of the *linum uſſitatiſſimum*, or *flax* ; a plant too well known in this country to require any deſcription.

The flax, when ripe, is pulled and ſteeped for ſome days in water, in order to ſeparate the green coloured glutinous matter which adheres to the inner bark. This matter undergoes a degree of putrefaction ; carbonic acid gas and hydrogen gas, are diſengaged * : it is decompoſed, and carried off by the water. If the water, in which the flax is ſteeped, be completely ſtagnant, the putrefaction is apt to go too far, and to injure the fibres of the lint ; but in a running ſtream, it does not go far enough, ſo that the green matter ſtill continues to adhere to the lint. Flax, therefore, ſhould be ſteeped in water neither completely ſtagnant, nor flowing too freely, like a running ſtream.

The flax is afterwards ſpread upon the graſs, and expoſed for ſome time to the air and ſun : this improves the colour of the lint, and renders the woody part ſo brittle, that it is eaſily ſeparated by the action of the lint mill. The ſubſequent operations, of *dreſſing*, *ſpinning*, *weaving*, and *bleaching*, do not belong to this article.

The fibres of lint have very little elaſticity. They appear to be quite ſmooth ; for no aſperities can be perceived by the microſcope, nor detected by the feel ; nor does linen irritate ſores, as is the caſe with cotton.

Linen may be dyed without the aſſiſtance of heat ; but it is more difficult to give it permanent colours than even cotton.

Thus we have given a ſhort deſcription of wool, ſilk, cotton, and linen. The firſt two are animal ſubſtances ; the two laſt vegetable. The animal contain much azot and hydrogen ; the vegetable much carbon : The animal are readily deſtroyed by acids and alkalies ; the vegetable withſtand the action of theſe ſubſtances better ; even nitric acid does not readily deſtroy the texture of cotton. The animal ſubſtances are more eaſily dyed than the vegetable, and the colours which they receive are more permanent than thoſe given to cotton and linen by the ſame proceſſes.

Such are the properties of the cloths on which the art of dyeing is exercited. But what is the nature of theſe *colours* which it is the object of that art to communicate ? We ſhall examine this ſubject in the following chapter.

CHAP. II. OF COLOURS.

Colours.

ALL viſible objects, as has been long ago ſufficiently eſtabliſhed, are ſeen by means of rays of light paſſing off from them in all directions, and partly entering the eye of the ſpectator.

386 Colour produced by light.

1. For the theory of light and viſion we are indebted to Sir Iſaac Newton. He firſt demonſtrated, that light is compoſed of ſeven rays, differing from each other in refrangibility, and other properties. Each of theſe rays is diſtinguiſhed by its particular colour. Hence their names, red, orange, yellow, green, blue, indigo, violet. By mixing together theſe different rays, in various proportions, all the colours known may be obtained. Thus red and yellow conſtitute orange ; yellow and blue conſtitute green ; blue and red conſtitute purple, violate, aurora, &c. according to their proportions. When all the rays are mixed together, they form a white.

387 Bodies reflect different rays.

2. Bodies differ very much from each other in their power of reflecting light. Some reflect it in vaſt quantity, as metals ; others reflect but little, as charcoal. In general, the ſmoother the ſurface of a body is, the greater is the quantity of light which it reflects. Hence the effect of poliſhing in increaſing the brightneſs of bodies. But it is not in the quantity of the light reflected alone that bodies differ from each other ; they differ alſo in the quality of the light which they reflect. Some bodies reflect one or more particular ſpecies of ray to the excluſion of the reſt. This is the reaſon that they appear to us of different colours. Thoſe bodies which reflect only red rays are red ; thoſe that reflect yellow rays are yellow ; thoſe that reflect all the rays equally are white ; thoſe that reflect too little to affect the eye are black. It is to the different combinations of rays reflected from the ſurface of bodies that all the different ſhades of colour are owing.

388 Hence their different colours.

Colour, then, in *opaque* bodies, is owing to their diſpoſition to *reflect* certain rays of light, and to *abſorb* the reſt ; in *tranſparent* bodies, to their diſpoſition to *tranſmit* certain rays, and to *abſorb* the others. But this ſubject has been diſcuſſed, at ſufficient length, in the article OPTICS, *Encycl.* ; to which, therefore, we beg leave to refer the reader. Here we mean only to inquire into the *cauſe* of this diſpoſition of the particles of bodies.

389 Newtonian theory to explain this difference.

3. Sir Iſaac Newton, to whom we are indebted for the exiſtence of optics as a ſcience, made a ſet of experiments to aſcertain the changes of colour which thin plates of matter aſſume in conſequence of an increaſe or dimi-

diminution of their thickneſs. Theſe experiments were of a very delicate nature; but Newton conducted them with ſo much addreſs, and varied and repeated them with ſo much induſtry, that he was enabled to render them ſurpriſingly accurate

Upon a large double convex lens of a 50 feet focus, he placed the plane ſurface of a planoconvex lens, and preſſed the lenſes ſlowly together. A circle, of a particular colour, appeared in the centre, where the two glaſſes touched each other. This circle gradually increaſed in diameter as the preſſure was augmented; and at laſt a new circle, of another colour, occupied the centre, while the firſt colour aſſumed the form of a circular ring. By increaſing the preſſure, a new coloured circle appeared in the centre, and the diameter of the other two increaſed. In this manner he proceeded, till he produced no leſs than 25 different coloured circular rings. Theſe he divided into ſeven orders, on account of the repetition of the ſame colour. They were as follows, reckoning from the central colour, which was always black *.

1. Black, blue, white, yellow, red.
2. Violet, blue, green, yellow, red.
3. Purple, blue, green, yellow, red
4. Green, red.
5. Greeniſh blue, red.
6. Greeniſh blue, pale red.
7. Greeniſh blne, reddiſh white.

Theſe different colours were occaſioned by the thin film of air between the two glaſſes. Now this film varies in thickneſs from the centre of the lens towards the circumference; that part of it which cauſes the black colour is thinneſt, and the other coloured circles are occaſioned by air gradually increaſing in thickneſs. Newton meaſured the *relative thickneſs* of the air which produced each of theſe coloured circles; and he found it as follows †:

1.	Black	1
	blue	$2\frac{2}{5}$
	white	$5\frac{1}{4}$
	yellow	$7\frac{1}{6}$
	red	$8\frac{1}{2}$
2.	Violet	$11\frac{1}{6}$
	blue	14
	green	$15\frac{1}{8}$
	yellow	$16\frac{2}{7}$
	red	$18\frac{1}{3}$
3.	Purple	21
	blue	$23\frac{2}{3}$
	green	$25\frac{1}{5}$
	yellow	$27\frac{1}{7}$
	red	31
4.	Green	35
	red	$40\frac{1}{3}$
5.	Gr. blue	46
	red	$52\frac{1}{2}$
6.	Gr. blue	$58\frac{3}{4}$
	red	65
7.	Gr. blue	71
	reddiſh white	77

The *abſolute* thickneſs of theſe films cannot be aſcertained, unleſs the diſtance between the two glaſſes, at that part where the black ſpot appears, were known. Now there is no method of meaſuring this diſtance; but it certainly is not greater than the thouſandth part of an inch.

He repeated theſe experiments with films of water, and even of glaſs, inſtead of air; and he found, that in theſe caſes the thickneſs of the films, reflecting any particular colour, was diminiſhed, and that this diminution was proportional to the denſity of the reflecting film.

From theſe experiments Sir Iſaac Newton concluded, that the diſpoſition of the particles of bodies to reflect or tranſmit particular rays depended upon their ſize and their denſity: and he even attempted to aſcertain the ſize, or at leaſt the thickneſs, of the particles of bodies from their colours. Thus a particle of matter, whoſe denſity is the ſame with that of glaſs which reflects a green of the third order, is of the thickneſs of $\frac{16\frac{1}{4}}{1000000}$ of an inch *.

In the year 1765, Mr Delaval publiſhed, in the Philoſophical Tranſactions, a very ingenious paper on the ſame ſubject. In this paper, he endeavours to prove, by experiment, that the colours of metallic bodies depend upon their denſity. He takes it for granted, at the ſame time, that the ſize of the particles of bodies is inverſely as the denſity of bodies. The denſeſt bodies, according to him, are red; the next in denſity, orange; the next, yellow; and ſo on, in the order of the refrangibility of the different rays. Some time after, the ſame ingenious gentleman, in his *Experimental Inquiry into the Cauſe of the Permanent Colours of Opaque Bodies*, extended his views to animal and vegetable ſubſtances, and endeavoured to prove the truth of Newton's theory by a very great number of experiments.

Such is a view of the opinion of Newton and Delaval reſpecting the cauſe of bodies reflecting or tranſmitting particular rays of light, as far, at leaſt, as that theory relates to colour. They aſcribed this cauſe *ſolely* to the *ſize* and the *denſity* of the particles of bodies.

By *particles*, it is evident that nothing elſe can be meant than the *integrant particles* of bodies. Newton, indeed, does not expreſs himſelf preciſely in this language; but it is plain that nothing elſe could be his meaning. Mr Delaval undoubtedly is of that opinion.

According to the Newtonian theory of colour, then, it depends ſolely upon the *ſize* of the integrant particles of bodies whoſe denſity is the ſame; and upon the *ſize* and the *denſity* jointly of all bodies (T).

390 Examin

It is evident that the truth of the Newtonian theory muſt depend upon its coincidence with what actually takes place in nature, and that therefore it can only be determined by experiment. Newton himſelf produced but very few experiments in ſupport of it; and though this deficiency was amply ſupplied by Mr Delaval, it is needleſs for us to adduce any of theſe here; becauſe, from the prodigious accumulation of chemical facts ſince theſe experiments were made, the very baſis upon which they ſtood has been deſtroyed, and conſequently all the evidence reſulting from them has been annihilated. They proceeded on the ſuppoſition, that acids render the particles of bodies *ſmaller*, and alkalies *larger* than they were before, without producing any other change whatever in the bodies on which they act. To attempt a refutation of this opinion at preſent would be unneceſſary, as it is well known not to be true.

Let us therefore compare the Newtonian theory of colour with thoſe chemical changes which we know for certain to alter the ſize of the particles of bodies, in order to ſee whether they coincide with it. If the theory be true, the two following conſequences muſt hold

---

* *Newton's Optics*, 191. Clarke's edition.

† *Ibid.* p. 225.

* *Newt* *Optics*, 2

(T) Newton, however, pointed ont an exception to this law, concerning which Mr Delaval has been more explicit. Combuſtible bodies do not follow that law, but ſome other. Mr Delaval has ſuppoſed, that this deviation is owing to the preſence of phlogiſton.

hold in all caſes: 1. Every alteration in the ſize of the integrant particles of bodies muſt cauſe theſe particles to aſſume a different colour. 2. Every ſuch alteration muſt correſpond preciſely with the theory; that is to ſay, the new colour muſt be the very colour, and no other, which the theory makes to reſult from an increaſe or diminution of ſize.

Argument deciſive.

Now neither of theſe conſequences holds in fact. We have no method indeed of aſcertaining the ſizes of the integrant particles of bodies, nor of meaſuring the preciſe degree of augmentation or diminution which they ſuffer; but we can in many caſes aſcertain, whether any new matter has been added to a particle, or any matter abſtracted from it; and conſequently whether it has been augmented or diminiſhed; which is ſufficient for our preſent purpoſe.

For inſtance, whatever be the ſize of an integrant particle of gold, it cannot be denied that an integrant particle of oxyd of gold is greater; becauſe it contains an integrant particle of gold combined with at leaſt one integrant particle of oxygen. Now the colour both of gold and of its oxyd is yellow, which ought not to be the caſe, according to the Newtonian theory. In like manner, the amalgam of ſilver is white, preciſely the colour of ſilver and of mercury; yet an integrant particle of the amalgam muſt be larger than an integrant particle either of ſilver or of mercury. Many other inſtances beſides theſe will occur to every one, of changes in the ſize of the particles taking place without any change of colour. All theſe are incompatible with the Newtonian theory.

It may be ſaid, perhaps, in anſwer to this objection, that there are different orders of colours; that the ſame colour is reflected by particles of different ſizes; and that the increaſed particles, in the inſtances above alluded to, retain their former colour, becauſe the increment has been preciſely ſuch as to enable them to reflect the ſame colour in the next higher order.

This very anſwer is a complete proof that the Newtonian theory is not ſufficient to account for the colours of bodies; for if particles of *different* ſizes reflect the ſame colour, *ſize* certainly is not the only cauſe of this reflection*. There muſt be ſome other cauſe very different from ſize. Nor is this all; the moſt common colour which remains after an increaſe of the ſize of the integrant particles of bodies is white; yet white does not appear in any of the orders except the firſt, and therefore its permanence cannot be accounted for by any ſuppoſition compatible with the Newtonian theory.

Even when alterations in the colour of bodies accompany the increaſe or diminution of the ſize of their particles, theſe alterations ſeldom or never follow an order which correſponds with the theory. As for metals, it is ſelf-evident that their colour does not depend upon their denſity. Platinum is the denſeſt body known, and yet it is not red, as it ought to be, but white like tin; a metal which has little more than one third of the denſity of platinum.

The green oxyd of iron, when combined with pruſſic acid, becomes white; yet the ſize of its particles muſt be increaſed. Now this change of colour is incompatible with the theory; for, according to it, every change from green to white ought to be accompanied by a diminution inſtead of an increaſe of ſize. A particle of indigo, which is naturally green, becomes blue by the addition of oxygen, which muſt increaſe its ſize. This change is alſo incompatible with the theory. But it is unneceſſary to accumulate inſtances, as they will naturally occur in ſufficient number to every one.

It follows irreſiſtibly from theſe facts, that the Newtonian theory is not ſufficient to explain the *cauſe* of colour; or what cauſes bodies to reflect or tranſmit certain rays, and to abſorb the reſt.

392
Bodies owe their colour to their affinity for light.

4. We have endeavoured, in the article CHEMISTRY, *Suppl.* to ſhew, that bodies have a particular affinity for the rays of light; and that the phenomena of light depend entirely upon theſe affinities. Indeed this conſequence follows from the properties of light eſtabliſhed by Newton himſelf. We ſhall not repeat here the proofs upon which the exiſtence of theſe affinities is founded: the reader may eaſily ſatisfy himſelf by conſulting the article above referred to.

Every coloured body, then, has a certain *affinity for* ſome of the rays of light. Thoſe rays for which it has a ſtrong affinity are abſorbed by it and retained, and the other rays for which it has no affinity are either reflected or tranſmitted, according to the nature of the body and the direction of the incident ray. Thus a red body has an affinity for all the rays except the red; it abſorbs therefore the other ſix, and reflects only the red: a green body abſorbs all but the green rays, or perhaps the red and yellow: a black body has a ſtrong affinity for all the rays, and therefore abſorbs them all: while a white body, having no ſtrong affinity for any of the rays, reflects or tranſmits them all.

If affinity, as we have endeavoured to ſhew in the article CHEMISTRY, *Suppl.* be an attraction of the ſame nature with gravitation, and increaſing as the diſtance diminiſhes, it muſt depend upon the nature of the attracting particles. Now the only differences which we can conceive to exiſt between the particles of bodies, are differences in *ſize*, in *denſity*, and in *figure*. Changes in theſe three things will account for all the varieties of affinity. Now if affinity depends upon theſe three things, and if colour depends upon the affinity between the particles of bodies and the different rays of light as cannot be denied, it is clear that the cauſe of the colour of bodies may be ultimately reſolved into the ſize, denſity, and figure, of their particles. Newton's theory, then, was defective, becauſe he omitted the *figure* of the particles, and aſcribed the whole to variations in *ſize* and *denſity*.

When we ſay, then, that colour is owing to *affinity*, we do not contradict the opinion of Newton, as ſome philoſophers have ſuppoſed, but merely extend it: Newton was *not miſtaken* in ſaying, that colour depends upon the ſize and the denſity of the particles of bodies; his miſtake lay in ſuppoſing that it depends upon theſe *alone*.

393
Why bodies change their colour.

5. Since the colour of bodies depends upon their affinity for light, and ſince every body has a certain colour, becauſe it abſorbs and retains particular rays while it tranſmits or reflects the reſt, it is evident that every body muſt continue of its firſt colour till one of two things happen; either till it be ſaturated with the rays which it abſorbs, and of courſe ceaſe to abſorb any more, or till its particles change their nature, by being either decompoſed or combined with ſome new ſubſtance. We have no poſitive proof that the firſt cauſe

---

* Bancroft Perma. Colours,

cauſe of change ever occurs, as many ſubſtances have been expoſed to the action of light for a very long time without any change of colour. The abſorbed light ſeems to make its eſcape, either in its own form, or in ſome unknown or unſuſpected one. The ſecond cauſe of change is very common: indeed its action may be detected in almoſt every caſe of alteration in the colour of bodies. The green oxyd of iron, by combining with oxygen, becomes red; and this red oxyd, when combined with pruſſic acid, aſſumes a blue colour, and with gallic acid a black colour. The cauſe of this change of colour, when the compoſition of a body changes, is obvious: every change of compoſition muſt alter the affinity, becauſe it muſt of neceſſity produce changes in the ſize, denſity, or figure of the particles, or perhaps in all of theſe. Now if the affinity of a body for other bodies be altered, it is natural to ſuppoſe that it will be altered alſo for light. Accordingly this happens in moſt inſtances. It does not, however, take place conſtantly, for very obvious reaſons. It may happen that the new denſity, ſize, or figure of the altered body is ſuch, as to render it ſtill proper for attracting the very ſame rays of light which it formerly attracted. Juſt as iron, after being combined with a certain doſe of oxygen, is converted into green oxyd, which ſtill retains an affinity for oxygen.

It is evident from all this, that in moſt caſes the permanence of colour in bodies will depend upon the permanence of their compoſition, or on the degree of facility with which they are acted upon by thoſe bodies, to the agency of which they are expoſed.

394 Permanency of colour of great importance in *dyeing*.

In *dyeing*, the permanence of colour is of very great importance. Of what value is the beauty of a colour, provided that colour be fugitive or liable to change into ſome other. In all caſes, therefore, it is of conſequence to attend to the ſubſtances to which dyed cloth is expoſed, and to aſcertain their action upon every particular dyeing ingredient. Now the bodies to which dyed cloth is almoſt conſtantly expoſed are *air* and *light*; the combined action of which has ſo much influence, that very few dyes can reſiſt it.

395 How dyes loſe their colour.

It is evident that thoſe ſubſtances which have a ſtrong affinity for oxygen cannot retain their colour, provided they be able to take it from atmoſpheric air. Thus the green colour of green oxyd of iron and of indigo is not permanent, becauſe theſe ſubſtances readily abſorb oxygen from air. In order, then, that a colour can have any permanence, the coloured body muſt not have ſo great an affinity for oxygen as to be able to take it from air. Thoſe bodies have in general the moſt permanent colours which are already ſaturated with oxygen, and therefore not liable to abſorb more. Such is the caſe with red oxyd of iron.

All coloured bodies are compounds; ſome of thoſe only excepted which ſtill retain an affinity for oxygen. Coloured bodies, therefore, are compoſed of ſeveral ingredients; and in every coloured body, at leaſt *ſome* of the ingredients have a ſtrong affinity for oxygen. Now, before the colour of a body can be permanent, its ingredients muſt be combined together by ſo ſtrong affinities, that oxygen gas is unable to decompoſe it by combining with one or more of its ingredients and carrying it off. If this decompoſition take place at once, it is impoſſible for the colour of a body to have any permanence. If it takes place ſlowly, the colour of the body gradually decays. The action of oxygen gas upon bodies is much increaſed in particular circumſtances. Almoſt all coloured bodies are decompoſed by oxygen gas by the aſſiſtance of heat. Thus if wheat flour be expoſed to the heat of 448°, it loſes its white colour, and becomes firſt brown and then black. At this temperature it is decompoſed, and a part, or even the whole of its hydrogen, combining with oxygen, flies off. Cloth is ſcarcely ever expoſed to ſo high a temperature; but there are other circumſtances in which it may be placed which may have a ſimilar effect. Thus the action of light ſeems in ſome ſubſtances to be ſimilar to that of heat, and to facilitate the decompoſition of the coloured matter by the combination of ſome of its ingredients with oxygen *.

Coloured bodies, in order to have permanent colours, muſt not be liable to be decompoſed by other ſubſtances more than by oxygen. For inſtance, if they contain oxygen and hydrogen, theſe two bodies muſt not be liable to combine together and form water, nor muſt oxygen and carbon be liable to combine and form carbonic acid gas. Light ſeems to have a tendency to decompoſe many bodies in this manner, and even to carry off oxygen from them in the form of oxygen gas. Thus it renders the nitrat of ſilver black by carrying off part of its oxygen, and it reduces oxy-muriatic acid to common muriatic acid by the ſame means.

Theſe are the cauſes which induce a change in the colour of coloured bodies, as far as they have been traced; namely, the addition of oxygen, the abſtraction of oxygen, partial decompoſition by ſome one of their ingredients combining with oxygen, complete or partial decompoſition by the ingredients entering into new combinations with each other. The coloured matters uſed in dyeing are very liable to theſe changes, becauſe they are in general animal or vegetable ſubſtances of a very compound nature. Of courſe their ingredients have often no very ſtrong affinity for each other, and therefore are very liable to decompoſition; and every one of the ingredients has in general a very ſtrong affinity for oxygen. This renders the choice of proper colouring matters for dyeing a very important point. In order to have permanency, they muſt not be liable to the above changes, not to mention their being able alſo to withſtand the action of ſoap, acids, alkalies, and every other ſubſtance to which dyed cloth may be expoſed.

396 Metho aſcertai ing the manen dyes.

It becomes therefore a point of ſome conſequence to be able to aſcertain whether cloth dyed of any particular colour be permanently dyed or not. The proper method of aſcertaining this is by actually expoſing ſuch cloth to the ſun and air; becauſe as theſe are the agents to which it is to be expoſed, and which have the moſt powerful action, it is clear, that if it withſtand them, the colour muſt be conſidered as permanent. But this is a tedious proceſs. Berthollet propoſed expoſing ſuch cloth to the action of oxy-muriatic acid; thoſe colours that withſtand it being conſidered as permanent. This method anſwers in many caſes: but it is not always to be depended on; for it deſtroys ſome permanent colours very ſpeedily, and does not alter others which are very fading *. But we ſhall have occaſion to reſume this ſubject afterwards.

397 Divi colour

Dyers divide colours into two claſſes; namely, *ſimple* and *compound*. The ſimple colours are thoſe which cannot

---

* Bertho on Dyein i. 45.

* Ban i. 49.

Dyeing in General.

cannot be produced by the mixture of other colours. They are in number four.

1. Blue, 3. Red,
2. Yellow, 4. Black.

Some add a fiſth, *brown;* but it may be produced by combining two others.

The compound colours are thoſe which are produced by mixing together any two ſimple colours in various proportions. They conſtitute all the colours except the four ſimple and their various ſhades.

Thus we have examined the nature of colours; but we have ſtill to explain the method of giving permanent colours to cloth. This ſhall be the ſubject of the next chapter.

CHAP. III. OF DYEING IN GENERAL.

FROM the theory of colour laid down in the laſt chapter, it follows, that permanent alterations in the colour of cloth can only be induced two ways; either by producing a chemical change in the cloth, or by covering its fibres with ſome ſubſtance which poſſeſſes the wiſhed for colour. Recourſe can ſeldom or never be had to the firſt method, becauſe it is hardly poſſible to produce a chemical change in the fibres of cloth without ſpoiling its texture and rendering it uſeleſs. The dyer, therefore, when he wiſhes to give a new colour to cloth, has always recourſe to the ſecond method.

98 1. The ſubſtances employed for this purpoſe are called *colouring matters*, or *dye ſtuffs*. They are for the moſt part extracted from *animal and vegetable ſubſtances*, and have uſually the colour which they are intended to give to the cloth. Thus a blue colour is given to cloth by covering its fibres with indigo, a blue powder extracted from a ſhrub; a red colour, by the colouring matter extracted by water from an inſect called *cochineal*, or from the root of a plant called *madder.*

99 2. Mr Delaval has publiſhed a very intereſting ſet of experiments on colouring matters in the ſecond volume of the Mancheſter Memoirs. He has proved, by a very numerous ſet of experiments, that they are all tranſparent, and that they do not *reflect* any light, but only tranſmit it: For every colouring matter which he tried, even when diſſolved in a liquid, and forming a tranſparent coloured ſolution, when ſeen merely by reflected light, was black, whatever was the colour of the matter; but when ſeen by tranſmitted light, it appeared of its natural colour *. This diſcovery, which Mr Delaval has eſtabliſhed very completely, and to which, as far at leaſt as dye ſtuffs are concerned, there are but few exceptions, is of very great importance to the art of dyeing, and explains ſeveral particulars which would otherwiſe be unintelligible.

Since the particles of the colouring matter with which cloth, when dyed, is covered, are tranſparent, it follows, that all the light reflected from dyed cloth muſt be reflected, not by the dye ſtuff itſelf, but by the fibres of the cloth below the dye ſtuff. The colour therefore does not depend upon the dye alone, but alſo upon the previous colour of the cloth. If the cloth be *black*, it is clear that we cannot dye it any colour whatever; becauſe as no light in that caſe is reflected, none can be tranſmitted, whatever dye ſtuff we employ. If the cloth were red, or blue, or yellow, we could not dye it any colour except black; becauſe as only red, or blue, or yellow rays were reflected, no other could be tranſmitted (x). Hence the importance of a fine white colour when cloth is to receive bright dyes: It then reflects all the rays in abundance; and therefore any colour may be given, by covering it with a dye ſtuff which tranſmits only ſome particular rays.

400 They muſt be combined with the cloth.

3. If the colouring matters were merely ſpread over the ſurface of the fibre of cloth by the dyer, the colours produced might be very bright, but they could not be permanent; becauſe the colouring matter would be very ſoon rubbed off, and would totally diſappear whenever the cloth was waſhed, or even barely expoſed to the weather. The colouring matter, then, however perfect a colour it poſſeſſes, is of no value, unleſs it alſo adheres ſo firmly to the cloth, that none of the ſubſtances uſually applied to cloth in order to clean it, &c. can diſplace it. Now this can only happen when there is a ſtrong *affinity* between the colouring matter and the cloth, and when they are actually combined together in conſequence of that affinity.

401 Can only be applied in a ſtate of ſolution.

4. Dyeing, then, is merely a chemical proceſs, and conſiſts in combining a certain colouring matter with the fibres of cloth. This proceſs can in no inſtance be performed, unleſs the dye ſtuff be firſt reduced to its integrant particles; for the attraction of aggregation between the particles of dye ſtuffs is too great to be overcome by the affinity between them and cloth, unleſs they could be brought within much ſmaller diſtances than is poſſible, while they both remain in a ſolid form. It is neceſſary, therefore, previouſly to diſſolve the colouring matter in ſome liquid or other, which has a weaker affinity for it than the cloth has. When the cloth is dipped into this ſolution, the colouring matter, reduced by this contrivance to a liquid ſtate, is brought within the attracting diſtance; the cloth therefore acts upon it, and by its ſtronger affinity takes it from the ſolvent, and fixes it upon itſelf. By this contrivance, too, the equality of the colour is in ſome meaſure ſecured, as every part of the cloth has an opportunity of attracting to itſelf the proper proportion of colouring particles.

The facility with which cloth imbibes a dye, depends upon two things, namely, the affinity between the cloth and the dye ſtuff, and the affinity between the dye ſtuff and its ſolvent. It is directly as the former, and inverſely as the latter. It is of importance to preſerve a due proportion between theſe two affinities, as upon that proportion much of the accuracy of dyeing depends. If the affinity between the colouring matter and the cloth be too great, compared with the affinity between the colouring matter and the ſolvent, the cloth will take the dye too rapidly, and it will be ſcarce poſſible to prevent its colour from being unequal. On the other hand, if the affinity between the colouring matter and the ſolvent be too great, compared with

---

(x) Theſe remarks hold only on the ſuppoſition, that the *whole* of the ſurface is of the given colour, which in many inſtances is not the caſe.

that between the colouring matter and the cloth, the cloth will either not take the colour at all, or it will take it very ſlowly and very faintly.

Wool has the ſtrongeſt affinity for almoſt all colouring matters, ſilk the next ſtrongeſt, cotton a conſiderably weaker affinity, and linen the weakeſt affinity of all. Therefore, in order to dye cotton or linen, the dye ſtuff ſhould in many caſes be diſſolved in a ſubſtance for which it has a weaker affinity than for the ſolvent employed in the dyeing of wool or ſilk. Thus we may uſe oxyd of iron diſſolved in ſulphuric acid, in order to dye wool; but for cotton and linen, it is better to diſſolve it in acetous acid.

402
Nature of mordants.

5. Were it poſſible to procure a ſufficient number of colouring matters having a ſtrong affinity for cloth, to anſwer all the purpoſes of dyeing, that art would be exceedingly ſimple and eaſy. But this is by no means the caſe: if we except indigo, the dyer is ſcarcely poſſeſſed of a dye ſtuff which yields of itſelf a good colour ſufficiently permanent to deſerve the name of a dye.

This difficulty, which at firſt ſight appears inſurmountable, has been obviated by a very ingenious contrivance. Some ſubſtance is pitched upon which has a ſtrong affinity both for the cloth and the colouring matter. This ſubſtance is previouſly combined with the cloth, which is then dipped into the ſolution containing the dye ſtuff. The dye ſtuff combines with the intermediate ſubſtance; which, being firmly combined with the cloth, ſecures the permanence of the dye. Subſtances employed for this purpoſe are denominated *mordants* (y).

The moſt important part of dyeing is undoubtedly the proper choice and the proper application of mordants, as upon them the permanency of almoſt every dye depends. Every thing which has been ſaid reſpecting the application of colouring matters, applies equally to the application of mordants. They muſt be previouſly diſſolved in ſome liquid, which has a weaker affinity for them than the cloth has to which they are to be applied; and the cloth muſt be dipped, or even ſteeped, in this ſolution, in order to ſaturate itſelf with the mordant.

Almoſt the only ſubſtances uſed as mordants are, earths, metallic oxyds, tan, and oil.

403
Earthy mordants.

6. Of earthy mordants, by far the moſt important and moſt generally uſed is alumina. It was uſed as a mordant in very early ages, and ſeems indeed to have been the very firſt ſubſtance employed for that purpoſe. Alumina has a very ſtrong affinity for wool and for ſilk; but its affinity for cotton and linen is a good deal weaker.

It is uſed as a mordant in two ſtates; either in the ſtate of alum, in which it is combined with ſulphuric acid and a little potaſs; or in the ſtate of acetite of alumina, in which it is combined with acetous acid.

Alum was employed as a mordant very early. The ancients, indeed, do not ſeem to have been generally acquainted with pure alum; they uſed it in that ſtate of impurity in which it is found native; of courſe it was uſed in dyeing long before the nature of its ingredients was underſtood, and therefore long before the part which it acts was ſuſpected. Indeed, it is but a very ſhort time ſince the office which mordants perform was ſuſpected: the firſt perſon that hit upon it was Mr Keir; he gave an account of the real uſe of mordants in his tranſlation of Macquer's Dictionary, publiſhed in 1771*.

* Macqu
p. 215.

Alum, when uſed as a mordant, is diſſolved in water, and very frequently a quantity of tartar is diſſolved along with it. Into this ſolution the cloth is put and kept in it till it has abſorbed as much alumina as is neceſſary. It is then taken out, and for the moſt part waſhed and dried. It is now a good deal heavier than it was before, owing to the alumina which has combined with it. The tartar ſerves two purpoſes: the potaſs which it contains combines with the ſulphuric acid of the alum, and thus prevents that very corroſive ſubſtance from injuring the texture of the cloth, which otherwiſe might happen; the tartarous acid, on the other hand, combines with part of the alumina, and forms a tartrite of alumina, which is more eaſily decompoſed by the cloth than alum.

Acetite of alumina has been introduced into dyeing ſince the commencement of the 18th century; and, like many other very important improvements, we are indebted for it to the ignorance of the calico printers, who firſt introduced it. As they did not underſtand the nature nor uſe of the mordants which they employed, they were accuſtomed to mix with their alum an immenſe farrago of ſubſtances, a great proportion of which were injurious inſtead of being of ſervice. Some one or other had mixed with alum acetite of lead: the good effects of this mixture would be ſoon perceived; the quantity of acetite was gradually increaſed, and the other ingredients omitted*. This mordant is now prepared, by pouring acetite of lead into a ſolution of alum: a double decompoſition takes place, the ſulphuric acid combines with the lead, and the compound precipitates in the form of an inſoluble powder; while the alumina combines with the acetous acid, and remains diſſolved in the liquid. This mordant is employed for cotton and linen, which have a weaker affinity than wool for alumina. It anſwers much better than alum, the cloth is more eaſily ſaturated with alumina, and takes, in conſequence, both a richer and a more permanent colour.

* Banc
p. 170.

Beſides alumina, *lime* is ſometimes uſed as a mordant. Cloth has a ſtrong enough affinity for it; but in general it does not anſwer ſo well, as it does not give ſo good a colour. When uſed, it is either in the ſtate of lime-water or of ſulphat of lime diſſolved in water.

40
Metall
morda

7. Almoſt all the metallic oxyds have an affinity for cloth; but only two of them are extenſively uſed as mordants, namely, the oxyds of tin and of iron.

The oxyd of tin was firſt introduced into dyeing by Kuſter (z), a German chemiſt, who brought the ſecret to London in 1543. This period forms an era in the hiſtory of dyeing. The oxyd of tin has enabled the moderns

---

(y) This term, impoſed by the French dyers before the action of mordants was underſtood, ſignifies *biters* or *corroders*. Theſe bodies were ſuppoſed to act merely by corroding the *cloth*. Mr Henry of Mancheſter has propoſed to ſubſtitute the word *baſis* for *mordant*; but that word is too general to anſwer the purpoſe well.

(z) Mr Delaval has ſuppoſed, that the Tyrians were acquainted with the uſe of tin in dyeing, and Mr Henry moderns greatly to ſurpaſs the ancients in the fineneſs of their colours: by means of it alone, *ſcarlet*, the brighteſt of all colours, is produced. The method of producing the celebrated purple dye of the ancients is underſtood at preſent, and the ſhell fiſh which yield the dye ſtuff are found abundantly on the coaſts of Britain and France; but no perſon thinks now of putting the ancient mode in practice, becauſe infinitely more beautiful colours can be produced at a ſmaller price. Much of this ſuperiority is owing to the employment of the oxyd of tin.

Tin, as Prouſt has proved, is capable of two degrees of oxydation: The firſt oxyd is compoſed of 0.70 parts of tin, and 0.30 of oxygen; the ſecond, or white oxyd, of 0.60 parts of tin, and 0.40 of oxygen *. The firſt oxyd abſorbs oxygen with very great facility even from the air, and is rapidly converted into white oxyd. This fact makes it certain, that it is the white oxyd of tin which is the real mordant: even if the other oxyd alone were applied to cloth, as it probably often is, it muſt ſoon be converted into white oxyd, by abſorbing oxygen from the atmoſphere.

Tin is uſed as a mordant in three ſtates; diſſolved in nitro-muriatic acid, in acetous acid, and in a mixture of ſulphuric and muriatic acids. Nitro-muriat of tin is the common mordant employed by dyers. They prepare it by diſſolving tin in diluted nitric acid, to which a certain proportion of muriat of ſoda, or of ammonia, is added. Part of the nitric acid decompoſes theſe ſalts, combines with their baſe, and ſets the muriatic acid at liberty. They prepared it at firſt with nitric acid alone; but that mode was very defective; becauſe the nitric acid very readily converts tin to white oxyd, and then is incapable of diſſolving it. The conſequence of which was, the precipitation of the whole of the tin. To remedy this defect, common ſalt, or ſal ammoniac, was very ſoon added; muriatic acid having the property of diſſolving white oxyd of tin very readily. A conſiderable ſaving of nitric acid might be obtained, by employing as much ſulphuric acid as is juſt ſufficient to ſaturate the baſe of the common ſalt, or ſal ammoniac, employed.

When the nitro-muriat of tin is to be uſed as a mordant, it is diſſolved in a large quantity of water, and the cloth is dipped in the ſolution, and allowed to remain till ſufficiently ſaturated. It is then taken out, and waſhed and dried. Tartar is uſually diſſolved in the water along with the nitro-muriat. The conſequence of this is a double decompoſition; the nitro-muriatic acid combines with the potaſs of the tartar, while the tartarous acid diſſolves the oxyd of tin. When tartar is uſed, therefore, in any conſiderable quantity, the mordant is not a nitro-muriat, but a tartrite of tin.

Mr Hauſſman, to whom the art of dyeing lies under numerous obligations, has propoſed to ſubſtitute acetite of tin for nitro-muriat as a mordant for cotton and linen. It may be prepared by mixing together acetite of lead and nitro-muriat of tin. This mordant is preferable for theſe ſtuffs; becauſe it is much more eaſily decompoſed than the nitro-muriat †.

Dr Bancroft has propoſed to ſubſtitute a ſolution of tin in a mixture of ſulphuric and muriatic acid, inſtead of nitro-muriat of tin, as a mordant for wool. This mordant, he informs us, is much cheaper, and equally efficacious. It may be prepared by diſſolving ſomewhat leſs than one part of tin in two parts of ſulphuric and three of muriatic acid, at the degree of concentration at which they are commonly ſold in this country ‡. This mordant, like the others, muſt be diſſolved in a ſufficient quantity of water, in order to be uſed.

Iron, like tin, is capable of two degrees of oxydation; but the green oxyd abſorbs oxygen ſo readily from the atmoſphere, that it is very ſoon converted into the red oxyd. It is only this laſt oxyd which is really uſed as a mordant in dyeing. The green oxyd is indeed ſometimes applied to cloth; but it very ſoon abſorbs oxygen, and is converted into the red oxyd. This oxyd has a very ſtrong affinity for all kinds of cloth. The permanency of the iron ſpots on linen and cotton is a ſufficient proof of this. As a mordant, it is uſed in two ſtates; in that of ſulphat of iron, and acetite of iron. The firſt is commonly uſed for wool. The ſalt is diſſolved in water, and the cloth dipped in it. It may be uſed alſo for cotton; but in moſt caſes acetite of iron is preferred. It is prepared by diſſolving iron, or its oxyd, in vinegar, ſour beer, &c. and the longer it is kept, the more is it preferred. The reaſon is, that this mordant ſucceeds beſt when the iron is in the ſtate of red oxyd. It would be better then to oxydate the iron, or convert it into ruſt, before uſing it; which might eaſily be done, by keeping it for ſome time in a moiſt place, and ſprinkling it occaſionally with water. Of late, pyrolignous acid has been introduced inſtead of acetous. It is obtained by diſtilling wood or tar.

Tan.

8. Tan, which has been already deſcribed in the firſt part of this article, has a very ſtrong affinity for cloth, and for ſeveral colouring matters. It is therefore very frequently employed as a mordant. An infuſion of *nut galls*, or of *ſumach* (A), or any other ſubſtance containing tan, is made in water, and the cloth is dipped in this infuſion, and allowed to remain till it has abſorbed a ſufficient quantity of tan. Silk is capable of abſorbing a very great proportion of tan, and by that means acquires a very great increaſe of weight. Manufacturers ſometimes employ this method of increaſing the weight of ſilk *.

Tan is often employed alſo, along with other mordants, in order to produce a compound mordant. Oil is alſo uſed for the ſame purpoſe in the dyeing of cotton and linen. The mordants, with which tan moſt frequently is combined, are alumina and oxyd of iron.

406
Other mordants.

Beſides theſe mordants, there are ſeveral other ſubſtances frequently uſed as auxiliaries, either to facilitate the combination of the mordant with the cloth, or to alter

* nn. de .xxviii

† *Ann. de Chim.* xxx. 15.

‡ *Bancroft*, p. 290.

* *Bertholet*, ii. 10.

---

ry has declared himſelf of the ſame opinion. But his reaſoning, as Dr Bancroft has ſhewn, proceeds upon a miſtake. He ſuppoſes that tin is *neceſſary* for the production of red colours.

(A) Sumach is the *rhus coriaria*; a ſhrub which is cultivated in the ſouthern parts of Europe. Its ſhoots are dried, and afterwards ground to powder; in which ſtate they are ſold to the dyer and tanner.

alter the ſhade of colour. The chief of theſe are, *tartar, acetite of lead, common ſalt, ſal ammoniac, ſulphat* or *acetite of copper*, &c.

407
Mordants affect the colour.

9. Mordants not only render the dye permanent, but have alſo conſiderable influence on the colour produced. The ſame colouring matter produces very different dyes, according as the mordant is changed. Suppoſe, for inſtance, that the colouring matter be cochineal; if we uſe the aluminous mordant, the cloth will acquire a crimſon colour; but the oxyd of iron produces with it a black. Theſe changes, indeed, might naturally have been expected: for ſince the colour of a dye ſtuff depends upon its affinity for light, every new combination into which it enters, having a tendency to alter theſe affinities, will naturally give it a new colour. Now, in all caſes, the colouring matter and mordant combine together: the colour of the cloth, then, muſt be that which the particles of the dye and of the mordant, when thus combined together, exhibit. Indeed ſome mordants may be conſidered in the light of colouring matters alſo, as they always communicate a particular colour to cloth. Thus, iron communicates a brown colour, and iron and tan together conſtitute a black dye.

In dyeing, then, it is not only neceſſary to procure a mordant which has a ſufficiently ſtrong affinity for the colouring matter and the cloth, and a colouring matter which poſſeſſes the wiſhed-for colour in perfection, we muſt procure a mordant and a colouring matter of ſuch a nature, that when *combined together* they ſhall poſſeſs the wiſhed-for colour in perfection. It is evident, too, that a great variety of colours may be produced with a ſingle dye ſtuff, provided we can change the mordant ſufficiently.

408
How applied.

10. Every thing which tends to weaken the affinity between the mordant and the cloth, or between the mordant and the colouring matter, and every thing which tends in any way to alter the nature of the mordant, muſt injure the permanency of the dye: becauſe, whenever the mordant is deſtroyed, there is no longer any thing to cauſe the dye ſtuff to adhere; and when its nature is altered, the colour of the dye muſt alter at the ſame time. All the obſervations, then, which were made in the laſt chapter, concerning the nature of colouring matters, and the changes to which they are ſubject, apply equally to mordants. Theſe ſubſtances, indeed, are ſcarcely liable themſelves to any alteration. They are of a much more ſimple nature, in general, than dye ſtuffs; and therefore not nearly ſo liable to decompoſition. But when the colouring matter itſelf is altered, it comes to the ſame thing. Its affinity for the mordant being now deſtroyed, there is nothing to retain it.

As the permanency of a dye depends upon the degree of affinity between the mordant and the colouring matter, it is clear, that a dye may want permanency, even though it reſiſt the oxy muriatic acid, and all the other ſaline teſts propoſed by chemiſts. Theſe ſubſtances may happen to have very little action on the dye ſtuff, and therefore may not affect it; yet it may ſoon diſappear, in conſequence of its want of affinity for the mordant.

409
Dye-ſtuffs do not cover the whole ſurface of the cloth.

11. The colouring matter with which cloth is dyed, does not cover every portion of its ſurface; its particles attach themſelves to the cloth at certain diſtances from each other: for cloth may be dyed different ſhades of the ſame colour, lighter or darker, merely by varying the quantity of colouring matter. With a ſmall quantity, the ſhade is light; and it becomes deeper as the quantity increaſes. Now this would be impoſſible, if the dye ſtuff covered the whole of the cloth. Newton has demonſtrated, that colours are rendered faint when the rays of light which occaſion them are mixed with white rays. Conſequently, from cloth dyed of a light ſhade, a conſiderable quantity of white rays paſſes off unchanged: but this could not be the caſe if the ſtuff were covered with coloured matter; becauſe all the white rays would be decompoſed as they paſs through the coloured matter. Therefore, in light ſhades, the colouring matter does not cover the cloth; its particles adhere to it, at a certain diſtance from each other, and from every part of the cloth which is uncovered, the white rays paſs off unchanged. Even when the ſhade of colour is as deep as poſſible, the colouring particles do not cover the whole of the cloth, but are at a certain diſtance from each other. This diſtance, undoubtedly, is diminiſhed in proportion to the deepneſs of the ſhade: for the deeper the ſhade, the ſmaller is the number of white rays which eſcape undecompoſed; the more, therefore, of the ſurface is covered, and, conſequently, the ſmaller is the diſtance at which each of them is placed. A ſhade may be even conceived ſo very deep, that not a particle of white light eſcapes the action of the colouring matter; in which caſe, the diſtance between the particles of colouring matter could not exceed double that diſtance at which a particle of matter is able to act upon light.

410
Compound colours.

That the particles of colouring matter, even when the ſhade is deep, are at ſome diſtance, is evident from this well-known fact, that cloth may be dyed two colours at the ſame time. All thoſe colours, to which the dyers give the name of *compound*, are in fact two different colours applied to the cloth at once. Thus cloth gets a *green* colour, by being firſt dyed *blue* and then *yellow*. The rays of light that paſs from green cloth thus dyed are blue and yellow; by the mixture of which it is well known that green is produced. In this caſe, it is clear, that each of the colouring matters performs the very ſame office as if it were alone; and that the new colour is not produced by the combination of the two colouring matters. That part of the white light, reflected from the cloth, which paſſes through the blue colouring matter, is decompoſed, and the blue rays only tranſmitted; and that part of the white light which paſſes through the yellow colouring matter is alſo decompoſed, and only the yellow rays tranſmitted. It is clear, therefore, that both of the colouring matters equally cover the naked fibres of the cloth; conſequently the one muſt be placed in the intervals of the other: wherefore the particles of each of the colouring matters are at ſome diſtance. Now the ſame effect happens how deep ſoever the ſhade be; and it makes no difference which of the two dyes be firſt given. Nay, if one of the dyes have a ſtrong affinity for the cloth, and the other only a weak affinity, the latter will ſoon diſappear, and leave the cloth of the colour which the firſt dye gives it.

The difference, then, in the ſhade of colour, and alſo the compound colours which cloth may receive, depend entirely upon the diſtance between the particles of the colouring matters attached to the cloth, and the poſſibi-

lity

lue.

lity of partly filling up the intervals, either with the ſame colouring matter, or with a different one.

Thus we have taken a view of the theory of dyeing, as far, at leaſt, as it is at preſent underſtood. It remains for us ſtill to give an account of the particular manner by which each of the colours is imparted to cloth. This ſhall be the ſubject of the three following chapters. In the *firſt* we ſhall treat of the manner of dyeing the ſimple colours; in the *ſecond*, of dyeing the compound colours; and in the *third*, of dyeing cloth partially ſeveral different colours at the ſame time, or of that branch of the art of dyeing which is known in this country by the name of *calico printing*.

CHAP. IV. OF DYEING SIMPLE COLOURS.

THE colours denominated by dyers *ſimple*, becauſe they are the foundation of all their other proceſſes, are four; namely, 1*ſt*, blue;—2*d*, yellow;—3*d*, red;—4*th*, black. To theſe they uſually add a fifth, under the name of *root*, or brown colour. Theſe ſhall form the ſubject of the following ſections.

SECT. I. *Of* BLUE.

411 e dyes.

THE only colouring matters employed in dyeing blue are *woad* and *indigo*: attempts, indeed, have been made to dye with pruſſiat of iron; but theſe attempts have hitherto failed.

412 oad.

1. The *iſatis tinctoria*, or *woad*, is a plant commonly enough cultivated in this kingdom, and even found wild in ſome parts of England. It is of a yellowiſh colour. Some perſons think that it was this plant with which the ancient Britons ſtained their bodies, to make them appear terrible to their enemies. When arrived at maturity, this plant is cut down, waſhed, dried haſtily in the ſun, ground in a mill, placed in heaps, and allowed to ferment for a fortnight; then well mixed together, formed into balls, which are piled upon each other, and expoſed to the wind and ſun. In this ſtate they gradually become hot, and exhale a putrid ammoniacal ſmell. The fermentation is promoted, if neceſſary, by ſprinkling the balls with water. When it has continued for a ſufficient time, the woad is allowed to fall to a coarſe powder. In this ſtate it is ſold to the dyers.

413 digo.

2. Indigo, is a blue coloured powder extracted from the *indigofera tinctoria*, and from ſeveral other ſpecies of the ſame genus of plants, which are cultivated for that purpoſe both in the Eaſt and Weſt Indies.

414 low prepared.

When the *indigofera* has arrived at maturity, it is cut a few inches above ground, placed in ſtrata in a large veſſel, and covered with water. The plants ſoon acquire heat, ferment, and diſcharge abundance of carbonic acid gas. When the fermentation is far enough advanced, which is judged of by the paleneſs of the leaves, the liquid, now of a green colour, is decanted into large flat veſſels, where it is conſtantly agitated till blue flocculæ begin to make their appearance. Lime water is now poured in, which cauſes the blue flocks to precipitate. The colourleſs liquid is decanted off, and the blue ſediment poured into linen bags. When the water has drained from it ſufficiently, it is formed into ſmall lumps, and dried in the ſhade. In this ſtate it is ſold to the dyer under the name of *indigo*.

Blue.

Dr Roxbourgh, who firſt drew the attention of manufacturers to the *nerium tinctorium*, a tree very common in Indoſtan, from the leaves of which indigo may be extracted with much advantage, has given a much ſhorter method of obtaining that pigment. The leaves are kept in a copper full of water, ſupported at the temperature of 160°, till they aſſume a yellowiſh hue, and the liquid acquire a deep green colour. The liquid is then to be drawn off, agitated in the uſual manner, till the blue flocculæ appear; and then the indigo is be precipitated with lime water *.

* *Bancroft*, 423.

This proceſs, which ſucceeds equally well with the indigofera, ſhews us that the plants, from which indigo may be extracted, contain a peculiar green pollen, ſoluble in water. The intention, both of the fermentation of the common method, and of the ſcalding, according to Dr Roxbourgh's method, is merely to extract this pollen. Mr Hauſſman firſt ſhewed, that this green baſis of indigo has a ſtrong affinity for oxygen; and the ſubſequent experiments of Drs Roxbourgh and Bancroft have confirmed his obſervations, and put them beyond the reach of doubt. It gradually attracts oxygen from the air; in conſequence of which, it acquires a blue colour, and becomes inſoluble in water. The agitation is intended to facilitate this abſorption, by expoſing a greater ſurface to the action of the air. The lime water, by abſorbing a quantity of carbonic acid, with which the green pollen ſeems to be combined, greatly facilitates the ſeparation of the indigo.

The method of preparing indigo, and of applying it to the purpoſes of dyeing, ſeems to have been very early known in India. But in Europe, though it had been occaſionally uſed as a paint *, its importance as a dye ſtuff was not underſtood before the middle of the 16th century. It is not even mentioned in the *Plictho*, which was publiſhed in 1548. At that period, then, the uſe of indigo muſt have been unknown to the Italian dyers. The Dutch were the people who firſt imported it from India, and made its importance known in Europe. It was afterwards cultivated in Mexico and the Weſt Indies with ſuch ſucceſs, that the indigo from theſe countries was preferred to every other. In conſequence of this preference, they ſupplied almoſt the whole of the European market. But within theſe few years, the Eaſt Indian indigo, owing entirely to the enlightened exertions of ſome of our own countrymen, has recovered its character, and is now imported, in very conſiderable quantities, into Britain.

* *Plinii*, l. 35. c. 6.

The indigo of commerce has different ſhades of colour, according to the manner in which it has been prepared, and the proportion of foreign ſubſtances with which it is mixed. The principal ſhades are copper colour, violet, and blue. That indigo, which has the ſmalleſt ſpecific gravity, is always moſt eſteemed; becauſe it is moſt free from impurities. Bergman † found the pureſt indigo of commerce which he could procure, compoſed of

47	pure indigo,
12	gum,
6	reſin,
22	earth,
13	oxyd of iron.
100 (B).	

† *Berg.* v. 36.

Pure

(B) Prouſt informs us, that he found magneſia, even abundantly, in indigo.—*Nicholſon's Jour.* III. 325.

415 Its properties.

Pure indigo is inſoluble in water, alcohol, æther, and oils: neither alkalies nor earths have any action on it; none of the acids hitherto tried have any effect on it, except the nitric and ſulphuric. Nitric acid very ſoon converts it into a dirty white colour, and at laſt decompoſes it completely *. When the acid is concentrated, it even ſets fire to the indigo (c); when it is diluted, the indigo becomes brown, cryſtals make their appearance, reſembling thoſe of oxalic and tartarous acids; and there remains behind, after the acid and the cryſtals are waſhed off, a viſcid ſubſtance, of a very bitter taſte, and poſſeſſing many of the properties of a reſin †.

Concentrated ſulphuric acid diſſolves indigo readily, and much heat is evolved. The ſaturated ſolution is opaque, and conſequently black; but it aſſumes a deep blue colour when diluted with water. This ſolution is well known in commerce under the name of *liquid blue.* Bancroft has given it the name of *ſulphat of indigo.* During the ſolution of the indigo, ſome ſulphurous acid, and ſome hydrogen gas, are evolved ‡, and the blue colour of the indigo is much heightened. Theſe facts have led Bancroft to ſuppoſe, that the indigo, during its ſolution, combines with an additional quantity of oxygen *. This *may* poſſibly be the caſe, but the phenomena are not ſufficient to eſtabliſh it: for the hydrogen gas and ſulphurous acid evolved may owe their formation, not to the action of the ſulphuric acid on indigo, but upon the impurities with which it is always mixed; and the improvement of the colour may be owing to the abſence of theſe impurities. The carbonats of fixed alkalies precipitate ſlowly from ſulphat of indigo a blue coloured powder, which poſſeſſes the properties of indigo; but it is ſoluble in moſt acids and in alkalies. Pure alkalies deſtroy the colour and properties of ſulphat of indigo: they deſtroy alſo precipitated indigo §. Theſe facts give ſome probability to Bancroft's opinion; but they do not eſtabliſh it: becauſe the differences between common and precipitated indigo may depend merely on the ſtate of greater minuteneſs to which it is reduced, which prevents the attraction of aggregation from obſtructing the action of other bodies. Even ſilica, when newly precipitated, is ſoluble in many menſtrua.

416 Method of dyeing with ſulphat of indigo.

3. Indigo has a very ſtrong affinity for wool, ſilk, cotton, and linen. Every kind of cloth, therefore, may be dyed with it, without the aſſiſtance of any mordant whatever. The colour thus induced is very permanent; becauſe the indigo is already ſaturated with oxygen, and becauſe it is not liable to be decompoſed by thoſe ſubſtances, to the action of which the cloth is expoſed. But it can only be applied to cloth in a ſtate of ſolution; and the only ſolvent known being ſulphuric acid, it would ſeem at firſt ſight that the ſulphuric acid ſolution is the only ſtate in which indigo can be employed as a dye.

The ſulphat of indigo is indeed often uſed to dye wool and ſilk blue; but it can ſcarcely be applied to cotton and linen, becauſe the affinity of theſe ſubſtances for indigo is not great enough to enable them readily to decompoſe the ſulphat. The colour given by ſulphat of indigo is exceedingly beautiful: it is known by the name of Saxon blue; becauſe the proceſs, which was diſcovered by councellor Barth in 1740, was firſt carried on at Groſſenhayn in Saxony. The method of the original inventor was very complicated, from the great number of uſeleſs ingredients which were mixed with the ſulphat. But theſe ingredients were gradually laid aſide, and the compoſition ſimplified by others, after the nature of it, which was for ſome time kept ſecret, became known to the public. The beſt proceſs is that of Mr Poerner *.

One part of indigo is to be diſſolved in four parts of concentrated ſulphuric acid; to the ſolution one part of dry carbonat of potaſs is to be added, and then it is to be diluted with eight times its weight of water. The cloth muſt be boiled for an hour in a ſolution, containing five parts of alum and three of tartar for every 32 parts of cloth. It is then to be thrown into a water bath, containing a greater or ſmaller proportion of the diluted ſulphat of indigo, according to the ſhade which the cloth is intended to receive. In this bath it muſt be boiled till it has acquired the wiſhed for colour. The alum and tartar are not intended to act as mordants, but to facilitate the decompoſition of the ſulphat of indigo. Bergman aſcertained that alum poſſeſſes this property. The alkali added to the ſulphat anſwers the ſame purpoſe. Theſe ſubſtances, alſo, by ſaturating part of the ſulphuric acid, ſerve, in ſome meaſure, to prevent the texture of the cloth from being injured by the action of the acid, which is very apt to happen in this proceſs.

417 Method of dyeing by decompoſing indigo.

4. But ſulphat of indigo is by no means the only ſolution of that pigment employed in dyeing. By far the moſt common method, and indeed the only method known before 1740, is to deprive indigo of the oxygen to which it owes its blue colour, and thus to reduce it to the ſtate of green pollen; and then to diſſolve it in water by means of alkalies, or alkaline earths, which in that ſtate act upon it very readily. Indigo is preciſely in the ſtate of green pollen when it is firſt extracted from the plant in the ſcalding proceſs deſcribed by Dr Roxbourgh. If, therefore, there were any method of ſtopping ſhort here, and of ſeparating the pigment while it retains its green colour, it would be preciſely in the ſtate beſt adapted for dyeing. Nothing more would be neceſſary but to diſſolve it in water by means of an alkali, and to dip the cloth into the ſolution †.

But as indigo is not brought home to us in that ſtate, the dyer is under the neceſſity of undoing the laſt part of the indigo maker's proceſs, by ſeparating again the oxygen, and reſtoring it to its original green colour. Two different methods are employed for this purpoſe. The firſt of theſe methods is to mix with indigo a ſolution of ſome ſubſtance which has a ſtronger affinity for oxygen than the green baſis of indigo. Green oxyd of iron, for inſtance, and different metallic ſulphurets. If, therefore, indigo, lime, and green ſulphat of iron, be mixed together in water, the indigo gradually

(c) The combuſtion of indigo by nitric acid, of the denſity 1.52°, was firſt publiſhed by Mr Sage; but Woulfe appears to have obſerved the fact before him, and to have pointed it out to Rouelle, who ſhewed it in his lectures. *Prouſt, Nicholſon's Jour.* III. 325.

gradually loſes its blue colour, becomes green, and is diſſolved, while the green oxyd of iron is converted into the red oxyd. The manner in which theſe changes take place is obvious. Part of the lime decompoſes the ſulphat of iron; the green oxyd, the inſtant that it is ſet at liberty, attracts oxygen from the indigo, decompoſes it, and reduces it to the ſtate of green pollen. This green pollen is immediately diſſolved by the action of the reſt of the lime. In like manner, indigo is diſſolved, when mixed in water, with pure antimony and potaſs, or with ſulphuret of arſenic and potaſs. For theſe intereſting facts we are indebted to Mr Hauſſman.

The ſecond method is to mix the indigo in water with certain vegetable ſubſtances which readily undergo fermentation. During this fermentation, the indigo is deprived of its oxygen, and diſſolved by means of quicklime or alkali, which is added to the ſolution. The firſt of theſe methods is uſually followed in dyeing cotton and linen; the ſecond, in dyeing wool and ſilk.

418 ow to in- ce a blue our on ol,

5. In the dyeing of wool, woad and bran are commonly employed as vegetable ferments, and lime as the ſolvent of the green baſe of the indigo. Woad contains itſelf a colouring matter preciſely ſimilar to indigo; by following the common proceſs, indigo may be extracted from it. In the uſual ſtate of woad, when purchaſed by the dyer, the indigo which it contains is probably not far from the ſtate of green pollen. Its quantity in woad is but ſmall, and it is mixed with a great proportion of other vegetable matter. Before the introduction of indigo into Europe, woad alone was employed as a blue dye; and even as late as the 17th century, the uſe of indigo was reſtricted in different countries, and dyers obliged to employ a certain quantity of woad (D). But theſe abſurd reſtrictions were at laſt removed, and woad is now ſcarcely uſed in dyeing, except as a ferment to indigo. The blue colouring matter, however, which it contains, muſt, in all caſes, contribute conſiderably to the dye.

A ſufficient quantity of woad, mixed with bran, is put into a wooden veſſel filled with warm water, whoſe temperature is kept up ſufficiently to enſure fermentation. Afterwards quicklime and indigo are added. The indigo is deprived of its oxygen, and diſſolved by the lime. When the ſolution is complete, the liquid has a green colour, except at the ſurface, where it is copper coloured, or blue, becauſe the indigo at the ſurface abſorbs oxygen from the air, and aſſumes its natural colour. The woollen cloth is dipped in, and paſſed thro' the liquid as equably as poſſible, piece after piece; thoſe pieces being firſt dyed which are to aſſume the deepeſt ſhade. No part of the cloth ſhould come in contact with the ſediment, which would ſpoil the colour. When the cloth is firſt taken out of the vat, it is of a green colour; but it ſoon becomes blue, by attracting oxygen from the air. It ought to be carefully waſhed, to carry off the uncombined particles. This ſolution of indigo is liable to two inconveniences: 1. It is apt ſometimes to run too faſt into the putrid fermentation: this may be known by the putrid vapours which it exhales, and by the diſappearing of the green colour. In this ſtate it would ſoon deſtroy the indigo altogether. The inconvenience is remedied by adding more lime, which has the property of moderating the putreſcent tendency. 2. Sometimes the fermentation goes on too languidly. This defect is remedied by adding more bran or woad, in order to diminiſh the proportion of quicklime.

419 Silk,

6. Silk is uſually dyed blue by the following proceſs: Six parts of bran, and ſix of indigo, with nearly one part of madder, are ſtirred into a ſufficient quantity of water, in which ſix parts of common potaſh of commerce is diſſolved. The liquid is kept at a temperature proper for fermentation. When the indigo, deprived of its oxygen by the fermentation, is diſſolved by the potaſs, the liquid aſſumes a green colour. The ſilk, previouſly well ſcoured, is put into the ſolution in ſmall quantities at a time; then wrung out of the dye, and hung up in the open air, till the green colour which it has at firſt is changed into blue. By this method, ſilk can only be made to receive a light blue colour. In order to give ſilk a dark blue, it muſt previouſly receive what is called a ground colour; that is, be previouſly dyed ſome other colour. A particular kind of red dye-ſtuff, called *archil* (E), is commonly employed for this purpoſe.

The madder employed in the above proceſs may, at firſt ſight, appear ſuperfluous; it ſeems, however, to contribute ſomething to the colour.

420 Cotton, and linen.

7. Cotton and linen are dyed blue by the following proceſs: One part of indigo, one part of green ſulphat of iron, and two parts of quicklime, are ſtirred into a ſufficient quantity of water. The ſolution is at firſt green, but it gradually aſſumes a yellow colour, and its ſurface is covered with a ſhining copper coloured pellicle. The cloth is to be allowed to remain in the ſolution for five or ſix minutes. When taken out, it has a yellow colour; but on expoſure to the atmoſphere, it ſoon becomes green, and then blue, in conſequence of the abſorption of oxygen. The indigo, in this proceſs, ſeems to be deprived of a greater quantity of oxygen than is neceſſary to reduce it to the ſtate of green pollen. Mr Hauſſman has obſerved, that the cloth acquires a much deeper colour, provided it be plunged, the inſtant it is taken out of the dyeing vat, into water acidulated with ſulphuric acid. It is uſual to dip the cloth into a ſucceſſion of vats, variouſly charged with colouring matter; beginning with the vat which contains leaſt colouring matter, and paſſing gradually to thoſe which contain moſt. By this contrivance the cloth is dyed more equally, than it probably would be, if it were plunged all at once into a ſaturated ſolution of colouring matter.

SECT. II. *Of YELLOW.*

421 Yellow dyes.

THE principal colouring matters employed to dye yellow are *weld*, *fuſtic*, and *quercitron bark*.

1. Reſeda luteola, known in this country by the name of

(D) The employment of indigo was ſtrictly prohibited in England in the reign of Queen Elizabeth; nor was the prohibition taken off till the reign of Charles II. It was prohibited alſo in Saxony. In the edict it is ſpoken of as a corroſive ſubſtance, and called *food for the devil*. Colbert reſtricted the French dyers to a certain quantity of it.

(E) This will be deſcribed in a ſubſequent ſection.

Yellow.

422 Weld. of *weld*, is a plant which grows wild very commonly in Scotland, and in moſt European countries. Cultivated weld has a more ſlender ſtem than the wild kind, but it is more valuable, becauſe it is much more rich in colouring matter. It is an annual plant, of a yellowiſh green colour, furniſhed with a great number of ſmall leaves. When ripe it is pulled, dried, tied up in parcels, and in that ſtate ſold to the dyer.

Weld readily yields its colouring matter to water. The ſaturated decoction of it is brown; but when ſufficiently diluted with water it becomes yellow. Acids render its colour ſomewhat paler, but alkalies give it a deeper ſhade. When alum is added to it, a yellow coloured precipitate falls down, conſiſting of alumina combined with the colouring matter of weld. The affinity therefore of this colouring matter for alumina is ſo great, that it is able to abſtract it from ſulphuric acid. Its affinity for oxyd of tin is at leaſt equally great; for muriat of tin cauſes a copious bright yellow precipitate, compoſed of the colouring matter and the oxyd combined. Moſt of the metallic ſalts occaſion ſimilar precipitates, but varying in colour according to the metal employed. With iron, for inſtance, the precipitate is dark grey, and with copper browniſh green *.

* *Berthollet*, ii. 260.

423 Fuſtic. 2. The *morus tinctoria* is a large tree which grows in the Weſt India iſlands. The wood of this tree is of a yellow colour, with orange veins. The French call it *yellow wood (bois jaune)*; but the Engliſh dyers have given it the abſurd name of *old fuſtic* (F). This wood has been introduced into dyeing ſince the diſcovery of America. The preciſe time is not known; but that it was uſed in England ſoon after the middle of the 17th century, is evident from Sir William Petty's paper on *Dyeing*, read to the Royal Society ſoon after its inſtitution. In that paper particular mention is made of *old fuſtic*.

Fuſtic gives out its colouring matter with great facility to water. The ſaturated decoction of it is of a deep reddiſh yellow colour; when ſufficiently diluted it becomes orange yellow. Acids render it turbid, give it a pale yellow colour, and occaſion a ſlight greeniſh precipitate, which alkalies rediſſolve. Alkalies give the decoction a very deep colour, inclining to red; ſome time after they have been added, a yellow matter ſeparates from the liquid, and either ſwims on the ſurface, or adheres to the ſides of the veſſel. Alum, ſulphat of iron, of copper, and of zinc, produce precipitates compoſed of the colouring matter combined reſpectively with the baſes of theſe different ſalts; and the colour varies according to the ſubſtance with which this colouring matter is combined. With alumina it is yellow; with iron, yellowiſh brown; with copper, browniſh yellow; and with zinc, greeniſh brown †.

† *Id.* ii. 269.

424 Quercitron. 3. The *quercus nigra*, to which Dr Bancroft has given the name of *quercitron*, is a large tree which grows naturally in North America. Dr Bancroft diſcovered, about the year 1784, that the bark of this tree contains a great quantity of yellow colouring matter, and ſince that time it has been introduced into dyeing with much advantage. To prepare it for the dyer, the epidermis is ſhaved off, and then it is ground in a mill. It ſeparates partly into ſtringy filaments, and partly into a fine light powder. Both of theſe contain colouring matter, and therefore are to be employed; but as they contain unequal quantities, they ſhould be uſed in their natural proportions.

Quercitron bark readily gives out its colouring matter to water at the temperature of 100°. The infuſion has a yellowiſh brown colour, which is rendered lighter by acids, and darker by alkalies. Alum occaſions a ſcanty precipitate of a deep yellow colour; muriat of tin, a copious bright yellow precipitate; ſulphat of tin, a dark olive precipitate; and ſulphat of copper, a precipitate of a yellow colour inclining to olive ‡.

‡ *Bancroft*, i. 320.

425 Other yellow dyes. 4. Beſides theſe dye ſtuffs there are others occaſionally uſed by dyers. The following are the moſt remarkable:

Geniſta tinctoria, or *dyers broom*. This plant yields a very inferior yellow; it is only uſed for coarſe woollen ſtuffs.

Serratula tinctoria, or *ſaw wort*. This plant yields a yellow nearly of the ſame nature with *weld*; for which, therefore, it is a good ſubſtitute

Juglans alba, or *American hiccory*. The bark of this tree yields a colouring matter exactly ſimilar to that of quercitron bark, but much ſmaller in quantity.

Anotta is a name given to a red paſte formed of the berries of the bixa orellana, a tree which is a native of America. This paſte yields its colouring matter to a ſolution of alkali in water. The ſolution affords an exceedingly beautiful yellow dye, but very fading, and incapable of being fixed by any known mordant.

Turmeric is the root of the *curcuma longa*, a plant which grows both in the Eaſt and Weſt Indies. It is richer in colouring matter than any other yellow dye ſtuff. It yields very beautiful yellows, but too fading to be of much uſe, and no mordant has any influence in contributing to their permanence.

416 Yellow requires a mordant. 5. Yellow colouring matters have too weak an affinity for cloth to produce permanent colours without the uſe of mordants. Cloth, therefore, before it be dyed yellow, is always prepared by combining ſome mordant or other with it. The mordant moſt commonly employed for this purpoſe is alumina. Oxyd of tin is ſometimes uſed when very fine yellows are wanted. Tan is often employed as a ſubſidiary to alumina, in order to fix it more copiouſly on cotton and linen. Tartar is alſo uſed as an auxiliary to brighten the colour; and muriat of ſoda, ſulphat of lime, and even ſulphat of iron, in order to render the ſhade deeper.

6. The yellow dyed by means of fuſtic is more permanent, but not ſo beautiful as that given by weld or quercitron. As it is permanent, and not much injured by acids, it is often uſed in dyeing compound colours

where

(F) The *rhus cotinus*, or Venice ſumach, is a ſmall ſhrub, formerly employed as a yellow dye, but now almoſt out of uſe. The French call it *fuſtet*, from which word it is probable, as Dr Bancroft ſuppoſes, that our dyers formed the term *fuſtic*. When the *morus tinctoria* was introduced as a dye-ſtuff, they gave it the ſame name: but in order to diſtinguiſh the two, they called the ſumach, which was a ſmall ſhrub, *young fuſtic*; and the morus, which was a large tree, *old fuſtic*. See *Bancroft*, i. 412.

llow. where a yellow is required. The mordant is alumina. When the mordant is oxyd of iron, fuſtic dyes a good permanent drab colour.

Weld and quercitron bark yield nearly the ſame kind of colour; but as the bark yields colouring matter in much greater abundance, it is much more convenient, and, upon the whole, cheaper than weld. It is probable, therefore, that it will gradually ſuperſede the uſe of that plant. The method of uſing each of theſe dye ſtuffs is nearly the ſame.

27 thod of icing a ow co- on l,

7. Wool may be dyed yellow by the following proceſs: Let it be boiled for an hour, or more, with about $\frac{1}{6}$th of its weight of alum, diſſolved in a ſufficient quantity of water. It is then to be plunged, without being rinced, into a bath of warm water, containing in it as much quercitron bark as equals the weight of the alum employed as a mordant. The cloth is to be turned through the boiling liquid till it has acquired the intended colour. Then a quantity of clean powdered chalk, equal to the hundredth part of the weight of the cloth, is to be ſtirred in, and the operation of dyeing continued for eight or ten minutes longer. By this method a pretty deep and lively yellow may be given fully as permanent as weld yellow [*].

For very bright *orange*, or *golden yellows*, it is neceſſary to have recourſe to the oxyd of tin as a mordant. A fine orange yellow may be given to woollen cloth, by putting, for every ten parts of cloth, one part of bark into a ſufficient quantity of hot water; after a few minutes, an equal weight of murio-ſulphat of tin is to be added, and the mixture well ſtirred. The cloth acquires the wiſhed for colour in a few minutes when briſkly turned in this bath [†].

The ſame proceſs will ſerve for producing *bright golden yellows*, only ſome alum muſt be added along with the tin. For the brighteſt golden yellow, the proportions ſufficient for dyeing 100 parts of cloth are, 10 parts of bark, 7 parts of murio-ſulphat of tin, and 5 parts of alum. All the poſſible ſhades of golden yellow may be given to cloth merely by varying the proportion of the ingredients according to the ſhade [‡].

In order to give the yellow that delicate *green* ſhade ſo much admired for certain purpoſes, the ſame proceſs may be followed, only tartar muſt be added in different proportions according to the ſhade. Thus to dye 100 parts of cloth a *full bright yellow*, delicately inclining to *green*, 8 parts of bark, 6 of murio-ſulphat, 6 of alum, and 4 of tartar, are to be employed. The tartar is to be added at the ſame time with the other mordants. If the proportion of alum and tartar be increaſed, the green ſhade is more lively: to render it as lively as poſſible, all the four ingredients ought to be employed in equal proportions. As theſe fine lemon-yellows are generally required only pale, 10 parts of each of the ingredients will be ſufficient to dye about 300 parts of cloth [§].

By adding a ſmall proportion of cochineal, the colour may be raiſed to a fine orange, or even an aurora [‖].

428 Silk,

8. Silk may be dyed different ſhades of yellow, either by weld or quercitron bark, but the laſt is the cheapeſt of the two. The proportion ſhould be from 1 to 2 parts of bark to 12 parts of ſilk, according to the ſhade. The bark, tied up in a bag, ſhould be put into the dyeing veſſel while the water which it contains is cold, and when it has acquired the heat of about 100°, the ſilk, previouſly alumed, ſhould be dipped in, and continued till it aſſumes the wiſhed-for colour. When the ſhade required is deep, a little chalk or pearlaſh ſhould be added towards the end of the operation. When a very lively yellow is wanted, a little murio-ſulphat of tin ſhould be added, but not too much, becauſe tin always injures the gloſſineſs of ſilk. The proportions may be 4 parts of bark, 3 of alum, and 2 of murio-ſulphat of tin [¶].

Silk is dyed fine orange and aurora colours by annotta. The proceſs is merely dipping the ſilk into an alkaline ſolution of annotta. To produce the orange ſhade the alkali is ſaturated with lemon juice. The colours thus produced are exceedingly beautiful, but they want permanency.

429 Cotton, and linen.

9. The common method of dyeing cotton and linen yellow, has been deſcribed in the article DYEING in the *Encyclopædia*. The cloth is firſt ſoaked in a ſolution of alum, and then dyed in a decoction of weld. After this it is ſoaked for an hour in a ſolution of ſulphat of copper, and, laſtly, it is boiled for an hour in a ſolution of hard ſoap. This proceſs, beſides the expence of it, is defective; becauſe the yellow is neither ſo beautiful nor ſo permanent as it might be if the mordant were uſed in a different form.

The method recommended by Dr Bancroft is much more advantageous, yielding more permanent and beautiful colours at a ſmaller expence. The mordant ſhould be acetite of alumina, prepared by diſſolving 1 part of acetite of lead, and 3 parts of alum, in a ſufficient quantity of water. This ſolution ſhould be heated to the temperature of 100°, the cloth ſhould be ſoaked in it for two hours, then wrung out and dried. The ſoaking may be repeated, and the cloth again dried as before. It is then to be barely wetted with lime water, and afterwards dried. The ſoaking in the acetite of alumina may be again repeated; and if the ſhade of yellow is required to be very bright and durable, the alternate wetting with lime water, and ſoaking in the mordant, may be repeated three or four times. By this contrivance a ſufficient quantity of alumina is combined with the cloth, and the combination is rendered more permanent by the addition of ſome lime. The dyeing bath is prepared by putting 12 or 18 parts of quercitron bark (according to the depth of the ſhade required), tied up in a bag, into a ſufficient quantity of cold water. Into this bath the cloth is to be put, and turned round in it for an hour, while its temperature is gradually raiſed to about 120°. It is then to be brought to a boiling heat, and the cloth allowed to remain in it after that only a few minutes. If it be kept long at a boiling heat the yellow acquires a ſhade of brown [*].

Another way of dyeing cotton and linen very permanent yellows, would be to imitate the method adopted for dyeing cotton in the Eaſt. That method is indeed exceedingly tedious, but it might be very much ſhortened by carefully attending to the uſes of the ingredients. The eſſential part of the proceſs is to cauſe the alumina to combine in ſufficient quantity with the cloth, and to adhere with ſufficient firmneſs to enſure a permanent colour. This is accompliſhed by uſing three mordants; firſt oil, then tan, and laſtly alum. The combination of theſe three ſubſtances produces a mordant which enſures a very permanent colour.

The cotton is firſt ſoaked in a bath compoſed of a ſufficient quantity of oil, and mixed with a weak ſolution

[*] Bancroft, i 15.

[†] bid. 329.

[‡] bid. 330.

[¶] Bancroft, i. 345.

[*] Ibid. 351.

tion of ſoda. Animal oil ſeems to anſwer beſt for the purpoſe. Vogler found that glue anſwered extremely well. The ſoda ſhould be cauſtic: In that ſtate it combines with the oil, and enables the cloth to abſorb it equally. It is then, after being waſhed, put into an infuſion of nut galls (the whiter the better). The tan combines with the oil, while the gallic acid carries off the alkali that may remain attached to the cloth. The infuſion ought to be hot; and the cotton, after coming out of it, ſhould be dried as quickly as poſſible. Care ſhould be taken that the quantity of galls do not exceed a juſt proportion compared with the oil, otherwiſe the colour will be darkened. The cotton, thus prepared, is to be put into a ſolution of alum. There is a ſtrong affinity between tan and alumina; in conſequence of which, the alum is decompoſed, and the alumina combines with the tan in ſufficient abundance †. The cotton, thus prepared, is to be dyed, as above deſcribed, with quercitron bark.

† *Chaptal, Ann de Chim.* xxvi. 251.

430 Chaptal's proceſs for cotton.

Mr Chaptal, whoſe ingenious labours have contributed exceedingly to elucidate the theory of dyeing, has propoſed an exceedingly ſimple and cheap method of dyeing cotton a fine permanent nankeen yellow. His proceſs is as follows (G).

Cotton has ſo ſtrong an affinity for oxyd of iron, that if put into a ſolution of that oxyd in any acid whatever, it decompoſes the ſalt, abſorbs the iron, and acquires a yellow colour. The cotton to be dyed is to be put into a cold ſolution of ſulphat of iron, of the ſp. gr. 1.020; it is then wrung out, and put directly into a ley of potaſs, of the ſp. gr. 1.010, into which a ſolution of alum has been poured till it was ſaturated with it. After the cotton has remained in this bath four or five hours, it may be taken out, waſhed, and dried. By this proceſs cotton may be dyed all the different ſhades of nankeen, by varying the proportion of the ſulphat of iron. This colour has the advantage of not being injured by waſhing, and of being exceedingly cheap §.

§ *Ibid.* 270.

Sect. III. *Of Red.*

431 Red dyes.

The principal colouring matters employed in dyeing *red* are, *kermes*, *cochineal*, *archil*, *madder*, *carthamus*, and *Brazil wood*.

432 Kermes,

1. In different parts of Aſia and the ſouth of Europe, there grows a ſmall ſpecies of oak, to which Linnæus gives the name of *quercus coccifera*. On this oak reſides a ſmall inſect, of a reddiſh brown colour; in commerce it is known by the name of *kermes*. This inſect is a ſpecies of *coccus*: Linnæus called it *coccus ilicis*. Theſe inſects are gathered in the month of June, when the female, which alone is uſeful, is ſwelled with eggs. They are ſteeped for ten or twelve hours in vinegar to kill the young inſects contained in the eggs, and afterwards dried on a linen cloth. In this ſtate they are ſold to the dyer.

Kermes readily gives out its colouring matter to water or alcohol. It was much uſed by the ancients in dyeing; the colours which it produced were highly eſteemed, being inferior in price only to their celebrated purple. They gave it the name of *coccus*.

The colour which it communicates to cloth is exceedingly permanent, but being far inferior in beauty to thoſe which may be obtained from cochineal, it has been but little employed by dyers ſince that ſplendid pigment came into common uſe.

433 Cochineal,

2. Cochineal is likewiſe an inſect, a ſpecies of *coccus*. Linnæus diſtinguiſhes it by the name *coccus cacti*. It inhabits different ſpecies of cacti, but the moſt perfect variety is confined to the *cactus coccinillifer*. The cochineal inſect was firſt diſcovered in Mexico; the natives had employed it in their red dyes before the arrival of the Spaniards. It became known in Europe ſoon after the conqueſt of Mexico; and the beauty of the colour which it communicates to cloth very ſoon attracted general attention. For many years it was miſtaken for a vegetable production, as had been the caſe alſo with the kermes. Different accounts of its real nature had indeed appeared very early in the Philoſophical Tranſactions; but the opinion of Pomet, who inſiſted that it was the ſeed of a particular plant, gained ſo much credit, that it was not entirely deſtroyed till the publication of Mr Ellis's paper in the 52d volume of the Philoſophical Tranſactions, which eſtabliſhed the contrary beyond the poſſibility of doubt.

The female cochineal inſect remains like the kermes, during her whole life adhering to a particular ſpot of the tree on which it feeds. After fecundation, her body ſerves merely as a nidus for her numerous eggs, and gradually ſwells as theſe advance towards maturity. In this ſtate the inſects are gathered, put into a linen bag, which is dipt into hot water to deſtroy the life of the young animals contained in the eggs, and then dried. In this ſtate they are ſent to Europe and ſold to the dyer.

The quantity of cochineal diſpoſed of in Europe is very great. Bancroft informs us, that the Spaniards annually bring to market about 600,000 lbs. of it. Hitherto the rearing of the inſects has belonged almoſt excluſively to that nation. Other nations have indeed attempted to ſhare it with them, but without any remarkable ſucceſs; as the Spaniards uſe every precaution to confine the true cochineal, and even the ſpecies of cactus on which it feeds, to Mexico. Mr Thiery de Menonville was fortunate enough to procure ſome ſpecimens of both, and to tranſfer them in ſafety to St Domingo; but after his death, the inſects were allowed to periſh. The wild cochineal inſect, which differs from the cultivated kind merely in being ſmaller, and containing leſs colouring matter, was produced in St Domingo, in conſiderable quantities, before the commencement of the preſent war. Several ſpirited Britiſh gentlemen have lately contrived to procure the inſect; and vigorous efforts are making to rear it in the Eaſt Indies. We have not yet learned the ſucceſs of theſe attempts; but we have reaſon to hope every thing from the zeal and abilities of thoſe gentlemen who have taken an active part in the enterprize.

Cochineal readily gives out its colouring matter to water. The decoction is of a crimſon colour, inclining to violet: It may be kept for a long time without putrifying or loſing its tranſparency. Sulphuric acid gives

---

(G) We ought to mention, that this proceſs, or at leaſt one very ſimilar, has been long well known to the calicoe printers of this country. Moſt of their brown yellows, or drabs, are dyed with iron.

gives it a red colour, inclining to yellow, and occaſions a ſmall fine red precipitate. Tartar gives it a yellowiſh red colour, which becomes yellow after a ſmall quantity of red powder has ſubſided. Alum brightens the colour of the decoction, and occaſions a crimſon precipitate. Muriat of tin gives a copious fine red precipitate; ſulphat of iron, a browniſh violet precipitate; ſulphat of zinc, a deep violate precipitate; acetite of lead, and ſulphat of copper, violet precipitates †.

Water is not capable of extracting the whole of the colouring matter of cochineal; but the addition of a little alkali or tartar enables the water to extract the whole of it *.

.34 chil,

3. Archil (H) is a paſte formed of the *lichen roccella*, pounded and kept moiſt for ſome time with ſtale urine. It gives out its colouring matter to water, to alcohol (I), and to a ſolution of ammonia in water.

The lichen roccella grows abundantly in the Canary iſlands, from which it is imported and ſold to the dyers. Other lichens are likewiſe uſed to dye red, eſpecially the *parellus*, from which the pigment called *litmus*, and by chemiſts *turſole*, is prepared; the *omphalodes* and *tartareus*, which are often employed in this country to dye coarſe cloths. To theſe many others might be added; but the reader may conſult the treatiſes of Hoffman and Weſtring on the ſubject.

135 dder,

4. The *rubia tinctorum* is a ſmall well known plant, cultivated in different parts of Europe for the ſake of its roots, which are known by the name of *madder*. They are about the thickneſs of a gooſe quill, ſomewhat tranſparent, of a reddiſh colour, and a ſtrong ſmell. They are dried, cleaned, ground in a mill, and in that ſtate uſed by dyers.

Madder gives out its colouring matter to water. The infuſion is of a browniſh orange colour; alum produces in it a deep browniſh red precipitate; alkaline carbonats, a blood red precipitate, which is rediſſolved on adding more alkali. The precipitate occaſioned by acetite of lead is browniſh red; by nitrat of mercury, purpliſh brown; by ſulphat of iron, a fine bright brown. After the red colouring matter has been extracted from madder by water, it is ſtill capable of yielding a brown colour ‡.

.36 thamus,

5. *Carthamus tinctorius* is an annual plant, cultivated in Spain, Egypt, and the Levant, for the ſake of its flowers, which alone are uſed in dyeing. After the juice has been ſqueezed out of theſe flowers, they are waſhed repeatedly with ſalt water, preſſed between the hands, and ſpread on mats to dry. Care is taken to cover them from the ſun during the day, and to expoſe them to the evening dews, in order to prevent them from drying too faſt. Such is the method followed in Egypt.

The flowers of carthamus contain two colouring matters; a yellow, which is ſoluble in water, and a red, inſoluble in water, but ſoluble in alkaline carbonats. The method of preparing them above deſcribed, is intended to carry off the yellow colouring matter, which is of no uſe, and to leave only the red. After the flowers are thus prepared, they are of a red colour, and have loſt nearly one-half of their weight. An alkaline ley readily extracts their colouring matter, which may be precipitated by ſaturating the alkali with an acid. Lemon juice is commonly uſed for this purpoſe, becauſe it does not injure the colour of the dye. Next to citric, ſulphuric acid is to be preferred, provided too great a quantity be not uſed. The red colouring matter of carthamus, extracted by carbonat of ſoda, and precipitated by lemon juice, conſtitutes the *rouge* employed by the ladies as a paint. It is afterwards ground with a certain quantity of talc. The fineneſs of the talc, and the proportion of it mixed with the carthamus, occaſion the difference between the cheaper and dearer kinds of *rouge*.

437 Brazil wood.

6. *Brazil wood*, or *fernambouc*, as it is called by the French, is the wood of the *caſalpinia criſta*, a tree which grows naturally in America and the Weſt Indian iſlands. It is very hard; its ſpecific gravity is greater than that of water; its taſte is ſweetiſh: its colour, when freſh cut, is pale; but after expoſure to the atmoſphere, it becomes reddiſh.

Brazil wood yields its colouring matter to alcohol, and likewiſe to boiling water. The decoction is of a fine red colour. The mineral acids make it yellow, and occaſion a reddiſh brown precipitate. Oxalic acid cauſes an orange red precipitate. Fixed alkali gives the decoction a crimſon colour, inclining to brown; ammonia, bright purple. Alum occaſions a copious crimſon precipitate, eſpecially if alkali is added at the ſame time. Sulphat of iron renders the decoction black. The precipitate produced by muriat of tin is roſe coloured; that by acetite of lead of a fine deep red *.

The decoction of Brazil wood is fitter for dyeing after it has ſtood ſome time, and undergone a kind of fermentation.

438 Re quires a mordant.

7. None of the red colouring matters has ſo ſtrong an affinity for cloth as to produce a permanent red, without the aſſiſtance of mordants. The mordants employed are alumina and oxyd of tin; oil and tan, in certain proceſſes, are alſo uſed; and tartar and muriat of ſoda are frequently called in as auxiliaries.

8. Coarſe woollen ſtuffs are dyed red with madder

† ertbollet, i 73.

* id 175.

Ban. , i. 271.

‡ ertbollet, i 15.

* Bertbollet, ii 240.

(H) If we believe Tournefort, this dye ſtuff was known to the ancients. They employed it to dye the colour known by the name of *purple* of Amorgos, one of the Cyclades iſlands. If this account be accurate, the knowledge of it had been loſt during the dark ages. It was accidentally diſcovered by a Florentine merchant about the year 1300, who obſerved, that urine gave a very fine colour to the lichen roccella. Mr Duſay diſcovered, that archil poſſeſſes the property of tinging indelibly white marble, of forming veins, and giving it the appearance of jaſper. See *Mem. Par.* 1732.

(I) The tincture of archil is uſed for making *ſpirit of wine thermometers*. It is a ſingular fact, that this tincture becomes gradually colourleſs when excluded from the contact of air, and that it again recovers its colour when expoſed to the atmoſphere. The phenomenon was firſt obſerved by the Abbé Nollet, and deſcribed by him in an eſſay, publiſhed among the memoirs of the Academy of Sciences for 1742.

or archil ; but fine cloth is almoſt excluſively dyed with cochineal ; though the colour which it receives from kermes is much more durable. Brazil wood is ſcarcely uſed, except as an auxiliary ; becauſe the colour which it imparts to wool is not permanent.

439 Wool how dyed crimſon, Wool is dyed *crimſon*, by firſt impregnating it with alumina by means of an alum bath, and then boiling it in a decoction of cochineal till it has acquired the wiſhed-for colour. The crimſon will be finer if the tin mordant be ſubſtituted for alum : indeed it is uſual with dyers to add a little nitro-muriat of tin when they want fine crimſons. The addition of archil and potaſs to the cochineal, both renders the crimſon darker and gives it more bloom ; but the bloom very ſoon vaniſhes. For paler crimſons, one half of the cochineal is withdrawn, and madder ſubſtituted in its place.

440 And ſcarlet. Wool may be dyed *ſcarlet*, the moſt ſplendid of all colours, by firſt boiling it in a ſolution of murio-ſulphat of tin ; then dyeing it pale yellow with quercitron bark, and afterwards crimſon with cochineal : For ſcarlet is a compound colour, conſiſting of *crimſon* mixed with a little *yellow*. This method was ſuggeſted by Dr Bancroft, who firſt explained the nature of the common method. The proportions which he gives are eight parts of murio-ſulphat of tin for 100 parts of cloth. After the cloth has been boiled in this ſolution for a quarter of an hour, it is to be taken out, and about four parts of cochineal, and two and a half parts of quercitron bark, are to be thrown into the bath. After theſe are well mixed, the cloth is to be returned again to the bath, and boiled in it, till it has acquired the proper colour *.

The common proceſs for dyeing ſcarlet is as follows: Twelve parts of tartar are diſſolved in warm water; then one part of cochineal is added, and ſoon after ten parts of nitro muriat of tin. When the bath boils, 100 parts of cloth are put in, turned briſkly through the bath, boiled in it for two hours ; then taken out, aired, waſhed, and dried. Into another bath eleven parts of cochineal are put ; and after its colouring matter is ſufficiently extracted, 28 parts of nitro-muriat of tin are added. In this bath the cloth is boiled for an hour, and then waſhed and dried.

Every preceding writer on dyeing took it for granted, that the yellow tinge neceſſary for ſcarlet was produced by the nitro muriat of tin, or rather by the nitric acid of that compound, and that the tartar was only uſeful in enlivening the colour. But Dr Bancroft aſcertained, by actual experiment, that nitro-muriat of tin has no ſuch effect ; that cloth, impregnated with this or any other tin mordant, and afterwards dyed with cochineal, acquires only a crimſon colour, unleſs tartar be added ; that the tartar has the property of converting part of the cochineal to yellow ; and therefore is the real agent in producing the ſcarlet colour. Good ſcarlet, indeed, cannot be made without tin ; becauſe every other mordant ſullies the colour, and renders it dull†.

441 Red dyes employed for ſilk, 9. Silk is uſually dyed red with cochineal or carthamus, and ſometimes with Brazil wood. Kermes does not anſwer for ſilk ; madder is ſcarcely ever uſed for that purpoſe, becauſe it does not yield a bright enough colour. Archil is employed to give ſilk a bloom ; but it is ſcarcely uſed by itſelf, unleſs when the colour wanted is lilac.

442 In dyeing crimſon, Silk may be dyed crimſon by ſteeping it in a ſolution of alum, and then dyeing it in the uſual way in a cochineal bath. But the common proceſs is to plunge the ſilk, after it has been alumed, into a bath formed of the following ingredients : Two parts of white galls, three parts of cochineal, three-ſixteenths of tartar, and three-ſixteenths of nitro-muriat of tin, for every ſixteen parts of ſilk. The ingredients are to be put into boiling water in the order they have been enumerated ; the bath is then to be filled up with cold water ; the ſilk put into it, and boiled for two hours. After the bath has cooled, the ſilk is uſually allowed to remain in it for three hours longer.

443 Poppy, The colours known by the names of poppy, cherry, roſe, and fleſh colour, are given to ſilk by means of carthamus. The proceſs conſiſts merely in keeping the ſilk, as long as it extracts any colour, in an alkaline ſolution of carthamus, into which as much lemon juice as gives it a fine cherry colour has been poured. To produce a deep poppy red, the ſilk muſt be put ſucceſſively into a number of ſimilar baths, and allowed to drain them. When the ſilk is dyed, the colour is brightened by plunging it into hot water acidulated with lemon juice. The ſilk ought to be previouſly dyed yellow with anotta.

444 Cherry, Cherry red is produced the ſame way, only the anotta ground is omitted, and leſs colouring matter is neceſſary. 445 Fleſh red, When a fleſh colour is required, a little ſoap ſhould be put into the bath, which ſoftens the colour, and prevents it from taking too quickly.

To leſſen the expence, ſome archil is often mixed with carthamus for dark ſhades.

The ſame ſhades may be dyed by means of brazil wood, but they do not ſtand.

446 Scarlet. Silk cannot be dyed a full ſcarlet ; but a colour approaching to ſcarlet may be given it, by firſt impregnating the ſtuff with murio-ſulphat of tin, and afterwards dyeing it in a bath compoſed of four parts of cochineal and four parts of quercitron bark. To give the colour more body, both the mordant and the dye may be repeated *. A colour approaching ſcarlet may be alſo given to ſilk, by firſt dyeing it crimſon, then dyeng it with *carthamus*, and laſtly yellow without heat. †.

447 How to dye cotton and linen red. 10. Cotton and linen are dyed red with madder. The proceſs was borrowed from the Eaſt ; hence the colour is often called *Adrianople* or *Turkey red*. The cloth is firſt impregnated with oil, then with galls, and laſtly with alum, in the manner deſcribed in the laſt ſection. It is then boiled for an hour in a decoction of madder, which is commonly mixed with a quantity of blood. After the cloth is dyed, it is plunged into a ſoda ley, in order to brighten the colour. The red given by this proceſs is very permanent, and when properly conducted it is exceedingly beautiful. The whole difficulty conſiſts in the application of the mordant, which is by far the moſt complicated employed in the whole art of dyeing.

Cotton may be dyed ſcarlet by means of murio-ſulphat of tin, cochineal, and quercitron bark, uſed as for ſilk ; but the colour is too fading to be of any value *.

SECT. IV. *Of BLACK.*

448 Black dyes. 1. THE ſubſtances employed to give a black colour to cloth are red oxyd of iron and tan. Theſe two ſubſtances

---

* *Bancroft*, i. 291.

† *Ibid.* 288.

* *Bancro* i. 312.

lack.

ſtances have a ſtrong affinity for each other; and when combined, aſſume a deep black colour, not liable to be deſtroyed by the action of air and light. The affinity which each of them has for the different kinds of cloth has been already mentioned.

2. Logwood is uſually employed as an auxiliary, becauſe it communicates luſtre, and adds conſiderably to the fulneſs of the black. It is the wood of the tree called by Linnæus *hæmatoxylum campechianum*, which is a native of ſeveral of the Weſt India iſlands, and of that part of Mexico which ſurrounds the Bay of Honduras. It yields its colouring matter to water. The decoction is at firſt a fine red bordering on violet, but if left to itſelf it gradually aſſumes a black colour. Acids give it a deep red colour; alkalies a deep violet, inclining to brown. Sulphat of iron renders it as black as ink, and occaſions a precipitate of the ſame colour. The precipitate produced by alum is dark red; the ſupernatent liquid becomes yellowiſh red *.

ertbollet, 55.

3. Cloth, before it receive a black colour, is uſually dyed blue. This renders the colour much fuller and finer than it otherwiſe would be. If the cloth be coarſe, the blue dye may be too expenſive; in that caſe a brown colour is given by means of walnut peels.

49
w to in-
a
k on
d,

4. Wool is dyed black by the following proceſs. It is boiled for two hours in a decoction of nut galls, and afterwards kept for two hours more in a bath compoſed of logwood and ſulphat of iron, kept during the whole time at a ſcalding heat, but not boiled. During the operation it muſt be frequently expoſed to the air; becauſe the green oxyd of iron, of which the ſulphat is compoſed, muſt be converted into red oxyd by abſorbing oxygen, before the cloth can acquire a proper colour. The common proportions are five parts of galls, five of ſulphat of iron, and 30 of logwood for every 100 of cloth. A little acetite of copper is commonly added to the ſulphat of iron, becauſe it is thought to improve the colour.

50
ilk,

5. Silk is dyed nearly in the ſame manner. It is capable of combining with a very great deal of tan; the quantity given is varied at the pleaſure of the artiſt, by allowing the ſilk to remain a longer or ſhorter time in the decoction. After the galling, the ſilk is put into a ſolution of ſulphat of iron, which is uſually mixed with a certain quantity of iron filings and of gum. It is occaſionally wrung out of the bath, expoſed for ſome time to the air, and again immerſed. When it has acquired a ſufficiently full colour, it is waſhed in cold water, and afterwards ſteeped in a decoction of ſoap to take off the harſhneſs, which ſilk always has after being dyed black.

51
en, and
on.

6. It is by no means ſo eaſy to give a full black to linen and cotton. The cloth, previouſly dyed blue, is ſteeped for 24 hours in a decoction of nut galls. A bath is prepared, containing acetite of iron, formed by ſaturating acetous acid with brown oxyd of iron. Into this bath the cloth is put in ſmall quantities at a time, wrought with the hand for a quarter of an hour, then wrung out and aired, again wrought in a freſh quantity of the bath, and afterwards aired. Theſe alternate proceſſes are repeated till the colour wanted is given. A decoction of alder bark is uſually mixed with the liquor containing the nut galls.

It would probably contribute to the goodneſs and permanence of the colour, if the cloth, before being galled, were impregnated with oil, by being ſteeped in a mixture of alkaline ley and oil combined, as is practiſed for dyeing cotton red.

Brown.

SECT. V. *Of BROWN.*

THAT particular *brown* colour, with a caſt of *yellow*, which the French call *fauve*, and to which the Engliſh writers on *dyeing* have appropriated the word *fawn*, though in fact a compound, is commonly ranked among ſimple colours; becauſe it is applied to cloth by a ſingle proceſs. The ſubſtances employed to produce this colour are numerous; but we ſhall ſatisfy ourſelves with enumerating the following:

452
Brown
dyes.

Walnut peels are the green covering of the walnut. When firſt ſeparated, they are white internally; but ſoon aſſume a brown, or even a black colour, on expoſure to the air. They readily yield their colouring matter to water. They are uſually kept in large caſks, covered with water, for above a year, before they are uſed. To dye wool brown with them, nothing more is neceſſary than to ſteep the cloth in a decoction of them till it has acquired the wiſhed-for colour. The depth of the ſhade is proportional to the ſtrength of the decoction. The root, as well as the peel of the walnut tree, contains the ſame colouring matter, but in ſmaller quantity. The bark of the birch, alſo, and many other trees, may be uſed for the ſame purpoſe.

It is very probable, that the brown colouring matter is in theſe vegetable ſubſtances combined with tan. This is certainly the caſe in ſumach, which is often employed to produce a brown. This combination explains the reaſon why no mordant is neceſſary; the tan has a ſtrong affinity for the cloth; and the colouring matter for the tan. The dye ſtuff and the mordant are already, in fact, combined together.

CHAP. V. OF COMPOUND COLOURS.

COMPOUND colours are produced by mixing together two ſimple ones; or, which is the ſame thing, by dyeing cloth firſt one ſimple colour, and then another. The reſult is a compound colour, varying in ſhade according to the proportions of each of the ſimple colours employed.

453
Diviſion of
compound
colours.

Compound colours are exceedingly numerous, varying almoſt to infinity, according to the proportions of the ingredients employed. They may be all arranged under the four following claſſes:

Mixtures of 1. blue and yellow,
2. blue and red,
3. yellow and red,
4. black and other colours.

To deſcribe all the different ſhades which belong to each of theſe claſſes, would be impoſſible; and even if it were poſſible, it would be unneceſſary; becauſe all the proceſſes depend upon the principles laid down in the preceding chapters, and may eaſily be conceived and varied by thoſe who underſtand theſe principles. In the following ſections, therefore, it will be ſufficient to mention the principal compound colours produced by the mixture of ſimple colours, and to exhibit a ſpecimen or two of the mode of producing them.

SECT. I. *Of Mixtures of BLUE and YELLOW.*

THE colour produced by mixtures of blue and yellow is

Mixtures of Blue and Yellow.

is *green*; which is diſtinguiſhed by dyers by a great variety of names, according to the depth of the ſhade, or the prevalence of either of the component parts. Thus we have *ſea green, meadow* or *graſs green, pea green*, &c. &c.

454 How to induce green

455 On wool,

Wool is uſually dyed green by giving it firſt a blue colour, and afterwards dyeing it yellow; becauſe, when the yellow is firſt given, ſeveral inconveniences follow: the yellow partly ſeparates again in the blue vat, and communicates a green colour to it; and thus renders it uſeleſs for every other purpoſe, except dyeing green. Any of the proceſſes for dyeing blue, deſcribed in the laſt chapter, may be followed; care being taken always to proportion the depth of the blue to the ſhade of green which is required. The cloth thus dyed blue may receive a yellow colour, by following the proceſſes deſcribed in the laſt chapter for that purpoſe. When the ſulphat of indigo is employed, it is uſual to mix all the ingredients together, and to dye the cloth at once: the colour produced is known by the name of *Saxon*, or *Engliſh green*. One of the moſt convenient methods of conducting this proceſs is the following:

Six or eight parts of quercitron bark, tied up in a bag, are to be put into the dyeing veſſel, which ſhould contain only a ſmall quantity of warm water. When the water boils, ſix parts of murio ſulphat of tin, and four parts of alum, are to be added. In a few minutes, the dyeing veſſel ſhould be filled up with cold water, till the temperature is reduced to about 130°. After this, as much ſulphat of indigo is to be poured in as is ſufficient to produce the intended ſhade of green. When the whole has been ſufficiently ſtirred, a hundred parts of cloth are to be put in, and turned briſkly for about fifteen minutes, till it has acquired the wiſhed-for ſhade *. By this method, a much more beautiful colour is obtained than is given by the uſual proceſs, in which fuſtic is employed to give the yellow ſhade.

456 Silk,

Silk, intended to receive a green colour, is uſually dyed yellow firſt, by means of weld, according to the proceſs deſcribed in the laſt chapter; afterwards, it is dipped into the blue vat, and dyed in the uſual manner. To deepen the ſhade, or to vary the tint, decoctions of logwood, anotta, fuſtic, &c. are added to the yellow bath. Or ſilk may be dyed at once green, by adding ſuitable proportions of ſulphat of indigo to the common quercitron bark bath, compoſed of four parts of bark, three parts of alum, and two parts of murio ſulphat of tin †.

457 Cotton, and linen.

Cotton and linen muſt be firſt dyed blue, and then yellow, according to the methods deſcribed in the laſt chapter. It is needleſs to add, that the depth of each of theſe colours muſt be proportioned to the ſhade of green colour which it is the intention of the dyer to give.

SECT. II. *Of Mixtures of* BLUE *and* RED.

458 Violet, purple, lilac,

THE mixture of blue and red produces *violet, purple*, and *lilac*, of various ſhades, and known by various names, according to the proportion of the ingredients employed. When the colour is deep, and inclines moſt to blue, it is called *violet*; but when the red is prevalent, it gets the name of *purple*. When the ſhade is light, the colour is uſually called *lilac*. For violet, therefore, the cloth muſt receive a deeper blue; for purple, a deeper red; and for lilac, both of theſe colours muſt be light.

Mixtures of Blue and Red.

459 How induced on wool,

Wool is uſually dyed firſt *blue*; the ſhade, even for violet, ought not to be deeper than that called *ſky blue*; afterwards it is dyed ſcarlet, in the uſual manner. The violets and purples are dyed firſt; and when the vat is ſomewhat exhauſted, the cloth is dipped in which is to receive the lilac, and the other lighter ſhades. By means of ſulphat of indigo, the whole proceſs may be performed at once. The cloth is firſt alumed, and then dyed in a veſſel, containing cochineal, tartar, and ſulphat of indigo, in proportions ſuited to the depth of the colour required *. A violet colour may alſo be given to wool, by impregnating it with a mordant compoſed of tin diſſolved in a mixture of ſulphuric and muriatic acids, formed by diſſolving muriat of ſoda in ſulphuric acid: to which ſolution a quantity of tartar and ſulphat of copper is added. The wool is then boiled in a decoction of logwood till it has acquired the wiſhed-for colour †.

460 Silk,

Silk is firſt dyed crimſon, by means of cochineal, in the uſual way, excepting only that no tartar, nor ſolution of tin, is employed: It is then dipped into the indigo vat till it has acquired the wiſhed-for ſhade. The cloth is often afterwards paſſed through an archil bath, which greatly improves the beauty of the colour. Archil is often employed as a ſubſtitute for cochineal: The ſilk firſt receives a red colour, in the uſual way, by being dyed in an archil bath; afterwards it receives the proper ſhade of blue. The violet, or purple, given by this proceſs is very beautiful, but not very laſting ‡.

Silk may be dyed violet or purple at once, by firſt treating it with a mordant, compoſed of equal parts of nitro-muriat of tin and alum, and then dipping it into a cochineal bath, into which a proper quantity of ſulphat of indigo has been poured. But this dye is fading; the blue colour ſoon decays, and the ſilk becomes red *.

461 Cotton, and linen.

Cotton and linen are firſt dyed blue, then galled, then ſoaked in a decoction of logwood; ſome alum and acetite of copper are added to the decoction, and the cloth is ſoaked again. This proceſs is repeated till the proper colour is obtained †. The colour produced by this method is not nearly equal in permanency to that deſcribed in this *Supplement* under the word IRON; to which we beg leave to refer the reader. The proceſs there deſcribed has been long known; but Mr Chaptal has ſimplified it ſomewhat.

SECT. III. *Of Mixtures of* YELLOW *and* RED.

462 Orange and olive,

THE colour produced by the mixture of *red* and *yellow* is *orange*; but almoſt an infinity of ſhades reſults from the different proportions of the ingredients, and from the peculiar nature of the yellow employed. Sometimes *blue* is combined with red and yellow on cloth: the reſulting colour is called *olive*.

463 How induced on wool,

Wool may be dyed orange by preciſely the ſame proceſs which is uſed for ſcarlet, only the proportion of red muſt be diminiſhed, and that of yellow increaſed. When wool is firſt dyed red with madder, and then yellow with weld, the reſulting colour is called *cinnamon colour*. The mordant, in this caſe, is a mixture of alum and tartar. The ſhade may be varied exceedingly, by uſing other yellow dye ſtuffs inſtead of weld, and by varying the proportions, according to circumſtances. Thus a reddiſh yellow may be given to cloth, by firſt dyeing it yellow, and then paſſing it through a madder bath.

464 Silk,

Silk is dyed orange by means of carthamus: the method

xtures Black h other ours.

method has been deſcribed in the laſt chapter. Cinnamon colour is given to it by dyeing it, previouſly alumed, in a bath compoſed of the decoctions of logwood, Brazil wood, and fuſtic, mixed together.

65 on, linen.

Cotton and linen receive a cinnamon colour by means of weld and madder. The proceſs is complicated. The cloth is firſt dyed with weld and acetite of copper, then dipped in a ſolution of ſulphat of iron, then galled, then alumed, and then dyed in the uſual way with madder *.

ertbollet, i 44.

For *olive*, the cloth is firſt dyed blue, then yellow, and laſtly paſſed through a madder bath. The ſhade depends upon the proportion of each of theſe colours. For very deep ſhades the cloth is alſo dipped into a ſolution of ſulphat of iron. Cotton and linen may be dyed *olive* by dipping them into a bath, compoſed of the decoction of four parts of weld and one of potaſs, mixed with the decoction of Brazil wood and a little acetite of copper †.

† Aplig- bid.

SECT. IV. *Of Mixtures of* BLACK *with other Colours.*

66 ys, and vns.

STRICTLY ſpeaking, the mixtures belonging to this ſection are not mixtures of *black colours* with other colours, but combinations of the *black dye* with other colours; the ingredients of which, galls and brown oxyd of iron, being both mordants, variouſly modify other colouring matters by combining with them. Thus if cloth be previouſly combined with brown oxyd of iron, and afterwards dyed yellow with quercitron bark, the reſult will be a *drab* of different ſhades, according to the proportion of mordant employed. When the proportion is ſmall, the colour inclines to olive or yellow; on the contrary, the drab may be deepened or ſaddened, as the dyers ſpeak, by mixing a little ſumach with the bark *. The precautions formerly mentioned in applying the oxyd muſt be obſerved.

ancr-ft, 43.

It is very common to dip cloth already dyed ſome particular colour into a ſolution of ſulphat of iron, and galls or ſome other ſubſtance containing tan, called the *black bath*, in order to alter the ſhade, and to give the colour greater permanency. We ſhall give a few inſtances: greater minuteneſs would be inconſiſtent with the nature of this article.

Cloth dyed blue, by being dipped into the *black* bath, becomes *bluiſh grey*. Cloth dyed *yellow*, by the ſame proceſs, becomes *blackiſh grey*, *drab*, or *yellowiſh brown*. Cloth previouſly alumed, and dyed in a decoction of cochineal and acetite of iron, acquires a permanent *violet colour* inclining to *brown*, or a *lilac*, if the dyeing veſſel be ſomewhat exhauſted *. Cloth ſteeped in a mordant, compoſed of alum and acetite of iron diſſolved in water, and afterwards dyed in a bath compoſed of the decoction of galls and madder mixed together, acquires a fine deep *brown*. The method of varying the ſhades of linen and cotton will be readily conceived, after we have given an account of calico printing, which forms the ſubject of the next chapter.

ubliche, bollet, 49.

CHAP. VI. OF CALICO PRINTING.

CALICO printing is the art of communicating different colours to particular ſpots or figures on the ſurface of cotton or linen cloth, while the reſt of the ſtuff retains its original whiteneſs.

Calico Printing.

467 Origin of calico printing.

This ingenious art ſeems to have originated in India, where we know it has been practiſed for more than 2000 years. Pliny indeed inform us, that the Egyptians were acquainted with calico printing; but a variety of circumſtances combine to render it more than probable that they borrowed it from India. The art has but lately been cultivated in Europe; but the enlightened induſtry of our manufacturers has already improved prodigiouſly upon the tedious proceſſes of their Indian maſters. No art has riſen to perfection with greater celerity: a hundred years ago it was ſcarcely known in Europe; at preſent, the elegance of the patterns, the beauty and permanency of the colours, and the expedition with which the different operations are carried on, are really admirable.

A minute detail of the proceſſes of calico printing would not only be foreign to the plan of this article, but of very little utility. To the artiſt the proceſſes are already known; an account of them therefore could give him no new information; while it would fatigue and diſappoint thoſe readers who wiſh to underſtand the principles of the art. We ſhall content ourſelves, therefore, with a ſhort view of theſe principles.

468 It conſiſts in applying mordants partially to cotton,

Calico printing conſiſts in impregnating thoſe parts of the cloth which are to receive a colour with a mordant, and then dyeing it as uſual with ſome dye ſtuff or other. The dye ſtuff attaches itſelf firmly only to that part of the cloth which has received the mordant. The whole ſurface of the cotton is indeed more or leſs tinged; but by waſhing it, and bleaching it for ſome days on the graſs with the wrong ſide uppermoſt, all the unmordanted parts reſume their original colour, while thoſe which have received the mordant retain it. Let us ſuppoſe, that a piece of white cotton cloth is to receive red ſtripes; all the parts where the ſtripes are to appear are penciled over with a ſolution of acetite of alumina. After this, the cloth is dyed in the uſual manner with madder. When taken out of the dyeing veſſel, it is all of a red colour; but by waſhing and bleaching, the madder leaves every part of the cloth white except the ſtripes impregnated with the acetite of alumina, which remain red. In the ſame manner, may yellow ſtripes, or any other wiſhed-for figure, be given to cloth, by ſubſtituting quercitron bark, weld, &c. for madder.

469 Which is afterwards dyed and bleached.

When different colours are to be given to different parts of the cloth at the ſame time, it is done by impregnating it with various mordants. Thus if ſtripes be drawn upon a cotton cloth with acetite of alumina, and other ſtripes with acetite of iron, and the cloth be afterwards dyed in the uſual way with madder and then waſhed and bleached, it will be ſtriped *red* and *brown*. The ſame mordants with quercitron bark give *yellow*, and *olive* or *drab*.

470 Mordants employed.

The mordants employed in calico printing are acetite of alumina and acetite of iron, prepared in the manner deſcribed in the third chapter of this part. Theſe mordants are applied to the cloth, either with a pencil or by means of blocks, on which the pattern, according to which the cotton is to be printed, is cut. As they are applied only to particular parts of the cloth, care muſt be taken that none of them ſpread to the part of the cloth which is to be left white, and that they do not interfere with one another when more than one are applied.

applied. If theſe precautions be not attended to, all the elegance and beauty of the print muſt be deſtroyed. It is neceſſary, therefore, that the mordants ſhould be of ſuch a degree of conſiſtence that they will not ſpread beyond thoſe parts of the cloth on which they are applied. This is done by thickening them with flour or ſtarch when they are to be applied by the block, and with gum arabic when they are to be put on with a pencil. The thickening ſhould never be greater than is ſufficient to prevent the ſpreading of the mordants; when carried too far, the cotton is apt not to be ſufficiently ſaturated with the mordant; of courſe the dye takes but imperfectly.

471 How applied.

In order that the parts of the cloth impregnated with mordants may be diſtinguiſhed by their colour, it is uſual to tinge the mordants with ſome colouring matter or other. The printers commonly uſe the decoction of Brazil wood for this purpoſe; but Bancroft has objected to this method, becauſe he thinks that the Brazil wood colouring matter impedes the ſubſequent proceſs of dyeing. It is certain, that the colouring matter of the Brazil wood is diſplaced during that operation by the ſuperior affinity of the dye ſtuff for the mordant. Were it not for this ſuperior affinity, the colour would not take at all. Dr Bancroft * adviſes to colour the mordant with ſome of the dye ſtuff afterwards to be applied; and he cautions the uſing of more for that purpoſe than is ſufficient to make the mordant diſtinguiſhable when applied to the cloth. The reaſon of this precaution is obvious. If too much dye be mixed with the mordant, a great proportion of the mordant will be combined with colouring matter; which muſt weaken its affinity for the cloth, and of courſe prevent it from combining with it in ſufficient quantity to enſure a permanent dye.

* *Bancroft*, i. 373.

Sometimes theſe two mordants are mixed together in different proportions; and ſometimes one or both is mixed with an infuſion of ſumach or of nut galls. By theſe contrivances, a great variety of colours are produced by the ſame dye ſtuff.

472 Subſequent treatment of the cloth

After the mordants have been applied, the cloth muſt be completely dried. It is proper for this purpoſe to employ artificial heat; which will contribute ſomething towards the ſeparation of the acetous acid from its baſe, and towards its evaporation; by which the mordant will combine in a greater proportion, and more intimately with the cloth.

When the cloth is ſufficiently dried, it is to be waſhed with warm water and cow dung, till all the flour or gum employed to thicken the mordants, and all thoſe parts of the mordants which are uncombined with the cloth, are removed. The cow dung ſerves to entangle theſe looſe particles of mordants, and to prevent them from combining with thoſe parts of the cloth which are to remain white. After this the cloth is thoroughly rinſed in clean water.

473 Dye ſtuffs uſed.

Almoſt the only dye ſtuffs employed by calico printers are, indigo, madder, and quercitron bark or weld. This laſt ſubſtance, however, is now but little uſed by the printers of this country, except for delicate greeniſh yellows. The quercitron bark has almoſt ſuperſeded it; becauſe it gives colours equally good, and is much cheaper, and more convenient, not requiring ſo great a heat to fix it. Indigo, not requiring any mordant, is commonly applied at once either with the block or a pencil. It is prepared by boiling together indigo, potaſs made cauſtic by quicklime, and orpiment: the ſolution is afterwards thickened with gum (K). It muſt be carefully ſecluded from the air, otherwiſe the indigo would ſoon be regenerated, which would render the ſolution uſeleſs. Dr Bancroft has propoſed to ſubſtitute coarſe brown ſugar for orpiment. It is equally efficacious in decompoſing the indigo and rendering it ſoluble; while it likewiſe ſerves all the purpoſes of gum *.

* *Bancroft* i. 123.

When the cloth, after being impregnated with the mordant, is ſufficiently cleanſed, it is dyed in the uſual manner. The whole of it is more or leſs tinged with the dye ſtuff. It is well waſhed, and then ſpread out for ſome days on the graſs, and bleached with the wrong ſide uppermoſt. This carries the colour off completely from all the parts of the cotton which has not imbibed the mordant, and leaves them of their original whiteneſs, while the mordanted ſpots retain the dye as ſtrongly as ever.

Let us now give an example or two of the manner in which the printers give particular colours to calicoes. Some calicoes are only printed of one colour, others have two, others three, or more, even to the number of eight, ten, or twelve. The ſmaller the number of colours, the fewer in general are the proceſſes.

474 Method of printing drabs,

1. One of the moſt common colours on cotton prints is a kind of nankeen yellow, of various ſhades, down to a deep yellowiſh brown or drab. It is uſually in ſtripes or ſpots. To produce it, the printers beſmear a block, cut out into the figure of the print, with acetite of iron thickened with gum or flour; apply it to the cotton; which, after being dried and cleaned in the uſual manner, is plunged

---

(K) Different proportions are uſed by different perſons. Mr Hauſſman mixes 25 gallons of water with 16 pounds of indigo well ground (or a greater or ſmaller quantity, according to the quality of the indigo and the depth of colour wanted); to which he adds 30 pounds of good carbonat of potaſs, placing the whole over a fire; and as ſoon as the mixture begins to boil, he adds, by a little at a time, 12 pounds of quick lime, to render the alkali cauſtic, by abſorbing its carbonic acid. This being done, 12 pounds of red orpiment are alſo added to the mixture; which is then ſtirred, and left to boil for ſome little time, that the indigo may be perfectly diſſolved; which may be known by its giving a yellow colour immediately upon being applied to a piece of white tranſparent glaſs. M. Oberkampf, proprietor of the celebrated manufactory at Jouy near Verſailles, uſes a third more of indigo; and others uſe different proportions, not only of indigo, but of lime, potaſs, and orpiment; which all ſeem to anſwer with nearly equal ſucceſs: but with the beſt copper-coloured Guatamala indigo, it is certain that a good blue may be obtained from only half the quantity preſcribed by Mr Hauſſman, by uſing as much ſtone, or oyſter ſhell lime, as of indigo, nearly twice as much potaſs, and a fourth part leſs of orpiment than of indigo. See *Bancroft*, I. 113.

plunged into a potaſs ley. The quantity of acetite of iron is always proportioned to the depth of the intended ſhade.

75 llow, 2. For yellow, the block is beſmeared with acetite of alumina. The cloth, after receiving this mordant, is dyed with quercitron bark, and then bleached.

76 ed, 3. Red is communicated by the ſame proceſs, only madder is ſubſtituted for the bark.

77 lue, 4. The fine light blues, which appear ſo often on printed cottons, are produced, by applying to the cloth a block beſmeared with a compoſition, conſiſting partly of wax, which covers all thoſe parts of the cloth which are to remain white. The cloth is then dyed in a cold indigo vat; and after it is dry, the wax compoſition is removed by means of hot water.

78 ac, own, 5. Lilac, flea brown, and blackiſh brown, are given by means of acetite of iron; the quantity of which is always proportioned to the depth of the ſhade. For very deep colours, a little ſumach is added. The cotton is afterwards dyed in the uſual manner with madder, and then bleached.

79 dove. 6. Dove colour and drab, by acetite of iron and quercitron bark.

80 lica- of dif- nt co- s to the cloth. When different colours are to appear in the ſame print, a greater number of operations are neceſſary. Two or more blocks are employed, upon each of which that part of the print only is cut which is to be of ſome particular colour. Theſe are beſmeared with different mordants, and applied to the cloth, which is afterwards dyed as uſual. Let us ſuppoſe, for inſtance, that three blocks are applied to cotton; one with acetite of alumina, another with acetite of iron, a third with a mixture of theſe two mordants, and that the cotton is then dyed with quercitron bark, and bleached. The parts impregnated with the mordants would have the following colours.

Acetite of alumina,	Yellow,
iron,	Olive, drab, dove (L),
The mixture,	Olive green, olive.

If part of the yellow be covered over with the indigo liquor, applied with a pencil, it will be converted into *green:* By the ſame liquid, blue may be given to ſuch parts of the print as require it.

If the cotton be dyed with madder inſtead of quercitron bark, the print will exhibit the following colours:

Acetite of alumina,	Red,
iron,	Brown, black,
The mixture,	Purple.

When a greater number of colours are to appear; for inſtance, when thoſe communicated by bark and thoſe by madder are wanted at the ſame time, mordants for part of the pattern are to be applied; the cotton is then to be dyed in the madder bath and bleached; then the reſt of the mordants, to fill up the pattern, are added, and the cloth is again dyed with quercitron bark and bleached. This ſecond dyeing does not much affect the madder colours; becauſe the mordants, which render them permanent, are already ſaturated. The yellow tinge is eaſily removed by the ſubſequent bleaching. Sometimes a new mordant is alſo applied to ſome of the madder colours; in conſequence of which they receive a new permanent colour from the bark. After the laſt bleaching, new colours may be added by means of the indigo liquor. The following table will give an idea of the colours which may be given to cotton by theſe complicated proceſſes.

I. *Madder dye.*	*Colours.*
Acetite of alumina,	Red,
iron,	Brown, black,
Ditto diluted,	Lilac,
Both mixed,	Purple.
II. *Bark dye.*	
Acetite of alumina,	Yellow,
iron,	Dove, drab,
Lilac and acetite of alumina,	Olive,
Red and acetite of alumina,	Orange.
III. *Indigo dye.*	
Indigo,	Blue,
Indigo and yellow	Green.

Thus no leſs than 12 colours may be made to appear together in the ſame print by theſe different proceſſes.

Theſe inſtances will ſerve to give the reader an idea of the nature of calico printing, and at the ſame time afford an excellent illuſtration of the importance of mordants in dyeing.

481 Colours for penciling. If it were poſſible to procure colours ſufficiently permanent, by applying them at once to the cloth by the block or the pencil, as is the caſe with the mordants, the art of calico printing would be brought to the greateſt poſſible ſimplicity: but at preſent this can only be done in one caſe, that of indigo; every other colour requires dyeing. Compoſitions indeed may be made by previouſly combining the dye ſtuff and the mordants. Thus *yellow* may be applied at once by employing a mixture of the infuſion of quercitron bark and acetite of alumina; *red*, by mixing the ſame mordant with the decoction of alumina, and ſo on. Unfortunately the colours applied in this way are far inferior in permanency to thoſe produced when the mordant is previouſly combined with the cloth, and the dye ſtuff afterwards applied ſeparately. In this way are applied almoſt all the fugitive colours of calicoes which waſhing or even expoſure to the air deſtroys.

As the application of colours in this way cannot always be avoided by calico printers, every method of rendering them more permanent is an object of importance. We ſhall therefore conclude this chapter with a deſcription of ſeveral colours of this kind propoſed by Dr Bancroft, which have a conſiderable degree of permanence.

A *yellow* printing colour may be formed by the following method: Let three pounds of alum, and three ounces of clean chalk, be firſt diſſolved in a gallon of hot water, and then add two pounds of ſugar of lead; ſtir this mixture occaſionally during the ſpace of 24 or 36 hours, then let it remain 12 hours at reſt, and afterwards decant and preſerve the clear liquor; this be-

---

(L) According to the proportion of acetite of iron employed.

Calico Printing.

ing done, pour ſo much more warm water upon the remaining ſediment, as after ſtirring and leaving the mixture to ſettle will afford clear liquor enough to make, when mixed with the former, three quarts of this aluminous mordant or acetite of alumine. Then take not leſs than ſix, nor more than eight, pounds of quercitron bark properly ground; put this into a tinned copper veſſel, with four or five gallons of clean ſoft water, and make it boil for the ſpace of one hour at leaſt, adding a little more water, if at any time the quantity of liquor ſhould not be ſufficient to cover the ſurface of the bark: the liquor having boiled ſufficiently, ſhould be taken from the fire, and left undiſturbed for half an hour, and then the clear decoction ſhould be poured off through a fine ſieve or canvas ſtrainer. This being done, let ſix quarts more of clear water be poured upon the ſame bark, and made to boil ten or fifteen minutes, both having been firſt well ſtirred; and being afterwards left a ſufficient time to ſettle, the clean decoction may then be ſtrained off, and put with the former into a ſhallow wide veſſel to be evaporated by boiling, until what remains, being joined to the three quarts of aluminous mordant before mentioned, and to a ſufficient quantity of gum or paſte for thickening, will barely ſuffice to make three gallons of liquor in the whole. It will be proper, however, not to add the aluminous mordant, until the decoction is ſo far cooled as to be but little more than blood warm; and theſe being thoroughly mixed by ſtirring, may afterwards be thickened by the gum of Senegal or by gum arabic, if the mixture is intended for penciling; or by a paſte made with ſtarch or flour, if it be intended for printing.

Calico Printing.

By ſubſtituting a pound of murio-ſulphat of tin for the aluminous mordant in the above compoſition, a mixture may be formed which affords a very bright and full yellow, of conſiderable durability.

Sulphat of tin, mixed with a decoction of quercitron bark, communicates to cotton a *cinnamon* colour, which is ſufficiently permanent *.

When the decoctions of quercitron bark and logwood are boiled together, and ſuitable proportions of ſulphat of copper and of verdigris are added to them, with a little carbonat of potaſs, a compound is formed, which gives a *green* colour to cotton. Bancroft has made trial of this; and though it has not fully anſwered his expectation, his attempts were attended with ſufficient ſucceſs to determine him to perſevere in his experiments †.

If acetite of iron be mixed with a decoction of quercitron bark, and the mixture be properly thickened, the compound will communicate to cotton a *drab* colour of ſome durability. This compound, mixed with the olive colouring liquor above deſcribed, will produce an olive. If a ſolution of iron, by a diluted muriatic acid, or by a diluted nitric acid, be employed for this purpoſe inſtead of iron liquor, it will produce colours a little more laſting; but theſe ſolutions ſhould be employed ſparingly, that they may not hurt the texture of the linen or cotton to which they are intended to be applied.

Bancroft, i. 400.

† *Ibid*, 401.

SUL

Subtriple || Sulphuret.

SUBTRIPLE, is when one quantity is the 3d part of another; as 2 is ſubtriple of 6. And *Subtriple Ratio* is the ratio of 1 to 3.

SUBTRIPLICATE RATIO, is the ratio of the cube roots. So the ſubtriplicate ratio of a to b, is the ratio of $\sqrt[3]{a}$ to $\sqrt[3]{b}$, or of $a^{\frac{1}{3}}$ to $b^{\frac{1}{3}}$.

SUCCESSION OF SIGNS, in aſtronomy, is the order in which they are reckoned, or follow one another, and according to which the ſun enters them; called alſo *conſequentia*. As Aries, Taurus, Gemini, Cancer, &c.

SULPHURET OF LIME having lately been recommended by an eminent chemiſt * as a ſubſtitute for *potaſh* in the new method of bleaching, which, if it anſwer, may certainly be afforded at leſs expence, we ſhall here give the method of preparing the ſulphuret.

Take of ſulphur, or brimſtone in fine powder, four pounds; lime, well ſlaked and ſifted, twenty pounds; water, ſixteen gallons:—theſe are all to be well mixed and boiled for about half an hour in an iron veſſel, ſtirring them briſkly from time to time. Soon after the agitation of boiling is over, the ſolution of the ſulphuret of lime clears, and may be drawn off free from the inſoluble matter, which is conſiderable, and which reſts upon the bottom of the boiler (A). The liquor in this ſtate is pretty nearly of the colour of ſmall beer, but not quite ſo tranſparent.

* *W. Higgins, M. R. T. A.*

SUN

Sulphuret, Sun.

Sixteen gallons of freſh water are afterwards to be poured upon the inſoluble dregs in the boiler, in order to ſeparate the whole of the ſulphuret from them. When this clears (being previouſly well agitated), it is alſo to be drawn off and mixed with the firſt liquor; to theſe again thirty-three gallons more of water may be added, which will reduce the liquor to a proper ſtandard for ſteeping the cloth.

Here we have (an allowance being made for evaporation, and for the quantity retained in the dregs) ſixty gallons of liquor from four pounds of brimſtone.

Although ſulphur by itſelf is not in any ſenſible degree ſoluble in water, and lime but very ſparingly ſo, water diſſolving but about one ſeven-hundredth part of its weight of lime; yet the ſulphuret of lime is highly ſoluble.

When the above proportion of lime and ſulphur is boiled with only twelve gallons of water, the ſulphuret partly cryſtallizes upon cooling; and when once cryſtallized it is not eaſy of ſolution.

SUN (ſee ASTRONOMY-*Index*, Encycl.) is certainly that celeſtial body which, of all others, ſhould moſt attract our attention. It has accordingly employed much of

---

(A) Although lime is one of the conſtituent principles of the ſulphuret, yet being ſo intimately united to the ſulphur, it has no longer the property of lime; upon the ſame principle that ſulphuric acid in ſulphat of potaſh has not the property of that acid.

of the time and meditation, not only of the aſtronomer, but alſo of the ſpeculative philoſopher, in all ages of the world; and many hypotheſes have been formed, and ſome diſcoveries made, reſpecting the nature and the uſes of this vaſt luminary.

Sir Iſaac Newton has ſhewn, that the ſun, by its attractive power, retains the planets of our ſyſtem in their orbits: he has alſo pointed out the method whereby the quantity of matter which it contains may be accurately determined. Dr Bradley has aſſigned the velocity of the ſolar light with a degree of preciſion exceeding our utmoſt expectation. Gallileo, Scheiner, Hevelius, Caſſini, and others, have aſcertained the rotation of the ſun upon its axis, and determined the poſition of its equator. By means of the tranſit of Venus over the diſk of the ſun, our mathematicians have calculated its diſtance from the earth, its real diameter and magnitude, the denſity of the matter of which it is compoſed, and the fall of heavy bodies on its ſurface. We have therefore a very clear notion of the vaſt importance and powerful influence of the ſun on its planetary ſyſtem; but with regard to its internal conſtruction, we are yet extremely ignorant. Many ingenious conjectures have indeed been formed on the ſubject; a few of which we ſhall mention as an introduction to Dr Herſchel's, of which, as it is the lateſt, and perhaps the moſt plauſible, we ſhall give a pretty full account nearly in his own words.

The dark ſpots in the ſun, for inſtance, have been ſuppoſed to be ſolid bodies revolving very near its ſurface. They have been conjectured to be the ſmoke of volcanoes, or the ſcum floating upon an ocean of fluid matter. They have alſo been taken for clouds. They were explained to be opaque maſſes ſwimming on the fluid matter of the ſun, dipping down occaſionally. It has been ſuppoſed that a fiery liquid ſurrounded the ſun, and that by its ebbing and flowing the higheſt parts of it were occaſionally uncovered, and appeared under the ſhape of dark ſpots; and that by the return of the fiery liquid, they were again covered, and in that manner ſucceſſively aſſumed different phaſes. The ſun itſelf has been called a globe of fire, though perhaps metaphorically. The waſte it would undergo by a gradual conſumption, on the ſuppoſition of its being ignited, has been ingeniouſly calculated; and in the ſame point of view its immenſe power of heating the bodies of ſuch comets as draw very near to it has been aſſigned.

In the year 1779 there was a ſpot on the ſun which was large enough to be ſeen with the naked eye. By a view of it with a ſeven feet reflector, charged with a very high power, it appeared to be divided into two parts. The largeſt of the two, on the 19th of April, meaſured 1′ 8″.06 in diameter, which is equal in length to more than 31,000 miles. Both together muſt certainly have extended above 50,000. The idea of its being occaſioned by a volcanic exploſion violently driving away a fiery fluid, ought to be rejected (ſays Dr Herſchel) on many accounts. "To mention only one, the great extent of the ſpot is very unfavourable to ſuch a ſuppoſition. Indeed a much leſs violent and leſs pernicious cauſe may account for all the appearances of the ſpot. When we ſee a dark belt near the equator of the planet Jupiter, we do not recur to earthquakes and volcanoes for its origin. An atmoſphere, with its natural changes, will explain ſuch belts. Our ſpot on the ſun may be accounted for on the ſame principles. The earth is ſurrounded by an atmoſphere compoſed of various elaſtic fluids. The ſun alſo has its atmoſphere; and if ſome of the fluids which enter into its compoſition ſhould be of a ſhining brilliancy, in the manner that will be explained hereafter, while others are merely tranſparent, any temporary cauſe which may remove the lucid fluid will permit us to ſee the body of the ſun through the tranſparent ones. If an obſerver were placed on the moon, he would ſee the ſolid body of the earth only in thoſe places where the tranſparent fluids of our atmoſphere would permit him. In others, the opaque vapours would reflect the light of the ſun without permitting his view to penetrate to the ſurface of our globe. He would probably alſo find, that our planet had occaſionally ſome ſhining fluids in its atmoſphere; as, not unlikely, ſome of our northern lights might not eſcape his notice, if they happened in the unenlightened part of the earth, and were ſeen by him in his long dark night. Nay, we have pretty good reaſon to believe, that probably all the planets emit light in ſome degree; for the illumination which remains on the moon in a total eclipſe cannot be entirely aſcribed to the light which may reach it by the refraction of the earth's atmoſphere. For inſtance, in the eclipſe of the moon October 22. 1790, the rays of the ſun refracted by the atmoſphere of the earth towards the moon, admitting the mean horizontal refraction to be 30′ 50″.8, would meet in a focus 189,000 miles beyond the moon; ſo that conſequently there could be no illumination from rays refracted by our atmoſphere. It is, however, not improbable, that about the polar regions of the earth there may be refraction enough to bring ſome of the ſolar rays to a ſhorter focus. The diſtance of the moon at the time of the eclipſe would require a refraction of 54′ 6″, equal to its horizontal parallax at that time, to bring them to a focus ſo as to throw light on the moon.

The unenlightened part of the planet Venus has alſo been ſeen by different perſons; and not having a ſatellite, thoſe regions that are turned from the ſun cannot poſſibly ſhine by a borrowed light; ſo that this faint illumination muſt denote ſome phoſphoric quality of the atmoſphere of Venus.

In the inſtance of the large ſpot on the ſun already mentioned, Dr Herſchel concludes, from appearances, that he viewed the real body of the ſun itſelf, of which we rarely ſee more than its ſhining atmoſphere. In the year 1783 he obſerved a fine large ſpot, and followed it up to the edge of the ſun's limb. Here he took notice that the ſpot was plainly depreſſed below the ſurface of the ſun, and that it had very broad ſhelving ſides. He alſo ſuſpected ſome part, at leaſt, of the ſhelving ſides to be elevated above the ſurface of the ſun; and obſerved that, contrary to what uſually happens, the margin of that ſide of the ſpot which was fartheſt from the limb was the broadeſt.

The luminous ſhelving ſide of a ſpot may be explained by a gentle and gradual removal of the ſhining fluid, which permits us to ſee the globe of the ſun. As to the uncommon appearance of the broadeſt margin being on that ſide of the ſpot which was fartheſt from the limb when the ſpot came near the edge of it, we may ſurmiſe that the ſun has inequalities on its ſurface, which may poſſibly be the cauſe of it. For when mountainous countries are expoſed, if it ſhould chance that the higheſt parts of the landſcape are ſituated ſo as to be near that ſide of the margin or penumbra of the ſpot which is towards the limb, they may partly intercept our view of it when the ſpot is ſeen very obliquely. This would require elevations at leaſt five or ſix hundred miles high; but conſidering the great attraction exerted by the ſun upon bodies at its ſurface, and the ſlow revolution it has upon its axis, we may readily admit inequalities to that amount. From the centrifugal force at the ſun's equator, and the weight of bodies at its ſurface, he computes, that the power of throwing down a mountain by the exertion of the former, balanced by the ſuperior force of keeping it in its place of the latter, is near 6¼ times leſs on the ſun than on our equatorial regions; and as an elevation ſimilar to one of three miles on the earth would not be leſs than 334 miles on the ſun, there can be no doubt but that a mountain much higher would ſtand very firmly. The little denſity of the ſolar body ſeems alſo to be in favour of the height of its mountains; for, *cæteris paribus*, denſe bodies will ſooner come to their level than rare ones. The difference in the vaniſhing of the ſhelving ſide, inſtead of explaining it by mountains, may alſo, and perhaps more ſatisfactorily, be accounted for from the real difference of the extent, the arrangement, the height, and the intenſity of the ſhining fluid, added to the occaſional changes that may happen in theſe particulars during the time in which the ſpot approaches to the edge of the diſk. However, by admitting large mountains on the face of the ſun, we ſhall account for the different opinions of two eminent aſtronomers; one of whom believed the ſpots depreſſed below the ſurface of the ſun, while the other believed them elevated above it. For it is not impoſſible that ſome of the ſolar mountains may be high enough occaſionally to project above the ſhining elaſtic fluid, when, by ſome agitation or other cauſe, it is not of the uſual height; and this opinion is much ſtrengthened by the return of ſome remarkable ſpots which ſerved Caſſini to aſcertain the period of the ſun's rotation. A very high country, or chain of mountains, may oftener become viſible, by the removal of the obſtructing fluid, than the lower regions, on account of its not being ſo deeply covered with it.

In 1791 the Doctor examined a large ſpot on the ſun, and found it evidently depreſſed below the level of the ſurface. In 1792 he examined the ſun with ſeveral powers from 90 to 500, when it appeared evidently, that the black ſpots are the opaque ground, or body of the ſun; and that the luminous part is an atmoſphere, which, being interrupted or broken, gives us a tranſient glimpſe of the ſun itſelf. He perceived likewiſe, that the ſhining ſurface of the ſun is unequal, many parts of it being elevated and others depreſſed; and that the elevations, to which Hevelius gave the name of *faculæ*, ſo far from reſembling torches, were rather like the ſhrivelled elevations upon a dried apple, extended in length, and moſt of them joined together, making waves or waving lines. The faculæ being elevations, very ſatisfactorily explains the reaſon why they diſappear towards the middle of the ſun, and reappear on the other margin; for about the place where we loſe them, they begin to be edgewiſe to our view; and if between the faculæ ſhould lie dark ſpots, they will moſt frequently break out in the middle of the ſun, becauſe they are no longer covered by the ſide-views of theſe faculæ.

The Doctor gives a very particular account of all his obſervations, which ſeem to have been accurately made, and we need ſcarcely add with excellent teleſcopes. For that account, however, we muſt refer to the memoir itſelf, and haſten to lay before our readers the reſult of his obſervations. "That the ſun (ſays he) has a very extenſive atmoſphere, cannot be doubted; and that this atmoſphere conſiſts of various elaſtic fluids, that are more or leſs lucid and tranſparent, and of which the lucid one is that which furniſhes us with light, ſeems alſo to be fully eſtabliſhed by all the phenomena of its ſpots, of the faculæ, and of the lucid ſurface itſelf. There is no kind of variety in theſe appearances but what may be accounted for with the greateſt facility, from the continual agitation which, we may eaſily conceive, muſt take place in the regions of ſuch extenſive elaſtic fluids.

"It will be neceſſary, however, to be a little more particular as to the manner in which I ſuppoſe the lucid fluid of the ſun to be generated in its atmoſphere. An analogy that may be drawn from the generation of clouds in our own atmoſphere, ſeems to be a very proper one, and full of inſtruction. Our clouds are probably decompoſitions of ſome of the elaſtic fluids of the atmoſphere itſelf, when ſuch natural cauſes, as in this grand chemical laboratory are generally at work, act upon them: we may therefore admit, that in the very extenſive atmoſphere of the ſun, from cauſes of the ſame nature, ſimilar phenomena will take place; but with this difference, that the continual and very extenſive decompoſitions of the elaſtic fluids of the ſun are of a phoſphoric nature, and attended with lucid appearances, by giving out light.

"If it ſhould be objected, that ſuch violent and unremitting decompoſitions would exhauſt the ſun, we may recur again to our analogy, which will furniſh us with the following reflections. The extent of our own atmoſphere, we ſee, is ſtill preſerved, notwithſtanding the copious decompoſitions of its fluids in clouds and falling rain; in flaſhes of lightning, in meteors, and other luminous phenomena; becauſe there are freſh ſupplies of elaſtic vapours continually aſcending to make good the waſte occaſioned by thoſe decompoſitions. But it may be urged, that the caſe with the decompoſition of the elaſtic fluids in the ſolar atmoſphere would be very different, ſince light is emitted, and does not return to the ſun, as clouds do to the earth when they deſcend in ſhowers of rain. To which I anſwer, that, in the decompoſition of phoſphoric fluids, every other ingredient but light may alſo return to the body of the ſun. And that the emiſſion of light muſt waſte the ſun, is not a difficulty that can be oppoſed to our hypotheſis: for as it is an evident fact that the ſun does emit light, the ſame objection, if it could be one, would equally militate againſt every other aſſignable way to account for the phenomenon.

"There are, moreover, conſiderations that may leſſen the preſſure of this alleged difficulty. We know the exceeding ſubtilty of light to be ſuch, that in ages of time its emanation from the ſun cannot very ſenſibly leſſen the ſize of this great body. To this may be added, that very poſſibly there may always be ways of reſtoration to compenſate for what is loſt by the emiſſion of light, though the manner in which this can be brought about ſhould not appear to us. Many of the operations of Nature are carried on in her great laboratory which we cannot comprehend, but now and then we ſee ſome of the tools with which ſhe is at work. We need not wonder that their conſtruction ſhould be ſo ſingular as to induce us to confeſs our ignorance of the method of employing them; but we may reſt aſſured that they are not a mere *luſus naturæ*." Here he alludes to the great number of ſmall teleſcopic comets; which he ſuppoſes, as others had done before him, may be employed to reſtore to the ſun what had been loſt by the emiſſion of light. "My hypotheſis, however, (continues he) does not lay me under any obligation to explain how the ſun can ſuſtain the waſte of light, nor to ſhew that it will ſuſtain it for ever; and I ſhould alſo remark that, as in the analogy of generating clouds, I merely allude to their production as owing to a decompoſition of ſome of the elaſtic fluids of our atmoſphere, that analogy, which firmly reſts upon the fact, will not be leſs to my purpoſe, to whatever cauſe theſe clouds may owe their origin. It is the ſame with the lucid clouds, if I may ſo call them, of the ſun. They plainly exiſt, becauſe we ſee them; the manner of their being generated may remain an hypotheſis—and mine, till a better can be propoſed, may ſtand good; but whether it does or not, the conſequences I am going to draw from what has been ſaid will not be affected by it."

Before he proceeds to draw theſe conſequences, he informs us that, according to the above theory, a dark ſpot in the ſun is a place in its atmoſphere, which happens to be free from luminous decompoſitions; that faculæ are, on the contrary, more copious mixtures of ſuch fluids as decompoſe each other; and that the regions, in which the luminous ſolar clouds are formed, adding thereto the elevation of the faculæ, cannot be leſs than 1843, nor much more than 2765 miles in depth. It is true, continues he, that in our atmoſphere the extent of the clouds is limited to a very narrow compaſs; but we ought rather to compare the ſolar ones to the luminous decompoſitions which take place in our *aurora borealis*, or luminous arches, which extend much farther than the cloudy regions. The denſity of the luminous ſolar clouds, though very great, may not be exceedingly more ſo than that of our *aurora borealis*. For if we conſider what would be the brilliancy of a ſpace two or three thouſand miles deep, filled with ſuch corruſcations as we ſee now and then in our atmoſphere, their apparent intenſity, when viewed at the diſtance of the ſun, might not be much inferior to that of the lucid ſolar fluid.

From the luminous atmoſphere of the ſun, he proceeds to its opaque body; which, by calculation from the power it exerts upon the planets, we know to be of great ſolidity; and from the phenomena of the dark ſpots, many of which, probably on account of their high ſituations, have been repeatedly ſeen, and otherwiſe denote inequalities in their level, we ſurmiſe that its ſurface is diverſified with mountains and valleys.

What has been ſaid, enables us to come to ſome very important concluſions, by remarking, that this way of conſidering the ſun and its atmoſphere removes the great diſſimilarity we have hitherto been uſed to find between its condition and that of the reſt of the great bodies of the ſolar ſyſtem.

The ſun, viewed in this light, appears to be nothing elſe than a very eminent, large, and lucid planet, evidently the firſt, or, in ſtrictneſs of ſpeaking, the only primary one of our ſyſtem, all others being truly ſecondary to it. Its ſimilarity to the other globes of the ſolar ſyſtem with regard to its ſolidity, its atmoſphere, and its diverſified ſurface, the rotation upon its axis, and the fall of heavy bodies, leads us on to ſuppoſe that it is moſt probably alſo inhabited, like the reſt of the planets, by beings whoſe organs are adapted to the peculiar circumſtances of that vaſt globe.

It may, however, not be amiſs to remove a certain difficulty, which ariſes from the effect of the ſun's rays upon our globe. The heat which is here, at the diſtance of 95 millions of miles, produced by theſe rays, is ſo conſiderable, that it may be objected, that the ſurface of the globe of the ſun itſelf muſt be ſcorched up beyond all conception.

This may be very ſubſtantially anſwered by many proofs drawn from natural philoſophy, which ſhew that heat is produced by the ſun's rays only when they act upon a calorific medium; they are the cauſe of the production of heat, by uniting with the matter of fire which is contained in the ſubſtances that are heated; as the colliſion of flint and ſteel will inflame a magazine of gunpowder, by putting all the latent fire it contains into action. But an inſtance or two of the manner in which the ſolar rays produce their effect, will bring this home to our moſt common experience.

On the tops of mountains of a ſufficient height, at an altitude where clouds can very ſeldom reach to ſhelter them from the direct rays of the ſun, we always find regions of ice and ſnow. Now if the ſolar rays themſelves conveyed all the heat we find on this globe, it ought to be hotteſt where their courſe is leaſt interrupted. Again, our aeronauts all confirm the coldneſs of the upper regions of the atmoſphere; and ſince, therefore, even on our earth, the heat of any ſituation depends upon the aptneſs of the medium to yield to the impreſſion of the ſolar rays, we have only to admit, that on the ſun itſelf, the elaſtic fluids compoſing its atmoſphere, and the matter on its ſurface, are of ſuch a nature as not to be capable of any exceſſive affection from its own rays: and indeed this ſeems to be proved by the copious emiſſion of them; for if the elaſtic fluids of the atmoſphere, or the matter contained on the ſurface of the ſun, were of ſuch a nature as to admit of an eaſy chemical combination with its rays, their emiſſion would be much impeded.

Our author then proceeds to ſupport his theory by analogical reaſonings; but as theſe will occur to ſuch of our readers as are converſant with the ſpeculations of aſtronomers, we paſs on to his reflections upon the conſequences of this theory. "That the ſtars are ſuns can hardly admit of a doubt. Their immenſe diſtance would perfectly exclude them from our view, if the light they ſend us were not of the ſolar kind. Beſides, the analogy may be traced much farther. The ſun turns on its axis; ſo does the ſtar Algol; ſo do the ſtars called β Lyræ, δ Cephei, η Antinoi, ο Ceti, and many more; moſt probably all. From what other cauſe can we ſo probably account for their periodical changes? Again, our ſun has ſpots on its ſurface; ſo has the ſtar Algol, and ſo have the ſtars already named, and probably every ſtar in the heavens. On our ſun theſe ſpots are changeable; ſo they are on the ſtar ο Ceti, as evidently appears from the irregularity of its changeable luſtre, which is often broken in upon by accidental changes while the general period continues unaltered. The ſame little deviations have been obſerved in other periodical ſtars, and ought to be aſcribed to the ſame cauſe. But if ſtars are ſuns, and ſuns are inhabitable, we ſee at once what an extenſive field for animation opens itſelf to our view.

"It is true, that analogy may induce us to conclude, that ſince ſtars appear to be ſuns, and ſuns, according to the common opinion, are bodies that ſerve to enlighten, warm, and ſuſtain a ſyſtem of planets, we may have an idea of numberleſs globes that ſerve for the habitation of living creatures. But if theſe ſuns themſelves are primary planets, we may ſee ſome thouſands of them with our own eyes, and millions by the help of teleſcopes, when at the ſame time the ſame analogical reaſoning ſtill remains in full force with regard to the planets which theſe ſuns may ſupport."

The Doctor then obſerves, that from other conſiderations, the idea of ſuns or ſtars being *merely* the ſupporters of ſyſtems of planets, is not abſolutely to be admitted as a general one. "Among the great number of very compreſſed cluſters of ſtars I have given (ſays he) in my catalogues, there are ſome which open a different view of the heavens to us. The ſtars in them are ſo very cloſe together, that, notwithſtanding the great diſtance at which we may ſuppoſe the cluſter itſelf to be, it will hardly be poſſible to aſſign any ſufficient mutual diſtance to the ſtars compoſing the cluſter, to leave room for crowding in thoſe planets, for whoſe ſupport theſe ſtars have been, or might be, ſuppoſed to exiſt. It ſhould ſeem, therefore, highly probable, that they exiſt for themſelves; and are, in fact, only very capital, *lucid*, primary planets, connected together in one great ſyſtem of mutual ſupport.

"The ſame remark may be made with regard to the number of very cloſe double ſtars, whoſe apparent diameters being alike, and not very ſmall, do not indicate any very great mutual diſtance: from which, however, muſt be deducted all thoſe where the different diſtances may be compenſated by the real difference in their reſpective magnitudes.

"To what has been ſaid may be added, that, in ſome parts of the milky way, where yet the ſtars are not very ſmall, they are ſo crowded, that in the year 1792, Aug. 22. I found by the gauges that, in 41 minutes of time, no leſs than 258,000 of them had paſſed through the field of view of my teleſcope.

"It ſeems, therefore, upon the whole, not improbable, that in many caſes ſtars are united in ſuch cloſe ſyſtems as not to leave much room for the orbits of planets or comets; and that conſequently, upon this account alſo, many ſtars, unleſs we would make them mere uſeleſs brilliant points, may themſelves be lucid planets, perhaps unattended by ſatellites."

What a magnificent idea does this theory give of the univerſe, and of the goodneſs, as well as power, of its Author? And how cold muſt be that heart, and clouded that underſtanding, who, after the contemplation of it, can for one moment liſten to the atheiſtical doctrines of thoſe men who preſume to account for all the phenomena of nature by chemical affinities and mechanical attraction? The man who, even in his heart, can ſay, that ſuch an immenſe ſyſtem, differing ſo widely in the ſtructure of the different parts of it, but everywhere crowded with life, is the effect of unintelligent agency, is indeed, to uſe the emphatic language of an ancient aſtronomer—*a fool*.

SUNDA, Straits of, are formed by the approach of the ſouth-eaſt extremity of the iſland of Sumatra to the north-weſt extremity of the iſland of Java (See theſe iſlands, *Encycl.*). The ſtraits are interſperſed with a number of ſmall iſles; the whole diſplaying a ſcenery ſcarcely to be exceeded in the ſoftneſs, richneſs, and gaiety of its appearance. The two great iſlands, which are low, and in ſome places marſhy near the ſhore, riſe afterwards, in a gradual ſlope, towards the interior of the country, admitting in their aſcent every variety of ſituation, and all the different tints of verdure. Of the ſmaller iſlands, a few have ſteep and naked ſides, ſuch as one in the middle of the ſtrait, which the Engliſh navigators have diſtinguiſhed, on that account, by the name of Thwart-the-way, and two very ſmall round ones, called, from their figures, the Cap and Button (ſee theſe iſlands, *Suppl.*); but moſt of the others are entirely level, founded upon beds of coral, and covered with trees. Some of theſe iſlands are ſurrounded with a white ſandy beach, viſited frequently by turtle; but moſt of them are adorned with thick ſhrubbery to the water's edge, the roots being waſhed by the ſea, or the branches dipping into it; and on the outſide are ſhoals, in which a multitude of little aquatic animals are buſied in framing calcareous habitations for their reſidence and protection. Thoſe fabrics gradually emerge above the ſurface of the water, and at length, by the adventitious adheſion of vegetable matter, giving birth to plants and trees, become new iſlands, or add to the ſize of thoſe already produced by the ſame means. It is impoſſible not to be ſtruck with the diverſified operations of Nature for obtaining the ſame end, whether employed in originally fixing the granite foundation of the Brazils, or in throwing up, by ſome ſudden and ſubſequent convulſion, the iſland of Amſterdam, or in continuing to this hour, through the means of animated beings, the formation of new lands in the Straits of Sunda.—*Sir George Staunton's Account of the Britiſh Embaſſy to China.*

SUNNUD, a grant, patent, or charter, in Bengal.

SUPERPARTICULAR Proportion, or Ratio, is that in which the greater term exceeds the leſs by unit or 1. As the ratio of 1 to 2, or 2 to 3, or 3 to 4, &c.

SUPERPARTIENT Proportion, or Ratio, is when the greater term contains the leſs term once, and leaves ſome number greater than 1 remaining. As the ratio

of 3 to 5, which is equal to that of 1 to $1\frac{2}{3}$;

of 7 to 10, which is equal to that of 1 to $1\frac{3}{7}$; &c.

SUPPLEMENT, of an Arch or Angle, in geometry or trigonometry, is what it wants of a ſemicircle, or of 180°; as the *complement* is what it wants of a quadrant, or of 90°. So, the ſupplement of 50° is 130°; as the complement of it is 40°.

SUTTON (Thomas, Eſq;), founder of the charterhouſe, was born at Knaith in Lincolnſhire, in 1532, of an ancient and genteel family. He was educated at Eton ſchool, and probably at Cambridge, and ſtudied the law in Lincoln's Inn; but this profeſſion not ſuiting his diſpoſition, he travelled into foreign countries, and made ſo long a ſtay in Holland, France, Spain, and Italy, as to acquire the languages of thoſe various nations. During his abſence, his father died, and left him a conſiderable fortune. On his return home, being a very accompliſhed gentleman, he became ſecretary to the earl of Warwick and his brother the earl of Leiceſter. By the former of theſe noblemen, in 1569, he was appointed maſter of the ordnance at Berwick; and diſtinguiſhing himſelf greatly in that ſituation, on the rebellion which at that time broke out in the north, he obtained a patent for the office of maſter-general of the ordnance for that diſtrict for life. He is named as one of the chiefs of thoſe 1500 men who marched into Scotland, by the order of Queen Elizabeth, to the aſſiſtance of the regent, the earl of Morton, in 1573; and he commanded one of the five batteries which obliged the ſtrong caſtle of Edinburgh to ſurrender to the Engliſh. He purchaſed of the biſhop of Durham the manors of Gateſhead and Wickham; which, producing coal-mines, became to him a ſource of extraordinary wealth. In 1580, he was reputed to be worth L. 50,000

Soon after this, he married a rich widow, who brought him a conſiderable eſtate; and taking up the buſineſs of a merchant, riches flowed in to him with every tide. He is ſaid to have had no leſs than thirty agents abroad. He was likewiſe one of the chief victuallers of the navy; and ſeems to have been maſter of the barque called Sutton, in the liſt of volunteers attending the Engliſh fleet againſt the Spaniſh armada. It is probable, alſo, that he was a principal inſtrument in the defeat of it, by draining the bank of Genoa of that money with which Philip intended to equip his fleet, and thereby hindering the invaſion for a whole year. He is likewiſe ſaid to have been a commiſſioner for prizes under Lord Charles Howard, High Admiral of England; and going to ſea with letters of marque, he took a Spaniſh ſhip worth L. 20,000. His whole fortune, at his death, appears to have been in land L. 5,000 *per annum*; in money, upwards of L. 60,000; the greateſt eſtate in the poſſeſſion of any private gentleman till much later times. He lived with great munificence and hoſpitality; but loſing his lady in 1602, he retired from the world, leſſened his family, and lived in a private frugal manner; and, having no iſſue, reſolved to diſtinguiſh his name by ſome important charity. Accordingly, he purchaſed of the Earl of Suffolk Howard-Houſe, or the late diſſolved charter-houſe, near Smithfield, for the ſum of L. 13,000, where he founded the preſent hoſpital, in 1611, for the relief of poor men and children. Before he had fixed upon this deſign, the court endeavoured to divert him from his purpoſe, and to engage him to make Charles I. then Duke of York, his heir, by conferring on him a peerage; but being free from ambition, and now near his grave, the luſtre of the coronet could not tempt him to change his plan. He died the 11th of December, 1611, at Hackney, aged 79. His body was conveyed, with the moſt ſolemn proceſſion, to Chriſt-church in London, and there depoſited, till 1614, when it was removed to the charter-houſe, and interred in a vault on the north ſide of the chapel, under a magnificent tomb.

SUWOROW (A) **RIMNIKSKI** (Count Alexander), was a man ſo eminent in his profeſſion, that, if war be an art founded on ſcience, it would be improper not to give ſome account of his life in a Work of this nature. Various accounts of him, indeed, are already in the hands of the public; but they differ ſo much from one another in the pictures which they preſent of the *man*, that it is not eaſy, if it be always poſſible, to diſtinguiſh truth from falſehood. With reſpect to the talents of the *General*, there is not room for the ſame difference of repreſentation; becauſe a train of military ſucceſſes, almoſt unrivalled, has rendered theſe conſpicuous to all Europe. In the ſhort detail that our limits permit us to give of the life of this ſingular man, we ſhall avail ourſelves of all the information, public and private, which we have been able to obtain, and believe to be authentic; and we hope to make our readers acquainted with ſome particulars reſpecting his perſon and domeſtic habits which are not yet generally known.

The family of Suworow is ſaid to have been from Sweden, and of a noble deſcent. The firſt of this name ſettled in Ruſſia about the latter end of the laſt century; and having engaged in the wars againſt the Tartars and the Poles, were rewarded by the Czars of that period with lands and peaſants. Baſil, the father of our hero, is ſaid to have been the godſon of Peter the Great; to have been held in high eſtimation for his political knowledge and extenſive erudition; and to have enjoyed, at his death, the two-fold rank of General and Senator *.

As this account is given by a man who profeſſes to have formed an intimate acquaintance with Suworow himſelf, it ought to be correct; and yet we cannot help entertaining ſome doubts of its truth, or at leaſt of its accuracy. It is well known, that extenſive erudition was in no eſteem in Ruſſia at the period when Baſil Suworow is here ſaid to have been ſo learned; and it is likewiſe known, that if, by erudition, be meant a knowledge of ancient literature, it was even deſpiſed, at a much later period, by all who were at once noble, and poſſeſſed of lands and peaſants (See RUSSIA, *Encycl.*). The truth is, as we have learned from unqueſtionable authority, that the family of Suworow was ancient and reſpectable; but being far from affluent, and their little property lying at the very extremity of the empire, we have reaſon to believe, that the ſubject of this memoir was the firſt of the family that ever was at court. Baſil, however, if his anceſtors were from Sweden, may have been free from the Ruſſian prejudices againſt Greek and Latin; and this is the more probable, that he certainly gave a learned education to his ſon.

That ſon, Alexander Baſilowitch Suworow, was, according to the author already quoted, born in the year 1730;

* See *the Hiſtory of the Campaigns of Count Alexander Suworow, by Frederick Antling.*

(A) This name is ſpelled ſometimes as we have ſpelled it, ſometimes SUWARROW, and ſometimes SUVOROFF. This laſt is according to the pronunciation; but we have adopted the orthography of the General himſelf, in his letter to Charette, the hero of Vendee.

1730 : we have ſome reaſon to believe, that he was not born before 1732. His father had deſtined him, we are told, for the robe ; but his early inclinations impelled him to the profeſſion of a ſoldier ; and in 1742 he was enrolled as a fuſilier in the guards of Seimonow. He was afterwards a corporal, then a ſerjeant, and, in 1754, he quitted the guards with the brevet of Lieutenant in the army. He made his firſt campaign in the ſeven years war againſt the Pruſſians, in the year 1759, entering upon actual ſervice under Prince Wolgonſki. As ſenior officer on duty, he attended on the commander in chief Count Fermor, who, admiring the conſummate reſolution which he appeared to poſſeſs, ſavoured him with his particular confidence. In 1761, he was ordered on ſervice in the light troops under General Berg ; and with the rank of a field-officer (we think that of Lieutenant-colonel) he performed prodigies of valour, and exhibited much of that character which was afterwards ſo fully developed and diſplayed. Even then he ſeems to have formed the reſolution of dying on the field of battle rather than ſuffer himſelf to be taken priſoner ; for when, with a handful of troops, he was once ſurrounded by a large detachment of Pruſſians, he determined to cut his way through them, or periſh in the attempt. In this daring enterpriſe he was not only ſucceſsful, but contrived to carry off with him twenty priſoners, though he was obliged to abandon two field-pieces, which he had a little before taken from a ſmaller detachment.

At the peace of 1762, he received from the Empreſs a colonel's commiſſion, written with her own hand ; and being advanced, in 1768, to the rank of brigadier, he was, in the month of November, ordered to repair, with all poſſible ſpeed, to the frontiers of Poland. At that unfavourable ſeaſon, he croſſed rivers and moraſſes, whoſe paſſage was rendered more difficult by ſlight froſts ; and, in the courſe of a month, traverſed 500 Engliſh miles, with the loſs of only a few men in the environs of Smolenſko.

The object of the Empreſs, at this time, was to ſubdue the Poliſh confederates, and to poſſeſs herſelf of certain provinces of that ill-fated kingdom. How completely ſhe and her two allies, the Emperor of Germany and the King of Pruſſia, ſucceeded in their enterpriſe, has been related elſewhere (ſee POLAND, *Encycl.*). It is ſufficient, in this memoir, to obſerve, that the ſucceſſes of the Ruſſians were chiefly owing to the military ſkill and intrepidity of Suworow, who was their only active General, and was indeed, for four years, almoſt conſtantly employed in offenſive operations againſt the confederates. Not to mention the numerous actions and ſkirmiſhes of an inferior kind, in which his conduct and courage were always diſplayed, the victory at Staloviz, over a ſuperior force, ably commanded, and the capture of Cracow, were alone ſufficient to intitle him to the character which he ever afterwards ſo well ſupported. The former of theſe drew the higheſt encomiums from the great Frederick of Pruſſia ; and the latter decided the fate of Poland. It is proper to add, that Suworow, on theſe occaſions, did not tarniſh his laurels by unneceſſary cruelty. When a French officer, who ſurrendered at Cracow, offered him his ſword, according to the cuſtom of war, he refuſed it, ſaying, that he would not take the ſword of a brave man, whoſe maſter was not at war with his ſovereign ; and, even to the leaders of the confederates, he granted better terms of capitulation than they had the preſumption to aſk.

In the year 1770, he had been promoted to the rank of Major general ; and for his exploits in the Poliſh war, the Empreſs conferred upon him, at different times, the orders of St Ann, St George, and Alexander Newſky.

After performing ſome important ſervices on the frontiers of Sweden, Suworow received orders, in the beginning of 1773, to join the army in Moldavia, under the command of Field-marſhal Romanzow ; and there he began that glorious career, which ſoon made his name a terror to the Turks. His firſt exploit was the taking of Turtukey ; of which he wrote the following laconic account to the commander in chief :

" Honour and glory to God ! Glory to you, Romanzow ! We are in poſſeſſion of Turtukey, and I am in it ! " SUWOROW."

During the remainder of the war, which was of ſhort continuance, Suworow was conſtantly engaged, and conſtantly ſucceſsful. In the beginning of the year 1774, he was promoted to the rank of Lietenant-general ; and on the 11th of June of the ſame year, he defeated the Turks in a great battle, in which they loſt 3000 men killed, ſome hundreds of priſoners, 40 pieces of artillery, and 80 ſtandards, with their ſuperb camp. Soon after this victory, peace was concluded between the two courts ; and Lieutenant-general Suworow was ordered to proceed with all poſſible haſte to Moſcow, to aſſiſt in appeaſing the interior troubles of that part of the empire.

Theſe troubles were occaſioned by a Coſſac rebel, of the name of *Pugatchew*, or *Pugatcheff*, who, at the head of a party of his diſcontented countrymen, had long eluded the vigilance of Count Panin, the commander in chief in Muſcovy, and frequently cut off detachments of the army which were ſent out in queſt of him. The chace of Pugatcheff, for ſuch it may be called, was now wholly entruſted to the well-known activity of Suworow ; and that General, after purſuing the rebel with inconceivable rapidity, through woods and deſerts, came up with him at a place called Urlaſk, and carried him priſoner to Count Panin, who ſent him to Moſcow, where he ſuffered the puniſhment due to his crimes. This inſurgent, it is ſaid, had at one time collected ſuch a force, and was followed with ſuch enthuſiaſm, that, if his underſtanding had been equal to his courage, and his moderation had kept pace with his power, he might have poſſeſſed himſelf of Moſcow, and made the Imperial Catharine tremble on her throne.

For ſeveral years after the taking of Pugatcheff, Suworow was employed in the Crimea, on the Cuban, and againſt the Nogay Tartars, in a kind of ſervice which, though it was of the utmoſt importance to the Empreſs, and required all the addreſs of the Lieutenant-general, furniſhed no opportunities for that wonderful diſplay of promptitude and reſource which had characteriſed his more active campaigns. One incident, however, muſt be mentioned, even in this ſhort memoir, becauſe it ſhews the natural diſpoſition of the man. During the winter that Suworow paſſed among the Tartars, he was frequently viſited by the chiefs of that nation ; and at one of theſe viſits, Mechmed Bay, the chief of the Gediſſens, often joked with Muſſa Bay, another chief, on his inclination to marry. Muſſa Bay was ſo extremely old, that Suworow thought the converſation ridiculous; and one day aſked him, What ground Mechmed could have for ſuch idle talk? Muſſa replied, that Mechmed Bey was right; that he wiſhed to marry; and that he hoped the General would make him a preſent of a beautiful Tartar girl of ſixteen! Suworow immediately bought a young Tartar ſlave of a Coſſac for 100 rubles, and ſent her to Muſſa Bey; who married her, lived with her a very few years, and died at the age of one hundred and eight! regretted, we are told, by the Lieutenant-general, who regarded him with great eſteem and attachment.

In the end of the year 1786, Suworow was promoted to the rank of General in Chief; and, at the breaking out of the war with the Turks in 1787, he ſhewed how well he was intitled to that rank, by his maſterly defence of Kinburn; a place of no ſtrength, but of great importance, as it is ſituated at the mouth of the Dneiper, oppoſite to Oczakow. For the zeal and abilities which he diſplayed on this occaſion, the Empreſs decorated him with the order of St Andrew; gave him ſix croſſes of the order of St George, to be diſtributed, according to his judgment, among ſuch of his officers as had moſt diſtinguiſhed themſelves; and, in a very flattering letter, regretted the wounds which he had received in defending the place.

At the ſiege of Oczakow, Suworow, who commanded the left wing of the army under Prince Potemkin, received a dangerous wound in the nape of the neck, which was followed by ſo ſmart a fever, that, for ſome time, his life was deſpaired of; but he perſevered in his long accuſtomed practice of preferring regimen to medicine, and his health was gradually re-eſtabliſhed. In the year 1789, he was appointed to the command of the army which was to co-operate with the Prince of Saxe Cobourg in Walachia; and, by marches of inconceivable rapidity, he twice, in the ſpace of two months, preſerved the army of that Prince from inevitable deſtruction. Putting himſelf at the head of 8000 Ruſſians, and literally running to the aid of his ally, he came up with the Turks in time to change the fate of the day at the battle of Forhani, which was fought on the 21ſt of July; and again at Rymnik, which, with 7000 men, he had reached with equal celerity, he gained, on the 22d of September, in conjunction with the Prince, one of the greateſt victories that have ever been atchieved. According to the leaſt exaggerated account, the Turkiſh army, commanded by the Grand Viſier in perſon, amounted to 90,000 or 100,000 men; of which 70,000 were choſen troops: whilſt the army of the allies exceeded not 25,000. At the commencement of the attack, Suworow, who had reconnoitered the country, and formed the plan of the battle, called out to his Ruſſians, "My friends, look not at the eyes of your enemies, but at their breaſts; it is there that you muſt thruſt your bayonets." No quarter was given to the Turks; and on this account the Ruſſian General has been charged with ſavage ferocity: but the charge, if not groundleſs, muſt be ſhared equally between him and the Prince of Cobourg. The commanders of the allied army, aware of the immenſe ſuperiority of their enemies, had reſolved, before the engagement, not to encumber themſelves with priſoners, whom they could not ſecure without more than hazarding the fate of the day: And where is the man, who admits the lawfulneſs of war, that will condemn ſuch conduct in ſuch critical circumſtances?

The taking of Bender and Belgrade were the immediate conſequences of the victory of Rymnik; and ſo ſenſible was the Emperor Joſeph how much the rapid movements and military ſkill of Suworow had contributed to that victory, that he immediately created him a Count of the Roman empire, and accompanied the diploma with a very flattering letter. Similar honours were conferred upon him by his own ſovereign, who ſent him the diploma of Count of the empire of Ruſſia, with the title of Rymnikſki, and the order of St Andrew of the firſt claſs.

In the autumn of 1790, Prince Potemkin wrote to Count Suworow, requeſting a particular conference. The General, who conjectured the object of it, ſent him the following anſwer: "The flotilla of row-boats will get poſſeſſion of the mouths of the Danube; Tulcia and Iſaccia will fall into our power; our troops, ſupported by the veſſels, will take Iſmailow and Brahilow, and make Tchiſtow tremble." He was perfectly right in his conjecture: it was to concert with him meaſures for the taking of Iſmailow that the Prince had requeſted the conference. He did not, however, receive orders to undertake that deſperate enterpriſe till the beginning of November, when he rapidly approached towards that fortreſs. His army, by ſea and land, conſiſted of 23,000 men; of whom one-half were Coſſacs, and of theſe many were ſick. The troops of the garriſon, which were under the orders of ſeven Sultans, amounted to 43,000 men, of whom nearly one half were Janiſſaries; the fortreſs was by much the ſtrongeſt of any on the Turkiſh frontier: it was under the command of an old warrior, who had twice refuſed the dignity of Grand Viſier, and had diſplayed againſt the Auſtrians conſiderable abilities, as well as the moſt intrepid courage; and the Grand Seignior had publiſhed a firman, forbidding the garriſon, on pain of death without trial, to ſurrender on any terms whatever.

Potemkin, knowing that Suworow had with him no battering cannon, and dreading the conſequences of a repulſe, wrote to the General, that if he was not certain of ſucceſs, he would do well not to riſk an aſſault. The laconic reply was; "My plan is fixed. The Ruſſian army has already been twice at the gates of Iſmailow; and it would be ſhameful to retreat from them the third time without entering the place." To ſpare the effuſion of blood, however, if poſſible, he ſent a note to the Seraſkier who commanded in Iſmailow, to aſſure him, upon Count Suworow's word of honour, that if he did not hang out a white flag that very day, the place would be taken by aſſault, and all the garriſon put to the ſword. The Seraſkier returned no anſwer to the note; but another commander was pleaſed to ſay, that "The Danube would ceaſe to flow, or the heavens bow down to the earth, before Iſmailow would ſurrender to the Ruſſians!"

Having concerted with the Admiral proper meaſures for the aſſault, Suworow paſſed the night, with ſome officers of his ſuite, in impatient vigilance for the appointed hour when the ſignals were to be given. Theſe were the firing of a muſket at three, four, and five in the morning, when the army ruſhed upon the place; and notwithſtanding the deſperate oppoſition of the Turks, the depth of the moat, and the height of the ramparts, they were completely maſters of Iſmailow by four o'clock P. M. In this one dreadful day the Ottomans loſt 33,000 men killed or dangerouſly wounded; 10,000 who were taken priſoners; beſides 6000 women and children, and 2000 Chriſtians of Moldavia, who fell in the general maſſacre. The place was given up to plunder for three days, according to agreement with the army before the aſſault; but we have authority to ſay, that no perſon was murdered in cold blood, who did not prefer his property to his life.

The Ruſſians found in Iſmailow 232 pieces of cannon, many large and ſmall magazines of gunpowder, an immenſe quantity of bombs and balls, 345 ſtandards almoſt all ſtained with blood, proviſions for the Turkiſh army for ſix months, and about 10,000 horſes, of which many were extremely beautiful. Suworow, who was inacceſſible to any views of private intereſt, did not appropriate to himſelf a ſingle article, not ſo much as a horſe; but having, according to his cuſtom, rendered ſolemn thanks to God for his victory, wrote to Prince Potemkin the following Spartan letter: "The Ruſſian colours wave on the ramparts of Iſmailow."

Peace being concluded with the Turks in December 1791, no political events occurred from that period to call forth the military talents of Suworow till 1794. In the beginning of that year mutinies having broken out among the Poliſh troops in the ſervice of Ruſſia, and the Empreſs, with her two potent allies, having digeſted the plan for the partition of Poland, Count Suworow received orders, in the month of May, to proceed, by forced marches, into Red Ruſſia, with a corps of 15,000 men, and to diſarm all the Poliſh troops in that province. This ſervice he performed without the effuſion of blood, diſarming in leſs than a fortnight 8000 men, diſperſed over a country of 150 miles in circuit. Soon afterwards he was ordered to march into the interior of Poland; the King of Pruſſia having been obliged to raiſe the ſiege of Warſaw, and the Empreſs perceiving that more vigorous meaſures than had hitherto been purſued, were neceſſary to accompliſh her deſigns.

To give a detailed account of his route to Warſaw, would be to write the hiſtory of the Poliſh war, and not the memoirs of Count Suworow. It has been raſhly ſuppoſed, that he had to contend only with raw troops, commanded by inexperienced leaders, who were not cordially united among themſelves; but the fact is otherwiſe, and Suworow never diſplayed greater reſource in the day of danger, than in the numerous battles and ſkirmiſhes in which he was engaged on his march to the capital of Poland. At laſt, after ſurmounting every obſtacle, he ſat down, on the 22d of October, before Praga, a ſtrongly fortified ſuburb of Warſaw, defended by a formidable artillery, and a garriſon of 30,000 men, rendered deſperate by their ſituation. The Ruſſian army exceeded not 22,000; and with that comparatively ſmall force he reſolved to ſtorm Praga, as he had ſtormed Iſmail. Having erected ſome batteries to deceive the garriſon into a belief that they were to be regularly beſieged, he concerted with the other Generals the mode of aſſault; and when every thing was ready, he gave his orders in theſe words: "Storm, and take the batteries, and cut down all who reſiſt; but ſpare the inhabitants, unarmed perſons, and all who ſhall aſk for quarter."

There are but few examples of a military operation ſo boldly conceived, ſo ſkilfully performed, or ſo important in its conſequences, as the taking of Praga. The aſſault was made at once in ſeven different places at five in the morning; and at nine the Ruſſians were maſters of the place, having penetrated by pure force a triple entrenchment. Of the Poles 13,000 lay dead on the field of battle, one-third of whom were the flower of the youth of Warſaw; above 2000 were drowned in the Viſtula; and 14,680 were taken priſoners, of whom 8000 were diſarmed and immediately ſet at liberty, and the remainder the next day. We mention theſe circumſtances, becauſe they completely refute the tales of thoſe Jacobin ſcribblers, who have ſo ſtrenuouſly endeavoured to tarniſh the laurels of the Ruſſian hero, by repreſenting him as having ordered a general maſſacre of men, women, and children. The artillery taken from the enemy conſiſted of 104 pieces of cannon and mortars, chiefly of large calibre. The Ruſſians had 580 men killed, of whom eight were ſuperior and ſtaff-officers, and 900 wounded, of whom 23 were officers.

Soon after the ſtorming of Praga, Warſaw capitulated, and Suworow was received into the city by the magiſtrates in a body, and in their ceremonial habits. When the preſident preſented to him the keys of the city, he preſſed them to his lips, and then, holding them up towards heaven, he ſaid, "Almighty God, I render thee thanks, that I have not been compelled to purchaſe the keys of this place as dear as . . . . ." Turning his face towards Praga, his voice failed him, and his cheeks were inſtantly bathed with tears. As he rode through the ſtreets, the windows were filled with ſpectators, who were delighted with the return of order, and the aſſurance of peace; and the air reſounded with the exulting exclamations of "Long live Catharine! Long live Suworow!"

Thus did Count Suworow, in the courſe of a very few months, overturn the kingdom and republic of Poland. It is not our buſineſs, in this article, to decide on the juſtice of the cauſe in which he was embarked. Of the Poliſh revolution, which gave riſe to the war that ſubverted the republic, and ſwept it from the number of ſovereign ſtates, the reader will find ſome account under the title POLAND in the *Encyclopædia*; but it is here proper to acknowledge, that we do not now think ſo favourably, as when we wrote that article, of the views and principles of thoſe who framed the conſtitution, which brought upon them the Ruſſian and Pruſſian arms. Subſequent events ſeem to have proved completely, that if Poland had not been conquered by the allied powers, it would ſoon have been involved, under Koſkiuſko and his Jacobinical adherents, in all the horrors of revolutionary France; and the unhappy king, inſtead of being carried captive into Ruſſia, would probably have finiſhed his courſe on a ſcaffold. Suworow, who never concerned himſelf with the intrigues of courts, and expreſſed on all occaſions the moſt ſovereign contempt of thoſe Generals who affected to poſſeſs the ſecrets of ſtateſmen, probably never enquired into the final object of the war, but thought it his duty to execute, in his own ſphere, the orders of his Imperial miſtreſs. So ſenſible was Catharine of the propriety of this conduct, and of the zeal and abilities which he had diſplayed in the Poliſh campaign, that immediately on receiving accounts of the ſtorming of worow.

Praga and the ſubmiſſion of Warſaw, ſhe announced to him, in a letter written with her own hand, his well-earned advancement to the rank of Field-marſhal General. Nor did her munificence ſtop there: She loaded him with jewels, and preſented him with an eſtate of 7000 peaſants, in the diſtrict of Kubin, which had been the ſcene of his firſt battle in the courſe of the campaign.

From the ſubjugation of Poland we hear little more of Field marſhal Suworow till he entered upon his glorious career in Italy. He is ſaid, indeed, to have given offence to the preſent Emperor ſoon after his acceſſion to the throne, by affording protection to ſome meritorious officers, whom his Majeſty had in an arbitrary manner diſmiſſed from the ſervice; but that offence was overlooked, and Suworow called again into action, when Paul joined the coalition againſt France.

Of the exploits of the Field marſhal in Italy, where, to uſe his own words, he deſtroyed armies and overturned ſtates, we have given a full account under the title REVOLUTION in this *Supplement*. In his former campaigns, the wiſdom of his meaſures, the diſtribution of his forces, the undaunted character of his operations, and the progreſſive continuance of his ſucceſſes, furniſh proofs of the ſuperiority of his talents hardly to be paralleled in the annals of modern war; but, animated by the nobleneſs of his cauſe, and confiding, as he ſaid, in the God of battles, he ſeems in his laſt campaign to have ſurpaſſed himſelf (B). It would appear, however, that his own Sovereign thought otherwiſe; and if he did, he was certainly as ſingular in that opinion as he is ſaid to be in many others. Conſidering the Field-marſhal as the conqueror of Italy, he had indeed created him a Prince by the ſtyle and title of Prince Suworow-*Italiſki*; but how did he receive him, when he returned into the Ruſſian dominions at the head of his veteran and victorious bands?

Suworow.

Though the old warrior thought himſelf almoſt betrayed at the end of the campaign by the crooked policy of the court of Vienna, he doubtleſs hoped to be received at the court of St Peterſburgh, if not with triumphal arches, at leaſt with the moſt public teſtimo-

---

(B) Were any other proof than a ſimple narrative of his ſucceſs neceſſary to evince the abilities diſplayed by Marſhal Suworow in the laſt campaign, that proof might be found in the ſad reverſes of the preſent. At the opening of the campaign of 1800, the allies poſſeſſed infinitely greater advantages over the enemy than at the beginning of the campaign of 1799; and we ventured to ſay, towards the end of the article REVOLUTION, in this *Supplement*, that the affairs of the French ſeemed in Italy to be deſperate. But how egregiouſly have we been miſtaken? By the moſt unaccountable infatuation, the Auſtrian commander in Italy would not *believe* that the French army of reſerve, which was advancing upon him with the uſual celerity of the Firſt Conſul's movements, conſiſted of more than *ſix thouſand men!* Inſtead therefore of marching rapidly to meet them before they could be wholly diſentangled from the paſſes over the Alps, he waited patiently for them in the plains of Marengo. If we may judge of the future by the paſt, we may ſurely ſay that ſuch would not have been the conduct of Suworow. Even after the two hoſtile armies met, and fought, on the 10th of July, one of the bloodieſt battles of the preſent war, the ſucceſs of the French was not ſuch as to intitle them to the acquiſitions which were the conſequence of their dear-bought victory. The fate of the day was long doubtful; and it was at laſt decided, not by any extraordinary exertions of the Conſul, but partly by the provident conduct of General Deſſaix, who, with the aid of freſh troops, erected a new battery at a critical point, and at a critical period; and ſtill more by the ſituation of General Melas, whoſe faculties, though frequently ſupported by wine and ſpirits, are ſaid to have wholly forſaken him in the latter part of the day. When he was in this ſtate, one falſe movement, which weakened his centre, afforded an opportunity to Deſſaix to make a vigorous and ſucceſsful charge with a body of cavalry that had not yet been engaged.

But even after this defeat, what was the ſtate of the two armies? The Auſtrians had loſt 9000 men, and the French from 12,000 to 14,000: the former, enraged at having had the victory ſo wreſted out of their hands, were eager to renew the conteſt on the following day; and the latter had obtained only the barren advantage of keeping poſſeſſion of the field of battle. In ſuch a ſituation, Suworow would certainly have encouraged the ardour of his men; but the Auſtrian commander, who complained laſt year of the Field-marſhal for being too little ſparing of blood, inſtead of following the example which he had ſet him at the battle of Trebia, concluded a capitulation unparalleled, we believe, in the annals of war; a capitulation by which he voluntarily ſurrendered into the hands of the enemy nearly all the fruits of one of the moſt glorious campaigns recorded in hiſtory. We wiſh not to throw any undue aſperſion upon the character of General Melas: We believe him to be a brave man, and ſuch he has been repreſented to us in various accounts which we have had directly from Germany; but all theſe accounts agree in repreſenting him likewiſe as fit, not to have the ſupreme command of a great army, but only to execute the orders of a ſuperior mind.

In Germany, the gallant Kray has been obliged to retreat before the equally gallant Moreau; but he has wiſely not hazarded the conſequences of a general action. We ſay *wiſely*; becauſe we have learned from authority which we cannot queſtion, that his army is in a ſtate little better than that of mutiny. To his officers he is in a great meaſure a ſtranger; and therefore theſe gentlemen think themſelves at liberty to diſobey his orders! What the conſequence of all this will be, it becomes not us to conjecture. An armiſtice has in the mean time * taken place both in Italy and in Germany; and it is not impoſſible that the Aulic Council, aided by the mob of Vienna, may induce the Emperor to make a ſeparate peace.—We need hardly make an apology for the length of this note, which our readers will conſider as a continuation, the lateſt that we ſhall have an opportunity to give, of the progreſs of the French revolution, which we once flattered ourſelves would, by this time, have taken a very different turn; and a different turn it would have taken if another Suworow had commanded in Italy.

* September the 4th 1800.

nies of his Sovereign's approbation. It is ſaid, that he expected to be ſent back at the head of a large army, with full powers to act as he ſhould judge proper for bringing the war to a happy termination, and reſtoring peace and order to Europe; and he certainly expreſſed, in letters to different correſpondents, his earneſt wiſh to conclude his military career with contributing to the accompliſhment of ſo deſirable an object. What then muſt have been his diſappointment, when the Ruſſian Emperor would not ſee him, and poſitively forbad his appearance at court? To the meſſenger who brought the order, the Field-marſhal gave a purſe of money, turned his carriage another way, and drove to a wooden houſe, at a diſtance from the court, and from his former friends, "where burſt his mighty heart;" and the conqueror of the Turks, the Poles, and the French republicans, died, almoſt unattended, on the 18th of May 1800. The ſovereign, who thus diſgraced him at the end of his life, gave him a magnificent funeral!

In his perſon Suworow was tall, conſiderably exceeding ſix feet, and full cheſted. His countenance was ſtern; but among his friends his manners were pleaſant, and his diſpoſitions were kind. His temper was naturally violent; but that violence he conſtantly laboured to moderate, though he was never able completely to extinguiſh it. According to M. Anthing, an effervefcent ſpirit of impatience predominated in his character; and it perhaps never happened (ſays that author) that the execution of his orders equalled the rapidity of his wiſhes. Though he diſliked all public entertainments, yet when circumſtances led him to any of them, he appeared to partake, and endeavoured to promote, the general pleaſure. Sometimes he condeſcended even to dance and play at cards, though very rarely, and merely that he might not interrupt the etiquette of public manners, to which, when not in the field, he was very attentive. In the field he may be ſaid to have ſpent the whole of his life from the period at which he firſt joined the army in the ſeven years war; for during the time that he was not engaged in actual warfare, and that time, taken altogether, did not exceed twelve years, he was always placed at the head of armies ſtationed on the frontier of ſome enemy's country. He was therefore a mere warrior, and as ſuch had no fixed habitation. With reſpect to his table and lodging, he contented himſelf with whatever he found, requiring nothing but what abſolute neceſſity demands, and what might be tranſported with eaſe from one place to another. His couch conſiſted of a heap of freſh hay ſufficiently elevated, and ſcattered into conſiderable breadth, with a white ſheet ſpread over it, with a cuſhion for his pillow, and with a cloak for his coverlid. He has been repreſented as dirty (c); but the repreſentation is falſe. M. Anthing aſſures, that he was clean in his perſon, and that, when not on actual ſervice, he waſhed himſelf frequently during the courſe of the day. It is among the ſingular, though unimportant circumſtances of his life (ſays the ſame author), that, for the laſt twenty years, he had not made uſe of a looking-glaſs, or incumbered his perſon with either watch or money.

He was ſincerely religious; took every opportunity of attending the offices of public devotion; and has been known, on Sundays and feſtivals, to deliver lectures on piety to thoſe whom duty called to attend on him. We are told by an anonymous writer, in a miſcellany not very forward to praiſe ſuch men as Suworow, or indeed to praiſe piety in men of any deſcription, that chancing one evening to overhear a captain abridge the prayer which his duty required him to repeat at the guard, the Field-marſhal called out to him, "Thou unconſcionable, abominable, impious man, thou wouldſt cheat Heaven! Thou wouldſt, no doubt, cheat likewiſe the Empreſs and me! I ſhall diſmiſs thee." His regard for ſacred things is indeed very apparent in the elegant letter which, on the 1ſt of October 1795, he wrote to Charette, the hero of Vendee, whom he congratulates upon taking up arms to reſtore the temples of the God of his fathers. Alluding to this trait of his character, and to his deteſtation of Jacobiniſm under every form, a late writer in a moſt reſpectable miſcellany has well characterized him as the

"Foe to religion's foe; of Ruſſia's throne
The prop, th' avenger, and the pride in one;
Whoſe conquering arms, in bold defiance hurl'd,
Cruſhed the rude monſter of the weſtern world."

We have already, when we thought not that we ſhould ſo ſoon be called upon to write his life, obſerved, that he was a ſcholar, a man of ſcience, and a poet. M. Anthing aſſures us, that from his earlieſt years he was enamoured of the ſciences, and improved himſelf in them; but that as the military ſcience was the ſole object of his regard, thoſe authors of every nation who inveſtigate, illuſtrate, or improve it, engroſſed his literary leiſure. Hence Cornelius Nepos was with him a favourite claſſic; and he read, with great avidity and attention, the hiſtories of Montecuculi and Turenne. Cæſar, however, and Charles XII. (ſays the ſame author) were the heroes whom he moſt admired, and whoſe activity and courage became the favourite objects of his imitation.

With reſpect to his moral character, we have every reaſon to believe that he was a man of the moſt incorruptible probity, immoveable in his purpoſes, and inviolable in his promiſes; that the cruelties of which he has been accuſed were the cruelties of Potemkin, and that by thoſe who knew him he was conſidered as a man of unqueſtionable humanity. The love of his country, and the ambition to contend in arms for its glory, were the predominant paſſions of his active life; and to them, like the ancient Romans, he ſacrificed every inferior ſentiment, and conſecrated, without reſerve, all the powers of his body and mind. His military career was one long and uniform courſe of ſucceſs and triumph, produced by his enterpriſing courage and extraordinary preſence of mind; by his perſonal intrepidity and promptitude of execution; by the rapid and unparalleled movements of his armies; and by their perfect aſſurance of victory when fighting under his banners. Such was Alexander Beſilovitch Count Suworow. In the year 1774 he married a daughter of the General Prince Iwan Proſorowſki, by whom he had two children, now living: Natalia, married to General Count Nicolai Zubow; and Arcadius Count Suworow,

a

(c) By the anonymous author of the life of Catharine II.

a youth of great promiſe, who accompanied his father in his unparalleled march from Italy to Switzerland.

SWALLOW's-Tail, in fortification, is a ſingle tenaille, which is narrower towards the place than toward the country.

SWAN (See Anas, *Encycl.*). It is now aſcertained, beyond the poſſibility of doubt, that there are *black* ſwans, of equal ſize, and the ſame habitudes, with the common white ſwan of this iſland. Theſe fowls have been ſeen chiefly in New Holland; and Captain Vancouver, when there, ſaw ſeveral of them in very ſtately attitudes, ſwimming on the water; and, when flying, diſcovering the under part of their wings and breaſts to be white. Black ſwans were likewiſe ſeen in New Holland by Governor Philips, Captain White, and by a Dutch navigator, ſo long ago as in 1697. Governor Philips deſcribes the black ſwan as a very noble bird, larger than the common ſwan, and equally beautiful in form. Mr White indeed ſays, that its ſize is not quite equal to that of the European ſwan; but both theſe authors agree with Captain Vancouver in mentioning ſome white feathers in its wings.

SWINTON (John), a very celebrated Engliſh antiquary, was a native of the county of Cheſter, the ſon of John Swinton of Bexton in that county, gent. He was born in 1703. The circumſtances of his parents were probably not affluent, as he was entered at Oxford in the rank of a ſervitor at Wadham college. This was in October 1719. It may be preſumed, that he recommended himſelf in that ſociety by his talents and behaviour, as on June 30. 1723, he was elected a ſcholar on a Cheſhire foundation in the college. In the December following, he took his firſt degree in arts. Before he became maſter of arts (which was on December 1. 1726), he had choſen the church for his profeſſion, and was ordained deacon by the biſhop of Oxford, May 30. 1725; and was afterwards admitted to prieſt's orders on May 28. 1727. He was not long without ſome preferment, being admitted to the rectory of St Peter le Bailey in Oxford (a living in the gift of the crown), under a ſequeſtration, and inſtituted to it in February 1728. In June, the ſame year, he was elected a fellow of his college; but, deſirous probably to take a wider view of the world, he accepted, not long after, the appointment of chaplain to the Engliſh factory at Leghorn, to which he had been choſen. In this ſituation he did not long enjoy his health; and leaving it on that account, he was at Florence in April 1733, where he attended Mr Coleman, the Engliſh envoy, in his laſt moments. Mr Swinton returned thro' Venice and Vienna; and, in company with ſome Engliſh gentlemen of fortune, viſited Preſburgh in Hungary, and was preſent at one of their aſſemblies.

It is poſſible that he had not quitted England in the ſummer of 1730, for he was elected a Fellow of the Royal Society in June that year, and admitted about three months later. It was probably while he was abroad that he was admitted into ſome foreign ſocieties; namely, the academy *degli Apatiſti* at Florence, and the *Etruſcan Academy* of Cortona. On his return, he ſeems to have taken up his abode at Oxford, where he reſided all the latter part of his life, and was for many years chaplain to the gaol in that city. It may be preſumed that he married in 1743; it was then, at leaſt, that he gave up his fellowſhip. In 1759 he became bachelor of divinity: in 1767, he was elected *Cuſtos Archivorum*, or keeper of the univerſity records: and, on April 4. 1777, he died; leaving no children. His wife ſurvived till 1784, and both were buried, with a very ſhort and plain inſcription, in the chapel of Wadham college.

Swinton.

It remains to take notice of the moſt important monuments of a literary man's life, his publications. Theſe were numerous and learned, but not of great magnitude. He publiſhed, 1. "De Linguæ Etruriæ Regalis vernacula Diſſertatio," 4to, 19 pages, Oxon, 1738. 2. "A critical eſſay concerning the words Δαιμων and Δαιμονιον, occaſioned by two late inquiries into the meaning of the demoniacs in the New Teſtament," 8vo, London, 1739. 3. "De priſcis Romanorum literis diſſertatio," 4to, 20 pages, Oxon, 1746. 4. "De Primogenio Etruſcorum Alphabeto, diſſertatio," Oxon, 1746. 5. "Inſcriptiones Citieæ: ſive in binas Inſcriptiones Phœnicias, inter rudera Citii nuper repertas, conjecturæ. Accedit de nummis quibuſdam Samaritanis et Phœniciis, vel inſolitam præ ſe literaturam ferentibus, vel in lucem hactenus non editis, diſſertatio," 4to, 87 pages, Oxon, 1750. 6. "Inſcriptiones Citieæ: ſive in binas alias Inſcriptiones Phœnicias, inter rudera Citii nuper repertas, conjecturæ," 4to, 19 pages. 7. "De nummis quibuſdam Samaritanis et Phœniciis, vel inſolitam præ ſe literaturam ferentibus, vel in lucem hactenus non editis, diſſertatio ſecunda," 4to, 36 pages. 8. "Metilia: ſive de quinario Gentis Metiliæ, e nummis vetuſtis cæteroquin minimum notæ, diſſertatio," 4to, 22 pages, Oxon, 1750. 9. Several diſſertations publiſhed in the Philoſophical Tranſactions of the Royal Society. As, "A diſſertation upon a Parthian Coin; with characters on the reverſe reſembling thoſe of the Palmyrenes," vol. xlix. p. 593. "Some remarks on a Parthian Coin, with a Greek and Parthian legend, never before publiſhed," vol. l. p. 16. "A diſſertation upon the Phœnician numeral characters anciently uſed at Sidon," vol. l. p. 791. "In nummum Parthicum hactenus ineditum conjecturæ," vol. li. p. 683. "A diſſertation upon a Samnite Denarius, never before publiſhed," vol. lii. p. 28. "An account of a ſubærated Denarius of the Plætorian family, adorned with an Etruſcan inſcription on the reverſe, never before publiſhed or explained," vol. lxii. p. 60. "Obſervations upon five ancient Perſian Coins, ſtruck in Paleſtine or Phœnicia before the diſſolution of the Perſian empire," vol. lxii. p. 345. Other papers by him may be found in the general index to the Philoſophical Tranſactions. 10. A part of the Ancient Univerſal Hiſtory, contained in the ſixth and ſeventh volumes of that great work. The particulars of this piece of literary hiſtory were communicated by Dr Johnſon to Mr Nichols, in a paper printed in the Gentleman's Magazine for December 1784, p. 892. The original of that paper, which affords a ſtrong proof of the ſteady attachment of Johnſon to the intereſts of literature, has been, according to his deſire, depoſited in the Britiſh Muſeum. The letter is as follows:

"To Mr Nichols.

"The late learned Mr Swinton of Oxford having one day remarked, that one man, meaning, I ſuppoſe, no man but himſelf, could aſſign all the parts of the Univerſal Hiſtory to their proper authors, at the requeſt of Sir Robert Chambers, or of myſelf, gave the account which I now tranſmit to you in his own hand, Swinton.

being willing, that of ſo great a work the hiſtory ſhould be known, and that each writer ſhould receive his due proportion of praiſe from poſterity. I recommend to you to preſerve this ſcrap of literary intelligence, in Mr Swinton's own hand, or to depoſite it in the Muſeum, that the veracity of the account may never be doubted.—I am, Sir, your moſt humble ſervant,

Dec. 6, 1784. SAM. JOHNSON."

The paper alluded to, beſides ſpecifying ſome parts written by other perſons, aſſigns the following diviſions of the hiſtory to Mr Swinton himſelf. "The hiſtory of the Carthaginians, Numidians, Mauritanians, Gætulians, Garamantes, Melano-Gætulians, Nigritæ, Cyrenaica, Marmarica, the Regio Syrtica, Turks, Tartars, and Moguls, Indians, and Chineſe, a diſſertation on the peopling of America, and one on the independency of the Arabs.

In the year 1740, Mr Swinton was involved in a law ſuit, in conſequence of a letter he had publiſhed. It appears from a paper of the time *, that a letter from the Rev. Mr Swinton, highly reflecting on Mr George Baker, having fallen into the hands of the latter, the court of King's Bench made the rule abſolute for an information againſt Mr Swinton. Theſe two gentlemen were alſo engaged for ſome time in a controverſy at Oxford; which took its riſe from a matter relative to Dr Thiſtlethwaite, ſome time warden of Wadham, which then attracted much attention. Mr Swinton had the manners, and ſome of the peculiarities, often ſeen in very recluſe ſcholars, which gave riſe to many whimſical ſtories. Among the reſt, there is one mentioned by Mr Boſwell, in the Life of Johnſon, as having happened in the year 1754. Johnſon was then on a viſit in the univerſity of Oxford. "About this time (he ſays) there had been an execution of two or three criminals at Oxford, on a Monday. Soon afterwards, one day at dinner, I was ſaying that Mr Swinton, the chaplain of the gaol, and alſo a frequent preacher before the univerſity, a learned man, but often thoughtleſs and abſent, preached the condemnation ſermon on repentance, before the convicts, on the preceding day, Sunday; and that, in the cloſe, he told his audience, that he ſhould give them the remainder of what he had to ſay on the ſubject the next Lord's day. Upon which, one of our company, a doctor of divinity, and a plain matter-of-fact man, by way of offering an apology for Mr Swinton, gravely remarked, that he had probably preached the ſame ſermon before the univerſity. Yes, Sir (ſays Johnſon); but the univerſity were not to be hanged the next morning!"

T.

Tacquet || Talus.

TACQUET (Andrew), a Jeſuit of Antwerp, who died in 1660. He was a moſt laborious and voluminous writer in mathematics. His works were collected, and printed at Antwerp, in one large volume in folio, 1669.

TALLOW-Tree. See Croton (*Encycl.*), where, however, we have fallen into a miſtake, which it is here our duty to correct. We learn from Sir George Staunton, that the candles made of the vegetable tallow are firmer than thoſe made of animal tallow, and free from all offenſive ſmell, contrary to what was raſhly ſaid in the article referred to. They are not, however, equal to thoſe of wax or ſpermaceti; but the latter of theſe ſubſtances is not within the reach of the Chineſe, and the art of blanching the former is little known to them. The tallow tree is ſaid to have been tranſplanted to Carolina, and to flouriſh there as well as in China.

TALOOK, an Arabic word, which ſignifies literally attachment, connection, dependence. In Bengal, however, where it occurs perpetually in the enumeration of the diſtricts and ſubdiviſions of that province contained in the inſtitutes of Akber, it ſignifies a tenure of land. Hence the *talook* of Caſhinat, the *talook* of Meheys the headman, the *talook* of Ahmed Khan, &c. See *A Diſſertation concerning the Landed Property of Bengal*, by Sir Charles Rouſe Boughton.

TALOOKDAR, the poſſeſſor of a talook.

TALOOKDARY, tenure of a talookdar.

TALUS, or Talud, in architecture, the inclination or ſlope of a work; as of the outſide of a wall, when its thickneſs is diminiſhed by degrees, as it riſes in height, to make it the firmer.

Talus || Tanning.

Talus, in fortification, means alſo the ſlope of a work, whether of earth or maſonry.

TAMASCAL, the name given in California to a kind of ſand-bath employed by the natives in the cure of the venereal diſeaſe. It is prepared by ſcooping a trench in the ſand, two feet wide, one foot deep, and of a length proportioned to the ſize of the patient; a fire is then made through the whole extent of it, as well as upon the ſand which was dug out of the hollow. When the whole is thoroughly heated, the fire is removed, and the ſand ſtirred about, that the warmth may be equally diffuſed. The ſick perſon is then ſtripped, laid down in the trench, and covered up to his chin with heated ſand. In this poſition a very profuſe ſweat ſoon breaks out, which gradually diminiſhes according as the ſand cools. The patient then riſes and bathes in the ſea, or the neareſt river. This proceſs is repeated till a complete cure is obtained. While the patient is undergoing the operation of the tamaſcal, he drinks a conſiderable quantity of a warm ſudorific, prepared by the decoction of certain herbs, chiefly of the ſhrub called by the Spaniards Gouvernante, which ſee in this *Supplement*.

TAN is a ſubſtance found in moſt vegetables, which, not having hitherto been reſolved into component parts, is therefore conſidered as ſimple. See *Vegetable and Animal* Substances in this *Suppl.*

TANNING is an art, of which a full account, according to the general practice in London and its vicinity, has been given under the proper title in the *Encyclopædia*. But ſince that article was written, the ſuperior knowledge which has been obtained of the tan-

---

* *The Champions, or Evening Advertiſer*, June 17th 1740.

ning principle, as well as of the compoſition of the ſkins of animals (See *Vegetable and Animal* SUBSTANCES, *Suppl.*), has ſuggeſted to ſcientific artiſts various methods of ſhortening the proceſs by which leather is manufactured. M. Seguin is ſaid to have thrown much light upon the art of the tanner as it is practiſed in France; and in 1795 Mr William Deſmond obtained a patent for practiſing Seguin's method in England. He obtains the tanning principle by digeſting oak bark, or other proper material, in cold water, in an apparatus nearly ſimilar to that uſed in the ſaltpetre works. That is to ſay, the water which has remained upon the powdered bark for a certain time, in one veſſel, is drawn off by a cock, and poured upon freſh tan. This is again to be drawn off, and poured upon other freſh tan; and in this way the proceſs is to be continued to the fifth veſſel. The liquor is then highly coloured, and marks, as Mr Deſmond ſays, from ſix to eight degrees on the hydrometer for ſalts. He calls this the tanning lixivium. The criterion to diſtinguiſh its preſence is, that it precipitates glue from its aqueous ſolution, and is alſo uſeful to examine how far other vegetable ſubſtances, as well as oak bark, may be ſuitable to the purpoſe of tanning. The ſtrong tanning liquor is to be kept by itſelf. It is found by trials with the glue, that the tanning principle of the firſt digeſter which receives the clear water, is, of courſe, firſt exhauſted. But the ſame tan will ſtill give a certain portion of the aſtringent principle, or gallic lixivium, to water. The preſence of this principle is aſcertained by its ſtriking a black colour when added to a ſmall quantity of the ſolution of vitriol of iron or green copperas. As ſoon as the water from the digeſter ceaſes to exhibit this ſigu, the tan is exhauſted, and muſt be replaced with new. The gallic lixivium is reſerved for the purpoſe of taking the hair off from hides.

Strong hides, after waſhing, cleaning, and fleſhing, in the uſual way, are to be immerſed for two or three days in a mixture of gallic lixivium and one thouſandth part by meaſure of denſe vitriolic acid. By this means the hair is detached from the hides, ſo that it may be ſcraped off with a round knife. When ſwelling or raiſing is required, the hides are to be immerſed for ten or twelve hours in another vat filled with water and one five-hundredth part of the ſame vitriolic acid. The hides being then repeatedly waſhed and dreſſed, are ready for tanning; for which purpoſe they are to be immerſed for ſome hours in a weak tanning lixivium of only one or two degrees; to obtain which, the latter portions of the infuſions are ſet apart; or elſe ſome of that which has been partly exhauſted by uſe in tanning. The hides are then to be put into a ſtronger lixivium, where in a few days they will be brought to the ſame degree of ſaturation with the liquor in which they are immerſed. The ſtrength of the liquor will by this means be conſiderably diminiſhed, and muſt therefore be renewed. When the hides are by this means completely ſaturated, that is to ſay, perfectly tanned, they are to be removed, and ſlowly dried in the ſhade.

Calf ſkins, goat ſkins, and the like, are to be ſteeped in lime-water after the uſual fleſhing and waſhing. Theſe are to remain in the lime water, which contains more lime than it can diſſolve, and requires to be ſtirred ſeveral times a day. After two or three days, the ſkins are to be removed, and perfectly cleared of their lime by waſhing and preſſing in water. The tanning proceſs is then to be accompliſhed in the ſame manner as for the ſtrong hides, but the lixivium muſt be conſiderably weaker. Mr Deſmond remarks, that lime is uſed inſtead of the gallic lixivium for ſuch hides as are required to have a cloſe grain; becauſe the acid mixed with that lixivium always ſwells the ſkins more or leſs; but that it cannot with the ſame convenience be uſed with thick ſkins, on account of the conſiderable labour required to clear them of the lime; any part of which, if left, would render them harſh and liable to crack. He recommends, likewiſe, as the beſt method to bring the whole ſurface of the hides in contact with the lixivium, that they ſhould be ſuſpended vertically in the fluid by means of tranſverſe rods or bars, at ſuch a diſtance as not to touch each other. By this practice much of the labour of turning and handling may be ſaved.

Mr Deſmond concludes his ſpecification, by obſerving, that in ſome caſes it will be expedient to mix freſh tan with the lixivium; and that various modifications of ſtrength, and other circumſtances, will preſent themſelves to the operator. He affirms that, in addition to the great ſaving of time and labour in this method, the leather, being more completely tanned, will weigh heavier, wear better, and be leſs ſuſceptible of moiſture than leather tanned in the uſual way; that cords, ropes, and cables, made of hemp or ſpeartery, impregnated with the tanning principle, will ſupport much greater weights without breaking, be leſs liable to be worn out by friction, and will run more ſmoothly on pulleys; inſomuch that, in his opinion, it will render the uſe of tar in may caſes, particularly in the rigging of ſhips, unneceſſary; and, laſtly, that it may be ſubſtituted for the preſervation of animal food inſtead of ſalt.

Mr Nicholſon, from whoſe Philoſophical Journal we have taken this account of Mr Deſmond's method of tanning, made ſome very proper enquiries at one of the firſt manufacturing houſes in the borough of Southwark, concerning its value. He was told by one of the partners, that the principle upon which the new proceſs is founded had been long known to them; but that they preferred the old and ſlower method, becauſe the hides are found to feed and improve in their quality by remaining in the pit. He could gain no ſatiſfactory information of what is meant by this feeding and improving; and, without taking upon us to decide between the advantages peculiar to Deſmond's method and thoſe of the common practice, we cannot help ſaying that this objection of the tanner at Southwark appears to us to be that of a man who either underſtands not the principles of his own art, or has ſome reaſon for oppoſing the progreſs of improvement, if it do not originate in his own houſe.

TASSIE (James) modeller, whoſe hiſtory is intimately connected with a branch of the fine arts in Britain, was born in the neighbourhood of Glaſgow of obſcure parents; and began his life as a country ſtone maſon, without the expectation of ever riſing higher. Going to Glaſgow on a fair day, to enjoy himſelf with his companions, at the time when the Foulis's were attempting to eſtabliſh an academy for the fine arts in that city, he ſaw their collection of paintings, and felt an irreſiſtible impulſe to become a painter. He removed to Glaſgow; and in the academy acquired a knowledge of drawing, which unfolded and

improved

improved his natural taſte. He was frugal, induſtrious, and perſevering; but he was poor, and was under the neceſſity of devoting himſelf to ſtone-cutting for his ſupport: not without the hopes that he might one day be a ſtatuary if he could not be a painter. Reſorting to Dublin for employment, he became known to Dr Quin, who was amuſing himſelf in his leiſure hours with endeavouring to imitate the precious ſtones in coloured paſtes, and take accurate impreſſions of the engravings that were on them.

That art was known to the ancients; and many ſpecimens from them are now in the cabinets of the curious. It ſeems to have been loſt in the middle ages; was revived in Italy under Leo X. and the Medici family at Florence; became more perfect in France under the regency of the Duke of Orleans, by his labours and thoſe of Homberg. By thoſe whom they inſtructed as aſſiſtants in the laboratory it continued to be practiſed in Paris, and was carried to Rome. Their art was kept a ſecret, and their collections were ſmall. It is owing to Quin and to Taſſie that it has been carried to ſuch high perfection in Britain, and attracted the attention of Europe.

Dr Quin, in looking out for an aſſiſtant, ſoon diſcovered Taſſie to be one in whom he could place perfect confidence. He was endowed with fine taſte: he was modeſt and unaſſuming: he was patient; and poſſeſſed the higheſt integrity. The Doctor committed his laboratory and experiments to his care. The aſſociates were fully ſucceſsful; and found themſelves able to imitate all the gems, and take accurate impreſſions of the engravings.

As the Doctor had followed the ſubject only for his amuſement, when the diſcovery was completed, he encouraged Mr Taſſie to repair to London, and to devote himſelf to the preparation and ſale of thoſe paſtes as his profeſſion.

In 1766 he arrived in the Capital. But he was diffident and modeſt to exceſs; very unfit to introduce himſelf to the attention of perſons of rank and of affluence: beſides, the number of engraved gems in Britain was ſmall; and thoſe few were little noticed. He long ſtruggled under difficulties which would have diſcouraged any one who was not poſſeſſed of the greateſt patience, and the warmeſt attachment to the ſubject. He gradually emerged from obſcurity, obtained competence; and what to him was much more, he was able to increaſe his collection, and add higher degrees of perfection to his art. His name ſoon became reſpected, and the firſt cabinets in Europe were open for his uſe; and he uniformly preſerved the greateſt attention to the exactneſs of the imitation and accuracy of the engraving, ſo that many of his paſtes were ſold on the Continent by the fraudulent for real gems. His fine taſte led him to be peculiarly careful of the impreſſion; and he uniformly deſtroyed thoſe with which he was in the leaſt diſſatisfied. The art has been practiſed of late by others; and many thouſands of paſtes have been ſold as Taſſie's, which he would have conſidered as injurious to his fame. Of the fame of others he was not envious; for he uniformly ſpake with frankneſs in praiſe of thoſe who executed them well, though they were endeavouring to rival himſelf.

To the ancient engravings he added a numerous collection of the moſt eminent modern ones; many of which approach in excellence of workmanſhip, if not in ſimplicity of deſign and chaſtity of expreſſion, to the moſt celebrated of the ancient. Many years before he died he executed a commiſſion for the late Empreſs of Ruſſia, conſiſting of about 15,000 different engravings (See GEM, *Encycl.*). At his death, in 1799, they amounted to near 20,000; a collection of engravings unequalled in the world. Every lover of the fine arts muſt be ſenſible of the advantage of it for improvement in knowledge and in taſte. The collection of Feloix at Paris conſiſted of 1800 articles; and that of Dehn at Rome of 2500.

For a number of years, Mr Taſſie practiſed the modelling of portraits in wax, which he afterwards moulded and caſt in paſte. By this, the exact likeneſs of many eminent men of the preſent age will be tranſmitted to poſterity as accurately as thoſe of the philoſophers and great men have been by the ancient ſtatuaries. In taking likeneſſes he was, in general, uncommonly happy; and it is remarkable, that he believed there was a certain kind of inſpiration (like that mentioned by the poets) neceſſary to give him full ſucceſs. The writer of this article, in converſing with him repeatedly on the ſubject, always found him fully perſuaded of it. He mentioned many inſtances in which he had been directed by it; and even ſome, in which, after he had laboured in vain to realize his ideas on the wax, he had been able, by a ſudden flaſh of imagination, to pleaſe himſelf in the likeneſs ſeveral days after he had laſt ſeen the original.

He poſſeſſed alſo an uncommonly fine taſte in architecture, and would have been eminent in that branch if he had followed it.

In private life Mr Taſſie was univerſally eſteemed for his uniform piety, and for the ſimplicity, the modeſty, and benevolence, that ſhone in the whole of his character.

TASTELESS EARTH (*aguſt erde*), the name given by Profeſſor Trommſdorff to a new ſimple earth, which he diſcovered in the Saxon beryl. It is diſtinguiſhed (he ſays) from other earths by the following properties: It is white, and totally inſoluble in water. In a freſh ſtate, when moiſtened with water, it is ſomewhat ductile. In the fire it becomes tranſparent and very hard, ſo as to ſcratch glaſs, but remains inſipid and inſoluble in water. The burnt earth diſſolves very eaſily in acids, and produces with them peculiar ſalts, which are entirely devoid of taſte; and hence he gave it the name of *taſteleſs earth*. Fixed alkalies do not diſſolve this earth either in the dry or in the wet way; and it is equally inſoluble with the carbonic acid and with cauſtic ammonia. It has a greater affinity to the oxalic than to other acids. Profeſſor Trommſdorff informs us, that a full account of this earth, accompanied with an accurate deſcription, by Dr Bernhardi, of the foſſil in which it is found, will appear in the firſt part of the eight volume of his *Journal of Pharmacy*.

TEETH, of various ſorts of machines, as of mill wheels, &c. Theſe are often called cogs by the workmen; and by working in the pinions, rounds, or trundles, the wheels are made to turn one another. Mr Emerſon (in his Mechanics, prop. 25.) treats of the theory of teeth, and ſhews that they ought to have the figure of epicycloids, for properly working in one another.

TEKAWY, in Bengal, money advanced by government cope, pera- of the e of ſic.

ment to the proprietors or cultivators of land to aſſiſt them under circumſtances of diſtreſs.

TELESCOPE, is an inſtrument which has been ſo completely deſcribed in the *Encyclopædia*, that it is introduced into this place merely to notice an ingenious ſuggeſtion of Mr Nicholſon's for improving the achromatic teleſcope, by adding an artificial iris to the object glaſs. Suppoſe (ſays he) a braſs ring to ſurround the object end of the teleſcope, and upon this let eight or more triangular ſlips of braſs be fixed, ſo as to revolve on equi-diſtant pins paſſing through each triangle near one of its corners. If the triangles be ſlided inwards upon each other, it may readily be apprehended that they will cloſe the aperture; and if they be all made to revolve or ſlide backwards alike, it is clear that their edges will leave an octagonal aperture, greater or leſs according to circumſtances. The equable motion of all the triangles may be produced either by pinions and one concave toothed wheel, or by what is called ſnail-work. Another kind of iris, more compact, may be made, by cauſing thin elaſtic ſlips of braſs to ſlide along parallel to the tube, and be conducted each through a ſlit in a braſs cap which ſhall lead them acroſs the aperture in a radial direction. It is probable alſo that the artiſt, who ſhall carry theſe hints into effect, may alſo think of ſeveral other methods.

This thought occurred to the author, from contemplating the contraction and dilatation of the iris of the eye, according as we look at an object more or leſs luminous. Theſe variations are ſo great, that in the obſervable variations of the human eye, the aperture is thirty times as large at one time as at another, whilſt in the cat the proportion is greater than a hundred to one.

In luc- tio

TEMPERAMENT OF THE SCALE OF MUSIC. When the conſiderate reader reflects on the large and almoſt numberleſs diſſertations on this ſubject, by the moſt eminent philoſophers, mathematicians, and artiſts, both of ancient and modern times, and the important points which divided, and ſtill divide, their opinions, he will not ſurely expect, in a Work like our's, the deciſion of a queſtion which has hitherto eluded their reſearches. He will rather be diſpoſed, perhaps, to wonder how a ſubject of this nature ever acquired ſuch importance in the minds of perſons of acknowledged talents (for ſurely no perſon will refuſe this claim to Pythagoras, to Ariſtotle, Euclid, Ptolemy, Galileo, Wallis, Euler, and many others, who have written elaborate treatiſes on the ſubject); and his ſurpriſe will increaſe, when he knows that the treatiſes on the ſcale of muſic are as numerous and voluminous in China, without any appearance of their being borrowed from the ingenious and ſpeculative Greeks.

The ingenious, in all cultivated nations, have remarked the great influence of muſic; and they found no difficulty in perſuading the nations that it was a gift of the gods. Apollo and his ſacred choir are perhaps the moſt reſpectable inhabitants of the mythological heavens of the Greeks. Therefore all nations have conſidered muſic as a proper part of their religious worſhip. We doubt not but that they found it fit for exciting or ſupporting thoſe emotions and ſentiments which were ſuited to adoration, thanks, or petition. Nor would the Greeks have admitted muſic into their ſerious dramas, if they had not perceived that it heightened the effect. The ſame experience made them employ it as an aid to military enthuſiaſm; and it is recorded as one of the reſpectable accompliſhments of Epaminondas, that he had the muſical inſtructions of the firſt maſters, and was eminent as a performer.

Temperament of the Scale of Muſic.

Thus was the ſtudy of muſic ennobled, and recommended to the attention of the greateſt philoſophers. Its cultivation was held an object of national concern, and its profeſſors were not allowed to corrupt it in order to gratify the faſtidious taſte of the luxurious or the ſenſualiſt, who ſought from it nothing but amuſement. But its influence was not confined to theſe public purpoſes; and, while the men of ſpeculation found in muſic an inexhauſtible fund of employment for their genius and penetration, and their poets felt its aid in their compoſitions, it was hailed by perſons of all ranks as the ſoother of the cares and anxieties, and ſweetener of the labours of life. *O Phœbi decus!—laborum dulce lenimen.* Poor Ovid, the victim of what remained of good in the cold heart of Octavius, found its balm.

Exul eram (ſays he): *requieſque mihi, non ſama petita eſt.*
Mens intenta ſuis ne foret uſque malis.

Cantet et inniteus limoſæ pronus arenæ
Adverſo tardam qui trahit amne ratem,
Quique ferens pariter lentos ad pectora remos,
In numerum pulsâ brachia verſat aquâ.
Feſſus ut incubuit baculo, ſaxove reſedit
Paſtor; arundineo carmine mulcet oves.
Cantantis pariter, pariter data penſa trahentis
Fallitur ancillæ, decipiturque labor.

2
Scale of muſic. It requires temperament.

It is chiefly in this humble department of muſical influence that we propoſe at preſent to lend our aid. What has been ſaid in the article MUSIC, *Encycl.* is ſufficient for informing the reader of what is received as the ſcale of muſic, and the inequality of its different ſteps, the tones major and minor, ſemitone, comma, &c. We ſhall only obſerve, that what is there delivered on temperament by M. d'Alembert, after Rameau, bears the evident mark of uncertainty or want of confidence in the principle adopted as the rule of temperament; and we have learned, ſince the printing of that article, that the inſtructions there delivered have not that perſpicuity and preciſion that are neceſſary for enabling a perſon to execute the temperament recommended by Rameau; that is, to tune a keyed inſtrument with certainty, according to that ſyſtem or conſtruction of the ſcale.

If ſuch be the caſe, we are in ſome meaſure diſappointed; becauſe we ſelected that treatiſe of D'Alembert as the performance of a man of great eminence as a mathematician and philoſopher, aiming at public inſtruction more than his own fame, by this elementary abſtract of the great work of the moſt eminent muſician in France.

Few can tune a harpſichord;

To be able to tune a harpſichord with certainty and accuracy, ſeems an indiſpenſable qualification of any perſon worthy of the name of a *muſician*. It would certainly be thought an unpardonable deficiency in a violin performer if he could not tune his inſtrument; yet we are well informed, that many profeſſional performers on the harpſichord cannot do it, or cannot do it any other way than by uncertain and painful trial, and, as it were, groping

groping in the dark; and that the tuning of harpſichords and organs is committed entirely to tuners by profeſſion. This is a great inconvenience to perſons reſiding in the country; and therefore many take leſſons from the profeſſed harpſichord tuners, who alſo profeſs to teach this art. We have been preſent during ſome of theſe leſſons; but it did not appear to us that the inſtructions were ſuch as could enable the ſcholar to tune an inſtrument when alone, unleſs the leſſons had been ſo frequent as to form the ear to an inſtantaneous judgment of tune by the ſame habit that had inſtructed the teacher. There ſeemed to be little principle that could be treaſured up and recollected when wanted.

3
Yet Nature furniſhes abundant means of doing this.

Yet we cannot help thinking that there are phenomena or facts in muſic, ſufficiently preciſe to furniſh principles of abſolute certainty for enabling us to produce temperaments of the ſcale which ſhall have determined characters, and among which we may chooſe ſuch a one as ſhall be preferable to the others, according to the purpoſes we have in view; and we think that theſe principles are of ſuch eaſy application, that any perſon, of a moderate ſenſibility to juſt intonation, may, without much knowledge or practice in muſic, tune his harpſichord with all deſirable accuracy. We propoſe to lay theſe before the reader. We might content ourſelves with ſimply giving the practical rules deduced from the principles; but it is ſurely more deſirable to perceive the validity of the principles. This will give us confidence in the deduced rules of practice. In the employment of ſacred muſic, an inſpired writer counſels us to ſing, not only "with the heart, but with the underſtanding alſo." We may, without irreverence, recommend the ſame thing here. Let us therefore attend a little to the dictate of untutored Nature, and ſee how ſhe teaches all mankind to form the ſcale of melody.

4
All nations ſing by one ſcale.

It is a moſt remarkable fact, that, in all nations, however they may differ in the ſtructure of that chaunt which we call the accent, or tone, or twang, in the colloquial language of a particular nation, or in the favourite phraſes or paſſages which are moſt frequent in their ſongs, all men make uſe of the ſame riſes and falls, or inflexions of voice, in their muſical language or airs. We have heard the ſongs of the Iroquois, the Cherokee, and the Eſquimaux, of the Carib, and the inhabitant of Paraguay; of the African of Negroland and of the Cape, and of the Hindoo, the Malay, and the native of Otaheite—and we found none that made uſe of a different ſcale from our own, although ſeveral ſeemed to be very ſorry performers by any ſcale. There muſt be ſome natural foundation for this uniformity. We may never diſcover this; but we may be fortunate enough to diſcover facts in the phenomena of ſound which invariably accompany certain modifications of muſical ſentiment. If we ſucceed, we are intitled to ſuppoſe that ſuch inſeparable companions are naturally connected; and to conclude, that if we can inſure the appearance of thoſe facts in ſound, we ſhall alſo give occaſion to thoſe muſical ſentiments or impreſſions.

5
Muſical pitch, what?

There is a quality in lengthened or continued ſound which we call its pitch or note, by which it may be accounted ſhrill or hoarſe. It may be very hoarſe in the beginning, and during its continuance it may grow more and more ſhrill by imperceptible gradations. In this caſe we are ſenſible of a kind of progreſs from the one ſtate of ſound to the other. Thus, while we gently draw the bow acroſs the ſtring of a baſs viol, if we at the ſame time ſlide the finger ſlowly along the ſtring, from the nut toward the bridge, the ſound, from being hoarſe, becomes gradually acute or ſhrill. Hoarſe and ſhrill therefore are not different qualities, although they have different names, but are different ſtates or degrees of the ſame quality, like cold and heat, near and far, early and late, or, what is common to all theſe, little and great. A certain ſtate of the air is accounted neither hot nor cold. All ſtates on one ſide of this are called warm, or hot; and all on the other are cold. In like manner, a certain ſound is the boundary between thoſe that are called hoarſe and thoſe called ſhrill. The chemiſt is accuſtomed to ſay, that the temperature of a body is higher when it is warmer, and lower when colder. In like manner, we are accuſtomed to ſay, that a perſon raiſes or depreſſes the pitch of his voice when it becomes more ſhrill or more hoarſe. The ancient Greeks, however, called the ſhriller ſounds *low*, and the hoarſer ſounds *high*; probably becauſe the hoarſer ſounds are generally ſtronger or louder, which we are alſo accuſtomed to conſider as higher. In common language, a low pitch of voice means a faint ſound, but in muſical language it means a hoarſer ſound. The ſound that is neither hoarſe nor ſhrill is ſome ordinary pitch of voice, but without any preciſe criterion.

6. The change obſerved in the pitch of a violin ſtring, when the finger is carried along the finger-board with a continued motion, is alſo continuous; that is, not by ſtarts: we call it gradual, for want of a better term, although gradual properly means *gradatim*, by degrees, ſteps, or ſtarts, which are not to be diſtinguiſhed in this experiment. But we may make the experiment in another way. After ſounding the open ſtring, and while the bow is yet moving acroſs it, we may put down the finger about $1\frac{2}{3}$ inches from the nut. This will change the ſound into one which is *ſenſibly* ſhriller than the former, and there is a manifeſt ſtart from the one to the other. Or we may put down the finger $2\frac{1}{2}$ inches from the nut; the ſound of the open ſtring will change to a ſhriller ſound, and we are ſenſible that this change or ſtep is greater than the former. Moreover, we may, while drawing the bow acroſs the ſtring, put down one finger at $1\frac{2}{3}$ inches, and, immediately after, put down another finger at $2\frac{1}{2}$ inches from the nut. We ſhall have three ſounds in ſucceſſion, each more ſhrill than the preceding, with two manifeſt ſteps, or ſubſultory changes of pitch.

7. Now ſince the laſt ſound is the ſame as if the ſecond had not been ſounded, we muſt conceive the ſum of the two ſucceſſive changes as equivalent or equal to the change from the firſt to the third. This change ſeems ſomehow to include the other two, and to be made up of them, as a whole is made up of its parts, or as $2\frac{1}{2}$ inches are made up of $1\frac{2}{3}$ and $\frac{5}{6}$ of an inch, or as the ſum 15 is made up of 10 and 5.

8
We hav notion o ſomethi like an terval b tween t notes of muſic.

Thus it happens that thinking perſons conceive ſomething like or analogous to a diſtance, or interval, between theſe ſounds. It is plain, however, that there can be no real diſtance or ſpace interpoſed between them; and it is not eaſy to acquire a diſtinct notion of the bulk or magnitude of theſe intervals. This conception is purely figurative and analogical; but the analogy is very good, and the obſervation of it, or conjecture

T pera- m of the le of ific.

jecture about it, has been of great ſervice in the ſcience of muſic, by making us ſearch for ſome preciſe meaſure of thoſe manifeſt intervals of muſical ſounds.

It muſt now be remarked, that it is in this reſpect alone that ſounds are ſuſceptible of muſic. Nor are all ſounds poſſeſſed of this quality. The ſmack of a whip, the exploſion of a muſket, the ruſhing of water or wind, the ſcream of ſome animals, and many other ſounds, both momentary and continuous, are mere noiſes; and can neither be called hoarſe nor ſhrill. But, on the other hand, many ſounds, which differ in a thouſand circumſtances of loudneſs, ſmoothneſs, mellowneſs, &c. which make them pleaſant or diſagreeable, have this quality of muſical pitch, and may thus be compared. The voice of a man or woman, the ſound of a pipe, a bell, a ſtring, the voice of an animal, nay, the ſingle blow on an empty caſk—may all have one pitch, or we may be ſenſible of the interval between them. We can, in all caſes, tighten or ſlacken the ſtring of a violin, till the moſt uninformed hearer can pronounce with certainty that the pitch is the ſame. We are indebted to the celebrated Galileo for the diſcovery of that phyſical circumſtance in all thoſe ſounds which communicates this remarkable quality to them, and even enables us to induce it on any noiſe whatever, and to determine, with the utmoſt preciſion, the muſical pitch of the ſound, and the interval between any two ſuch ſounds. Of this we ſhall ſpeak fully hereafter; and at preſent we only obſerve, that two ſounds, having the ſame pitch, are called UNISONS by muſicians, or are ſaid to be in *uniſon* to one another.

10. When two untaught men attempt to ſing the ſame air together, they always ſing in uniſon, unleſs they expreſsly mean to ſing in different pitches of voice. Nay, it is an extremely difficult thing to do otherwiſe, except in a few very peculiar caſes. Alſo, when a man and woman, wholly uninſtructed in muſic, attempt to ſing the ſame air, they alſo *mean* to ſing the ſame muſical notes through the whole air; and they generally imagine that they do ſo. But there is a manifeſt difference in the ſounds which they utter, and the woman is ſaid to ſing more SHRILL, and the man more HOARSE. A very plain experiment, however, will convince them that they are miſtaken. *N. B.* We are now ſuppoſing that the performers have ſo much of a muſical ear, and flexible voice, as to be able to ſing a common ballad, or a pſalm tune, with tolerable exactneſs, and that they can prolong or dwell upon any particular note when deſired.

Let them ſing the common pſalm tune called St David's, in the ſame way that they practiſe at church; and when they have done it two or three times, in order to fix their voices in tune, and to feel the general impreſſion of the tune, let the woman hold on in the firſt note of the tune, which we ſuppoſe to be *g*, while the man ſings the firſt three in ſucceſſion, namely *g*, *d*, $\bar{g}$. He will now perceive, that the laſt note ſung by himſelf is the ſame with that ſung by the woman, and which ſhe thinks that ſhe is ſtill holding on in the firſt note of the tune. Let this be repeated till the performance becomes eaſy. They will then perceive the perfect ſameneſs, in reſpect of muſical pitch, of the woman's firſt note of this tune and the man's third note. Some difference, however, will ſtill be perceived; but it will not be in the pitch, but in the ſmoothneſs, or clearneſs, or other agreeable quality of the woman's note.

Temperament of the Scale of Muſic.

11 There are ſeven ſteps in the natural ſcale, and eight notes.

When this is plainly perceived, let the man try by what continued ſteps he muſt raiſe his pitch, in order to arrive at the woman's note from his own. If he is accuſtomed to common ballad ſinging, he will have no great difficulty in doing this; and will find that, beginning with his own note, and ſinging gradually up, his eighth note will be the woman's note. In ſhort, if two flutes be taken, one of which is twice as long as the other, and if the man ſing in uniſon with the larger flute, the woman, while ſinging, as ſhe thinks, the ſame notes with the man, will be found to be ſinging in uniſon with the ſmaller flute.

12 OCTAVE.

This is a remarkable and moſt important fact in the phenomena of muſic. This interval, comprehending and made up of ſeven ſmaller intervals, and requiring eight ſounds to mark its ſteps, is therefore called an OCTAVE. Now, ſince the female performer follows the ſame dictates of natural ear in ſinging her tune that the man follows in ſinging his, and all hearers are ſenſible that they are ſinging the ſame tune, it neceſſarily follows, that the two ſerieſes of notes are perfectly ſimilar, though not the ſame: For there muſt be the ſame interval of an octave between any ſtep of the lower octave and the ſame ſtep of the upper one. In whatever way, therefore, we conceive one of theſe octaves to be parcelled out by the different ſteps, the partition of both muſt be ſimilar. If we repreſent both by lines, theſe lines muſt be ſimilarly divided. Each partial interval of the one muſt bear the ſame relation to the whole, or to any other interval, as its ſimilar interval in the other octave bears to the whole of that octave, or to the other correſponding interval in it.

13 All octaves are ſimilar.

Farther, we muſt now obſerve, that although this ſimilarity of the octaves was firſt obſerved or diſcovered by means of the ordinary voices of man and woman, and is a legitimate inference from the perfect ſatisfaction that each feels in ſinging what they think the ſame notes, this is not the only foundation or proof of the ſimilarity. Having acquired the knowledge of that phyſical circumſtance, on which the pitch of muſical ſounds depends, we can demonſtrate, with all the rigour of geometry, that the ſeveral notes in the man and woman's octave *muſt* have the ſame relation to their reſpective commencements, and that theſe two great intervals are ſimilarly divided. But farther ſtill, we can demonſtrate that this ſimilarity is not confined to theſe two octaves. This may even be proved, to a certain extent, by the ſame original experiment. Many men can ſing two octaves in ſucceſſion, and there are ſome rare examples of perſons who can ſing three. This is more common in the female voice. This being the caſe, it is plain that there will be two octaves common to both voices; and therefore four octaves in ſucceſſion, all ſimilar to each other. The ſame ſimilarity may be obſerved in the ſounds of inſtruments which differ only by an octave. And thus we demonſtrate that all octaves are ſimilar to each other. This ſimilarity does not conſiſt merely in the ſimilarity of its diviſion. The ſound of a note and its octave are ſo like each other, that if the ſtrength or loudneſs be properly adjuſted, and there be no difference in kind, or other circumſtances of clearneſs, ſmoothneſs, &c. the two notes, when ſounded together, are indiſtinguiſhable, and appear only like a more brilliant note. They coaleſce into one ſound. Nay, moſt clear mellow notes, ſuch as theſe of a fine human voice, really contain each two notes, one of which is octave to the other.

14 All muſic contained in the octave; hence called DIAPASON.

We ſaid that this reſemblance of octaves is an important fact in the ſcience of muſic. We now ſee why it is ſo. The whole ſcale of muſic is contained in one octave, and all the reſt are only repetitions of this ſcale. And thus is the doctrine of the ſcale of melody brought within a very moderate compaſs, and the problem is reduced to that of the repartition of a ſingle octave, and ſome attention to the junction with the ſimilar ſcales of the adjoining octaves. This partition is now to be the ſubject of diſcuſſion.

15 Melodies, or tunes, or airs, were the firſt muſic.

In the infancy of ſociety and cultivation, it is probable that the melodies or tunes, which delighted the ſimple inhabitants, were equally ſimple. Being the ſpontaneous effuſions of individuals, perhaps only occaſional, and never repeated, they would periſh as faſt as produced. The airs were probably connected with ſome of the rude rhimes, or gingles of words, which were bandied about at their feſtivals; or they were aſſociated with dancing. In all theſe caſes they muſt have been very ſhort, conſiſting of a few favourite paſſages or muſical phraſes. This is the caſe with the common airs of all ſimple people to this day. They ſeldom extend beyond a ſhort ſtanza of poetry, or a ſhort movement of dancing. The artiſt who could compoſe and keep in mind a piece of conſiderable length, muſt have been a great rarity, and a minſtrel fit for the entertainment of princes; and therefore much admired, and highly rewarded: his excellencies were almoſt incommunicable, and could not be preſerved in any other way but by repeated performance to an attentive hearer, who muſt alſo be an artiſt, and muſt patiently liſten, and try to imitate; or, in ſhort, to get the tune by heart. It muſt have been a long time before any diſtinct notion was formed of the relation of the notes to each other. It was perhaps impoſſible to recollect today the preciſe notes of yeſterday. There was nothing in which they were fixed till inſtrumental muſic was invented. This has been found in all nations; but it appears that long continued cultivation is neceſſary for raiſing this from a very ſimple and imperfect ſtate. The moſt refined inſtrument of the Greek muſicians was very far below our very ordinary inſtruments. And, till ſome method of notation was invented, we can ſcarcely conceive how any determined partition of the octave could be made generally known.

16 KEY-NOTE or FUNDAMENTAL.

Accordingly, we find that it was not till after a long while, and by very rude and awkward ſteps, that the Greeks perceived that the whole of muſic was compriſed in the octave. The firſt improved lyre had but four ſtrings, and was therefore called a TETRACHORD; and the firſt flutes had but three holes, and four notes; and when more were added to the ſcale, it was done by joining two lyres and two flutes together. Even this is an inſtructive ſtep in the hiſtory of muſical ſcience: For the four ſounds of the inſtrument have a natural ſyſtem, and the awkward and groping attempts to extend the muſic, by joining two inſtruments, the ſcale of the one following, or being a continuation of that of the other, pointed out the DIAPASON or *totality* of the octave, and the relation of the whole to a principal ſound, which we now call the *fundamental* or *key*, it being the loweſt note of our ſcale, and the one to which the other notes bear a continual reference. It would far exceed the limits of this Work to narrate the ſucceſſive changes and additions made by the Greeks in their lyre; yet would this be a very ſure way of learning the natural formation of our muſical ſcale. We muſt refer our readers to Dr Wallis's Appendix to his edition of the Commentary of Porphyrius in Ptolemy's Harmonics, as by far the moſt perſpicuous account that is extant of the Greek muſic. We ſhall pick out from among their different attempts ſuch plain obſervations as will be obvious to the feelings of any perſon who can ſing a common tune.

17 The octav is naturall divided into two TETRACHORDS.

Let ſuch a perſon firſt ſing over ſome plain and cheerful, or at leaſt not mournful, tune, ſeveral times, ſo as to retain a laſting impreſſion of the chief note of the tune, which is generally the laſt. Then let him begin, on the ſame note, to ſing in ſucceſſion the riſing ſteps of the ſcale, pronouncing the ſyllables *do*, *re*, *mi*, *fa*, *ſol*, *la*, *ſi*, *do*. He will perhaps obſerve, that this chaunt naturally divides itſelf into two parts or phraſes, as the muſicians term it. If he does not, of himſelf, make this remark, let him ſing it, however, in that manner, pauſing a little after the note *fa*. Thus, *do*, *re*, *mi*, *fa*; *ſol*, *la*, *ſi*. *do*.—*Do*, *re*, *mi*, *fa*; *ſol*, *la*, *ſi*, *do*.

Having done this ſeveral times, and then repeated it without a pauſe, he will become very ſenſible of the propriety of the pauſe, and of this natural diviſion of the octave. He will even obſerve a conſiderable ſimilarity between theſe two muſical phraſes, without being able, at firſt, to ſay in what it conſiſts.

18 The ſteps of the ſca are unequal, and the two t trachords are ſimilar.

Let him now ſtudy each phraſe apart, and try to compare the magnitude of the changes of ſound; or ſteps which he makes in riſing from *do* to *re*, from *re* to *mi*, and from *mi* to *fa*. We apprehend that he will have no difficulty in perceiving, after a few trials, that the ſteps *do re*, and *re mi*, are ſenſibly greater than the ſtep *mi fa*. We feel the laſt ſtep as a ſort of ſlide; as an attempt to make as little change of pitch as we can. Once this is perceived, it will never be forgotten. This will be ſtill more clearly perceived, if, inſtead of theſe ſyllables, he uſe only the vowel *a*, pronounced as in the word *hall*, and if he ſing the ſteps, ſliding or ſlurring from the one to the other. Taking this method, he cannot fail to notice the ſmallneſs of the third ſtep.

19. Let the ſinger farther conſider, whether he does not feel this phraſe muſical or agreeable, making a ſort of tune or chaunt, and ending or cloſing agreeably after this ſlide of a ſmall, or, as it were, half ſtep. It is generally thought ſo; and is therefore called a CLOSE, a CADENCE, when we end with a half ſtep aſcending.

20. Let the ſinger now reſume the whole ſcale, ſinging the four laſt notes *ſol*, *la*, *ſi*, *do*, louder than the other four, and calling off his attention from the low phraſe, and fixing it on the upper one. He will now be able to perceive that this, like the other, has two conſiderable ſteps; namely, *ſol la* and *la ſi*, and then a ſmaller ſtep, *ſi do*. A few repetitions will make this clear, and he will then be ſenſible of the nature of the ſimilarity between theſe two phraſes, and the propriety of this great diviſion of the ſcale into the intervals *do*, *fa*, and *ſol*, *do*, with an interval *fa*, *ſol* between them.

This was the foundation of the tetrachords, or lyres of four ſtrings, of the Greeks. Their earlieſt muſic or modulation ſeems to have extended no farther than this phraſe. It pleaſed them, as a ring of four bells pleaſes many country pariſhes.

21 CLOSE CADEN

The ſinger will perceive the ſame ſatiſfaction with the cloſe of this ſecond phraſe as with that of the former: and if he now ſing them both, in immediate ſucceſſion,

ſucceſſion, with a ſlight pauſe between, we imagine that he will think the cloſe or cadence on the upper *do* even more ſatisfactory than that on the *fa*. It ſeems to us to complete a tune. And this impreſſion will be greatly heightened, if another perſon, or an inſtrument, ſhould ſound the lower *do*, while he cloſes on the upper *do* its octave *Do* ſeems to be expected, or looked for, or ſought after. We take *ſi* as a ſtep to *do*, and there we reſt.

22
e third l ſeventh p are the alleſt.

Thus does the octave appear to be naturally compoſed of ſeven ſteps. of which the firſt, ſecond, fourth, fifth, and ſixth, are more conſiderable, and the third and ſeventh very ſenſibly ſmaller. Having no direct meaſures of their quantity, nor even a very diſtinct notion of what we mean by their quantity, magnitude, or bulk, we cannot pronounce, with any certainty, whether the greater ſteps are equal or unequal; and we preſume them to be equal. Nor have we any diſtinct notion of the proportion between the larger and ſmaller ſteps. In a looſe way we call them half notes, or ſuppoſe the riſe from *mi* to *fa*, or from *ſi* to *do*, to be one-half of that from *do* to *re*, or from *re* to *mi*.

23
ie Pytharean diſ- veries did t im- ove the eek mu-

Accordingly, this ſeems to have been all the muſical ſcience attained by the Greek artiſts, or thoſe who did not profeſs to ſpeak philoſophically on the ſubject. And even after Pythagoras publiſhed the diſcovery which he had made, or more probably had picked up among the Chaldeans or Egyptians, by which it appeared, that accurate meaſures of ſounds, in reſpect to gravity and acuteneſs, were attainable, it was affirmed by Ariſtoxenus, a ſcholar of Ariſtotle, and other eminent philoſophers, that theſe meaſures were altogether artificial, had no connection with muſic, and that the ear alone was the judge of muſical intervals. The artiſt had no other guide in tuning his inſtrument; becauſe the ratios, which were ſaid to be inherent in the ſounds (though no perſon could ſay how), were never perceived by the ear. The juſtice of this opinion is abundantly confirmed by the awkward attempt of the Greeks to improve the lyre by means of theſe boaſted ratios. Inſtead of illuſtrating the ſubject, they ſeem rather to have brought an additional obſcurity upon it, and threw it into ſuch confuſion, that although many voluminous diſſertations were written on it, and on the compoſition of their muſical ſcale, the account is ſo perplexed and confuſed, that the firſt mathematicians and artiſts of Europe acknowledge, that the whole is an impenetrable myſtery. Had the philoſophers never meddled with it, had they allowed the practical muſicians to conſtruct and tune their inſtruments in their own way, ſo as to pleaſe their ear, it is ſcarcely poſſible that they ſhould not have hit on what they wanted, without all the embarraſſment of the chromatic and enharmonic ſcales of the lyre. It is ſcarcely poſſible to contrive a more cumberſome method of extending the ſimple ſcale of Nature to every caſe that could occur in their muſical compoſitions, than what aroſe from the employment of the muſical ratios. This ſeems a bold aſſertion; but we apprehend that it will appear to be juſt as we proceed.

24
ie tranſ- ſition of ſic made ercalary tes neceſ- y in the ave.

The practical muſicians could not be long of finding the want of ſomething more than the mere diatonic ſcale of their inſtruments. As they were always accompanied by the voice, it would often happen that a lyre or flute, perfectly tuned, was too low or too high for the voice that was to accompany it. A ſinger can pitch his tune on any ſound as a key; and if this be too high for the ſinger who is to accompany him, he can take it on a lower note. But a lyriſt cannot do this. Suppoſe his inſtrument two notes too low, and that his accompanyiſt can only ſing it on the key which is the *ſi* of the lyre. Should the lyriſt begin it on that key, his very firſt ſtep is wrong, being but a half ſtep, whereas it ſhould be a whole one. In ſhort, all the ſteps but one will be found wrong, and the lyriſt and ſinger will be perpetually jarring. This is an evident conſequence of the inequality of the fourth and ſeventh ſteps to the reſt. And if the other ſteps, which we imagine to be equal, be not exactly ſo, the diſcordance will be ſtill greater.

Diſputes of the Pythagoreans and Ariſtoxeneans about muſical ratios.

The method of remedying this is very obvious. If the intervals *mi fa* and *ſi do*, are half notes, we need only to interpoſe other ſounds in the middle between each of the whole notes; and then, in place of ſeven unequal ſteps, we ſhall have twelve equal ones, or twelve intervals, each of them equal to a ſemitone. The lyre thus conſtructed will now ſuit any voice whatever. It will perfectly reſemble our keyed inſtruments, the harpſichord, or organ, which have twelve ſeemingly equal intervals in the octave. Accordingly, it appears that ſuch additions were practiſed by the muſicians of Greece, and approved of by Ariſtoxenus, and by all thoſe who referred every thing to the judgment of the ear. And we are confident that this method would have been adopted, if the philoſophers had had leſs influence, and if the Greeks had not borrowed their religious ceremonies along with their muſical ſcience. Both of theſe came from the ſame quarter; they came united; and it was ſacrilegious to attempt innovations. The doctrine of muſical ratios was an occupation only for the refined, the philoſophers; and by ſubjecting muſic to this myſterious ſcience, it became myſterious alſo, and ſo much the more venerable. The philoſophers ſaw, that there was in Nature a certain inſcrutable connection between mathematical ratios and thoſe intervals which the ear reliſhed and required in melody: but they were ignorant of the nature and extent of this connection.

Ratios of octave, diapente, and diateſſaron.

What is this connection, or what is meant when we ſpeak of the ratios of ſounds? Simply this:—Pythagoras is ſaid to have found, that if two muſical cords be ſtrained by equal weights, and one of them be twice the length of the other, the ſhort one will ſound the octave to the note of the other. If it be two-thirds of the length of the long ſtring, it will ſound the fifth to it. If the long ſtring ſound *do*, the ſhort one will ſound *ſol*. If it be three-fourths of the length, it will ſound the fourth or *fa*. Thus the ratio of 2 : 1 was called the ratio of the DIAPASON; that of 3 : 2 was called the DIAPENTE; and that of 4 : 3 the DIATESSARON. Moreover, if we now take all the four ſtrings, and make that which ſounds the graveſt note, and is the longeſt, twelve inches in length; the ſhort or octave ſtring muſt be ſix inches long, or one-half of twelve; the diapente muſt be eight inches, or two-thirds of twelve; and the diateſſaron muſt be nine inches, which is three-fourths of twelve. If we now compare the diapente, not with the graveſt ſtring, but with the octave of ſix inches, we ſee that they are in the ratio of 4 to 3, or the ratio of diateſſaron. And if we compare the diateſſaron with

the

the octave, we ſee that their ratio is that of 9 : 6, or of 3 : 2, or the ratio of diapente. Thus is the octave divided into a fifth and a fourth, *do ſol*, and *ſol do*, in ſucceſſion. Alſo the fourth *do fa*, and the fifth *fa do*, make up the octave. The note which ſtands as a fifth to one of the extreme ſounds of the octave, ſtands as a fourth to the other. And, laſtly, the two fourths *do fa*, and *ſol do*, leave an interval *fa ſol* between them; which is alſo determined by nature, and the ratio correſponding to it is evidently that of 9 to 8.

25
The diſcovery of Pythagoras is either a fable, or falſely narrated.

This is all that was known of the connection of muſic with mathematical ratios. It is indeed ſaid by Iamblichus, that Pythagoras did not make this diſcovery by means of ſtrings, but by the ſounds made by the hammers on the anvil in a ſmith's ſhop. He obſerved the ſounds to be the key, the diateſſaron, and the diapente of muſic; and he found, that the weights of the hammers were in this proportion; and as ſoon as he went home, he tried the ſounds made by cords, when weights, in the proportions above-mentioned, were appended to them. But the whole ſtory has the air of a fable, and of ignorance. The ſounds given by a ſmith's anvil have little or no dependence on the weight of the hammers; and the weights which are in the proportions of the numbers mentioned above will by no means produce the ſounds alleged. It requires *four* times the weight to make a ſtring ſound the octave, and *twice and a quarter* will produce the diapente, and *one and ſeven-ninths* will produce the diateſſaron. It is plain, therefore, that they knew not of what they were ſpeaking: yet, on this ſlight foundation, they erected a vaſt fabric of ſpeculation; and in the courſe of their reſearches, theſe ratios were found to contain all that was excellent. The attributes of the Divinity, the ſymmetry of the univerſe, and the principles of morality, were all reſolvable into the harmonic ratios.

26
Conjoined and disjoined tetrachords.

In the attempts to explain, by means of the myſterious properties of the ratios 2 : 1, 3 : 2, 4 : 3, and 9 : 8, which were thus defined by Nature, it was obſerved, that their favourite lyres of four ſtrings could be combined in two principal manners, ſo as to produce an extenſive ſcale. One lyre may contain the notes *do, re, mi, fa*; and the acuter lyre may contain the notes *ſol, la, ſi, do*; and, being ſet in ſucceſſion, having the interval *fa ſol* between the higheſt note of the one and the loweſt of the other, they make a complete octave. Theſe were called *disjoined tetrachords*. Again, a third tetrachord may be joined with the upper tetrachord laſt mentioned, in ſuch ſort, that the loweſt note of the third tetrachord may be the ſame with the higheſt of the ſecond. Theſe were called *conjoined* tetrachords (A).

27
The lyres were tuned entirely by the ear,

By thus conſidering the ſcale as made up of tetrachords, the tuning of the lyre was reduced to great ſimplicity. The muſician had only to make himſelf perfect in the ſhort chaunt *do, re, mi, fa*, or to get it by heart, and to ſing it exactly. This intonation would apply equally to the other *ſol, la, ſi, do*. We are well informed that this was really the practice. The directions given by Ariſtoxenus, Nicanor, and others, for varying the tuning, according to certain occaſional accommodations, ſhew diſtinctly that they did not tune as we do, ſounding the two ſtrings together, except in the caſe of the diapaſon or octave. It was all done by the judgment of the ear in melody. The moſt valuable circumſtance in the diſcovery of Pythagoras was the determination of the interval between the fourth and the fifth, by which the tetrachords were ſeparated. The filling up of each tetrachord was left entirely to the ear; and when the doctrine of the mathematical ratios ſhewed that the large intervals *do re, re mi, fa ſol, ſol la, la ſi*, ſhould not be preciſely equal, Ariſtoxenus refuſed the authority of the reaſons alleged for this inequality, becauſe the ear perceived none of the ratios as ratios, and could judge only of ſounds. He farther aſſerted, that the inequalities which the Pythagoreans enjoined, were ſo trifling, that no ear could poſſibly perceive them. And accordingly, the theoriſts diſputed about the reſpective ſituations of the greater and ſmaller tones (ſo they named the great ſteps) ſo much ſpoken of, and had different ſyſtems on the ſubject.

28
And by melody alone:

But the ſtrongeſt proof of the indiſtinct notion that the theoriſts entertained about the influence of theſe ratios in muſic is, that they would admit no more but thoſe introduced by Pythagoras; and their reaſons for the rejection of the ratio of 5 to 4, and of 6 to 5, were either the moſt whimſical fancies about the perfections of the ſacred ratios, or aſſumptions expreſsly founded on the ſuppoſition, that the ear perceives and judges of the ratios as ratios; than which nothing can be more falſe. Had they admitted the ratio of 5 to 4, they would have obtained the third note of the ſcale, and would at once have gotten the whole ſcale of our muſic. The ratios of 6 : 5, and 16 : 15, follow of courſe; and every ſound of the tetrachords would have been determined. For 5 : 4 being the ratio of the major third, which is perfectly pleaſing to the ear, as the *mi* to the note *do*, and 3 : 2 being the ratio of the fifth *do ſol*, there is another interval *mi ſol* determined; and this ratio, being the difference between *do ſol* and *do mi*, or between 3 : 2 and 5 : 4, is evidently 6 : 5. In like manner, the interval *mi fa* is determined, and its ratio, being 4 : 3 — 5 : 4, is 16 : 15.

But farther; we ſhall find, upon trial, that if we put in a ſound above *ſol*, having the relation 5 : 4 to *fa*, it will be perfectly ſatisfactory to the ear if ſung as the note *la*. And if, in like manner, we put in a note above *la*, having the relation 5 : 4 to *ſol*, we find it ſatisfactory to the ear when uſed as *ſi*. If we now examine the ratios of theſe artificial notes, we ſhall find the ratio of the notes *ſol la* to be 10 : 9, and that of *la ſi* to be 9 : 8, the ſame with that *fa ſol*; alſo *ſi do* will appear to be 16 : 15, like that of *mi fa*.

We have no remains of the muſic of the Greeks, by which we can learn what were their favourite paſſages or muſical phraſes; and we cannot ſee what cauſed them to prefer the fourth to the major third. Few muſicians of our times think the fourth in any degree comparable with the major third for melodiouſneſs, and ſtill fewer for harmoniouſneſs. The piece or tune publiſhed by Kircher from Alypius is very ſuſpicious, as no

---

(A) This is the *principle*, but not the preciſe *form*, of the disjoined and conjunct tetrachords. The Greeks did not begin the tetrachord with what we make the firſt note of our chaunt of four notes, but began one of them with *mi*, and the other with *ſi*; to which they afterwards added a note below. This beginning ſeems to have been directed by ſome of their favourite cadences; but it would be tedious to explain it.

npera- t of the le of Iuſic.

no other perſon has ſeen the MS.; and the collection found at Buda is too much disfigured, and probably of too late a date, to give us any ſolid help. In all probability, the common melodies of the Greeks abounded in eaſy leaps up and down on the third and fifth, and on the fourth and ſixth, juſt as we obſerve in the airs for dancing among all ſimple people. Their accompliſhed performers had certainly great powers both of invention and execution; and the chromatic and enharmonic diviſions of the ſcale were certainly practiſed by them, and not merely the ſpeculations of mathematicians. To us, the enharmonic ſcale appears the moſt jarring diſcord; but this is certainly owing to our not ſeeing any pieces of the muſic ſo compoſed, and becauſe we cannot in the leaſt judge by harmony what the effect of enharmonic melody would be. But we have ſufficient evidence from the writings of the ancient Greeks, that the enharmonic muſic fell into diſuſe even before the time of Ptolemy, and was totally and irrecoverably loſt before the 5th century. Even the chromatic was little practiſed, and was chiefly employed for extending the common ſcale to keys which were ſeldom uſed. The uncertainties reſpecting even the common ſcale remained the ſame as ever; and although Ptolemy gives (among others) the very ſame that is now admitted as the only perfect one, namely, his *diatonicum intenſum*, his reaſons of preference, though good, are not urged with ſtrong marks of his confidence in them, nor do they ſeem to have prevailed.

29 t me- y is re in- ficient.

Theſe obſervations ſhew clearly, that the perception of melody alone is not ſufficiently preciſe for enabling us to acquire exact conceptions of the ſcale of muſic. The whole of the practicable ſcience of the ancients ſeems to amount to no more than this, that the octave contained five greater and two ſmaller intervals, which the voice employed, and the ear reliſhed. The greater intervals ſeemed all of one magnitude; and the ſmaller intervals appeared alſo equal, but the ear cannot judge what proportion they bear to the larger ones. The muſicians thought them larger than one-half of the great intervals (and indeed the ratio 16 : 15 of the artificial *mi fa* and *ſi do*, is greater than the half of 9 : 8 or 10 : 9). Therefore they allowed the theoriſts to call them *limmas* inſtead of *hemitones*; but they, as well as the theoriſts, differed exceedingly in the magnitudes which they aſſigned them.

30 rcular re- eſenta- n of the le. Plate XLIV.

The beſt way that we can think of for expreſſing the ſcale of the octave is, by dividing the circumference of a circle in the points C, D, E, F, G, A, and B (fig. 1.), in the proportion we think moſt ſuitable to the natural ſcale of melody. According to the practical notion now under our conſideration, the arches CD, DE, FG, GA, and AB, are equal, containing nearly 59°; and the arches EF and BC are alſo equal, but ſmaller than the others, containing about 33½. Now, ſuppoſe another circle, on a piece of card paper, divided in the ſame manner, to move round their common centre, but inſtead of having its points of diviſion marked C, D, E, &c. let them be marked *do, re, mi, fa, ſol, la, ſi*. It is plain, that to whatever point of the outer circle we ſet the point *do* of the inner one, the other points of the outer circle will ſhew the common notes which are fit for thoſe ſteps of the ſcale. The ſimilarity of all octaves makes this ſimple octave equivalent to a rectilineal ſcale ſimilarly divided, and repeated as often as we pleaſe. Fig. 1. repreſents this inſtrument, and will be often referred to. A ſort of ſymmetry may be obſerved in it. The point D ſeems to occupy the middle of the ſcale, and *re* ſeems to be the middle note of the octave. The oppoſite arch GA, and the correſponding interval *ſol la*, ſeems to be the middle interval of the octave. The other notes and intervals are ſimilarly diſpoſed on each ſide of theſe. This circumſtance ſeems to have been obſerved by the Greeks, by the inhabitants of India, by the Chineſe, and even by the Mexicans. The note *re*, and the interval *ſol la*, have gotten diſtinguiſhed ſituations in their inſtruments and ſcales of muſic.

Tempera-ment of the Scale of Muſic.

31 Ariſtoxenean ſcale of mean tones and limmas.

With reſpect to the diviſion of the circles, we ſhall only obſerve at preſent, that the dotted lines are conformable to the principles of Ariſtoxenus, the whole octave being portioned out into five larger and equal intervals, and two ſmaller, alſo equal. The larger are called *mean* or *medium tones*; and the ſmaller are called *limmas* or *ſemitones*. The full lines, to which the letters and names are affixed, divide the octave into the artificial portions, determined by means of the muſical ratios, the arches being made proportional to the meaſures of thoſe ratios. Thus the arches CD, FG, AB, are proportional to the meaſure or logarithm of the ratio 9 : 8; GA and DE are proportional to the logarithm of 10 : 9; and the arches EF and BC are proportional to the logarithm of 16 : 15. We have already mentioned the way in which thoſe ratios were applied, and the authority on which they were ſelected. We ſhall have occaſion to return to this again. The only farther remark that is to be made with propriety in this place is, that the diviſion on the Ariſtoxenean principles, which is expreſſed in this figure, is one of an indefinite number of the ſame kind. The only principle adopted in it is, that there ſhall be five mean tones, and two ſmall equal ſemitones; but the magnitude of theſe is arbitrary. We have choſen ſuch, that two mean tones are exactly equal to the arch CE, determined by the ratio 5 : 4. The reaſons for this preference will appear as we proceed (B).

By this little inſtrument (the invention, we believe, of a Mr D'Ormiſſon, about the beginning of laſt century), we ſee clearly the inſufficiency of the ſeven notes of the octave for performing muſic on different keys. Set the flower de luce at the Ariſtoxenean B, and we ſhall ſee that E is the only note of our lyre which will do for one of the ſteps of the octave in which we intend to ſing and accompany. We have no ſounds in the lyre for *re, mi, ſol, la, ſi*. The remedy is as clearly pointed out. Let a ſet of ſtrings be made, having the ſame relation to *ſi* which thoſe of the preſent lyre have to *do*, and inſert them in the places pointed out by the Ariſtoxenean diviſions of the moveable octave. We need only five of them, becauſe the *ſi* and *fa* of the preſent lyre will anſwer. Theſe new ſounds are marked by a +.

32 Found imperfect, and required TEMPERAMENT.

But it was ſoon found, that theſe new notes gave but indifferent melody, and that either the ear could not determine

---

(B) We ſhall be abundantly exact, if we make CD=61°,72; CE=115°,9; CF=149°,42; CG=210°,58; CA=265°,3; and CB=326°,48.

determine the equality of the tones and ſemitones exactly enough, or that no ſuch partition of the octave would anſwer. The Pythagoreans, or partiſans of the muſical ratios, had told them this before. But they were in no better condition themſelves; for they found, that if a ſeries of ſounds, in perfect relation to the octave, be inſerted in the manner propoſed, the melody will be no better. They put the matter to a very fair trial. It is eaſy to ſee, that no ſyſtem of mean tones and limmas will give the ſame muſic on every key, unleſs the tones be increaſed, and the limmas diminiſhed, till the limma becomes juſt half a tone. Then all the intervals will be perfectly equal. The mathematicians computed the ratios which would produce this equality, and deſired the Ariſtoxeneans to pronounce on the muſic. It is ſaid, that they allowed it to be very bad in all their moſt favourite paſſages. Nothing now remained to the Ariſtoxeneans but to attempt occaſional methods of tuning. They ſaw clearly, that they were making the notes unequal which Nature made equal. The Pythagoreans, in like manner, pointed out many alterations or corrections of intervals which ſuited one tetrachord, or one part of the octave, but did not ſuit another. Both parties ſaw that they were obliged to deviate from what they thought natural and perfect: therefore they called theſe alterations of the natural or perfect ſcale a *temperament*.

The accompliſhed performers were the beſt judges of the whole matter, and they derived very little aſſiſtance from the mathematicians: For although the rigid rules delivered by them be acknowledged to be perfectly exact, the execution of thoſe rules is not ſuſceptible of the ſame exactneſs. Their lyres are tuned, not by mathematical operations, but by the ear. It does not appear that they had muſical inſtruments with divided finger boards, like our baſs viols and guitars; and even on theſe, it is well known that the preſſure and touch of the finger may vary ſo much, that the moſt exact placing of the frets will not inſure the nice degrees of the ſounds. The flutes are the only inſtruments of the ancients that are capable of accurate ſounds. But flutemakers know very well, that they cannot be tuned by mathematical operations, but by the ear alone. This accounts for the great prices paid for a well tuned flute. Some have coſt L. 700, and L. 50 was a very common price.

33 The Greeks did not cultivate the harmony of ſimultaneous ſounds

Such ſeems to have been the ſtate of the ancient muſic. There was little or no ſcience in it. There was, indeed, a moſt abſtruſe and refined ſcience coupled with it; but by a very ſlight connection: and it ſeems to have been nothing more than an amuſement for the ingenious and ſpeculative Greeks. Nor could it, in our opinion, be better, ſo long as they had no guide in tuning but the judgment of the ear in melody. Many writers inſiſt that the Greeks had a knowledge of what *we* call *harmony* alſo The word ἁρμονια is conſtantly uſed by them: but it does not mean what we call harmony, the pleaſant coaleſcence of ſimultaneous ſounds. It comes from ἁρμος, or from ἁρμοζω, and ſignifies *aptitude*, *fitneſs*, and would, in general, be better tranſlated by *ſymmetry*. But we cannot conceive that they paid any marked attention to the effect of ſimultaneous ſounds, ſo as to enjoy the pleaſure of certain conſonances, and employ them in their compoſitions. We judge in this way from the rank which they gave them in their ſcale. To prefer the fourth to the major third ſeems to us to be impoſſible, if it be meant of ſimultaneous ſounds. And the reaſon which is aſſigned for the preference can have no value in the opinion of a muſician. It is becauſe the ratio of 4 : 3 is ſimpler than that of 5 : 4. For the ſame reaſon, the fifth is preferred to both, and the octave to all the three, and uniſon to every other conſonance. They would not allow the major third 5 : 4 to be a concord at all. We have made numberleſs trials of the different concords with perſons altogether ignorant of muſic. We never ſaw an inſtance of one who thought that mere uniſon gave any poſitive pleaſure. None of all whom we examined had much pleaſure from an octave. All, without exception, were delighted with a fifth, and with a major third; and many of them preferred the latter. All of them agreed in calling the pleaſure from the fifth a *ſweetneſs*, and that from the major third a *cheerfulneſs*, or *ſmartneſs*, or by names of ſimilar import. The greater part preferred even the major ſixth to the fourth, and ſome felt no pleaſure at all from the fourth. Few had much pleaſure from the minor third or minor ſixth. *N. B.* Care was taken to ſound theſe concords without any preparation -- merely as ſounds — but not as making part of any muſical paſſage. This circumſtance has a great effect on the mind. When the minor third and ſixth were heard as making part of the minor mode, all were delighted with it, and called it ſweet and mournful. In like manner, the chord $^{6}_{4}$ never failed to give pleaſure. Nothing can be a ſtronger proof of the ignorance of the ancients of the pleaſures of harmony.

34 The pleaſures of harmony ſeem to be a modern diſcovery.

We do not profeſs to know when this was diſcovered. We think it not unlikely that the Greeks and Italians got it from ſome of the northern nations whom they called *Barbarians*. We cannot otherwiſe account for its prevalence through the whole of the Ruſſian empire—the ancient Slavi had little commerce with the empire of Rome or of Conſtantinople; yet they ſung in parts in the moſt remote periods of their hiſtory of which we have any account; and to this day, the moſt uncultivated boor in the Ruſſian empire would be aſhamed to ſing in uniſon. He liſtens a little while to a new tune, holding his chin to his breaſt; and as ſoon as he has got a notion of it, he burſts out in concert, throwing in the harmonic notes by a certain rule which he feels, but cannot explain. His harmonics are generally alternate major and minor thirds. and he ſeldom miſſes the proper cadences on the fifth and key. Perhaps the invention of the organ produced the diſcovery. We know that this was as early as the ſecond century (c). It was hardly poſſible to make much uſe of that inſtrument without perceiving the pleaſure of concordant ſounds.

The

(c) It is ſaid that the Chineſe had an inſtrument of this kind long before the Europeans. Cauſeus ſays, that it was brought from China by a native, and was ſo ſmall as to be carried in the hand. It is certain that the Emperor Conſtantine Copronymus ſent one to Pepin king of France in 757, and that his ſon Charlemagne got another from the Emperor Michael Paleologus. But they appear to have been known in the Engliſh churches before that time.

pera- of the ale of uſic.

35 mony e a t ge in ſcience uſic.

The diſcovery of the pleaſures of harmony occaſioned a total change in the ſcience of muſic During the dark ages of Europe, it was cultivated chiefly by the monks: the organ was ſoon introduced into the churches, and the choral ſervice was their chief and almoſt their only occupation. The very conſtruction of this inſtrument muſt have contributed to the improvement of muſic, and inſtructed men in the nature of the ſcale. The pipes are all tuned by their lengths; and theſe lengths are in the ratios of the ſtrings which give the ſame notes, when all are equally ſtretched. This muſt have revived the ſtudy of the muſical ratios. The tuning of the organ was performed by conſonance, and no longer depended on the nice judgment of ſounds in ſucceſſion. The dulleſt ear, even with total ignorance of muſic, can judge, without the ſmalleſt error, of an exact octave, fifth, third, or other concord; and a very mean muſician could now tune an organ more accurately than Timotheus could tune his lyre. Other keyed inſtruments, reſembling our harpſichord, were invented, and inſtruments with fretted finger boards. Theſe ſoon ſupplanted the lyres and harps, being much more compendious, and allowing a much greater variety and rapidity of modulation. All theſe inſtruments were the fruits of harmony, in the modern ſenſe of that word. The deficiences of the old diatonic ſcale were now more apparent, and the neceſſity of a number of intercalary notes. The finger-board of an organ or harpſichord, running through a ſeries of octaves, and admitting much more than the accompanyment of one note, pointed out new ſources of muſical pleaſure ariſing from the fulneſs of the harmoy; and, above all, the practice of choral ſinging ſuggeſted the poſſibility of a pleaſure altogether new. While a certain number of the choir performed the Cantus or Air of the muſic, it was irkſome to the others to utter mere ſounds, ſupporting or compoſing the harmony of the Cantus, without any melody or air in their own parts. It was thought probable that the harmonic notes might be ſo portioned out among the reſt of the choir, that the ſucceſſion of ſounds uttered by each individual might alſo conſtitute a melody not unpleaſant, and perhaps highly grateful. On trial, it was found very practicable. Canons, motets, fugues, and other harmonies, were compoſed, where the airs performed by the different parts were not inferior in beauty to the principal. The notes which could not be thrown into this agreeable ſucceſſion, were left to the organiſt, and by him thrown into the baſs.

36. By all theſe practices, the imperfections of the ſcale of fixed ſounds became every day more ſenſible, eſpecially in full harmony. Scientific muſic, or the properties of the ratios, now recovered the high eſtimation in which they were held by the ancient theoriſts; and as the muſicians were now very frequently men of letters, chiefly monks, of ſober characters and decent manners, muſic again became a reſpectable ſtudy. The organiſt was generally a man of ſcience, as well as a performer. At the firſt revival of learning in Europe, we find muſic ſtudied and honoured with degrees in the univerſities, and very ſoon we have learned and excellent diſſertations on the principles of the ſcience. The inventions of Guido, and the diſſertations of Salinas, Zarlino, and Xoni, are among the moſt valuable publications that are extant on muſic. The improvements introduced by Guido are founded on a very refined examination of the ſcale; and the temperaments propoſed by the other two have ſcarcely been improved by any labours of modern date. Both theſe authors had ſtudied the Greek writers with great care, and their improvements proceed on a complete knowledge of the doctrines of Pythagoras and Ptolemy

Temperament of the Scale of Muſic.

37 Galileo diſcovered that muſical pitch conſiſted in the frequency of the aëreal undulations.

At laſt the celebrated Galileo Galilei put the finiſhing hand to the doctrines of thoſe ancient philoſophers, by the diſcovery of the connection which ſubſiſts in nature between the ratios of numbers and the muſical intervals of ſounds. He diſcovered, that theſe numbers expreſs the frequency of the recurring pulſes or undulations of air which excite in us the ſenſation of ſound. He demonſtrated that if two ſtrings, of the ſame matter and thickneſs, be ſtretched by equal weights, and be twanged or pinched ſo as to vibrate, the times of their vibrations will be as their lengths, and the frequency or number of oſcillations made in a given time will be inverſely as their lengths. The frequency of the ſonorous undulations of the air is therefore inverſely as the length of the ſtring. When therefore we ſay that 2 : 1 is the ratio of the octave, we mean, that the undulations which produce the upper ſound of this interval are twice as frequent as thoſe which produce its fundamental ſound. And the ratio 3 : 2 of the diapente or fifth, indicates, that in the ſame time that the ear receives three undulations from the upper ſound, it receives only two from the lower. Here we have a natural connection, not peculiar to the ſounds produced by ſtrings; for we are now able to demonſtrate, that the ſounds produced by bells are regulated by the ſame law. Nay, the improvements which have been made in the ſcience of motion ſince the days of Galileo, ſhew us that the undulations of the air in pipes, where the air is the *only* ſubſtance moved, is regulated by the ſame law. It ſeems to be the general property of ſounds which renders them ſuſceptible of muſical pitch, of acuteneſs, or gravity; and that a certain frequency of the ſonorous undulations gives a determined and unalterable muſical note. The writer of this article has verified this by many experiments. He finds, that *any noiſe whatever*, if repeated 240 times in a ſecond, at equal intervals, produces the note C *ſol fa ut* of the Gindonian gamut. If it be repeated 360 times, it produces the G *ſol re ut*, &c. It was imagined, that only certain regular agitations of the air, ſuch as are produced by the tremor or vibration of elaſtic bodies, are fitted for exciting in us the ſenſation of a muſical note. But he found, by the moſt diſtinct experiments, that any noiſe whatever will have the ſame effect, if repeated with due frequency, not leſs than 30 or 40 times in a ſecond. Nothing ſurely can have leſs pretenſion to the name of a muſical ſound than the ſolitary ſnap which a quill makes when drawn from one tooth of a comb to another: but when the quill is held to the teeth of a wheel, whirling at ſuch a rate, that 720 teeth paſs under it in a ſecond, the ſound of *g in alt.* is heard moſt diſtinctly; and if the rate of the wheel's motion be varied in any proportion, the noiſe made by the quill is mixed in the moſt diſtinct manner with the muſical note correſponding to the frequency of the ſnaps. The *kind* of the original noiſe determines the kind of the continuous ſound produced by it, making it harſh and fretful, or ſmooth and mellow, according as the original noiſe is abrupt or gradual: but even the moſt abrupt noiſe produces a tolerably ſmooth ſound when ſufficiently frequent. Nothing can be more abrupt than the ſnap juſt now mentioned; yet the *g* produced by it has the ſmoothneſs of a bird's chirrup. An experiment was made, which was leſs promiſing of a ſound than any that can be thought of. A ſtop cock was ſo conſtructed, that it opened and ſhut the paſſage through a pipe 720 times in a ſecond. This apparatus was fitted to the pipe of a conduit leading from the bellows to the wind cheſt of an organ. The air was ſimply allowed to paſs gently along this pipe by the opening of the cock. When this was repeated 720 times in a ſecond, the ſound *g in alt.* was moſt ſmoothly uttered, equal in ſweetneſs to a clear female voice. When the frequency was reduced to 360, the ſound was that of a clear but rather harſh man's voice. The cock was now altered in ſuch a manner, that it never ſhut the hole entirely, but left about one third of it open. When this was repeated 720 times in a ſecond, the ſound was uncommonly ſmooth and ſweet. When reduced to 360, the ſound was more mellow than any man's voice at the ſame pitch. Various changes were made in the form of the cock, with the intention of rendering the primitive noiſe more analogous to that produced by a vibrating ſtring. Sounds were produced which were pleaſant in the extreme. The intelligent reader will ſee here an opening made to great additions to practical muſic, and the means of producing muſical ſounds, of which we have at preſent ſcarcely any conception; and this manner of producing them is attended with the peculiar advantage, that an inſtrument ſo conſtructed can never go out of tune in the ſmalleſt degree. But of this enough at preſent.

38
This frequency is expreſſed by the muſical ratios of Pythagoras.

This diſcovery of Galileo's completed the Pythagorean theories, by ſupplying the only thing wanted for procuring confidence in them. We now ſee that the muſic of ſounds depends on principles as certain and as plain as the elements of Euclid, and that every thing relating to the ſcale of muſic is attainable by mathematics. It is very true that we do not perceive the ratio 3 : 2 in the diapente, as having any relation to the numbers 3 and 2. But we perceive the ſweetneſs of ſound which characteriſes this concord. This is undoubtedly the perception of a certain phyſical fact involving this ratio, as much as the ſweetneſs on our tongue is the perception of a certain manner of acting of the particles of ſugar during their diſſolution in the ſaliva.

CONCORD, DISCORD, are properties of particular ratios of frequency.

The pleaſure ariſing from certain conſonances, ſuch as *do ſol*, is not more diſtinctly perceived than is the diſagreeable feeling which other conſonances produce, ſuch as *do re*; and it was a fair field of diſquiſition to diſcover why the one pleaſed and the other diſpleaſed. We cannot ſay that this queſtion has been completely decided. It has been aſcribed to the coincidence of vibrations. In the octave, every ſecond vibration of the treble note may be made to coincide with every vibration of the baſs. But the pleaſure ariſing from the different conſonances does by no means follow the proportions of thoſe coincidences of vibrations; for when two notes are infinitely near to the ſtate which would produce a complete coincidence, the actual coincidence is then exceedingly rare; and yet we know that ſuch ſounds yield very fine harmony. In tuning any concord, when the two notes are very diſcordant, the coinciding vibrations recur very frequently; and as we approach nearer and nearer to perfect concord, theſe coincidences become rarer and rarer; and if it be infinitely near to perfect concord, the coincidences of vibration will be infinitely diſtant from each other. This, and many other irrefragable arguments, demonſtrate that coaleſcence of ſound, which makes the pleaſing harmony of a fifth, for example, does not ariſe from the coincidence of vibrations; and the only thing which we can demonſtrate to obtain in all the caſes where we enjoy this pleaſure, is a certain arrangement of the component pulſes, and a certain law of ſucceſſion of the diſlocations or intervals between the non-coinciding pulſes. We are perfectly able to demonſtrate that when, by continually ſcrewing up one of the notes of a conſonance, we render the real coincidence of pulſes leſs frequent; the diſlocations, or deviations from perfect coincidence, approach nearer and nearer to a certain defineable law of ſucceſſion; and that this law obtains completely, when the perfect ratio of the duration of the pulſe is attained, although perhaps at that time not one pulſe of the one ſound coincides with a pulſe of the other. Suppoſe two organ pipes, ſounding the note C *ſol fa ut*, at the diſtance of ten feet from each other, and that their pulſes begin and end at the ſame inſtants, making the moſt perfect coincidence of pulſes—there is no doubt but that there will be the moſt perfect harmony; and we learn by experience that this harmony is perfectly the ſame, from whatever part of the room we hear it. This is an unqueſtionable fact. A perſon ſituated exactly in the middle between them will receive coincident pulſes. But let him approach one foot nearer to one of the pipes, it is now demonſtrable that the pulſes, at their arrival at his ear, will be the moſt diſtant from coincidence that is poſſible; for every pulſe of one pipe will biſect the pulſe from the other: but the law of ſucceſſion of the deviations from coincidence will then obtain in the moſt perfect manner. A muſical ſound is the ſenſation of a certain form of the aerial undulation which agitates the auditory organ. The perception of harmonious ſound is the ſenſation produced by another definite form of the agitation. This is the compoſition of two other agitations; but it is the compound agitation only that affects the ear, and it is its form or kind which determines the ſenſation, making it pleaſant or unpleaſant.

39
Hence ariſes the great uſe of mathematics in muſic.

Our knowledge of mechanics enables us to deſcribe this form, and every circumſtance in which one agitation can differ from another, and to diſcover general features or circumſtances of reſemblance, which, in fact, accompany all perceptions of harmony. We are ſurely intitled to ſay that theſe circumſtances are ſure teſts of harmony; and that when we have enſured their preſence, we have enſured the hearing of harmony in the adjuſted ſounds. We can even go farther in ſome caſes: We can explain ſome appearances which accompany imperfect harmony, and perceive the connection between certain diſtinct reſults of imperfect coincidences, and the magnitude of the deviations from perfect harmony which are then heard. Thus, we can make uſe of theſe phenomena, in order to aſcertain and meaſure thoſe deviations; and if any rules of temperament ſhould require a certain determinate deviation from perfect harmony in the tuning of an inſtrument, we can ſecure the appearance of that phenomenon which correſponds to the deviation, and thus can produce the preciſe temperament

mpera-
it of the
ale of
Muſic.

rament ſuggeſted by our rules. We can, for example, deſtroy the perfect harmony of the fifth C *g*, and flatten the note *g* till it deviates from a perfect fifth in the exact ratio of 320 to 321, which the muſicians call the one-fourth of a comma. The moſt exquiſite ear for melody is almoſt inſenſible of a deviation four times greater than this; and yet a perſon who has no muſical ear at all, can execute this temperament by the rules of harmony without the error of the fortieth part of a comma.

40
ATINGS
mper-
: conſo-
ces.

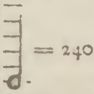
For this moſt valuable piece of knowledge we are indebted to the late Dr Robert Smith of Cambridge, a very eminent geometer and philoſopher, and a good judge of muſic, and very pleaſing performer on the organ and harpſichord. This gentleman, in his Diſſertation on the Principles of Harmonics, publiſhed for the firſt time in 1749, has paid particular attention to a phenomenon in coexiſtent ſounds, called a *beating*. This is an alternate enforcement and diminution of the ſtrength of ſound, ſomething like what is called a cloſe ſhake, but differing from it in having no variation in the pitch of the ſounds. It is a ſort of undulation of the ſound, in which it becomes alternately louder and fainter. It may be often perceived in the ſound of bells and muſical glaſſes, and alſo in the ſounds of particular ſtrings. It is produced in this way: Suppoſe two uniſons quite perfect; the vibrations of each are either perfectly coincident, or each pulſe of one ſound is interpoſed in the ſame ſituation between each pulſe of the other. In either caſe they ſucceed each other with ſuch rapidity, that we cannot perceive them, and the whole appears an uniform ſound. But ſuppoſe that one of the ſounds has 240 pulſes in a ſecond, which is the undulation that is produced in a pipe of 24 inches long; ſuppoſe that the other pipe is only 23 inches and $\frac{7}{10}$ths long. It will give 243 pulſes in a ſecond. Therefore the 1ſt, the 80th, the 160th, and the 240th pulſe of the firſt pipe will coincide with the 1ſt, the 81ſt, the 162d, and the 243d pulſe of the other. In the inſtants of coincidence, the agitation produced by one pulſe is increaſed by that produced by the other. The commencement of the next two pulſes is ſeparated a little, and that of the next is ſeparated ſtill more, and ſo on continually: the *diſlocations* of the pulſes, or their deviations from perfect coincidence, continually increaſing, till we come to the 40th pulſe of the one pipe, which will commence in the middle of the 41ſt pulſe of the other pipe; and the pulſes will now biſect each other, ſo that the agitations of the one will counteract or weaken thoſe of the other. Thus the compounded ſound will be ſtronger at the coincidences of the pulſes, and fainter when they biſect each other. This reinforcement of ſound will therefore recur thrice in every ſecond. The frequency of the pulſes are in the ratio of a comma, or 81 : 80. Therefore this conſtitutes an *uniſon imperfect by a comma.* If therefore any circumſtance ſhould require that theſe two pulſes ſhould form an uniſon imperfect by a comma, we have only to alter one of the pipes, till the two, when ſounded together, beat thrice in a ſecond. Nothing can be plainer than this. Now let us ſuppoſe a third pipe tuned an exact fifth to the firſt of theſe two. There will be no beating obſervable; becauſe the recurrence of coincident pulſes is ſo rapid as to appear a continued ſound. They recur at every ſecond vibration of the baſs, or 120 times in a ſecond. But now, inſtead of ſounding the third pipe along with the firſt, let it ſound along with the ſecond. Dr Smith demonſtrates, that they will beat in the ſame manner as the uniſons did, but thrice as often, or nine times in a ſecond. When therefore the fifth C *g* beats nine times in a ſecond, we know that it is too ſharp or too flat (very nearly) by a comma.

Temperament of the Scale of Muſic.

41
Dr Smith applies them to the ſcience and practice of muſic with great effect.

Dr Smith ſhews, in like manner, what number of beats are made in any given time by any concord, imperfect or tempered, in any aſſigned degree. We humbly think that the moſt inattentive perſon muſt be ſenſible of the very great value of this diſcovery. We are obliged to call it *his* diſcovery. Merſennus, indeed, had taken particular notice of this undulation of imperfect conſonances, and had offered conjectures as to their cauſe; conjectures not unworthy of his great ingenuity. Mr Sauveur alſo takes a ſtill more particular notice of this phenomenon *, and makes a moſt ingenious uſe of it for the ſolution of a very important muſical problem; namely, to determine the preciſe number of pulſes which produce any given note of the gamut. His method is indeed operoſe and delicate, even as ſimplified and improved by Dr Smith. The following may be ſubſtituted for it, founded on the mechaniſm of ſounding cords. Let a violin, guitar, or any ſuch inſtrument, be fixed up againſt a wall, with the finger-board downward, and in ſuch a manner, that a violin ſtring, ſtrained by a weight, may preſs on the bridge, but hang free of the lower end of the finger-board. Let another ſtring be ſtrained by one of the tuning pins till it be in uniſon with ſome note (ſuppoſe C) of the harpſichord. Then hang weights on the other ſtring, till, upon drawing the bow acroſs both ſtrings, at a ſmall diſtance below the bridge, they are perfect uniſons, without the ſmalleſt beating or undulation, and taking care that the preſſure of the bow on that ſtring which is tuned by the pin be ſo moderate as not to affect its tenſion ſenſibly. Note exactly the weight that is now appended to it. Now increaſe this weight in the proportion of the ſquare of 80 to the ſquare of 81; that is, add to it its 40th part very nearly. Now draw the bow again acroſs the ſtrings with the ſame caution as before. The ſounds will now beat remarkably; for the vibrations of the loaded ſtring are now accelerated in the proportion of 80 to 81. Count the number of undulations made in ſome ſmall number (ſuppoſe 10) of ſeconds. This will give the number of beats in a ſecond; 80 times this number are the ſingle pulſes of the loweſt ſound; and 81 times the ſame number gives the pulſes of the higheſt of theſe imperfect uniſons.

Pulſes of



= 240.

If this experiment be tried for the C in the middle of our harpſichords, it will be found to contain 240 pulſes very nearly; for the ſtrings will beat thrice in a ſecond. The beats are beſt counted by means of a little ball hung to a thread, and made to keep time with the beats.

42
They afford exact meaſures of the temperament of concords,

Here, then, is a phenomenon of the moſt eaſy obſervation, and requiring no ſkill in muſic, by which the pitch of any ſound, and the imperfection of any concord, may be diſcovered with the utmoſt preciſion; and by this method may concordant ſounds be produced, which are abſolutely perfect in their harmony, or having any degree of imperfection or temperament that we pleaſe. An inſtrument may generally be tuned to perfect harmony, in ſome of its notes, without any difficulty,

* Mem. Acad. Par. 1701, 1702, 1707, and 1713.

ficulty, as we ſee done by every blind Crouder. But if a certain determinate degree of imperfection, different perhaps in the different concords, be neceſſary for the proper performance of muſical compoſitions on inſtruments of fixed ſounds, ſuch as thoſe of the organ or harpſichord kind, we do not ſee how it can be diſputed, that Dr Smith's theory of the beating of imperfect conſonances is one of the moſt important diſcoveries, both for the practice and the ſcience of muſic, that have been offered to the public. We are inclined to conſider it as the moſt important that has been made ſince the days of Galileo. The only rivals are Dr Brook Taylor's mechanical demonſtration of the vibrations of an elaſtic cord, and its companion, and of the undulations of the air in an organ pipe, and the beautiful inveſtigations of Daniel Bernoulli of the harmonic ſounds which frequently accompany the fundamental note. The muſical theory of Rameau we conſider as a mere whim, not founded in any natural law; and the theory of the grave harmonics by Tartini or Romieu is included in Dr Smith's theory of the beating of imperfect conſonances. This theory enables us to execute any harmonic ſyſtem of temperament with preciſion, and certainty, and eaſe, and to decide on its merit when done.

We are therefore ſurpriſed to ſee this work of Dr Smith greatly undervalued, by a moſt ingenious gentleman in the Philoſophical Tranſactions for 1800, and called a large and obſcure volume, which leaves the matter juſt as it was, and its reſults uſeleſs and impracticable. We are ſorry to ſee this; becauſe we have great expectations from the future labours of this gentleman in the field of harmonics, and his late work is rich in refined and valuable matter. We preſume humbly to recommend to him attention to his own admonitions to a very young and ingenious gentleman, who, he thinks, proceeded too far in animadverting on the writings of Newton, Barrow, and other eminent mathematicians. We alſo beg his leave to obſerve, that Dr Smith's application of his theory may be very erroneous (we do not ſay that it is perfect), in conſequence of his notion of the proportional effects produced on the general harmony by equal temperaments of the different concords. But the theory is untouched by this improper uſe, and ſtands as firmly as any propoſition in Euclid's Elements. We are bound to add to theſe remarks, that we have oftener than once heard muſic performed on the harpſichord deſcribed in the ſecond edition of Dr Smith's Harmonics, both before it was ſent home by the maker (the firſt in his profeſſion), and afterwards by the author himſelf, who was a very pleaſing performer, and we thought its harmony the fineſt we ever heard. Mr Watt, the celebrated engineer, and not leſs eminent philoſopher, built a handſome organ for a public ſociety, and, without the leaſt ear or reliſh for muſic, tuned three octaves of the open diapaſon by one of Dr Smith's tables of beats, with the help of a variable pendulum. Signior Doria, leader of the Edinburgh concert, tried it in preſence of the writer of this article, and ſaid, " Belliſſima – ſopra modo belliſſima!" Signior Doria attempted to ſing along with it, but would not continue, declaring it impoſſible, becauſe the organ was ill tuned. The truth was, that, on the major key of E♭, the tuning was exceedingly different from what ſhe was accuſtomed to, and ſhe would not try another key. We mention this particular, to ſhew how accurately Mr Watt had been able to execute the temperament he intended.

43
And accurate methods of temperament.

This theory is valuable, therefore, by giving us the management of a phenomenon intimately connected with harmony, and affording us preciſe and practicable meaſures of all deviations from it. It bids fair, for this reaſon, to give us a method of executing any ſyſtem of temperament which we may find reaſon to prefer. But we have another ground of eſtimation of this theory. By its aſſiſtance, we are able to aſcertain with certainty and preciſion the true untempered ſcale of muſic, which eluded all the attempts of the ingenious Greeks; and we determine it in a way ſuited to the favourite muſic of modern times, of which almoſt all the excellencies and pleaſures are derived from harmony. We do not ſay that this *total* innovation in the principle of muſical pleaſure is unexceptionable; we rather think it very defective, believing that the thrilling pleaſures of muſic depend more upon the melody or air. We appeal even to inſtructed muſicians, whether the heart and affections are not more affected *(and with much more diſtinct variety of emotion)* by a fine melody, ſupported, but not obſerved, by harmonies judiciouſly choſen? It appears to us that the effect of harmony, always filled up, is more uniformly the ſame, and leſs touching to the ſoul, than ſome ſimple air ſung or played by a performer of ſenſibility and powers of utterance. We do not wonder, then, that the ingenious Greeks deduced all their rules from this department of muſic, nor at their being ſo ſatisfied with the pleaſures which it yielded, that they were not ſolicitous of the additional ſupport of harmony. We ſee that melody has ſuffered by the change in every country. There is no Scotchman, Iriſhman, Pole, or Ruſſian, who does not lament that the ſkill in compoſing heart-touching airs is degenerated in his reſpective nation; and all admire the productions of their muſe of " the days that are paſt." They are " pleaſant and mournful to the ſoul."

But we ſtill prefer the harmonical method of forming the ſcale, on account of its preciſion and facility: and we prefer the theory of beats, *becauſe it alſo gives us the moſt ſatisfactory ſcale of melody*; and this, not by repeated corrections and recorrections, but by a direct proceſs. By a table of beats, every note may be fixed at once, and we have no occaſion to return to it and try new combinations; for the beatings of the different concords to one baſs being once determined, every beating of any one note with any other is alſo fixed.

44
Fundamental experiment.

We therefore requeſt the reader's patient attention to the experiment which we have now to propoſe. This experiment is beſt made with two organ pipes equally voiced, and pitched to the note C in the middle of our harpſichords. Let one of them at leaſt be a ſtopped pipe, its piſton being made extremely accurate, and at the ſame time eaſily moved along the pipe. Let the ſhank of it be divided into 240 equal parts. The advantage of this form of the experiment is, that the ſounds can be continued, with perfect uniformity, for any length of time, if the bellows be properly conſtructed. In default of this apparatus, the experiment may be made with two harpſichord wires in perfect uniſon, and touched by a wheel rubbed with roſin inſtead of a bow, in the way the ſounds of the vielle or hurdygurdy are produced. This contrivance alſo will continue the ſounds uniformly at pleaſure. A ſcale of 240 parts muſt

muſt be adapted to one ſtring, and numbered from that end of the ſtring where the wheel or bow is applied to it. Great care muſt be taken that the ſhifting of the moveable bridge do not alter the ſtrain on the wire. We may even do pretty well with a bow in place of the wheel; but the ſound cannot be long held on in any pitch. In deſcribing the phenomena, we ſhall rather abide by the ſtring, becauſe the numbers of the ſcale, or length of the ſounding part of the wire, correſpond, in fact, much more exactly with the ſounds. The deviations of the ſcale of the pipe do not in the leaſt affect the concluſions we mean to draw, but would require to be mentioned in every inſtance, which would greatly complicate the proceſs.

Having brought the two open ſtrings into perfect uniſon, ſo that no beating whatever is obſerved in the conſonance, ſlide the moveable bridge ſlowly along the ſtring while the wheel is turning, beginning the motion from the end moſt remote from the bow. All the notes of the octave, and all kinds of concords and diſcords, will be heard; each of the concords being preceded and followed by a ruffling beating, and that ſucceeded by a grating diſcord. After this general view of the whole, let the particular harmonious ſtations of the bridge be more carefully examined as follows.

45 Determination of the octave, and character of the concord.

I. Shift the moveable bridge to the diviſion 120. If it has been exactly placed, we ſhall hear a perfect octave without any beating. It is, however, ſeldom ſo exactly ſet, and we generally hear ſome beating. By gently ſhifting the bridge to either ſide, this beating becomes more or leſs rapid; and when we have found in which direction the bridge muſt be moved, we can then ſlide it along till the beating ceaſe entirely, and the ſounds coaleſce into one ſound. We can ſcarcely hear the treble or octave note as diſtinguiſhable from the baſs or fundamental afforded by the other ſtring. If the notes are duly proportioned in loudneſs, we cannot hear the two as diſtinct ſounds, but a note ſeemingly the ſame with the fundamental, only more brilliant. (*N B.* It would be a great improvement of the apparatus to have a micrometer ſcrew for producing thoſe ſmall motions of the bridge.)

Having thus produced a fine octave, we can now perceive that, as we continue to ſhift the bridge from its proper place, in either direction, the beating becomes more and more rapid, changes to a violent rattling flutter, and then degenerates into a moſt diſagreeable jar. This phenomenon is obſerved in the deviation of every concord whatever from perfect harmony, and muſt be carefully kept in remembrance.

46 Harmony more ſtrict than melody.

Before we quit this concord, the octave, produced by the biſection of the pipe or ſtring, we muſt obſerve, that, with reſpect to ourſelves, the octave $c\bar{c}$ muſt beat almoſt twice in a ſecond, before we can obſerve clearly any miſ-tune in it, by ſounding the notes in ſucceſſion, or as ſteps in the ſcale of melody. We never knew any ear ſo nice as to diſcover a miſ-tuning when it beats but once in three ſeconds. We think ourſelves intitled therefore to ſay, that we are inſenſible of a temperament in melody amounting to one third of a comma; and we never knew a perſon ſenſible of a temperament half this bulk

When the imperfection of the octave is clearly ſenſible by ſounding the notes in ſucceſſion, it is extremely diſagreeable, feeling like a ſtruggle or endeavour to attain a certain note, and a failure in the attempt. This ſeems owing to the familiar ſimilarity of octaves, in the habitual talking and ſinging of men and women together. But when the notes are ſounded together, although we are not much more ſenſible of the imperfection of the harmony directly, as a failure in the ſweetneſs of the concord, we are very ſenſible of this phenomenon of beating; and any perſon who can diſtinguiſh a weak ſound from a ſtronger one, can eaſily perceive, in this indirect manner, any fraction of a comma, however minute. This makes the tuning by harmony much more exact than by melody alone. It is alſo much more accommodated to the genius of modern muſic. The ancients had favourite paſſages, which were frequently introduced into their airs, and they were ſolicitous to have theſe in good tune. It appears from paſſages in the writings of Galen, that different performers excelled chiefly in their ſkill in making thoſe occaſional temperaments which their muſic required. Our muſic is much more ſtrict, by reaſon of our harmonic accompanyments, which are an abominable noiſe when miſ-tuned in a degree, which would have paſſed with the ancients for very good melody. Ariſtoxenus ſays, that the ear cannot diſcover the error of a comma. This would now be intolerable.

47 It gives the beſt ſcale for melody.

But another advantage attends our method. We obtain, by its aſſiſtance, the moſt perfect ſcale of melody; perfect in a degree attainable only by chance by the Greeks. This is now to be our buſineſs to unfold.

48 Determination of the Vth.

II. Set the moveable bridge at 158, and ſound the two ſtrings. They will beat very diſagreeably, being plainly out of tune. Slide it gradually toward 160, and the beats will grow ſlower and ſlower; will change to a gentle and not unpleaſant undulation; and at laſt, when the bridge is at 160, will vaniſh entirely, and the two ſounds will coaleſce into one ſweet concord, in which neither of the component ſounds can be diſtinguiſhed. If the ſound given by the ſhort ſtring be now examined as a ſtep in the ſcale of melody, it will be found a fifth to the ſound of the long ſtring or fundamental note, perfectly ſatiſfactory to the niceſt ear. Thus one ſtep of the ſcale has been aſcertained.

III. Slide the bridge ſlowly along the ſtring. The beating will recommence, will become a flutter, and then a jarring noiſe; and will again change to an angry flutter, beating about eight times in a ſecond, when the bridge ſtands at 169 nearly. Puſhing it ſtill on, but very ſlowly, the flutter will become an indiſtinct jarring noiſe; which, by continuing the motion, will again become a flutter, or beat about ſix in the ſecond. The bridge is now about 171.

49 Determination of the 4th.

IV. Still continuing the motion, the flutter becomes a jarring noiſe, which continues till the bridge is near to 180, when the rapid flutter will again be heard. This will become ſlower and ſlower as we approach to 180; and when the bridge reaches that point, all beating vaniſhes, and we have a ſoft and agreeable concord, but far inferior to the former concord in that cheering ſweetneſs which characteriſes the fifth. When this note is compared with that of the fundamental ſtring as a ſtep in the ſcale of melody, it is found to correſpond to the note *fa*, or the fourth ſtep in the ſcale, and in that employment to give complete ſatisfaction to the ear.

V. Still advancing the moveable bridge toward the nut, we ſhall hear the beatings return again ; and after fluttering and degenerating to a jarring noiſe, by a very ſmall motion of the bridge, they will again be heard, will grow ſlower, accompanied with a ſort of angry expreſſion, and will ceaſe entirely when the bridge reaches the 192d diviſion of our ſcale. Here we have another concord of very peculiar character, being remarkably enlivening and gay. This ſound gives perfect ſatisfaction to the ear, if employed as the third ſtep in the ſcale of melody, being the note *mi* of that ſeries, at leaſt in all gay or cheerful airs.

50 Determination of the IIId.

51. VI. As we move the bridge from 192 to 200, we hear again the ſame beatings, which, in the immediate vicinity to 192, have a peeviſh fretful expreſſion, inſtead of the angry waſpiſh expreſſion before mentioned. When the bridge has paſſed that ſituation which produces only grating diſcordance, we hear the beatings again, and they become ſlower, and ceaſe altogether when the bridge arrives at 200. Here we have another conſonance, which muſt be called a *concord*, becauſe it is rather agreeable than otherwiſe, but ſtrongly marked by a mournful melancholy in the expreſſion. In the ſcale of melody, it forms the third ſtep in thoſe airs which expreſs lamentation or grief. It is called the *minor third*, to diſtinguiſh it from the laſt enlivening concord, which, being a larger interval, is called the *major third*.

52 Determination of the 3d.

It is well known, that theſe two thirds give the diſtinguiſhing characters to the only two modes of melodious compoſition that are admitted into modern muſic. The ſeries containing the major third is called the *major*, and that containing the minor third is called the *minor mode*. It is worthy of remark, that the fanatical preachers, in their conventicles and field ſermons, affect this mode in their harangues, which are often diſtinctly muſical, modulating entirely by muſical intervals, and keeping the whole of their chaunt in ſubordination to a fundamental or key note. This is not unnatural, when we conſider the general ſcope of their diſcourſes, namely, to inſpire melancholy and humiliating thoughts, awakening ſorrow, and the like. It is not ſo eaſy to account for the uſual whine of a beggar, who generally craves charity in the major third. This is the caſe, at leaſt, in the northern parts of this iſland.

53. If we continue to ſhift the bridge ſtill nearer to the end of the ſtring, we ſhall hear nothing but a ſucceſſion of vile diſcordant noiſes, ſomewhat leſs offenſive when the bridge is about the diviſions 213 and 216, but even there very unpleaſant.

54 Determination of the 6th.

VII. Let us therefore change our manner of proceeding a little, and again place the bridge at 160, which will give us the pleaſing concord of the fifth. Inſtead of puſhing it from that place toward the nut, let it be moved toward the wheel or bow. Without repeating what we have ſaid of the reappearance of the beatings, their acceleration, and their degenerating into a jarring diſcord, to be afterwards ſucceeded by another beating, &c. &c. we ſhall only obſerve, that when we place the bridge at 150, we have no beatings, and we hear a conſonance, which is in a ſlight degree pleaſant, and may therefore be called a *concord*. It has the other marks of a concord which we have been making ſo much uſe of ; for the beatings recommence when we ſhift the bridge to either ſide of 150. This note makes the ſixth ſtep in the deſcending ſcale of mournful melody ; that is, when we are paſſing from the acute to the graver notes, with the intention of putting an emphaſis on the third and the fundamental. Although not eminent as a concord with the fundamental alone, it has a moſt pleaſing effect when liſtened to in ſubordination to the whole ſeries, or when ſounded along with other proper accompanyments of the fundamental.

55 Determination of the VIth.

VIII. Placing the bridge at 144, we obtain another very pleaſing concord, differing in its expreſſion from any of the foregoing. We find it difficult to expreſs its character. It is greatly inferior to the fifth in ſweetneſs, and to the major third in gaiety, but ſeems to poſſeſs, in a lower degree, both of thoſe qualities. In the ſcale of cheerful melody, it is the ſixth note, which we have diſtinguiſhed by the ſyllable *la*. It is alſo uſed even in mournful melody, when we are aſcending, with the intention of cloſing with the octave.

56 Scale of the upper octave.

In ſhifting the bridge from 144 to 120, we obtain nothing but diſcordant, or at leaſt diſagreeable conſonances. And, laſtly, if we move the bridge beyond 120, to diviſions which are reſpectively the halves of thoſe numbers which produced the concords already treated of, we obtain the ſame ſteps in the ſcale of the upper octave. Thus if the bridge be at 80, we have the fifth to the octave note, or twelfth to the fundamental. If it be at 60, we obtain the double octave, &c. &c. &c.

57 Characters of the different concords.

We have perhaps been raſh in affixing certain moral or ſentimental characters to certain concords ; for we have ſeen inſtances of perſons who gave them different denominations ; but theſe were never contradictory to ours, but always expreſſed ſome ſentiment allied to that which we have aſſigned. We never met with an inſtance of a perſon capable of a little diſcriminating reflection, who did not acknowledge a manifeſt ſentimental diſtinction among the different concords which could not be confounded. We doubt not but that the Greeks, a people of exquiſite ſenſibility to all the beauties of taſte and ſentiment, paid much attention to theſe characters, and availed themſelves of them in their compoſitions. We do not think it at all unlikely, that greater effects have been produced by their muſic, which was ſtudied with this expreſs view, than have ever been produced by the modern muſic, with all the addition of harmony. We have allowed too great a ſhare of our attention to mere harmony. Our great authors are much leſs ſolicitous to compoſe an enchanting air, than to conſtruct a full ſcore of rich and well conducted harmony. We do not profeſs to be nice judges in muſical compoſition, but we may tell what we ourſelves experience. We find our minds worked up by a continuance of fine harmony into a *general* ſenſibility ; into a frame of mind which would prepare and fit us for receiving ſtrong impreſſions of moral ſentiment, if theſe were diſtinctly made. But we have ſeldom felt any diſtinct emotions excited by mere inſtrumental muſic. And when the harmonies have been merely to ſupport the performance of a voice, the words have been either ſo frittered by muſical diviſions, as to become in ſome meaſure ludicrous—or have been ſo indiſtinct, and made ſo trifling a part of the muſic, that there was nothing done to give a particular ſhape to the moral impreſſion on our mind. We have generally been ſtrongly affected by ſome of the anthems which were in vogue in former times ; and we think that we perceived the cauſe

of

npera- t of the ale of lufic. of this difference: There was a great ſimplicity in the voice parts: the ſyllables were not drawled out into long muſical phraſes, but pronounced nearly according to their proper quantities; ſo that the ſentiment of the ſpeaker was expreſſed with all the force of good declamation, and the harmony of the accompanyment then ſtrengthened the appropriate effect of the melody. We mean not to offer theſe obſervations as of much authority, but merely to mention ſome facts, and to aſſign what we felt to be their cauſes, in order to promote, in ſome degree, however inſignificant, the cultivation of muſical ſcience. With this view, we venture to ſay, that ſome of the beſt compoſitions of Knapp of York *uniformly* affect us more than the more admired anthems of Bird and Tallis. A cadence, which Knapp gives almoſt entirely to the melody, is laboured by Bird or Tallis with all the rules of art; and you have its characters of perfect or imperfect, full or diſappointed, cadences, and ſuch an apparatus of preparation and reſolution of diſcords, that you foreſee it at the diſtance of ſeveral bars, and then the part aſſigned to the voice ſeems a very trifle, and merely to fill up a blank in the harmony. Such compoſitions ſmell of the lamp, and fail of their purpoſe, that of charming the *learned* ear. But enough of this digreſſion.

58. Thus have we found a natural relation between certain ſounds ſtrongly marked by very preciſe characters. The concordance of ſound is marked by the abſence of all undulation, and the deviations from this harmony are ſhewn to be meaſurable by the frequency of thoſe undulations. We have alſo found, that the notes, which are thus harmonious along with the fundamental, are ſteps in the ſcale of natural muſic (for we muſt acknowledge melody to be the primitive muſic, dictated by nature). We have got the notes *do—mi*, *fa*, *ſol*, *la—do*, aſcertained in a way that can no longer be miſtaken.

59 ios belonging to con- s, &c. Let us now examine what phyſical or mechanical relations theſe ſounds ſtand into each other. Our monochord gives us the lengths of the ſtrings; and the diſcovery of Galileo ſhews us, that theſe are alſo the durations of the aëreal pulſes which produce the ſenſations of muſical notes. Their ratios may therefore be truly called the ratios of the ſounds. Now we ſee that the ſtrings which produce the ſounds *do ſol* are 240 and 160. Theſe are in the ratio of 3 to 2. In this manner we may ſtate all the ratios obſerved in our experiment, *viz.*

Do : *mi* have the ratio of	240 to 192, or of	5 to 4
Do : *fa*	240 : 180	4 : 3
Do : *ſol*	240 : 160	3 : 2
Do : *la*	240 : 144	5 : 3
Mi : *ſol*	192 : 160	6 : 5, = *do* : *mi*♭
Fa : *ſol*	180 : 160	9 : 8
Sol : *la*	160 : 144	10 : 9
Mi : *fa*	192 : 180	16 : 15

Here we get the ſight of all the ratios which the ingenious and unwearied ſpeculations of the Greek mathematicians enliſted into the ſervice of muſic, without being able to give a good reaſon why. The ratio 5 : 4, which their faſtidious metaphyſicians rejected, and which others wiſhed to introduce from motives of mere neceſſity to fill up a blank, is pointed out to us by one of the fineſt concords. The interval between the fourth and the fifth is, *very fortunately*, a ſtep of the ſcale.

The next ſtep *ſol la* is more important. For the ear for melody would have been very well ſatisfied with an interval equal to *fa ſol*. or 9 : 8; but if the moveable bridge be ſet at the diviſion 142$\frac{2}{9}$, correſponding to ſuch a ſtep, we ſhould have a very offenſive fluttering. It is reaſonable therefore to conclude, *from analogy*, that the interval *ſol la* does not correſpond to the ratio 9 : 8; and that 10 : 9, which is, at leaſt, equally ſatisfactory to the ear, is the proper ſtep, even in the ſcale of melody. If we conſider what may be called the ſcale of harmony, there is no room left for doubt. To enjoy the greateſt poſſible pleaſure of harmony, we muſt not only take each note as it is related to the fundamental, but alſo as it is related to other notes of the ſcale. It may chance to be convenient to aſſume, for the fundamental of our occaſional ſcale of modulation, the ſtring of the lyre which is tuned as *fa* to its proper fundamental; or it may increaſe the harmony (and we know that it does), if we accompany the note *do* with both of the notes *fa* and *la*. To have the fine concord of the major third, it is neceſſary that the interval *fa la* be equivalent to the ratio 5 : 4. Now *fa* is 180, and 5 : 4 = 180 : 144. Therefore, by making the ſtep *ſol la* equal to 9 : 8, we ſhould loſe this agreeable concord, and get diſcord in its place.

Temperament of th Scale of Muſic.

60 Obſervations on the ſtep *la*.

And thus is evinced, in oppoſition to Ariſtoxenus, the propriety of having both a major and a minor tone: the firſt expreſſed by 9 : 8, and the laſt by 10 : 9. The difference between theſe ſteps is the ratio 81 : 80, called a comma by the Greek theoriſts.

61 Determination of the VIIth. We ſtill want two ſteps of the ſcale, and two ſounds or notes correſponding to them, namely *re* and *ſi*; and we wiſh to eſtabliſh them on the ſame authority with the reſt. We ſee that this cannot be done by a concordance with the fundamental *do*. The ear ſufficiently informs us that the ſteps *do re* and *la ſi* muſt be tones, and not ſemitones, like *mi fa*. The ſenſible ſimilarity of the two tetrachords *do re mi fa* and *ſol la ſi do*, alſo teaches us that the ſtep *ſi do* ſhould be a ſemitone like *mi fa*. This ſeems to be all that mere melody can teach us. But we have little information whether we ſhall make *la ſi* a major or a minor tone. If we copy the tetrachord *do re mi fa* exactly, we ſhall make the ſtep *ſi do* like *mi fa*, and equivalent to the ratio 16 : 15. This requires the moveable bridge to be placed at 128. The ſound produced by this diviſion is perfectly ſatisfactory to the ear as a ſtep of the ſcale of melody. Moreover, our ſatisfaction is not confined to the compariſon of it with the note *do*, into which we ſlide by this gentle ſtep. It makes agreeable melody when uſed as the third to the note *ſol*. If we examine it mathematically, we find it a perfect major third to *ſol*; for *ſol* requires the 160th diviſion. Now 160 : 128 = 5 : 4, which is the ratio of the pulſes of a major third. All theſe reaſons ſeem enough to make us adopt this determination of the note *ſi*.

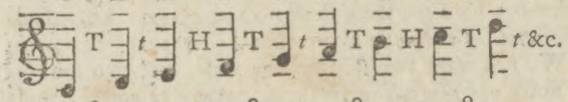
62 Determination of the IId. It remains to conſider how we ſhall divide the interval *do—mi*. It is a perfect major third. So is *fa la*, and ſo is *ſol ſi*. But in the firſt of theſe two, we have ſeen that it muſt be compoſed of a major tone with a minor tone above it; and in the ſecond we have a minor tone followed by a major tone above. We are left uncertain therefore whether *do re* ſhall reſemble *fa la* or *ſol ſi* in the poſition of its two parts. Ariſtoxenus and his followers declared the ear to be equally pleaſed with both. Ptolemy's *Syſtema Diatonicum Intenſum* makes *do re* a major tone, and other ſyſtems make it a minor. E-

even

ven in modern times it has been conſidered as uncertain; and the only reaſon which we have to offer for a preference of the major tone for the firſt ſtep is, that, ſo far as we can judge by our own feelings, the ſounds in the relation of 9 : 8 are leſs diſcordant than ſounds in the relation of 10 : 9, and becauſe all the other ſteps have been determined by means of concords with the key. We refer, for a more particular examination of the principles on which theſe arrangements are valued, to *Dr Smith's Harmonics*, Prop. I. where he ſhews how one is preferable to another, in proportion as it affords a greater number of perfect concords among the neighbouring notes, which is the favourite object in all modern muſic. Upon this principle our arrangement is by far the beſt, becauſe it admits five more concords in the octave than the other. But we have conſidered the ſubject in a different manner, merely to avail ourſelves of the phenomenon by which all the ſteps, except one, ſeem to be naturally aſcertained, and by which the connection between harmony and melody ſeems to be pointed out to us.

63. It will be convenient to repreſent the tones major and minor and the hemitone, by the ſymbols T, *t*, and H. Alſo to mark the notes by the Roman numerals, or by cyphers, according as they are the extremes of major or minor intervals. By this notation the octave may be repreſented thus:

C D E F G A B *c* *d* *e*



$\frac{8}{9}$ $\frac{9}{10}$ $\frac{15}{16}$ $\frac{8}{9}$ $\frac{9}{10}$ $\frac{8}{9}$ $\frac{15}{16}$ $\frac{8}{9}$ &c.

K II III 4 V VI VII VIII IX X &c.

The reader will remark, that the primary diviſions which we aſſigned to the repreſentation of an octave in fig. 1. by the circumference of a circle, are in conformity to this Ptolemaic partition of the octave. He will alſo be ſenſible, that the diviſion into five equal mean tones and two equal hemitones, which is expreſſed by the dotted lines, agreeing with the Ptolemaic diviſion only at C and E, is effected by biſecting the arch CE; and therefore the deviation of the ſound ſubſtituted for the Ptolemaic D is half the difference of CD and DE, that is, half a comma. The deviations therefore at F, G, A, and B, are each a quarter of a comma.

Logarithmic meaſures of the muſical intervals.

It is well known, that if the logarithm of the length of one ſtring be ſubtracted from that of another, the difference is a meaſure of the ratio between them. Therefore 30103 is the meaſure of the muſical interval called the octave, and then the meaſures of the

Comma	540 or	54
Hemitone	2803	280
Minor tone	4576	458
Major tone	5115	512
3d	7918	792
IIId	9691	969
4th	12494	1249
Vth	17609	1761
6th	20412	2041
VIth	22185	2219
VIIth	27300	2730
VIIIth	30103	3010

This is a very convenient circumſtance. If we take only the four firſt figures as integers, and make the octave conſiſt of 3010 parts, we have a ſcale more exact than the niceſt harmony requires. The circumference of a circle may be ſo divided into 301 degrees, and the moveable circle have a nonius, ſubdividing each into 10. Or it may be divided into 55,8 degrees, each of which will be a comma. Either of theſe diviſions will make it a moſt convenient inſtrument for expeditiouſly examining all temperaments of the ſcale that can be propoſed. Or a ſtraight line may be ſo divided, and repeated thrice. Then a ſliding ruler, divided in the ſame manner, and applied to it, will anſwer the ſame purpoſe. We ſhall ſee many uſeful employments of theſe inſtruments by and by.

64. Having thus endeavoured to communicate ſome plain notion of the formation and ſingular nature of that gradation of ſounds which produces all the pleaſures of muſic, and of the manner of obtaining the ſteps of this gradation with certainty and preciſion, we proceed to conſider how thoſe muſical paſſages may be performed on ſuch keyed inſtruments as the organs and harpſichords, as they are now conſtructed. Theſe inſtruments have twelve ſounds and intervals in every octave, in order that an air may be performed in any pitch; that is, taking any one of the ſounds as a key note. It is plain that this cannot be done with accuracy; for we have now ſeen that the interval *mi fa* is bigger than half of *do re* or *re mi*, &c. and therefore the intercalary ſound formerly mentioned to be inſerted between C and D, D and E, &c. will not do indiſcriminately for the ſharp of the ſound below and the flat of the ſound above it. When the tones are reduced to a mean ſize, the ear is ſcarcely ſenſible of the change in melody, and the harmony of the fifths and fourths is not greatly hurt. But when the half notes are inſerted, and employed to make up harmonious intervals, as recommended by Zarlino, the harmony is very coarſe indeed.

65 Why temperament neceſſary.

But we muſt make the reader ſenſible of the neceſſity of ſome temperament, even independent of thoſe artificial notes. Therefore

Let the ſcholar tune upwards the four Vths $c\,g$, $g\,\bar{d}$, $\bar{d}\,\bar{a}$, $\bar{a}\,\bar{\bar{e}}$, all perfect, admitting no beating whatever. This is eaſily done, either with the organ or the wheel monochord already deſcribed. Then tune downwards the perfect octaves $\bar{\bar{e}}\,\bar{e}$, $\bar{e}\,e$. Now examine the IIId $c\,e$ which reſults from this proceſs. If the inſtrument be of the pitch hitherto ſuppoſed (*c* making 240 pulſes in a ſecond), this IIId will be heard beating 15 times in a ſecond, which is a diſcordance altogether intolerable, the note *e* being too ſharp in the ratio of 81 to 80, which makes a comma. It is eaſily found, by calculation, that *e* makes $303\frac{1}{4}$ pulſes, inſtead of 300, required for the IIId to *c*.

N. B. It may not be amiſs to inform our readers, that if any concord, whoſe perfect ratio is $\frac{m}{n}$ (*m* being the greateſt term of the ſmalleſt integers expreſſing that ratio), be tempered ſharp by the fraction $\frac{p}{q}$ of a comma, and if M and N be the pulſes made by the acute and grave notes of the concord during any number of ſeconds, the number *b* of beats made in the ſame time by this concord will be $= \frac{2\,q\,m\,N}{161\,p - q}$, or $\frac{2\,q\,n\,M}{161\,p + q}$; and npera- t of the ale of ſuſic.

and if it be tempered flat, then $b = \frac{2\,q\,m\,\mathrm{N}}{161\,p+q}$, or $\frac{2\,q\,n\,\mathrm{M}}{161\,p-q}$ (*Smith's Harm.* 2d edit. p. 82, &c.)

66. It is impoſſible, therefore, to have perfect Vths and perfect IIIds at the ſame time. And it will be found, that the 3d *e g* reſulting from this proceſs, and the VIth $c\,\bar{a}$, are ſtill more diſcordant, rattling at an intolerable rate. Now the major and minor thirds, alternately ſucceeding each other, form the greateſt part of our harmonies; and the VIth is alſo a very frequent accompanyment. It is neceſſary therefore to ſacrifice ſomewhat of the perfect harmony of the Vths, in order that we may not be diſguſted with the diſcord of thoſe other harmonies: and it is this mutual accommodation, and not the changes made neceſſary by the introduction of intercalary notes, which is properly called TEMPERAMENT. It will greatly aſſiſt us in underſtanding the effects of the temperaments of the different concords, if we examine all the diviſions of the circular repreſentation of the octave and muſical ſcale given in fig. 1. by placing the index of the moveable circle on that note of the outer circle for which we want the proper harmonies, or accompanyments, which are either the IIId and Vth, or the 4th and VIth. We ſhall thus learn, in the *firſt* place, the deviations of the different perfect notes of the ſcale from the notes required for this new fundamental; and we muſt then ſtudy what effect the ſame temperament produces on the agreeableneſs of the harmony of different concords having the ſame baſs or the ſame treble, taking it for granted that the hurt to the harmony of any individual concord is proportional to its temperament.

67 w this y be ob- ed by beats.

It is in this delicate department of muſical ſcience that we think the great merit of Dr Smith's work conſiſts. We ſee that the deviation from perfect harmony is always accompanied with beats, and increaſes when they increaſe in frequency—whether it increaſes in the ſame proportion may be a queſtion. We think that Dr Smith's determination of the equality of imperfect harmony in his 13th propoſition includes every mathematical or phyſical circumſtance that appears to have any concern in it. What relates immediately to our ſenſations is, as yet, an impenetrable ſecret. The theory of beats, as delivered by this author, affords very eaſy, though ſometimes tedious, methods of meaſuring and of enſuring all the varieties which can obtain in the beating of imperfect conſonances. It appears to us therefore very unjuſt to ſay, with the late writer in the Philoſophical Tranſactions, that this obſcure volume has left the matter where it found it. The author has given us *effective* principles, although he may have been miſtaken in the application; which however we are far from affirming. Our limits will not allow us to give any account of that theory; and indeed our chief aim in the preſent article is to give a method of temperament which requires no ſcientific knowledge of the ſubject. But we could not think of loſing the opportunity of communicating, by the way, to unlearned perſons, ſome more diſtinct notions of the ſcale of muſical ſounds, and of its foundation in nature, than ſcholars uſually receive from the greater number of mere muſic maſters. The acknowledged connection of the muſical ratios with the pleaſures of harmony and melody, has (we hope) been employed in an eaſy and not obſcure manner; and the phenomena which we have faithfully narrated, ſhew plainly that, by diminiſhing the rattling undulations of tempered concords, we are certain of improving the harmony of our inſtruments. We ſhall proceed therefore on this principle for the uſe of the mere performer, but at the ſame time introducing ſome very ſimple deductions from Smith's theory, for which we expect the thanks of all ſuch readers as wiſh to ſee a little of the reaſons on which they are to proceed.

Tempera-ment of the Scale of Muſic.

68 Method in practice.

The experiment, of which we have juſt now given an account, ſhews that four conſecutive fifths compoſe a greater interval than two octaves and a major third. Yet, in the conſtruction of our muſical inſtruments of fixed ſounds, they muſt be conſidered as of equal extent; ſince we have 7 half intervals in the Vth, and 12 in the octave, and four in the IIId, four Vths contain 28, and two octaves contain 24; and theſe, with the four which compoſe a IIId, make alſo 28. It is plain, therefore, that whatever we do with the IIIds, we muſt leſſen the Vths. If therefore we keep the IIId perfect, we muſt leſſen each of the Vths by $\frac{1}{4}$th of a comma; for we learned, by the beating of the imperfect IIId *c e*, that the whole exceſs of the four Vths was a comma. Therefore the Vth *c g* muſt be flattened $\frac{1}{4}$th of a comma. But how is this to be done with accuracy? Recollect the formula given a little ago, where the number of beats b in any number of ſeconds is $= \frac{2\,q\,m\,\mathrm{N}}{161 \times p+q}$. In the preſent caſe $q = 1$, $m = 3$, $\mathrm{N} = 240$ per ſecond, and $p = 4$. Therefore the formula is $= \frac{2 \times 3 \times 240}{161 \times 4 + 1} = \frac{1440}{645} = 2{,}25$ in a ſecond, or 9 beats in four ſeconds very nearly.

In like manner, the next Vth $g\,\bar{d}$ muſt be flattened $\frac{1}{4}$th of a comma, by making it beat half as faſt again, or $13\frac{1}{2}$ beats in four ſeconds (becauſe in this Vth $\mathrm{N} = 360$). But as this beating is rather too quick to be eaſily counted, it will be better to tune downwards the perfect octave *g* G, which will reduce N to 180 for the Vth G *d*. This will give us 1,68 per ſecond, or 10 beats in 6 ſeconds very nearly.

There is another way of avoiding the employment of too quick beats. Inſtead of tuning the octave *g* G, make *c* G beat as often as *c g*. This is even more exactly an octave to *g* than can be eſtimated by a good ear. Dr Smith has demonſtrated, that when a note makes a minor concord with another note below it, and therefore a major concord with the octave to that note, it beats equally with both; but if the major concord be below, it beats twice as faſt with the octave above. Now, in the preſent caſe, *c g* is a Vth, and *c* G a 4th. For the ſame reaſon *c f* would beat twice as faſt as *c* F.

In the next place, the Vth $d\,\bar{a}$ muſt be made to beat flat 15 times in 6 ſeconds.

In like manner, inſtead of tuning upward the Vth $\bar{a}\,\bar{\bar{e}}$, tune downward the octave $\bar{a}\,a$, and then tune upward the Vth *a e*, and flatten it till it beat 15 times in 8 ſeconds.

If we take 15 ſeconds for the common period of all theſe beats, we ſhall have

The beats of $cg = 34$.
$Gd = 25$.
$\bar{d}a = 37\frac{1}{2}$.
$ae = 28$.

69. We ſhall now find ce to be a fine IIId, without any ſenſible beating; and then we proceed in the ſame way, always tuning upward a perfect Vth; and when this would lead us too high, and therefore produce too quick beating, we ſhould tune downward an octave. Do this till we reach b※, which ſhould be the ſame with $\bar{c}$, or a perfect octave above c. This will be a full proof of our accurate performance. But the beſt proceſs of tuning is to ſtop when we get to g※. Then we tune Vths downward from c, and octaves upward when the Vths would lead us too low. Thus we get cF, Ff, fb^b, $b^b \bar{b}^b$, $\bar{b}^b e^b$, and thus complete the tuning of an octave. We take this method, inſtead of proceeding upwards to $\bar{b}$※; becauſe thoſe notes marked ſharp or flat are, when tuned in this way, in the beſt relation to thoſe with which they are moſt frequently uſed as IIIds.

70 Uſe of a variable pendulum. This proceſs of temperament will be greatly expedited by employing a little pendulum, made of a ball of about two ounces weight, ſliding on a light deal rod, having at one end a pin hole through it. To prepare this rod, hang it up on a pin ſtuck into the wainſcoting, and ſlide the ball downward, till it makes 20 vibrations in 15″, by comparing it with a houſe clock. In this condition mark the rod at the upper edge of the ball. In like manner, adjuſt it for 24, 28, 32, 36, 40, 44, 48, vibrations, making marks for each, and dividing the ſpaces between them by the eye, noticing their gradual diminution. Then, having calculated the beats of the different Vths, ſet the ball at the mark ſuited to the particular concord, and temper the ſound till the beats keep pace exactly with the pendulum.

71 Abſolute number of pulſes how known. But, previous to all this, we muſt know the number of pulſes made in a ſecond by the C of our inſtrument. For this purpoſe we muſt learn the pulſes of our tuning fork. To learn this, a harpſichord wire muſt be ſtretched by a weight till it be uniſon or octave below our fork: then, by adding $\frac{1}{10}$th of the weight to what is now appended, it will be tempered by a comma, and will beat, when it is ſounded along with the fork; and we muſt multiply the beats by 80: The product is the number of pulſes required. And hence we calculate the pulſes of the C of our inſtrument when it is tuned in perfect concord with the fork.

The uſual concert pitch and the tuning forks are ſo nearly conſonant to 240 pulſes for C, that this proceſs is ſcarcely neceſſary, a quarter of a tone never occaſioning the change of an entire beat in any of our numbers.

72 Syſtem of temperament with perfect IIId. The intelligent reader cannot but obſerve, that this ſyſtem of tuning with perfect IIds, which is preferred to all others by many great maſters, is the one repreſented by our circular figure of the octave. The IIId is there perfect, and the Vth CG is deficient by a quarter of a comma. We cannot here omit taking notice of a moſt valuable obſervation of Dr Smith's on this temperament, and, in general, on any diviſion of the octave into mean tones and equal limmas.

73 Proportional variations of temperament. The octave being made up of five mean tones and two limmas, it is plain that, by enlarging the tones, we diminiſh the limmas, and that the increment of the tone is two fifths of the contemporaneous diminution of the limma. If, therefore, we employ the ſymbol v to expreſs any minute variation of this temperament, and make the increment of a mean tone $= 2v$, the contemporaneous variation which this induces on a limma will be $= -5v$; and if the tone be diminiſhed by the ſame quantity $-2v$, the limma will increaſe by the quantity $5v$. Let us ſee what are the contemporaneous changes made on all the intervals of the octave when the tone is diminiſhed by $2v$.

1. A Vth is made up of three tones and a limma. Therefore the variation of its temperament is $= -6v + 5v$, or is $= -v$. That is, the Vth is flattened from its former temperament, whatever that may have been, by the quantity $-v$. Conſequently the 4th, which is always the complement of the Vth to the octave, has its temperament ſharpened by the quantity v.

2. A IId, being a tone diſtant from the fundamental, has its temperament changed by $-2v$.

Therefore a minor 7th is raiſed by $2v$.

3. A minor 3d is made up of a tone and a limma: therefore its variation is $= -2v + 5v$, or $= 3v$.

Therefore a major VIth (its complement) loſes $-3v$.

4. A maj. IIId, or two tones, has its variation $= -4v$.

Therefore a minor 6th has its variation $= 4v$.

5. A maj. VIIth, the complement of a limma has $-5v$.

6. A tritone, or IVth. muſt have the variation $= -6v$.

Therefore the falſe 5th muſt have - - - $6v$.

74 Geometrical conſtruction founded on this. From this obſervation, Dr Smith deduces the following ſimple mathematical conſtruction: In the ſtrait line CE (fig. 2.) take the ſix equal parts Cg, gd, da, aE, Eb, bt, and draw through the points of diviſion the ſix parallel lines gG, dD, &c. Let theſe lines repreſent ſo many ſcales of the octave, ſo placed that the points C, g, d, &c. may repreſent the points C, g, d, &c. of the circular ſcale in fig. 1. where it is cut by the dotted lines repreſenting the ſyſtem of mean tones and limmas. Then, 1*ſt*, take a certain length dG on the firſt line, to the right hand of the line CE, to repreſent a quarter of a comma. G will mark the place of the perfect Vth, while g repreſents that of the mean or tempered Vth. 2*dly*, Set off dD, double of gG, in like manner, to the right hand on the ſecond parallel. This will be the place of the perfect IId to the key note C. 3*dly*, Alſo ſet off aA, on the third parallel, to the left hand, equal to gG. This will mark the place of A, the VIth to the key note C. 4*thly*, Place E on the point e, becauſe, in the ſyſtem of mean tones repreſented in fig. 1. the IIIds were kept perfect. 5*thly*, Make bB, to the right hand on the fifth line, equal to gG, to mark the place of the perfect VIIth to the key note C. And, 6*thly*, make tT, to the right hand on the ſixth line, equal to twice gG. This will ſerve for ſhewing the contemporaneous temperament of the tritone, or IVth, contained between F and B, as alſo of its complement, the falſe 5th in fig. 1.

It is evident that the temperament of all the notes of the octave, according to the above mentioned ſyſtem, are properly repreſented in this figure. The Vth is tempered flat by the quarter comma Gg; the IId is tempered flat by the half comma Dd; the VIth is tempered ſharp by a quarter comma Aa; the IIId is perfect; the VIIth is flat by a quarter comma Bb; and the 4th is ſharp by a quarter comma Gg.

75 The TEMPERER. Now, let any other ſtraight line Ct' be drawn from C acroſs theſe parallels. This will mark, by the intervals

npera-
t of the
ale of
lufic.

vals g'G, d'D, &c. the temperaments of another ſyſtem of mean tones and limmas. For it is evident, that the contemporaneous variations gg', dd', &c. from the former temperament, are in the juſt proportions to each other; gg' being $= - v$, the variation proper for the Vth, and the oppoſite temperament for its complement or 4th. In like manner, aa' is $= 3v$, the variation competent to the VIth; and Ee' is $= 4v$, the proper variation for the IIId.

In like manner, bb' is $= 5v$, the variation of the VIIth and 2d. And, laſtly, tt' is the variation $6v$ of the tritone, and its complement, the falſe fifth.

For all theſe reaſons, any ſtraight line Ce' or Ce'', drawn from C acroſs the parallels, may juſtly be called the TEMPERER.

76 This is a very uſeful conſtruction: For it is plain, that the ſounds which can be placed in our organs and harpſichords, which have only twelve keys for an octave, muſt approach to a ſyſtem of mean tones. The diviſion of the octave into twelve equal intervals is ſuch a ſyſtem of mean tones exactly. Now, in ſuch ſyſtems, when a line is drawn from C acroſs the parallels, we ſee, at one glance, not only all the temperaments of the notes with the key note, but alſo the temperaments of thoſe concords which the notes employed in full harmony make with each other. Thus, in the harmony of K — III — V, the III and V make a minor 3d with each other; and in the harmony of K — 4 -- VI, the 4 and VI make a major 3d with each other. Now the reader will eaſily ſee, that the firſt of theſe concords has its interval diminiſhed on both ſides, when the III is tempered ſharp, but only on one ſide when it is tempered flat. The mathematical reader will alſo eaſily ſee, that the contemporaneous temperament Aa' of the VIth is always equal to the ſum g'G and Ee', and that Aa' is equal to the difference of g''G and Ee''. Therefore the temperament of this ſubordinate concord, in the full harmony K — III — V, is, in all caſes, the ſame with the contemporaneous temperament of the VIth.

In like manner, he will perceive that the temperament of the ſubordinate IIId, in the harmony of K — 4 — VI, is equal to the contemporaneous temperament of the III.

We alſo ſee, in general, that the whole harmony is more hurt when the temperer lies in the angle ECK, with the IIId tempered ſharp, than when it is in the angle ACE, when the IIId is flat; and that the ſum of all the temperaments of the concords with the key is the ſmalleſt when the IIIds are perfect. This ſyſtem of mean tones, with perfect IIIds, would therefore be the beſt, if the harmony of different concords were equally hurt by the ſame temperament.

77
tain
es of
at uſe.

We do not know any thing that has been publiſhed on the ſcience of muſic that gives more general and ſpeedy inſtruction than this ſimple figure. If it be drawn of ſuch a ſize as to allow the comma EK to be divided into a number of equal parts, ſufficiently ſenſible, all trouble of calculation will be ſaved.

We would therefore propoſe to accompany this figure with proper ſcales.

The *firſt* ſcale ſhould have Gg divided into $13\frac{1}{2}$ parts. This will expreſs the logarithmic meaſures of the temperaments mentioned in n° 63. a comma being = 54.

The *ſecond* ſcale ſhould have gG divided into 36 parts. This gives the beats made in 16 ſeconds by the notes c, g, when tempered by any quantity Gg'.

Temperament of the
Scale of
Muſic.

The *third* ſcale ſhould have gG divided into 60 parts, for the beats made by the notes c, e, or the notes c, $\bar{a}$.

The *fourth* ſcale ſhould have gG divided into 72 parts. This gives the beats made by the key note C, with its minor third e^b.

The *fifth* ſcale ſhould have gG divided into 48 parts, for the beats made by the notes c, f.

The *ſixth* ſcale ſhould have gG divided into 89 parts, on which Aa' is meaſured, to get the beats of the ſubordinate concord formed by g and e in the harmony of K — III — V.

And, *laſtly*, gG, divided into 80 parts, will give the beats made by f and $\bar{a}$ in the harmony of K — 4 — VI.

78
Harmoniouſneſs,
what?

We are ignorant of the immediate efficient cauſes of the pleaſure we receive from certain conſonances, and ſhould therefore receive, with ſatisfaction, any thing that can help us to approximate to a meaſure of its degrees. We know that, in fact, the pleaſantneſs of any individual concord increaſes as the undulations called *beats* diminiſh in frequency. It is probable that we ſhall not deviate very far from the truth, if we ſuppoſe the harmoniouſneſs of an individual tempered concord to be proportional to the ſlowneſs of theſe undulations. But it by no means follows, that a tempered Vth and a IIId are equably pleaſant, each in its kind, when they beat equally ſlow. There is a difference *in kind* in the pleaſures of theſe concords: and this muſt ariſe from the peculiar manner in which the component pulſes of each concord divide each other. We are certain that this is all the difference that obtains between them in Nature. But the harmoniouſneſs here ſpoken of is the arrangement which produces this pleaſure. We are intitled to ſay, that this is equal in two given inſtances, when the arrangements are preciſely ſimilar; and when the things arranged are the ſame, nothing ſeems to remain in which the inſtances can differ.

At any rate, it is of conſequence to be able to proportion and diſtribute theſe undulations at pleaſure. They are unpleaſant; and when reinforced by uniting, muſt be more ſo. The theory puts it in our power to prevent this union: perhaps by making them very unequal; or, if this ſhould give a chance of periodical accumulation, we may find it better to make them all equal. Surely to have all this in our power is very deſirable; and this is obtained by the theory of the beats of imperfect conſonances.

79
Temperament of a
whole octave by
beats.

But we are forgetting the proceſs of tuning, and have only tuned three or four notes of our octave. We muſt tune the reſt by conſidering their relation to notes already tuned. Thus, if gc makes 36 beats in 16 ſeconds, Fc ſhould make one third leſs, or about 24 in the ſame time; becauſe N in the formula is now 160 inſtead of 240. Proceeding in this way, we ſhall tune the octave C$\overset{=}{c}$ moſt accurately as a ſyſtem of mean tones with perfect IIIds, by making the notes beat as follows. A point is put over the note that is to be tuned from the other, and $a +$, or $a -$, means that the concord is to be tempered ſharp or flat. Thus g is tuned from c,

Make	$c\dot{g}$ beat	—	36 times in 16 ſeconds
	$\dot{G}c$	+	36
	$G\dot{d}$	—	27, *i. e.* $\frac{3}{4}$ths of gc
	$c\dot{f}$	—	48

Make

Make $c\ \dot{\bar{a}}$ beat	+60 times in 16 ſeconds
$c\ \dot{e}$	0, *i. e.* a perfect IIId
$d\ \dot{f}$ ※	0
$e\ \dot{g}$ ※	0
$\bar{a}\ \dot{\bar{c}}$ ※	0
$\dot{b}^b\ f$ downward	—24, *i. e.* $\frac{8}{9}$ths of $c\,g$
$b^b\ \dot{\bar{b}}^b$	0, *i. e.* a perfect octave
$\bar{b}^b\ \dot{e}^b$ downward	—43, *i. e.* $\frac{6}{5}$ths of $c\,g$
C $\dot{\bar{c}}$	0 an octave.

Other proceſſes may be followed, and perhaps ſome of them better than the proceſs here propoſed. Thus, b^b and e^b may be tuned as perfect IIIds to *d* and *g* downwards. Alſo, as we proceed in tuning, we can prove the notes, by comparing them with other notes already tuned, &c. &c. &c.

We have directed to tune the two notes b^b and e^b by taking the leading Vth downwards. We ſhould have come at the ſame pipes in the character of *a*※ and *d*※ in the proceſs of tuning upwards by Vths. But this would not have produced preciſely the ſame ſounds, although, in our imperfect inſtruments, one key muſt ſerve for *a*※ and b^b. By tuning them as here directed, they are better fitted for the places in which they will be moſt frequently employed in our uſual modulations.

80 Another ſyſtem very fit for our inſtruments.

It may reaſonably be aſked, Why ſo much is ſacrificed in order to preſerve the IIIds perfect? Were they allowed to retain ſome part of the ſharp temperament that is neceſſary for preſerving the Vths perfect, we ſhould perhaps improve the harmony. And ſince enlarging the Vth makes the tone greater, and therefore the limma *mi fa* much ſmaller, it will bring it nearer to the magnitude of a half tone; and this will be better ſuited for its double ſervice of the ſharp of the note below, and the flat of the note above. Accordingly, ſuch a temperament is in great repute, and indeed is generally practiſed, although the VIths and the ſubordinate chords of full harmony are evidently hurt by it. Even Dr Smith recommends it as well ſuited to our defective inſtruments, and gives an extremely eaſy method of executing it by means of the beats. His method is to make the Vth and IIId beat equally faſt, along with the key, the Vth flat, and the IIId ſharp. He demonſtrates (on another occaſion), that concords beat equally faſt with the ſame baſs when their temperaments are inverſely as the major terms of their perfect ratios. Therefore draw EG, and divide it in *p*, ſo that E*p* may be to *p*G as 3 to 5. Then draw C*p*, cutting *g* G in *g'*, and EK in *e'*; and this temperer will produce the temperament we want. It will be found, that E *e'* and G *g'* are each of them 32 of their reſpective ſcales.

Fig. 2.

Therefore make $c\,g$ beat	32 times in 16 ſeconds
G c	32
G d	24
G b	24, and tune $b\ \bar{b}$
$d\ \bar{a}$	36, and tune $a\ \bar{a}$
$d\ f$ ※	36
$a\ e$	27
$a\ c$ ※	27
$e\ \bar{b}$	$40\frac{1}{2}$, proving $b\ \bar{b}$
$e\ g$ ※	$40\frac{1}{2}$
F c	$21\frac{1}{3}$, and tune F f
F a beat	$21\frac{1}{3}$, proving a
$b^b\ \underline{f}$	$28\frac{1}{2}$, and tune $b^b\ \bar{b}^b$
$e^b\ b^b$	$38\frac{1}{2}$
$c\ \bar{c}$	0.

It may be proper to add to all theſe inſtructions a caution about the manner of counting the clock while the tuner is counting the beats. If this is to continue for 16 ſeconds, let the perſon who counts the clock ſay *one* at the beat he begins with, and then telling them over *to himſelf*, let him ſay *done* inſtead of 17. Thus 16 intervals will elapſe while the tuner is counting the beats. Were he to begin to count at *one*, and ſtop when he hears ſixteen, he would get the number of beats in 15 ſeconds only.

81. We do not heſitate to ſay, that this method of tuning by beats is incomparably more exact than by the mere judgment of the ear. We cannot miſtake more than one beat. This miſtake in the concord of the Vth amounts to no more than $\frac{1}{108}$th of a comma; and in the IIId it is only $\frac{1}{180}$.

82 Practical inſtructions.

It may be objected that it is fit only for the organ and inſtruments of continued ſounds, but will not do for the quickly periſhing ſounds of the harpſichord. True, it is the only method worthy of that noble inſtrument, and this alone is a title to high regard. But farther; the accuracy attainable by it, renders it the only method fit for the examination of ſyſtems of temperament. Even for the harpſichord it is much more exact, and more certain in its proceſs, than any other. It does not proceed, by a random trial of a flattened ſeries of Vths, and a compariſon with the reſulting IIId, and a ſecond trial, if the firſt be unſatisfactory. It ſays at once, let the Vth beat ſo many times in 16 ſeconds. Even in the ſecond method, without counting, and merely by the equality of the beats of the Vth and IIId, the progreſs is eaſy. Both are tuned perfect. The Vth is then flattened a little, and the IIId ſharpened;—if the Vth beat faſter than the IIId, alter it firſt.

All difficulty is obviated by the ſimple contrivance of a variable pendulum, already deſcribed. This may be made exact by any perſon that will take a little pains; and when once made, will ſerve for every trial. When the ball is ſet to the proper number, and the pendulum ſet a ſwinging, we can come very near the truth by a very few trials.

N. B. In tuning a piano forte, which has always two ſtrings to a key, we muſt never attempt tuning them both at once; the back uniſon of both notes of the concord muſt be damped, by ſticking in a bit of ſoft paper behind it.

We hope that the inſtructions now given, and the application of them to two very reſpectable ſyſtems of temperament, are ſufficient for enabling the attentive reader to put this method of tuning ſucceſsfully in practice, and that he perceives the efficiency of it for attaining the deſired end. But before we take leave of it, we beg leave to mention another circumſtance, which evinces the juſt value of the general theory of the beats of imperfect conſonances as delivered by Dr Smith.

83 Origin of the Tartinian ſound

Theſe reinforcements of ſound, which are called *beatings*, are noiſes. If any noiſe whatever be repeated, with ſufficient frequency, at equal intervals, it becomes a muſical note, of a certain determinate pitch. If it recur 60 times in a ſecond, it becomes the note C *fa ut*, or the double octave below the middle C of our harp-

mpera-
t of the
ale of
Muſic.

harpſichords, or the note of an open pipe eight feet long. Now there is a ſimilar (we may call it the very ſame) reinforcement of ſound in every concord. Where the pulſe of one ſound of the concord biſects the pulſe of the other, the two ſounds are more uniformly ſpread: but where they coincide, or almoſt coincide, the condenſation of one undulation combines with that of the other, and there comes on the ear a ſtronger condenſation, and a louder ſound. This may be called a *noiſe*; and the equable and frequent recurrence of this noiſe ſhould produce a muſical note. If, for inſtance, *c* and *a* are ſounded together: There is this noiſe at every third pulſe of *c*, and every fifth pulſe of *a*; that is, 80 times in a ſecond. This ſhould produce a note which is a 12th below *c*, and a 17th major below *a*; that is, the double octave below *f*, which makes 320 vibrations in a ſecond. That is to ſay, along with the two notes *c* and *a* of the concord, and the compound ſound, which we call the *concord of the VIth*, we ſhould hear a third note FF in the baſs. Now this is known to be a fact, and it is the grave harmonic obſerved by Romieu and Tartini about the year 1754, and verified by all muſicians ſince that time. Tartini prized this obſervation as a moſt important diſcovery, and conſidered it as affording a foundation for the whole ſcience of muſic. We ſee that it is all included in the theory of beats publiſhed five years before, namely, in 1749; and every one of theſe grave harmonics, or Tartinian ſounds, as they have been called, are immediate conſequences of this theory. The ſyſtem of harmonious compoſition which Tartini has, with wonderful labour and addreſs, founded on it, has therefore no ſolidity. It is, however, preferable to Rameau's, becauſe it proceeds on a fact founded on the nature of muſical ſounds; whereas Rameau's is a mere whim, proceeding on a falſe aſſumption; namely, "that a muſical ſound is eſſentially accompanied by its octave, 12th, and 17th *in alto*."—This is not true, though ſuch accompanyment be very frequent, and it be very difficult to prevent it. Mr Rameau ought to have ſeen this. Are theſe acute harmonics muſical ſounds or not? He ſurely will not deny this. Therefore they, too, are eſſentially accompanied by *their* harmonics, and this abſolutely and neceſſarily *ad infinitum*; which is certainly abſurd. We ſhall have a better occaſion for conſidering this point when we deſcribe the *TRUMPET-Marigni* in a future article.

84
r Smith's
ſtem of
QUAL
ARMO-
Y.

We have taken notice of only two ſyſtems of temperament; both of them are ſyſtems of mean tones, and are in good repute as practicable methods. It would be almoſt an endleſs taſk to mention all the ſyſtems of temperament which have been propoſed. Dr Smith, aſter having, with great ingenuity, appreciated the changes of harmoniouſneſs that are induced on the different concords by the ſame temperament, and having aſſigned that proportion of temperament which renders them equally harmonious, each in its kind, gives a ſyſtem of temperament, which he calls EQUAL HARMONY. Each concord (excepting the octave) is tempered in the inverſe proportion of the product of the terms of its perfect ratio. It is very nearly equivalent to a diviſion of the octave into 50 equal parts. We do not give any farther account of it here, although we think its harmony preferable to any thing that we have ever heard. We heard it, as executed for him, and under his inſpection, by the celebrated harpſichord-maker Kirkmann, both when the inſtrument was yet in the hands of the maker, and afterwards by the ingenious author. We have alſo heard ſome excellent muſicians declare, that the organ of Trinity college chapel at Cambridge was greatly improved in its harmony by the change made on its temperament under the inſpection of Dr Smith. When we name Stanley, we preſume that the authority will not be diſputed. We mention this, becauſe the writer in the Philoſophical Tranſactions ſpeaks of this ſyſtem, with flattened major thirds, as of no value. But we do not give any farther account of it, becauſe it is not ſuited to our inſtruments, which have but twelve ſounds in the octave.

Temperament of the Scale of Muſic.

85.

The reader will pleaſe to recollect, that the great object of temperament is twofold. Firſt, to enable us to tranſpoſe muſic from one pitch to another, ſo that we may make any note of the organ the fundamental of the piece. This undoubtedly requires a ſyſtem approaching to one of mean tones, becauſe the harmony muſt be the ſame in every key. This requires temperament, becauſe a ſound muſt be occaſionally conſidered, either as the ſharp of the note below it, or the flat of the one above. This cannot produce perfect harmony, becauſe the limma of the perfect diatonic ſcale is greater than a half tone. Thus a temperament is neceſſary merely for the ſake of the melody. But, *ſecondly*, the nature of modern muſic requires every note to be accompanied, or conſidered as accompanied, with full harmony. This is, in fact, the ſame thing with modulating on every different note as a fundamental; but it requires a much cloſer attention to the perfection of the intervals, becauſe a defect or exceſs in an interval that would ſcarcely offend the ear, if the notes were heard in ſucceſſion, is quite intolerable when they are ſounded together. Here the difference between the major and minor tone is of almoſt as great moment as the difference of the limma from a ſemitone. The ſecond object, therefore, is to obtain, in the compaſs of three octaves, as many good concords of full harmony; that is, conſiſting of a fundamental with its major third and its fifth, erect or inverted, as poſſible. There is no other harmony, although our notes have frequently a different ſituation and appearance.

86
Maxims of temperament very gratuitous.

It is no wonder that, in a ſubject where we are yet to ſeek for a principle, the attempts to attain this object have been very various, and very gratuitous. The mathematicians, even in modern times, have allowed themſelves to be led away by fancies about the ſimplicity and conſequent perfection of ratios; and having no clear principle, it is no wonder that ſome of their deductions are contrary to experience. According to Euler, thoſe ratios which are moſt perfect, that is, moſt ſimple, admit of leaſt temperament. The octave is therefore infinitely perfect; for it is allowed by all, that it muſt not have the ſmalleſt temperament. A Vth muſt be leſs tempered than a IIId. Even the practical muſician thinks that he has tempered theſe two concords equally, when the offenſive quality of each is made equally ſo; but in this caſe it is demonſtrable, that the Vth has been much more tempered than the IIId. But this could not be diſcovered till we got the theory of beats.

Moſt of the mathematical muſicians adhered to ſyſtems of mean tones; or, which are equivalent to ſuch ſyſtems, giving ſimilar harmonies on every key of the

Temperament of the Scale of Muſic.

harpſichord. This is ſurely the moſt natural, and is peculiarly ſuggeſted by the tranſpoſing of muſic from one pitch to another: but they differ exceedingly, and without giving any convincing arguments, in their eſtimation of the effects of the ſame temperament on different concords. Much of this, we apprehend, ariſes from diſpoſition. Perſons of a gay diſpoſition reliſh the harmony of the IIId, and prefer a ſharp to a flat temperament of this concord. Perſons of a more penſive diſpoſition, prefer ſuch temperaments as allow the minor thirds to be more perfect.

87 Equal harmony rejected.

But there are many, eminent both as performers and as theoriſts, who reject any ſyſtem which gives the ſame harmonies on every note of the octave. They obſerve, that in the progreſs of the cultivation of muſic in Europe, the melodies of all nations have gradually approached to a certain uniformity. Certain cadences, cloſes, ſtrains, and phraſes, are becoming every day more common; and even in the conduct of a conſiderable piece of muſic, and the gradual but ſlow paſſage of the modulation from one key into another, there is a certain regularity. Nay, they add, that this cannot be greatly deviated from without becoming very offenſive. We may remain ignorant of the cauſe of this uniformity; but its exiſtence ſeems to prove that it ariſes from ſome natural principle; and therefore it ought to be complied with, and our temperaments ſhould be accommodated to it. The reſult of this uniformity in the muſic of our times is, that the modulation on ſome keys is much leſs frequent than on others, and this frequency decreaſes in a certain order. Suppoſing that we begin on C. A piece of plain muſic ſeldom goes farther than G and F. A little more fancy and refinement leads the compoſer into D, or into B^b, &c. &c. It would therefore be deſirable to adjuſt our temperaments ſo, that the harmonies in C ſhall be the beſt poſſible, and gradually leſs perfect in the order of modulation. Thus we ſhall, in our general practice, have finer harmony than if it were made equal throughout the octave; becauſe the unavoidable imperfections are thrown into the leaſt frequented places of the ſcale. The practical muſicians add to this, that by ſuch a temperament the different keys acquire characters, which fit each of them more particularly for the expreſſion of different ſentiments, and for exciting different emotions. This is very perceptible in our harpſichords as they are generally tuned. The major key of A is remarkably brilliant; that of F is as remarkably ſimple, &c.

We cannot ſay that we are altogether convinced by theſe arguments. The violin is unqueſtionably the inſtrument of the greateſt powers. A concert of inſtruments of this kind, unembarraſſed by the harpſichord, or any inſtruments incapable of occaſional temperament, is the fineſt muſic we have. The performers make no ſuch degradations of harmony, but keep it as perfect as poſſible throughout; and a violin performer is ſenſible of violence and conſtraint when he accompanies a keyed inſtrument into theſe unfrequented paths. Let him play the ſame muſic alone, and he will play it quite differently, and much more to his own ſatisfaction. We imagine, too, that much of the uniformity ſpoken of is the reſult of imitation and faſhion, and even of the temperaments that we have preferred. There is an evident diſtinction in the native muſic of different nations. An experienced muſician will know, from a few bars, whether an air is Iriſh, Scotch, or Poliſh. This diſtinction is in the modulation; which, in thoſe nations, follows different courſes, and ſhould therefore, on the ſame principle, lead to different temperaments.

With reſpect to the variety of characters given to the different keys, we muſt acknowledge the fact. We have tuned a piano forte in the uſual manner; but inſtead of beginning the proceſs with C, we began it with D. An excellent performer of voluntaries ſat down to the inſtrument, and began to indulge his rich fancy; but he was confounded at every ſtep: he thought the inſtrument quite out of tune. But when he was informed how it had been tuned, and then tried a known plain air on it, he declared it to be perfectly in tune. It is ſtill very doubtful, however, whether we ſhould not have much finer muſic, by equaliſing the harmony in the different keys, and truſting for the different expreſſion ſo much ſpoken of to a judicious mixture of other notes called *diſcords*.

88 Cauſe of this uncertainty now removed by Dr Smith's theory.

After all, the great uncertainty about the moſt proper temperament has remained ſo long undetermined, becauſe we had no method of executing with certainty any temperament that was offered to the public. What ſignifies it on what principle it may be proper to flatten a Vth one fifth of a comma, and ſharpen a VIth one-ſeventh of a comma, unleſs we are able to do both the one and the other? Till Dr Smith publiſhed the theory of beats, the monochord was the only aſſiſtance we had: but however nicely it may be divided, it is ſcarcely poſſible to make the moveable bridge ſo ſteady and ſo accurate in its motion, that it will not ſenſibly derange the tenſion of the ſtring. We have ſeen ſome very nice and coſtly monochords; but not one of them could be depended on to one eighth of a comma. Even if perfect, they give but momentary ſounds by pinching. The bow cannot be truſted, becauſe its preſſure changes the tenſion. Mr Watt's experiments with his monochord of continued ſound ſhewed this evidently. A pitch-pipe with a ſliding piſton promiſes the greateſt accuracy; but we are ſadly diſappointed, becauſe the graduation of the piſton cannot be performed by any mathematical rule. It muſt be puſhed more than half way down to produce the octave, more than one-third to produce the Vth, &c. and this without any rule yet diſcovered. Thanks to Dr Smith we can now produce an inſtrument tuned exactly, according to any propoſed ſyſtem, and then ſubmit it to the fair examination of muſicians. Even the ſpeculatiſt may now form a pretty juſt opinion of the merits of a ſyſtem, by calculating, or meaſuring by ſuch ſcales as we have propoſed, the beats produced by the tempered concords in all parts of the octave. No one who has liſtened with attention to the rattling beats of a full organ, with its twelfth and ſeſquialter ſtops all ſounding, will deny that they are hoſtile to all harmony or good muſic. We cannot be much miſtaken in preferring any temperament in proportion as it diminiſhes the number of thoſe beats. We ſhould therefore examine them on this principle alone; attending more particularly to the beats of the third major, becauſe theſe are in fact the loudeſt and moſt diſagreeable: and we muſt not content ourſelves with the beats of each concord with the fundamental of the full harmony, whether K—III—V, or K—4—VI, or K—3—V, or K—4—6, which ſometimes occurs. We muſt attend equally to the beats of the two notes

of

pera- of the le of ific. of accompanyment with each other: theſe are generally the moſt faulty.

This examination is neither difficult nor tedious. 1. Write down, in one column, the lengths of the ſtrings or diviſions of the monochord; in another write their logarithms; in a third the remainders, after ſubtracting each from the logarithm of the fundamental. 3. Have at hand a ſimilar table for the perfect diatonic ſcale. 4. Compare theſe, one by one, and note the difference, + or —, in a 4th column. Theſe are the temperaments of each note of the ſcale. 5. Compare every couple of notes which will compoſe a major or minor third, or a fifth, by ſubtracting the logarithm of the one note from that of the other. The differences are the intervals tempered. 6. Compare theſe with the perfect intervals of the diatonic ſcale, and note the differences, + or —, and ſet them down in a fifth column. Theſe are all the temperaments in the ſyſtem. 7. If we have uſed logarithms conſiſting of five decimal places, which is even more than ſufficient, conſider theſe numeral temperaments as the q of the formula given in n° 65. for calculating the beats, and then p is always = 540. Or we may make another column, in which the temperaments are reduced to ſome eaſy fraction of a comma. 9.

90 m of Young. We ſhall content ourſelves with giving one example; the temperament propoſed by Mr Young in the Philoſophical Tranſactions for 1800. It is contained in the following table.

1.	2.	3.	4.	5.

major third - - 9691
fifth - - - 17609

The firſt column of the above table contains the ordinary deſignations of the notes. The ſecond contains the correſponding lengths of the monochord. The third contains the logarithms of column ſecond. The fourth contains the difference of each logarithm from the firſt. The next column contains, firſt, the temperaments of all the major thirds, having for their loweſt note the ſound correſponding to the letter. Thus 494, or $\frac{494}{540}$ of a comma, is the temperament of the IIId, B — D※, and C※ — F. Secondly, it contains all the minor thirds formed on the notes repreſented by the letters. The column below contains the temperaments of the Vths. *N. B.* Theſe temperaments are calculated by the author. We have found ſome of them a little different. Thus we make the temperament of C — G only 108. Below this we have ſet down the meaſures of the perfect intervals, which are to be compared with the differences of the logarithms in column third.

Temperament of the Scale of Music, Templars.

91 Syſtem of Kirnberger.

We preſume not to decide on the merits of this temperament: Only we think that the temperaments of ſeveral thirds, which occur very frequently, are much too great; and many inſtances of the 6th, which is frequent in the flat key, are ſtill more ſtrongly tempered. A temperament, however, which very nearly coincides with Dr Young's, has great reputation on the continent. This is the temperament by Mr Kirnbergher, publiſhed at Berlin in 1771, in his book called *Die Kunſt des reinen Satzes in der Muſik.* The eminent mathematician Major Templehoff has made ſome important obſervations on this temperament, and on the ſubject in general, in an eſſay publiſhed in 1775, Berlin. Dr Young's is certainly preferable.

The monochord is thus divided by Kirnbergher:

C =	1,0000	F =	7500	B^b =	5625
C※	9492	F※	7111	B	5313
D	8889	G	6667	*c*	5000
E^b	8437	G※	6328		
E	8000	A	5963		

We conclude this article (perhaps too long) by earneſtly recommending to perſons who are not mathematically diſpoſed, the ſliding ſcales, either circular or rectilineal, containing the octave divided into 301 parts; and a drawing of fig. 2. on card paper, of proper ſize, having the quarter comma about two inches, and a ſeries of ſcales correſponding to it. This will ſave almoſt the whole of the calculation that is required for calculating the beats, and for examining temperaments by this teſt. To readers of more information, we earneſtly recommend a careful peruſal of Smith's Harmonics, ſecond edition. We acknowledge a great partiality for this work, having got more information from it than from all our patient ſtudy of the moſt celebrated writings of Ptolemy, Huyghens, Euler, &c. It is our duty alſo to ſay, that we have got more information concerning the muſic of the Greeks from Dr Wallis's appendix to his edition of Porphyrius's Commentary on Ptolemy's Harmonics, than from any other work.

TEMPLARS. In the account of this order, which is publiſhed in the *Encyclopædia*, we have, with many others, ſuppoſed that the guilt of which they were accuſed at the ſuppreſſion of the order was leſs enormous than their enemies alleged. For the honour of human nature, we are ſtill unwilling to believe that this was not the caſe. Juſtice, however, compels us to admit, that the Abbé Barruel has brought together ſuch a cloud of witneſſes againſt the Templars, that we know not how to reſiſt their evidence; and that he has completely proved, that *Philip le Bel* was not influenced by avarice when he ſuppreſſed that order in France. "It has been ſaid, that he and Clement V. had concerted between them the diſſolution of the Templars. The falſity of ſuch an aſſertion is evident on the inſpection of their letters. Clement V. at firſt will give no credit

dit to the accuſations againſt the Templars; and even when he receives inconteſtable proofs from Philip le Bel, he had ſtill ſo little concerted the plan with that Prince, that every ſtep taken by the one or the other occaſions diſputes on the rights of the church or of the throne.

“ It was alſo ſaid, that the king wiſhed to ſeize on the great riches of theſe knights: but at the very commencement of his proceedings againſt the order, he ſolemnly renounced all ſhare in their riches; and perhaps no Prince in Chriſtendom was truer to his engagement. Not a ſingle eſtate was annexed to his domain; and all hiſtory bears teſtimony to the fact.

“ We next hear of a ſpirit of revenge which actuated this Prince; and during the whole courſe of this long trial, we do not hear of a ſingle perſonal offence that he had to revenge on the Templars. In their defence, not the moſt diſtant hint, either at the revengeful ſpirit, or at any perſonal offence againſt the king, is given; ſo far from it, until the period of this great cataſtrophe, the grand maſter of the order had been a particular friend of the king's, who had made him godfather to one of his children.

“ In fine, the rack and torture is ſuppoſed to have forced confeſſions from them which otherwiſe they never would have made; and in the minutes, we find the avowal of at leaſt 200 knights all made with the greateſt freedom, and without any coercion. Compulſion is mentioned but in the caſe of one perſon; and he makes exactly the ſame avowal as 12 other knights, his companions, freely made (A). Many of theſe avowals were made in councils where the biſhops begin by declaring, that all who had confeſſed through fear of the torture ſhould be looked upon as innocent, and that no Knight Templar ſhould be ſubjected to it (B). The Pope Clement V. was ſo far from favouring the king's proſecutions, that he began by declaring them all to be void and null. He ſuſpended the archbiſhops, biſhops, and prelates, who had acted as inquiſitors in France. The king accuſes the Pope in vain of favouring the Templars; and Clement is only convinced after having been preſent at the interrogatories of 72 knights at Poictiers, in preſence of many biſhops, cardinals, and legates. He interrogated them, not like a judge who ſought for criminals, but like one who wiſhed to find innocent men, and thus exculpate himſelf from the charge of having favoured them. He hears them repeat the ſame avowals, and they are freely confirmed. He deſired that theſe avowals ſhould be read to them after an interval of ſome days, to ſee if they would ſtill freely perſevere in their depoſitions. He hears them all confirmed. *Qui perſeverantes in illis, eas expreſſe et ſponte prout recitatæ fuerant approbârunt.* He wiſhed ſtill further to interrogate the grand maſter and the principal ſuperiors, *præceptores majores*, of the divers provinces of France, Normandy, Poitou, and of the Tranſmarine countries. He ſent the moſt venerable perſons to interrogate thoſe of the ſuperiors, whoſe age or infirmities hindered them from appearing before him. He ordered the depoſitions of their brethren to be read to them, to know if they acknowledged the truth of them. He required no other oath from them than to anſwer freely and without compulſion; and both the grand maſter and the ſuperiors of theſe divers provinces depoſe and confeſs the ſame things, confirm them ſome days after, and approve of the minutes of their depoſitions taken down by public notaries. Nothing leſs than ſuch precautions could convince him of his error: it was then only that he revoked his menaces and his ſuſpenſion of the French biſhops, and that he allows the king to proceed in the trials of the Templars.

“ Let ſuch pretexts be forgotten, and let us only dwell on the avowals which truth alone forced from theſe criminal knights.

“ Their depoſitions declare, that the Knights Templars, on their reception, denied Chriſt, trampled on the croſs, and ſpit upon it; that Good Friday was a day which was particularly conſecrated to ſuch outrages; that they promiſed to proſtitute themſelves to each other for the moſt unnatural crimes; that every child begotten by a Templar was caſt into the fire; that they bound themſelves by oath to obey, without exception, every order coming from the grand maſter; to ſpare neither ſacred nor prophane; to look upon every thing as lawful when the good of the order was in queſtion; and, above all, never to violate the horrible ſecrets of their nocturnal myſteries, under pain of the moſt terrible chaſtiſements (C).

“ In making their depoſitions, many of them declared they had only been forced into theſe horrors by impriſonment and the moſt cruel uſage; that they wiſhed, after the example of many of their brethren, to paſs into other orders, but that they did not dare, fearing the power and vengeance of their order; that they had ſecretly confeſſed their crimes, and had craved abſolution. In this public declaration, they teſtified, by their tears, the moſt ardent deſire of being reconciled to the church.

“ All repeat the ſame depoſition, except three, who declare they have no knowledge of the crimes imputed to their order. The Pope, not content with this information taken by men of religious orders and by French noblemen, requires that a new trial ſhould take place in Poitou before cardinals and others whom he himſelf nominates: Again, with the ſame freedom, and for the third time, the grand maſter and other chiefs, in preſence of Clement V. repeat their depoſitions. Molay even requeſted, that one of the lay brothers, who was about his perſon, ſhould be heard, and this brother confirms the declaration. During many years theſe informations were continued and renewed at Paris, in Champagne, in Normandy, in Quercy, in Languedoc, in Provence. In France alone, above 200 avowals of the ſame nature are to be found: nor did they vary in England, where, at the ſynod of London held in 1311, 78 Engliſh knights were heard, and two whole months were ſpent in taking informations and in verifying their declarations. Fifty-four Iriſh were alſo heard, and many Scotch, in their reſpective countries. It was in conſequence of theſe declarations that the order of the Templars was aboliſhed in thoſe kingdoms, and that the parliament

mplars, emple-man.

parliament diſpoſed of their goods (D). The ſame declarations were taken and proved in Italy, at Ravenna, at Bologna, at Piſa, and at Florence, though in all theſe councils the prelates were very ready to abſolve all thoſe knights who could ſucceed in their juſtifications.

"I would willingly aſſert (continues the Abbé), that it was the ſmaller part of the Templars who ſuffered themſelves to be carried away by ſuch abominations. Some even at Paris were declared innocent. In Italy a ſtill greater number were abſolved; of all thoſe who were judged at the councils of Mayence and Salamanca, none were condemned: and hence we may conclude, that of the 9000 houſes belonging to the order, many had not been tainted, and that whole provinces were to be excepted from the general ſtain of infamy. But the condemnations, the juridical depoſitions, the method of initiating the knights, almoſt become general; the ſecrecy of their receptions, where neither prince, nor king, nor any perſon whatever, could be preſent during the laſt half century, are ſo many teſtimonies which corroborate the divers accuſations contained in the articles ſent to the judges; that is to ſay, that at leaſt two-thirds of the order knew of the abominations practiſed without taking any ſteps to extirpate them. *Quod omnes, vel quaſi duæ partes ordinis ſcientes dictos errores corrigere neglexerint.*

"This certainly cannot mean that two thirds of the knights had equally partaken of theſe abominations. It is evident, on the contrary, that many deteſted them as ſoon as they were acquainted with them; and that others only ſubmitted to them, though initiated, after the harſheſt treatment and moſt terrible threats. Nevertheleſs, this proves, that the greateſt part of theſe knights were criminal, ſome through corruption, others through weakneſs or connivance; and hence the diſſolution of the order became neceſſary."

g. Dict.

TEMPLEMAN (Peter), M. D. the ſon of an eminent attorney at Dorcheſter in the county of Dorſet, by Mary daughter of Robert Haynes, was born March 17, 1711, and was educated at the Charter-houſe (not on the foundation), whence he proceeded to Trinity-college, Cambridge, and there took his degree of B. A. with diſtinguiſhed reputation. During his reſidence at Cambridge, by his own inclination, in conformity with that of his parents, he applied himſelf to the ſtudy of divinity, with a deſign to enter into holy orders; but after ſome time, from what cauſe we know not, he altered his plan, and applied himſelf to the ſtudy of phyſic. In the year 1736, he went to Leyden, where he attended the lectures of Boerhaave, and the profeſſors of the other branches of medicine in that celebrated univerſity, for the ſpace of two years or more. About the beginning of 1739, he returned to London, with a view to enter on the practice of his profeſſion, ſupported by a handſome allowance from his father. Why he did not ſucceed in that line was eaſy to be accounted for by thoſe who knew him. He was a man of a very liberal turn of mind, of general erudition, with a large acquaintance among the learned of different profeſſions, but of an indolent, inactive diſpoſition; he could not enter into juntos with people that were not to his liking; nor cultivate the acquaintance to be met with at tea-tables; but rather choſe to employ his time at home in the peruſal of an ingenious author, or to ſpend an attic evening in a ſelect company of men of ſenſe and learning. In this he reſembled Dr Armſtrong, whoſe limited practice in his profeſſion was owing to the ſame cauſe. In the latter end of the year 1750 he was introduced to Dr Fothergill by Dr Cuming, with a view of inſtituting a Medical Society, in order to procure the earlieſt intelligence of every improvement in phyſic from every part of Europe. At the ſame period he tells his friend, "Dr Mead has very generouſly offered to aſſiſt me with all his intereſt for ſucceeding Dr Hall at the Charter-houſe, whoſe death has been for ſome time expected. Inſpired with gratitude, I have ventured out of my element (as you will plainly perceive), and ſent him an ode." Dr Templeman's epitaph on Lady Lucy Meyrick (the only Engliſh copy of verſes of his writing that we know of), is printed in the eighth volume of the "Select Collection of Miſcellany Poems, 1781." In 1753 he publiſhed the firſt volume of "Curious Remarks and Obſervations in Phyſic, Anatomy, Chirurgery, Chemiſtry, Botany, and Medicine; extracted from the Hiſtory and Memoirs of the Royal Academy of Sciences at Paris;" and the ſecond volume in the ſucceeding year. A third was promiſed, but we believe never printed. It appears, indeed, that if he had met with proper encouragement from the public, it was his intention to have extended the work to twelve volumes, with an additional one of index, and that he was prepared to publiſh two ſuch volumes every year. His tranſlation of "Norden's Travels" appeared in the beginning of the year 1757; and in that year he was editor of "Select Caſes and Conſultations in Phyſic, by Dr Woodward," 8vo. On the eſtabliſhment of the Britiſh Muſeum, in 1753, he was appointed to the office of keeper of the reading-room, which he reſigned on being choſen, in 1760, ſecretary to the then newly inſtituted Society of Arts, Manufactures, and Commerce. In 1762, he was elected a correſponding member of the Royal Academy of Science of Paris, and alſo of the Œconomical Society at Berne. Very early in life Dr Templeman was afflicted with ſevere paroxyſms of an aſthma, which eluded the force of all that either his own ſkill, or that of the moſt eminent phyſicians then living, could ſuggeſt to him; and it continued to haraſs him till his death, which happened September 23, 1769. He was eſteemed a man of great learning, particularly with reſpect to languages; ſpoke French with great fluency, and left the character of a humane, generous, and polite member of ſociety.

Templeman, Terané.

TERANE´, a town in Egypt, ſituated on what Mr Browne calls the *left* of the moſt weſtern mouth of the Nile, at a very ſmall diſtance from the river. Its latitude is 30° 24′. The buildings are chiefly unburned brick, though there are alſo ſome of ſtone. The town and diſtrict, containing ſeveral villages, belonged, before the French invaſion, to Murad Bey, who uſually entruſted its government, and the collection of its revenue, to one of his Caſhefs. That revenue ariſes principally from natrôn (See NATRUM, *Encycl.*), found in

Terane, Terebratulæ.

in great quantities in certain lakes about thirty-five miles from Terané; and it is on account of theſe lakes only that the town is worthy of notice in this work; for though there are many columns in its neighbourhood, which indicate the ſite of ancient ſtructures, none of them have inſcriptions aſcertaining their antiquity.

The eaſtern extremity of the moſt weſtern lake Mr Browne found to be 30° 31′ North. No vegetation appears, except reeds, on the margin of the lake, which is very irregular in its form; ſo that it is not eaſy to ſay what may be the quantity of ground covered with water. It is higher in winter than in ſummer; and when it was viſited by our author, its breadth did not exceed a mile, though its length was nearly four. Towards the end of the ſummer, it is ſaid, theſe lakes are almoſt dry; and the ſpace that the water has retired from is then occupied by a thick depoſition of ſalt. Not far removed from the eaſtern extremity, a ſpring riſes with ſome force, which much agitates the reſt of the water. Cloſe to that ſpring the depth was far greater than Mr Browne's height; in other parts it was obſervable that it did not generally exceed three feet. The thermometer near this ſpring ſtood at 76, while in the open air it was 87. The more weſtern lake differs not materially from the eaſtern in ſize, form, or productions. The colour of the water in both is an imperfect red; and where the bottom is viſible, it appears almoſt as if covered with blood. Salt, to the thickneſs of five or ſix inches, lies conſtantly in the more ſhallow parts. The ſurface of the earth, near the lake, partakes more or leſs generally of the character of natrôn, and, in the parts fartheſt removed, offers to the foot the ſlight reſiſtance of ploughed ground after a ſlight froſt. The ſoil is coarſe ſand. The water of the lake, on the ſlighteſt evaporation, immediately depoſits ſalt. There is a mountain not far from the lakes, where natrôn is found in inſulated bodies, near the ſurface, of a much lighter colour than that produced in the lake, and containing a greater portion of alkali. How thick the ſubſtance of natrôn commonly is in the lake, our author did not accurately determine; but thoſe employed to collect it report, that it never exceeds a cubit, or common pike; but it appears to be regenerated as it is carried away. If ever it ſhould be brought to ſuperſede the uſe of barilla, the quantity obtainable ſeems likely to anſwer every poſſible demand.

TEREBRATULÆ (ANOMIÆ, *Lin.* ſee that article *Encycl.*) have been ſuppoſed not to exiſt now but as petrified ſhells. This, however, is a miſtake. The anomia is an inhabitant of every region, and has exiſted in every age. As many terebratulæ were caught by Perouſe's people during his voyage of diſcovery, and as Lamanon the naturaliſt thought they ſhould be conſidered as a genus by themſelves, he has given us the following deſcription of the *anomia*, or, as he calls it, *terebratula*, on the coaſt of Tartary:

The length of the ſhell varies from ſix to twenty lines, and its breadth from five to eighteen; there are, however, conſiderable varieties of proportion between different individuals, beſides thoſe ariſing from the different ages of the animal. It would be improper, therefore, to diſtinguiſh the various ſpecies of anomiæ by the proportion of their ſhells. The waving lines on the edges of the ſhell are equally defective, as diſtinctive characters; for our author obſerved in the ſame ſpecies the ſhell approaching or receding indifferently from the circular form, and, in ſome, the edges of the valves are on the ſame plane; whereas in others, one of the valves forms a ſalient angle in the middle of its curve, and the other a re-entering angle.

Terebratulæ.

The ſhell is of a moderate thickneſs, about that of a common muſcle; it is ſomewhat tranſparent, convex like the cockle: neither of the ſhells is more ſenſibly arched than the other; that, however, which has the ſpur, is rather the moſt ſo, eſpecially in the ſuperior part.

On the ſurface of the ſhell are ſeen a number of ſlight tranſverſe depreſſions, of a ſemicircular waved form, which reach the part where the ſhell ceaſes to be circular, in order to form the angle which ſupports the ſummit.

Theſe ſtriæ are covered with a very thin and ſlightly-adhering perioſteum; in ſome ſpecimens there are from one to three ſhallow broad depreſſions, radiating inſenſibly from the centre of the ſhell, and becoming more marked as they approach the edges, where they form, with the correſponding parts of the other ſhell, thoſe ſalient and re-entering angles which have been mentioned. The perioſteum is rather more firmly fixed on the latter angles than on the former.

The ſhells are equal in the rounded part of their edge, and cloſe very exactly; however, towards the ſummit, the ſpur of one of the ſhells reaches conſiderably beyond the other ſhell, conſequently they are unequal, as in oyſters.

The ſpur, or ſummit, is formed by the folding from within of the edge of the ſhell, and the elongation of its upper part. The folded edges form an oval aperture of a moderate ſize, through which the animal extends the muſcle, by means of which it attaches itſelf to other ſubſtances. This ſhell is not, therefore, perforated, as its name of terebratula would ſeem to imply, the opening not being worked in one of the ſhells, but formed by the elongation of one ſhell, the folding in of its edges, and the approach of the other ſhell. The ſummit is not pointed, but round.

The ligament, as in the oyſter, is placed between the ſummits, and does not appear on the outſide; it adapts itſelf to the pedicle of the animal. As the ſummit takes up a conſiderable part of the ſhell, the valves are only capable of opening a very little without running the riſk of being broken. It is very firm, though ſlender, and not eaſily to be diſcovered, being fixed in a ſmall groove, which is filled up when the ſhell is ſhut by the correſponding part of the oppoſite ſhell. This ligament preſerves its texture, even for a conſiderable time after the ſhell is emptied and become dry.

Oyſters are without a hinge, the teeth which form it in many other ſhells not exiſting in them. The anomia has been conſidered as an oyſter, becauſe its hinge or teeth have not been examined: they are not viſible indeed in the foſſile ſpecimens; but in opening them when alive, the teeth compoſing the hinge are ſufficiently viſible, being even much larger than in the greater part of bivalve ſhells. The foſſil terebratulæ are almoſt always found with their ſhells cloſed; whereas the other bivalves have uſually theirs either open or ſeparated: the reaſon of this ſeems to ariſe from the nature of the hinge, that of the anomia not allowing it to ſeparate, and the ligament, which is very tight, contributing to keep the two ſhells united. The teeth which form the hinge of the anomia approach very near to thoſe of the *ſpondyle*, deſcribed by M. Adanſon. In this laſt they are formed by two rounded projections, and in the anomia by the ſame a little elongated. It is above theſe teeth that the ligament is placed in the larger ſhell: there are between it and the teeth two cavities, one on each ſide, which ſerve to receive the teeth of the other valve. The teeth of the larger ſhell have, beſides, a ſlight projection, which fits into a longitudinal furrow in the other ſhell in front of the teeth.

The ſubſtance which covers the inſide of the ſhell holds, as in oyſters, a middle place between *nacre* and the interior ſubſtance of ſhells, which are deſtitute of it. The degree of its luſtre, poliſh, and thickneſs, varies with the age and circumſtances of individuals.

The colour of the teeth is always white; that of the outer ſurface of the ſhell verges more or leſs to the ochry red, eſpecially on the border. The inſide has alſo a very ſlight tint of this colour, on a varying greyiſh-white ground.

There is viſible on each ſide of the ſhell the impreſſion of two very diſtinct tendons; a circumſtance which forms a very eſſential difference between this genus and that of the oyſter: this latter having only one tendon ariſing from the middle of the body. The impreſſions of the tendon in the largeſt ſhell are oblong, ſituate near the ſummit, and hollowed; each of them has curved tranſverſe ridges, divided into two parts by a longitudinal furrow, repreſenting the wings of certain inſects. In the other valve the inſertions have a different form; their ſituation is the ſame, but they are very irregularly rounded and encompaſſed by two fulcations, which are ſeparated from each other by an intervening ridge, and then are continued in a right line towards the opening of the ſhell as far as about two thirds of its length. That part of the ſummit of the ſhell along which the pedicle of the animal paſſes, is longitudinally ſtriated in the larger ſhell, of which the middle ſtria is the deepeſt: the longitudinal ſtriæ are divided into equal parts by a tranſverſe depreſſion. There are no ſimilar marks on the other ſhell.

Our author diſſected the animal itſelf, and found what he calls the *manteau* of the anomia, formed of a very fine membrane, lining the inſide of both ſhells, and containing the body of the animal. Its origin is of the ſame breadth as the hinge of the ſhell, whence it divides into two lobes, lining both the ſhells: it forms, therefore, only a ſingle aperture, terminating at each end of the hinge, and of the ſame breadth with the interior ſurface of the ſhell: it appears to have only one trachea, which is formed by the two lobes of the manteau.

Our naturaliſt having opened the ſhell, divided the ligament as delicately as poſſible, unfixed the hinge, and detaching from the larger ſhell the lobe of the manteau, turned over the body of the animal. This operation expoſed to view the large muſcles which adhered to the ſhell; they are ſoft, membranous, and, as it were, fleſhy on the inſide, being covered with ſmall ſanguiferous glands. From the lower part of each muſcle there proceeds a pretty ſtrong tendon, which reaches to the extremity of the manteau; they run parallel to the edge of the ſhell, and at a conſiderable diſtance from each other; and are each encloſed in a ſort of flatted ſac, of the ſhape of a ribbon, which is filled with a red viſcid matter. It appears that the place of inſertion of the muſcles, as well as the muſcles themſelves, which extend along the lobe of the manteau, furniſh real blood, which is contained in three ſmall fleſhy red glandular bodies of unequal ſize, which are viſible after having taken off the muſcles; perhaps theſe conſtitute the heart of the animal.

The muſcles which are inſerted into the other ſhell are alſo divided into ſeveral parts: ſome are ſeen extending along the correſponding lobe of the manteau; many others riſe up in a kind of tuft, which is fixed into the ſhell above: ſome again ſubdivide into ſuch minute ramifications as not to allow of tracing their courſe, even with the aſſiſtance of a microſcope; but others, more apparent, contribute to the formation of the pedicle which paſſes through the opening left between the two ſhells, is connected to each of them by ſeveral fibres, and fixes itſelf to ſome external body, principally to other bivalves. The muſcles of the anomia have therefore three attachments, namely, to the inner ſurface of each ſhell, and to ſome external body.

The form of the pedicle is cylindrical, being encloſed in a muſcular ſubſtance, which contains ſeveral fibres; it is from a line to a line and a half long, and two thirds in diameter. It adheres ſo forcibly to different ſubſtances, as that the animal, and all the muſcles which contribute to the formation of the pedicle, may more eaſily be torn through than the pedicle detached from the place of its adheſion. The glutinous ſubſtance which connects them to each other, reſiſts even the heat of boiling water. It is by means of this pedicle that the animal raiſes its ſhell ſo as to be, while in the water, in a poſition inclined to the horizon. The ſmalleſt valve is always the loweſt, being that upon which the animal reſts; the ſuperior one being the larger, and ſerving as a covering. Our author thinks the animal has the power of loco-motion.

After raiſing the lobe of the manteau he obſerved the ears. They are large, compoſed of two membranaceous laminæ on each ſide, of which the ſuperior is the narrower. Theſe laminæ are connected to each other by a thin membrane, ſo as to form only a ſingle pouch. They have on their edges long fringes, which hang looſe upon the manteau; but a very remarkable circumſtance is, that their ears are ſupported by little bones like thoſe of fiſh. The form of the ears is that of an arch; they are ſeparated from each other on their lower part, where the fringes are the longeſt; ſo that the two ears on one ſide are perfectly diſtinct from thoſe on the other ſide. The commencement of the ears is at the teeth of the hinge.

Between the ears are ſituate the ſtomach, œſophagus, and mouth; the whole forming a triangle, of which the mouth is the baſe. It is placed at the ſide of the hinge, and conſiſts of a large tranſverſe opening without lips or jaw-bone. The œſophagus is very ſhort, but is capable of elongation when the animal opens its mouth. The ſtomach, which is of the ſhape of a pointed ſac, is connected by a membrane to the bones of the ear. On opening the ſtomach, he found a ſmall ſhrimp half digeſted.

At the bottom of the ſtomach is ſeen the inteſtine, of which it is, as it were, a continuation. It is extremely ſhort, not exceeding half a line in a ſhell fifteen

Terebratulæ, Ternai.

lines acroſs, and is compoſed of a very ſlender membrane. The excrements are diſcharged upon the lobes of the manteau, but they are eaſily thrown out by the motions of the two lobes.

The little bones of the ears, already mentioned, had not formerly been obſerved in any of the teſtaceous animals; whence the terebratulæ approach nearer to fiſh than the inhabitants of any other ſhell. In the anomiæ which are preſerved in cabinets, there is found only a very ſmall portion of theſe bones, whence they have obtained the improper appellations of *tongue* or *fork*, which indicate only the form of the fragments, and not their uſe.

The ſmall bones of the ears are compoſed of ſeveral pieces, the principal of which is of an oval form; it ſprings from the ſide of the hinge, of which it appears to be a continuation; thence it extends about two-thirds of the breadth of the ſhell, where it is reflected, and reſts againſt the upper part of the fork, to the branches of which it is united by a ſimple ſuperpoſition; a kind of articulation very common among the numerous ſmall bones that compoſe the heads of fiſh. The fork extends from the ſummit a little more than one-third of the breadth of the ſhell: it is formed by a pivot which divides into two long and pointed branches; theſe are remarkably brittle, and ſupport the extremities of the bones of the larger ears. The lamina, which compoſes a ſecond ſet of ears, reſts upon a curved bone, which on one ſide is attached to the inferior internal part of the bone of the larger ears, and on the other reaches to the ſide of the mouth of the animal, where it is united to another flat little bone, which is applied to a ſimilar bone on the other ſide. Theſe laſt little bones are exactly below the membrane which forms the mouth. All theſe bones are flat, very brittle, and ſurrounded with fibres and membranes. By their articulations the ears are enabled to move; they alſo ſupport the body of the animal, which touches neither of the ſhells, but remains between them as upon treſſels. The ſpace between the branches of the bones of the ears is filled up with a tranſparent firm membrane; at the baſe of the fork is a ſimilar one, and a perpendicular partition dividing the ſpace occupied by the body of the animal from the reſt of the ſhell. There are two orifices in this membrane communicating with the ſpace between the two lobes of the manteau, and which ſerves as a trachea; for we have remarked, in the deſcription of the manteau, that the two lobes are entirely ſeparated from each other, and therefore do not form a real trachea.

From this deſcription, it follows that the anomia ought to be ſeparated from the genus oyſter, ſince it has a toothed hinge, ſeveral ligaments, and an interior organization wholly different; neither ought it to be confounded with the cockle, the ſhells of which are both equal, and are deſtitute of any ſenſible perioſteum, without reckoning other differences. It has ſtill leſs analogy with the other bivalves, and therefore ought to conſtitute a peculiar genus; the ſpecies of which, both foſſil and living, are very numerous.

See Plate XLIII. where fig. 1. is a front view of a terebratula of middle ſize. Fig. 2. is a view of the internal ſtructure.—A A, laminæ of the ſuperior ears—B B, laminæ of the inferior—C, the ſtomach—D, the anus—E E, the manteau—F, the œſophagus.

Ternai.

TERNAI, the name given by Perouſe to a very fine bay which he diſcovered on the coaſt of Tartary, in Lat. 45° 13′ North, and in Long. 135° 9′ Eaſt from Paris. The bottom is ſandy, and diminiſhes gradually to ſix fathoms within a cable's length of the ſhore. The tide riſes five feet; it is high water at 8^h 15^m at full and change; and the flux and reflux do not alter the direction of the current at half a league from the ſhore.

"Five ſmall creeks (ſays La Perouſe), ſimilar to the ſides of a regular polygon, form the outline of this roadſtead; theſe are ſeparated from each other by hills, which are covered to the ſummit with trees. Never did France, in the freſheſt ſpring, offer gradations of colour of ſo varied and ſtrong a green; and though we had not ſeen, ſince we began to run along the coaſt, either a ſingle fire or canoe, we could not imagine that a country ſo near to China, and which appeared ſo fertile, ſhould be entirely uninhabited. Before our boats had landed, our glaſſes were turned towards the ſhore, but we ſaw only bears and ſtags, which paſſed very quietly along the ſea ſide. The ſame plants which grow in our climates carpeted the whole ſoil, but they were ſtronger, and of a deeper green; the greater part were in flower. Roſes, red and yellow lilies, lilies of the valley, and all our meadow flowers in general, were met with at every ſtep. Pine trees covered the tops of the mountains; oaks began only half way down, and diminiſhed in ſtrength and ſize in proportion as they came nearer the ſea; the banks of the rivers and rivulets were bordered with willow, birch, and maple trees, and on the ſkirts of the foreſts we ſaw apple and medlar trees in flower, with clumps of hazle nut trees, the fruit of which already made its appearance. Our ſurpriſe was redoubled, when we reflected on the population which overburdens the extenſive empire of China, ſo that the laws do not puniſh fathers barbarous enough to drown and deſtroy their children, and that this people, whoſe polity is ſo highly boaſted of, dares not extend itſelf beyond its wall, to draw its ſubſiſtence from a land, the vegetation of which it would be neceſſary rather to check than to encourage. At every ſtep after we had landed, we perceived traces of men by the deſtruction they had made; ſeveral trees, cut with ſharp-edged inſtruments; the remains of ravages by fire were to be ſeen in ſeveral places, and we obſerved ſome ſheds, which had been erected by hunters in a corner of the woods. We alſo found ſome ſmall baſkets, made of the bark of birch trees, ſewed with thread, and ſimilar to thoſe of the Canadian Indians; rackets for walking on the ſnow; in a word, every thing induced us to think that the Tartars approach the borders of the ſea in the ſeaſon for hunting and fiſhing; that they aſſemble in colonies at that period along the rivers; and that the bulk of the nation live in the interior of the country on a ſoil perhaps better calculated for the multiplication of their immenſe flocks and herds."

Our navigators caught in the bay vaſt quantities of fine fiſh, ſuch as cod, harp-fiſh, trout, ſalmon, herrings, and plaice; but though game was plenty on ſhore, they had no ſucceſs in hunting. The meadows, ſo delightful to the ſight, could ſcarce be croſſed; the thick graſs was three or four feet high, ſo that they found themſelves in a manner buried in it, and they were under the perpetual dread of being bitten by ſerpents, of which

which they ſaw a great number on the banks of the rivulets. They found, however, immenſe quantities of ſmall onions, ſorrel, and celery; which, together with the freſh fiſh, ſerved as antidotes againſt the ſcurvy.

TERRE-PLEIN, or TERRE-PLAIN, in fortification, the top, platform, or horizontal ſurface of the rampart, upon which the cannon are placed, and where the defenders perform their office. It is ſo called becauſe it lies level, having only a little ſlope outwardly to counteract the recoil of the cannon. Its breadth is from 24 to 30 feet; being terminated by the parapet on the outer ſide, and inwardly by the inner talus.

TERRELLA, or little earth, is a magnet turned of a ſpherical figure, and placed ſo as that its poles, equator, &c. do exactly correſpond with thoſe of the world. It was ſo firſt called by Gilbert, as being a juſt repreſentation of the great magnetic globe we inhabit. Such a terrella, it was ſuppoſed, if nicely poiſed, and hung in a meridian like a globe, would be turned round like the earth in 24 hours by the magnetic particles pervading it; but experience has ſhewn that this is a miſtake.

TETRAEDRON, or TETRAHEDRON, in geometry, is one of the five Platonic or regular bodies or ſolids, comprehended under four equilateral and equal triangles. Or it is a triangular pyramid of four equal and equilateral faces.

TETRAGON, in geometry, a quadrangle, or a figure having four angles. Such as a ſquare, a parallelogram, a rhombus, and a trapezium. It ſometimes alſo means peculiarly a ſquare.

TETRAGON, in aſtrology, denotes an aſpect of two planets with regard to the earth, when they are diſtant from each other a fourth part of a circle, or 90 degrees. The tetragon is expreſſed by the character □, and is otherwiſe called a ſquare or quartile aſpect.

THEBES, in Egypt. Having in the *Encyclopædia* given Mr Bruce's account of this ancient city, which repreſents it as having been a paltry place, ſo contrary to the deſcription of Homer, juſtice to the father of poetry requires that we here notice what has been ſaid of it by a ſubſequent traveller, who remained three days among its ruins. According to Mr Browne, "the maſſy and magnificent forms of the ruins that remain of ancient Thebes, the capital of Egypt, the city of Jove, the city with 100 gates, muſt inſpire every intelligent ſpectator with awe and admiration. Diffuſed on both ſides of the Nile, their extent confirms the claſſical obſervations, and Homer's animated deſcription ruſhes into the memory:

'Egyptian Thebes, in whoſe palaces vaſt wealth is ſtored; from each of whoſe hundred gates iſſue two hundred warriors, with their horſes and chariots.'

"Theſe venerable ruins, probably the moſt ancient in the world, extend for about three leagues in length along the Nile. Eaſt and weſt they reach to the mountains, a breadth of about two leagues and a half. The river is here about three hundred yards broad. The circumference of the ancient city muſt therefore have been about twenty-ſeven miles.

"In ſailing up the Nile, the firſt village you come to within the precincts is Kourna, on the weſt, where there are few houſes, the people living moſtly in the caverns. Next is Abuhadjadj, a village, and Karnac, a ſmall diſtrict, both on the eaſt. Far the largeſt portion of the city ſtood on the eaſtern ſide of the river. On the ſouth-weſt Medinet-Abu marks the extremity of the ruins; for Arment, which is about two leagues to the ſouth, cannot be conſidered as a part.

"In deſcribing the ruins, we ſhall begin with the moſt conſiderable, which are on the eaſt of the Nile. The chief is the Great Temple, an oblong ſquare building of vaſt extent, with a double colonnade, one at each extremity. The maſſy columns and walls are covered with hieroglyphics; a labour truly ſtupendous. 1. The Great Temple ſtands in the diſtrict called *Karnac*. 2. Next in importance is the temple at *Abuhadjadj*. 3. Numerous ruins, avenues marked with remains of ſphinxes, &c. On the weſt ſide of the Nile appear, 1. Two coloſſal figures, apparently of a man and woman, formed of a calcareous ſtone like the reſt of the ruins. 2. Remains of a large temple, with caverns excavated in the rock. 3. The magnificent edifice ſtyled the *palace of Memnon*. Some of the columns are about forty feet high, and about nine and a half in diameter. The columns and walls are covered with hieroglyphics. This ſtands at *Kourna*. 4. Behind the palace is the paſſage ſtyled *Bibân-el-Moluk*, leading up the mountain. At the extremity of this paſſage, in the ſides of the rock, are the celebrated caverns known as the ſepulchres of the ancient kings."

Though Mr Browne agrees with Pococke and Bruce, that the paſſage in Homer refers not to the gates of the city, he is yet of opinion, contrary to them, that Thebes had been a walled town. He ſays, indeed, that ſome faint remains of its ſurrounding wall are viſible at this day; and he thinks that he diſcovered the ruins of three of its gates, though he does not affirm this with abſolute confidence.

THEODOSIUS, a celebrated mathematician, flouriſhed in the times of Cicero and Pompey; but the time and place of his death are unknown. This Theodoſius, the Tripolite, as mentioned by Suidas, is probably the ſame with Theodoſius the philoſopher of Bythinia, who, Strabo ſays, excelled in the mathematical ſciences, as alſo his ſons; for the ſame perſon might have travelled from the one of thoſe places to the other, and ſpent part of his life in each of them; like as Hipparchus was called by Strabo the Bythinian, but by Ptolemy and others the Rhodian.

Biog. Dict.

Theodoſius chiefly cultivated that part of geometry which relates to the doctrine of the ſphere, concerning which he publiſhed three books. The firſt of theſe contains 22 propoſitions; the ſecond, 23; and the third, 14; all demonſtrated in the pure geometrical manner of the ancients. Ptolemy made great uſe of theſe propoſitions, as well as all ſucceeding writers. Theſe books were tranſlated by the Arabians, out of the original Greek, into their own language. From the Arabic the work was again tranſlated into Latin, and printed at Venice. But the Arabic verſion being very defective, a more complete edition was publiſhed, in Greek and Latin, at Paris 1558, by John Pena, Regius Profeſſor of aſtronomy. And Vitello acquired reputation by tranſlating Theodoſius into Latin. This author's works were alſo commented on and illuſtrated by Clavius, Heleganius, and Guarinus, and laſtly by De Chales, in his Curſus Mathematicus. But that edition of Theodoſius's Spherics, which is now moſt in uſe, was tranſlated and publiſhed by our countryman the learned Dr Barrow, Theon, Theophilanthropiſts

row, in the year 1675, illuſtrated and demonſtrated in a new and conciſe method. By this author's account, Theodoſius appears, not only to be a great maſter in this more difficult part of geometry, but the firſt conſiderable author of antiquity who has written on that ſubject.

Theodoſius, too, wrote concerning the Celeſtial Houſes; alſo of Days and Nights; copies of which, in Greek, were in the King's library at Paris. Of which there was a Latin edition, publiſhed by Peter Daſypody, in the year 1572.

THEON, of Alexandria, a celebrated Greek philoſopher and mathematician, who flouriſhed in the 4th century, about the year 380, in the time of Theodoſius the Great; but the time and manner of his death are unknown. His genius and diſpoſition for the ſtudy of philoſophy were very early improved by cloſe application to all its branches; ſo that he acquired ſuch a proficiency in the ſciences as to render his name venerable in hiſtory, and to procure him the honour of being preſident of the famous Alexandrian ſchool. One of his pupils was the admirable Hypatia, his daughter, who ſucceeded him in the preſidency of the ſchool; a truſt which, like himſelf, ſhe diſcharged with the greateſt honour and uſefulneſs. See her life, *Encycl.*

The ſtudy of Nature led Theon to many juſt conceptions concerning God, and to many uſeful reflections in the ſcience of moral philoſophy. Hence, it is ſaid, he wrote with great accuracy on Divine Providence. And he ſeems to have made it his ſtanding rule, to judge the truth of certain principles, or ſentiments, from their natural or neceſſary tendency. Thus, he ſays, that a full perſuaſion that the Deity ſees every thing we do, is the ſtrongeſt incentive to virtue; for he inſiſts, that the moſt profligate have power to refrain their hands, and hold their tongues, when they think they are obſerved, or overheard, by ſome perſon whom they fear or reſpect. With how much more reaſon then, ſays he, ſhould the apprehenſion and belief, that God ſees all things, reſtrain men from ſin, and conſtantly excite them to their duty? He alſo repreſents this belief concerning the Deity as productive of the greateſt pleaſure imaginable, eſpecially to the virtuous, who might depend with greater confidence on the favour and protection of Providence. For this reaſon, he recommends nothing ſo much as meditation on the preſence of God: and he recommended it to the civil magiſtrate as a reſtraint on ſuch as were profane and wicked, to have the following inſcription written, in large characters, at the corner of every ſtreet—GOD SEES THEE, O SINNER.

Theon wrote notes and commentaries on ſome of the ancient mathematicians. He compoſed alſo a book, intitled *Progymnaſmata*, a rhetorical work, written with great judgment and elegance; in which he criticiſed on the writings of ſome illuſtrious orators and hiſtorians; pointing out, with great propriety and judgment, their beauties and imperfections; and laying down proper rules for propriety of ſtyle. He recommends conciſeneſs of expreſſion, and perſpicuity, as the principal ornaments. This book was printed at Baſle in the year 1541; but the beſt edition is that of Leyden, in 1626, in 8vo.

THEOPHILANTHROPISTS, a ſect of deiſts, who, in September 1796, publiſhed at Paris a ſort of catechiſm or directory for ſocial worſhip, under the title of *Manuel des Theanthrophiles*. This religious breviary found favour: the congregation became numerous; and in the ſecond edition of their manual they aſſumed the leſs harſh denomination of *Theophilanthropes, i. e.* lovers of God and man. A book of hymns, a liturgy for every decade of the French year, and an homiletical ſelection of moral leſſons, are announced, or publiſhed, by their unknown ſynod. Thus they poſſeſs a ſyſtem of pious ſervices adapted to all occaſions, which ſome one of the individuals who attend reads aloud; for they object to the employment of a regular lecturer, in conſequence of their hoſtility to prieſts.—This novel ſect was countenanced by Larcveillere Lepaux, one of the Directory, and, ſoon after its formation, opened temples of its own in Dijon, and in other provincial towns. They had declamations, in the ſpirit of ſermons, which abounded with ſuch phraſes as *l'eternal geometre*, and the like, and which have long ſince been familiar to thoſe who frequent the lodges of free maſonry. Whether the ſect now exiſts, or fell at the laſt revolution which annihilated the directory, we have not learned; but a tranſlation of its *Manuel* into Engliſh, for the uſe, we ſuppoſe, of our Jacobins, was made ſo early as the year 1797. From this contemptible performance, we learn that the creed of the Theophilanthropiſts is compriſed in the four following propoſitions:

Theophilanthropiſts.

The Theophilanthropiſts believe in the exiſtence of God, and the immortality of the ſoul.

The ſpectacle of the univerſe atteſts the exiſtence of the Firſt Being.

The faculty which we poſſeſs of thinking, aſſures us, that we have, within ourſelves, a principle which is ſuperior to matter, and which ſurvives the diſſolution of the body.

The exiſtence of God, and the immortality of the ſoul, do not need long demonſtrations; they are ſentimental truths, which every one may find written in his heart, if he conſult it with ſincerity.

Thus a ſort of religious inſtinct is ſet up as the ſole foundation of piety, which every one has as much right to diſavow as another to aſſert; and the obligations of which, therefore, can in no way be ſhewn to be incumbent on thoſe to whom this novel illumination is not vouchſafed. Society, under ſuch a ſyſtem, gains no means of influencing the conduct of refractory members.

The morality of the Theophilanthropiſts is founded on one ſingle precept: *Worſhip God, cheriſh your kind, render yourſelves uſeful to your country!*

Among the duties comprehended under the denomination of cheriſhing our kind, we find that of *not lending for uſury*: the others are chiefly extracted from the goſpels, and do not interfere with the province of the civil magiſtrate. The queſtion of monogamy is not diſcuſſed.

Among the duties to our country are placed thoſe of fighting in its defence, and of paying the taxes. It was certainly prudent in the ſtateſman to ſlide theſe duties into the catalogue of his eſtabliſhed maxims of morality; and he ran thereby little riſk of provoking heretical animadverſions on his creed in France.

The following inſcriptions are ordered to be placed above the altars in the ſeveral temples or ſynagogues of the Theophilanthropiſts; but for what reaſon altars are admitted into ſuch ſynagogues we are not informed:

g. Dic

Firſt inſcription, "We believe in the Exiſtence of God, in the immortality of the ſoul."

Second inſcription, "Worſhip God, cheriſh your kind, render yourſelves uſeful to the country."

Third inſcription, "Good is every thing which tends to the preſervation or the perfection of man.—Evil is every thing which tends to deſtroy or to deteriorate him."

Fourth inſcription, "Children, honour your fathers and mothers. Obey them with affection. Comfort their old age.—Fathers and mothers, inſtruct your children."

Fifth inſcription, "Wives, regard in your huſbands the chiefs of your houſes.—Huſbands, love your wives, and render yourſelves reciprocally happy."

This pentalogue is chiefly objectionable on account of the vague drift of the fifth commandment: the whole has too general a turn for obvious practical application. The introduction of ceremonies, of ſculpture, of painting, and of engraving, is forbidden. If poetry and muſic may concur to render the worſhip impreſſive, why not the other fine arts? The fine arts have never illuſtrated a country which excluded them from the public temples. Are they to be extinguiſhed in France by Theophilanthropic iconoclaſts?

At p. 28. of the Manuel, this ſurpriſing maxim occurs: *Avoid innovations!* A ſect fifteen months old grown as teſty as the church of Rome! They acknowledge, that perhaps better inſcriptions may be found; yet they forbid the exchange. They prefer *mumpſimus* to the *ſumpſimus* of genuine Chriſtianity!

THEOPHILUS, a writer and biſhop of the primitive church, was educated a Heathen, and afterwards converted to Chriſtianity. Some have imagined that he is the perſon to whom St Luke dedicates the Acts of the Apoſtles; but they are groſsly miſtaken; for this Theophilus was ſo far from being contemporary with St Luke and the apoſtles, that he was not ordained biſhop of Antioch till *anno* 170; and he governed this church twelve or thirteen years. He was a vigorous oppoſer of certain heretics of his time, and compoſed a great number of works; all of which are loſt, except three books to Autolycus, a learned Heathen of his acquaintance, who had undertaken to vindicate his own religion againſt that of the Chriſtians. The firſt book is properly a diſcourſe between him and Autolycus, in anſwer to what this Heathen had ſaid againſt Chriſtianity. The ſecond is to convince him of the falſehood of his own, and the truth of the Chriſtian religion. In the third, after having proved that the writings of the Heathens are full of abſurdities and contradictions, he vindicates the doctrine and the lives of the Chriſtians from thoſe falſe and ſcandalous imputations which were then brought againſt them. Laſtly, at the end of his work, he adds an hiſtorical chronology from the beginning of the world to his own time, to prove that the hiſtory of Moſes is at once the moſt ancient and the trueſt; and it appears from this little epitome, how well this author was acquainted with profane hiſtory. Theſe three books are filled with a great variety of curious diſquiſitions concerning the opinions of the poets and philoſophers, and there are but few things in them relating immediately to the doctrines of the Chriſtian religion. Not that Theophilus was ignorant of theſe doctrines, but, having compoſed his works for the converſion of a Pagan, he inſiſted rather on the external evidence or proofs from without, as better adapted, in his opinion, to the purpoſe. His ſtyle is elegant, and the turn of his thoughts very agreeable; and this little ſpecimen is ſufficient to ſhew that he was indeed a very eloquent man.

g. Dict.

The piece is intitled, in the Greek manuſcripts, "The books of Theophilus to Autolycus, concerning the Faith of the Chriſtians, againſt the malicious detractors of their religion." They were publiſhed, with a Latin verſion, by Conradus Geſner, at Zurich, in 1546. They were afterwards ſubjoined to Juſtin Martyr's works, printed at Paris in 1615 and 1636; then publiſhed at Oxford, 1684, in 12mo, under the inſpection of Dr Fell; and, laſtly, by Jo. Chriſt. Wolfius, at Hamburgh, 1723, in 8vo.

It is remarkable, that this patriarch of Antioch was the firſt who applied the term *Trinity* to expreſs the Three Perſons in the Godhead.

THERAPEUTÆ, ſo called from the extraordinary purity of their religious worſhip, were a Jewiſh ſect, who, with a kind of religious phrenzy, placed their whole felicity in the contemplation of the Divine nature. Detaching themſelves wholly from ſecular affairs, they transferred their property to their relations or friends, and withdrew into ſolitary places, where they devoted themſelves to a holy life. The principal ſociety of this kind was formed near Alexandria, where they lived, not far from each other, in ſeparate cottages, each of which had its own ſacred apartment, to which the inhabitant retired for the purpoſes of devotion. After their morning prayers, they ſpent the day in ſtudying the law and the prophets, endeavouring, by the help of the commentaries of their anceſtors, to diſcover ſome allegorical meaning in every part. Beſides this, they entertained themſelves with compoſing ſacred hymns in various kinds of metre. Six days of the week were, in this manner, paſſed in ſolitude. On the ſeventh day they met, clothed in a decent habit, in a public aſſembly; where, taking their places according to their age, they ſat, with the right hand between the breaſt and the chin, and the left at the ſide. Then ſome one of the elders, ſtepping forth into the middle of the aſſembly, diſcourſed, with a grave countenance and a calm of tone voice, on the doctrines of the ſect; the audience, in the mean time, remaining in perfect ſilence, and occaſionally expreſſing their attention and approbation by a nod. The chapel where they met was divided into two apartments; one for the men, the other for the women. So ſtrict a regard was paid to ſilence in theſe aſſemblies, that no one was permitted to whiſper, or even to breathe aloud; but when the diſcourſe was finiſhed, if the queſtion which had been propoſed for ſolution had been treated to the ſatisfaction of the audience, they expreſſed their approbation by a murmur of applauſe. Then the ſpeaker, riſing, ſung a hymn of praiſe to God, in the laſt verſe of which the whole aſſembly joined. On great feſtivals, the meeting was cloſed with a vigil, in which ſacred muſic was performed, accompanyed with ſolemn dancing: and theſe vigils were continued till morning, when the aſſembly, after a morning prayer, in which their faces were directed towards the riſing ſun, was broken up. So abſtemious were theſe aſcetics, that they commonly ate nothing before the ſetting ſun, and often faſted two or three days. They abſtained from wine, and their ordinary food was bread and herbs.

Much diſpute has ariſen among the learned concerning this ſect. Some have imagined them to have been Judaizing Gentiles; but Philo ſuppoſes them to be Jews, by ſpeaking of them as a branch of the ſect of Eſſenes, and expreſsly claſſes them among the followers of Moſes. Others have maintained, that the Therapeutæ were an Alexandrian ſect of Jewiſh converts to the Chriſtian faith, who devoted themſelves to a monaſtic life. But is is impoſſible; for Philo, who wrote before Chriſtianity appeared in Egypt, ſpeaks of this as an eſtabliſhed ſect. From comparing Philo's account of this ſect with the ſtate of philoſophy in the country where it flouriſhed, we conclude, that the Therapeutæ were a body of Jewiſh fanatics, who ſuffered themſelves to be drawn aſide from the ſimplicity of their ancient religion by the example of the Egyptians and Pythagoreans. How long this ſect continued is uncertain; but it is not improbable that, after the appearance of Chriſtianity in Egypt, it ſoon became extinct.

THERMOMETRIC SPECTRUM, is a name given to the ſpace in which a thermometer may be placed, ſo that it ſhall be affected by the ſun's rays refracted by a priſm. It is, in part, the ſame with the PRISMATIC SPECTRUM, which exhibits the different colours produced by the ſolar light.

The philoſophical inſtrument now called a *thermometer*, was firſt named THERMOSCOPE; and was prized by the naturaliſt, becauſe it gave him indications of the preſence and agency of fire in many caſes where our ſenſation of warmth or heat was unable to diſcover it. It was not long before it was obſerved that it alſo affords us meaſures of the changes which take place either in the quantity or the activity of the cauſe of heat, and of many other important phenomena uſually accompanied by heat. They were then called *thermometers*. But in both of theſe offices, it is ſtill a doubt whether it indicates and meaſures any real ſubſtance, a being *ſui generis*, to which we may give the name *fire*, *phlogiſton*, *caloric*, *heat*, or any other; or only indicates and meaſures certain ſtates or conditions, in which all bodies may be found, without the addition or abſtraction of any material ſubſtance.

We think that this queſtion has a greater chance now of being decided than in any former time, in conſequence of a recent and very important diſcovery made by that unwearied obſerver of the works of God, the celebrated Dr Herſchel. Being greatly incommoded when looking at the ſun, by the great heats produced in the eye-pieces of his teleſcopes, he thought that the laws of refraction enabled him to diminiſh them by a proper conſtruction of his eye-pieces. He began his attempts like a philoſopher, by examining the heat produced in the various parts of the priſmatic ſpectrum. Comparing the gradation of heat with that of illumination, he found that they did not, by any means, follow the ſame law. The illumination increaſed gradually from the violet end of the ſpectrum, where it was exceedingly faint, to the boundary of the green and yellow, where it was the moſt remarkable; and after this, it decreaſed as the illuminated object approached the red extremity of the ſpectrum. But the calorific power of the refracted light increaſed all the way from the extreme violet to the extreme red; and its laſt augmentations were conſiderable, and therefore unlike the uſual approaches of a quantity to its maximum ſtate. This made him think of placing the thermometer a little way beyond the extremity of the viſible ſpectrum. To his great aſtoniſhment, he found that the thermometer was more affected there than in the hotteſt part of the *illuminated* ſpectrum. Expoſing the thermometer at various diſtances beyond the extreme red, but in the plane of refraction, he found that it was moſt ſtrongly affected when placed beyond that extremity, about one-fifth of the whole length of the ſpectrum; from thence the calorific influence of the ſun gradually diminiſhed, but was ſtill very conſiderable, at a diſtance from the extreme red equal to three-fifths of the length of the luminous ſpectrum. Theſe firſt-ſuggeſted modes of trial appeared to Dr Herſchel to be too rude to intitle him to ſay that the warming influence did not extend ſtill farther. Indeed the inſtrument ſcarcely performed the part of a thermometer, but merely that of an indicator of heat, or a thermoſcope.

Here is a very new, and wonderful, and important, piece of information. We apprehend that all the philoſophers of Europe, as well as the unlearned of all nations, believe that the *warming* influence of the ſun, and of other luminous bodies, is conjoined with their power of *illumination*. Moſt of the philoſophers admitted the emiſſion of a matter called *light*, projected from the ſhining body, and moving with aſtoniſhing velocity, in thoſe lines which the mathematicians called *rays*, becauſe they diverged from the ſhining point, as the *radii* or ſpokes of a wheel diverge from the nave. This notion ſeems to be the ſimple ſuggeſtion of Nature; and it alſo ſeems to be the opinion entertained by Sir Iſaac Newton. His demonſtration of the laws of reflection and refraction proceeds on this ſuppoſition alone, and the particles of light are held by him to be affected by accelerating and deflecting forces, in the ſame way as a ſtone thrown from the hand is affected by gravity. Huyghens, indeed, Dr Hooke, and Euler, imagined that viſion and illumination were effected in the ſame way that hearing, and reſonance, and echo, are effected—that there is no matter projected from the ſhining body; but that we are ſurrounded by an elaſtic fluid, which is thrown into vibrations by certain tremors of the viſible object—and that thoſe vibrations of this fluid affect our eye in the ſame way as the undulation of elaſtic air, produced by the tremors of a ſtring or a bell, affect our ear. According to theſe philoſophers, a ray of viſion is merely the line which paſſes through all theſe undulations at right angles.

Theſe two opinions ſtill divide the mathematical philoſophers of Europe; but the majority, and particularly the moſt eminent for mathematical and mechanical ſcience, are (with the exception of Huyghens and Euler) on the ſide of the vulgar. This opinion has been greatly ſtrengthened of late years by the diſcoveries in chemiſtry. The influence of light on the growth of plants, the total want of aromatic oils in ſuch as grow in the dark, and their formation and appearance in the very ſame plant, along with the green colour, as ſoon as the plant is placed in the light (even that of open day without ſunſhine, or in the light of a candle), is a ſtrong indication of ſome ſubſtance being obtained from the light, abſorbed by the plant, and combined with its other ingredients. The ſame concluſion is drawn from the

the effects of the ſun's light on vegetable colours, on the nitric and nitrous acids, on mangan eſe, on the calces or oxyds of metals, and numberleſs other inſtances, which all concur in rendering it almoſt unqueſtionable that the ſun's rays, and thoſe of other ſhining bodies, may be, and daily are, combined with the other ſubſtances of which bodies are compoſed, and may be again ſeparated from them. And, ſhould any doubts remain, it would ſeem that the theory of combuſtion, fiſt conceived and imperfectly publiſhed by Dr Hooke in his *Micrography*, p. 103. and in his *Lampas*, p. 1. &c. adopted by Mayow (ſee Hooke and Mayow in this *Suppl.*), forgotten, and lately revived and confirmed by Mr Lavoiſier, removes them entirely. In the beautiful and well-contrived experiments of the laſt gentleman, the light, accompanied by its heat, which had been abſorbed in the proceſs of growth or other natural operations, re-appeared in their primitive form, and might again be abſorbed and made to undergo the ſame round of changes.

Scheele, not inferior to Newton in caution, patience, and accuracy, and attentive to every thing that occurred in his experiments, diſcovered the ſeparability of the illuminating and the warming influences of ſhining bodies. He remarked, that a plate of glaſs, the moſt colourleſs and pellucid that can be procured, when ſuddenly interpoſed between a glowing fire and the face, inſtantly cuts off the warming power of the fire, without cauſing any ſenſible diminution of its brilliancy. He followed this diſcovery into many obvious conſequences, and found them all fully confirmed by obſervation and experiment. The writer of this article, immediately on hearing of Scheele's experiments, repeated them with complete ſucceſs: but he found, that when the glaſs plate had acquired the higheſt temperature which it could acquire in that ſituation, it did not any longer intercept the heat, or at leaſt in a very ſmall and almoſt inſenſible degree. It ſeemed to abſorb the heat, till ſaturated, without abſorbing any conſiderable portion of the light.

This ſeparability of heat from light does not ſeem to have met with the attention it deſerved. Dr Scheele's untenable theories on theſe ſubjects turned away the attention of the chemiſts from this diſcovery, and the mathematical philoſophers ſeem not to have heard of it at all. The late Dr Hutton of Edinburgh was more ſenſible of its importance; and in his laſt endeavours to ſupport the falling cauſe of phlogiſton, makes frequent alluſions to it. But in his attempts to explain the curious obſervations of Meſſrs Sauſſure and Pictet, in which there are unqueſtionable appearances of radiated heat, he reaſons ſo unconſequentially, that few readers proceed farther, ſo as to notice ſeveral obſervations of facts where the illuminating and warming influences are plainly ſeparated. In all theſe inſtances, however, Dr Hutton conſiders the inviſible rays as light, but not as heat; maintaining that they are inviſible, or do not render bodies viſible, only becauſe our eyes are inſenſible to their feeble action.

It was reſerved for Dr Herſchel to put this matter beyond diſpute by theſe valuable experiments. For did the inviſibility of any of the light beyond the extreme red of the priſmatic ſpectrum ariſe from the inſenſibility of our organs, the ſpectrum would gradually fade away beyond the red; but it ceaſes abruptly. Theſe thoughts could not eſcape this attentive obſerver. He therefore examined more particularly thoſe inviſible rays, cauſing them to be reflected by mirrors, and refracted through lenſes; and, in ſhort, he ſubjected them to all the ſubſequent treatments which Newton applied to the colouring rays. He found them retain their ſpecific refrangibilities and reflexibilities with as much uniformity and obſtinacy as Newton had obſerved in the colour-making rays. They were made to paſs through lenſes while the illuminating rays were intercepted by an opaque body, and the inviſible rays were then collected into a focus. They were reflected, both by the anterior and poſterior ſurfaces of tranſparent bodies. In all theſe trials they retained their power of expanding the liquor of a thermometer, and exciting the ſenſation of heat.

Theſe trials were not confined to the ſolar light or the ſolar rays: They were alſo made on the emanations from a candle, from an open fire, and from red hot iron; then they were made with bodies not hot enough to ſhine; with the heat of a common ſtove, and the heat from iron which was not viſible in the dark. The event was the ſame in all; and it was clearly proved that heat, or the cauſe of heat, is as ſuſceptible of radiation as light is; and that this radiation is performed in both according to the ſame laws.

We look with impatience for the ſubſequent experiments of this celebrated philoſopher on this ſubject; for we conſider them as of the greateſt and moſt extenſive importance for explaining the operations of Nature. We ſee, with indiſputable evidence, that there are rays from the ſun, and other bodies, which do not illuminate. It does not follow, however, that there are rays which do not warm; for the thermometer was affected in every part of the coloured ſpectrum. Dr Herſchel ſeems to think that the power of affecting the organ of ſight depends on the particular degrees of mechanical momentum which are indicated by the different degrees of refrangibility. We confeſs that we think it unlikely that ſuch a power ſhould terminate abruptly. We do not obſerve this in analogous phenomena: the evaneſcence of our ſenſations of ſound, of muſical pitch, of heat, &c. are all gradual. We think it more likely that illuminating and warming are ſpecific effects of different things. We ſhould have entertained this opinion independent of all other experience; and we think it ſtrongly confirmed by the experiments of Dr Scheele already mentioned. We are diſpoſed therefore to believe that there are rays which illuminate, but which do not warm; and rays which warm without illuminating. We have experiments in proſpect, by which we hope to put this to the teſt.

Theſe experiments of Dr Herſchel afford another good argument for the common opinion concerning light, namely, that *it is a matter emitted from the ſhining body*, and not merely the undulations of an elaſtic medium; for if it were undulation, then, ſince there is heat in the yellow light, it would follow that a certain frequency of undulation produces both the ſenſation of heat and the ſenſation of a yellow colour. In this caſe they ſhould be inſeparable.

This follows, in the ſtricteſt manner, from the principles or aſſumptions adopted by Euler in his mechanical theory of undulations. The chromatic differences in the rays of light are affirmed to ariſe entirely from the different frequencies of the æthereal undulations; and he endeavours to ſhew that theſe differences in frequency produce a difference in refrangibility. It is evident that this reaſoning is equally concluſive with reſpect to the calorific or heating power of the rays. The light and the heat are both undulations: theſe differ only in frequency; and this frequency is indicated (according to Euler) by the refrangibility. There is a certain frequency therefore which excites the ſenſation of yellow. The ſame frequency, indicated by the ſame refrangibility, produces heat; therefore the frequency which produces this degree of heat alſo produces the ſenſation of yellow. We muſt not ſay that the momentum of the undulation may produce heat, but is inſufficient for the production of light, as a ſtring may vibrate too feebly for being heard; for we ſee, by Dr Herſchel's experiments, that, with a momentum ſufficient for making the moſt brilliant ſpectrum, there are rays (and thoſe which have the greateſt momentum) which produce heat, and yet are inviſible.

It does not follow, from any of Dr Herſchel's experiments, that the rays emitted by iron, which is not hot enough to ſhine in a dark room, have *all* the different degrees of refrangibility obſerved by him. Perhaps none of them would fall on the chromatic ſpectrum. We think, however, that this is not probable. It may be tried by collecting them to a focus by a lenſe, intercepting, however, all thoſe which are leſs refrangible than the red making rays. We truſt that the thermometer in the focus will ſtill be affected.

This is but a very imperfect account of this important diſcovery; but we thought that it would be highly intereſting to our readers. The preſs was employed on this very ſheet when we received the information from a friend, who had ſeen Dr Herſchel's Diſſertation, which will appear in the firſt volume publiſhed by the Royal Society. We truſt that the ingenious author will ſoon follow it up with the inveſtigation of the ſubject in all its conſequences.

We hope that he will examine what will reſult from mixing ſome of the inviſible rays with ſome of the coloured ones. We know that the yellow and the blue, when mixed, produce the ſenſation of green. Perhaps the inviſible rays may alſo change the appearance. We do not, however, expect this.

We alſo hope that Dr Herſchel will examine whether the inviſible rays of the ſun produce any effect on vegetable colours; whether they blacken the calces of ſilver and biſmuth, luna cornea, and decompoſe the nitrous and the oxygenated muriatic acid, &c. &c. We ſhould thus get more inſight into the nature of caloric and of combuſtion. Combuſtion may perhaps be reſtored to its rank in the phenomena of Nature, and no longer be ſunk in the general gulph of oxygenation, and thus obliterated from the memory of chemiſts. It is perhaps the moſt remarkable phenomenon of material Nature; and *fire* and burning will never go out of the language of plain men. Fire, and all its concomitants, have, in all times, been conſidered as even the *chief* objects of chemical attention; and an unlearned perſon will ſtare, when a chemiſt tells him that there is no ſuch thing, and that what he calls the burning of a piece of coal is only the making it ſour. He will perhaps ſmile; but it will not be a ſmile of aſſent.

It was one darling object of the Revolutionary Committee of Chemiſts, aſſembled at Paris in 1787, to baniſh from our minds, *by means of a new language*, all remembrance of any thing which we did not derive from the philoſophers of France. We think ourſelves in a condition to prove this by letters to this country from the ſcene of action; in which the expected victory is ſpoken of in terms of exultation, and with ſo little reſtraint, that the writer forgets that it is DR BLACK whom he is informing that *l'air fixe* and *la pauvre phlogiſtique* will ſoon be forgotten; and yet the writer was a gentleman of uncommon modeſty and worth, and ſincerely attached to Dr Black. We give this as a remarkable inſtance of the *eſprit de corps*, and of the nature and towering ambition of that nation. From this they have not ſwerved; and they hope to gain this ſummit of ſcientific dominion in the ſame way as *the ſame philoſophers* hope to baniſh Chriſtianity by means of their new kalendar. It may, however, turn out that both Dr Hooke and Mr Lavoiſier are miſtaken, when they make the oxygen gas the ſole ſource of both the light and the heat which accompany combuſtion. One of them may perhaps be furniſhed by the body which all, except the new philoſophers, call combuſtible.

The objections which may be made to the theory of Huyghens and Euler, on the acknowledged principles of mechanics, appear to us unanſwerable. Euler has never attempted to anſwer thoſe taken from the different diſperſing powers of different ſubſtances. The objections made to the Newtonian, or vulgar theory of emiſſion, are not ſuch as imply abſurdity; they are only difficulties. The chief of them, *viz.* the ſameneſs of velocity in all lights whatever, is of this kind. It is merely an improbability. But the objections to the theory of undulation, deduced from the chemical effects of light, are not leſs ſtrong than thoſe deduced from mechanical principles. It is quite inconceivable that the undulation of a medium, which pervades all bodies, ſhall produce aromatic oils in ſome, a green fæcula in others, ſhall change ſulphuric acid into ſulphur, &c. &c. No effects are produced by the undulations of air, or the tremors of elaſtic bodies, which have the moſt diſtant analogy or reſemblance to theſe.

That the ſun and other ſhining bodies emit the matter of light and heat, ſeems therefore to merit the general reception which it meets with from the philoſophers. But even of this claſs there are differences in opinion. Some imagine that light only is emitted, and that the heat which we feel is occaſioned by the action of the luminous rays on our atmoſphere, or on the ground. Were the ſun's calorific rays as denſe at the ſurface of the ſun as his luminous rays are, the heat there muſt exceed (ſay they) all that we can form any conception of. Yet we ſee, that when the nucleus of the ſun is laid bare by ſome natural operation, which, like a volcanic exploſion, throws aſide the luminous ocean which covers it to a prodigious depth, the naked parts of this nucleus are black. Therefore the intenſe heat in that place is not able to make it ſhining hot, as it does in all our experiments with intenſe heats, giving a dazzling glare. This is thought highly improbable; and it is therefore ſuppoſed that there is, primitively, no heat in the ſun's rays, but that they act on our air, or other terreſtrial matter, combining with it, and diſengaging heat from it, or producing that particular ſtate and condition which we call *heat*.

We think that Dr Herſchel's diſcovery militates ſtrongly and irreſiſtibly againſt this opinion; and ſhews, that

that whatever reaſon we have for ſaying that the ſun's rays bring light from the ſun we have the ſame authority for ſaying, that they bring heat, fire, caloric, phlogiſton, or by whatever other name we chooſe to diſtinguiſh the cauſe of warmth, expanſion, liquefaction, ebullition, &c.

We muſt either ſay that light and heat are not ſubſtances of a peculiar kind, ſuſceptible of union with the other ingredients of bodies, but merely a ſtate of undulation of an elaſtic medium, as ſound is the undulation of air; or we muſt ſay that the ſun's rays contain light and heat, in a detached ſtate, fit for appearing in their ſimpleſt form, producing illumination and expanſion, and for uniting chemically with other matter. Whichever of theſe opinions we adopt, it is pretty clear that all attempts to diſcover a difference in the weight of hot and cold bodies may be given over. In the firſt caſe, it is ſelf-evident; in the ſecond, we have abundant evidence, that if light and heat, being gravitating matter, like all other bodies, were added to, or abſtracted from bodies, in ſufficient quantity to be ſenſibly heavy, the rays of the ſun, or even the light of a candle, would occaſion inſtant deſtruction by its mere momentum; ſince every particle of radiated light and heat moves at the rate of 200,000 miles in a ſecond.

This diſcovery of Dr Herſchel's adds greatly to the probability of the opinion which we expreſſed on another occaſion, that the forces or powers of natural ſubſtances, which are the immediate cauſes of the chemical phenomena, are no way different from the mechanical forces which render bodies heavy, coherent, elaſtic, expanſive, &c.; in ſhort, that they are what we call *accelerating forces*. We deduced this from the fact, that mechanical force can be oppoſed to them, ſo as to prevent their action in circumſtances where it would otherwiſe certainly take place. Thus, by external preſſure, we can prevent that union of water and caloric which would convert it into elaſtic ſteam. We can even diſunite them again, when ſteam is already produced, by forcibly condenſing it into a ſmaller ſpace. Now, the refraction and reflection of heat are performed according to the ſame preciſe laws which we obſerve in the refraction and reflection of light; and Sir Iſaac Newton has demonſtrated that thoſe phenomena ariſe from the action of accelerating forces, whoſe direction is perpendicular to the acting ſurfaces. The matter of heat, therefore, is like other matter in its mechanical properties; and, in the motion of refraction, it is acted on and deflected, juſt as a projectile is acted on and deflected by gravity. It continues in motion till its velocity and direction are changed by deflecting forces, exerted by the particles of the tranſparent medium or the reflecting ſurface. It would take up too much room, but it is a very eaſy proceſs, to demonſtrate that this regular refraction of heat is altogether incompatible with the uſually ſuppoſed notion of caloric; namely, that it is an expanſive fluid like air, but incomparably more elaſtic: from which property very plauſible explanations have been given of the elaſticity of gaſes, ſteams, and ſuch like fluids. Every intelligent mechanician will be ſenſible, that all this ſort of chemical ſcience falls to the ground, when it is proved, by exhibition of the fact, that radiated heat is refracted in the ſame way with radiated light. We muſt look for the explanation of the immenſe exploſive force of fulminating ſilver, gold, &c. in ſome very different principles from thoſe which are now in vogue. We apprehend, too, that the very phenomenon of this refraction gives indication of forces which are ſufficiently powerful for this explanation: For when we reflect on the aſtoniſhing velocity of the ray of heat; on the minute ſpace along which it is deflected, and conſequently the time of this action, minute beyond all imagination; and when we compare theſe circumſtances with the deflection produced by gravity in the motion of a projectile—it is evident that the deflecting force of refraction muſt exceed the greateſt force that we have any knowledge of, in a greater proportion than the weight of Mount Ætna exceeds that of a particle of ſand. We would deſire Mr de la Place to ſuſpend his hopes of eſtabliſhing univerſal fataliſm, till he can reconcile theſe phenomena with his fundamental principle, "*that all forces which are diffuſed from a ſingle point, neceſſarily and eſſentially diminiſh in the inverſe duplicate ratio of the diſtances.*" Till he can do this, he had better ſtill allow, with Newton, that the ſelection of the duplicate ratio for the action of gravity (by which alone the ſolar ſyſtem can be rendered permanent and orderly) is a mark of wiſdom and benevolence. We would adviſe him to reconcile his mind to this; and perhaps, like the modeſt and admiring Newton, he may, in good time, find comfort in the thought.

It is alſo highly worthy of remark, that this refracting force, almoſt immenſe, which is ſo plainly exerted between the particles of bodies and light, when conſidered as of the ſame kind with thoſe that produce chemical union, appears abundantly ſufficient for explaining ſome of the moſt wonderful phenomena of chemiſtry; ſuch as the prodigious elaſticity of ſteam, of gunpowder, and the ſtill more aſtoniſhing exploſion of fulminating gold and ſilver. Some of the phenomena of deflected light are produced by theſe optical forces acting at diſtances ſufficiently great to admit of meaſurement; as in the Newtonian obſervations on the paſſage of light near the edges of opaque bodies. Theſe deflections enable us to compare the deflecting forces with gravity. The *refracting* force, however, is vaſtly greater than even this, as may be ſeen by the greater deflection which is produced by it; and, being exerted along a ſpace incomparably ſmaller, it muſt be greater ſtill. Here, then, are forces fully adequate to the phenomena of fulmination. And we would again deſire Mr De la Place to remark that, although theſe exploding forces are irreſiſtible, their action ſeems to vaniſh entirely beyond the limits of mathematical contact. This is plain from the fact, that thoſe exploſions do not project the fragments to great diſtances. This is remarkably the caſe in all the moſt eminent of them. Common or nitric gunpowder is perhaps the only great exception. This particular circumſtance will ſurely ſuggeſt to this eminent analyſt the *inverſe triplicate* ratio of the diſtance as more likely to explain the phenomena than his favourite law.

We truſt that our readers will not be diſpleaſed with this ſhort ſketch of Dr Herſchel's diſcovery, and the few reflections which it naturally ſuggeſted to our minds. We ſhall not be greatly ſurpriſed, although it ſhould produce a ſort of counter revolution in chemical ſcience, in conſequence of new conceptions which it may give us of the union of bodies with light and heat. The phenomena of the vegetable and animal economy ſhew that they are ſuſceptible of combination with other ſubſtances beſides the baſis of vital air. Whatever changes this may produce in the great revolution which has already taken place in chemical ſcience, they will (in our opinion) be favourable to true philoſophy; becauſe Dr Herſchel's diſcovery co-operates with other arguments of ſound mathematical reaſoning, to overturn that principle on which De la Place hopes to found his atheiſtical doctrine of fate and neceſſity. It contributes therefore to reſtore to the face of Nature that ſmiling feature of providential WISDOM which Newton had the honour of exhibiting to the view of rational men. The ſun is the ſource of light and genial warmth to a vaſt ſyſtem, which is held together, in almoſt eternal order and beauty, by a law of attraction ſelected by Infinite Wiſdom, as the only one adequate to this magnificent purpoſe.

THEVENOT (Melchiſedec), librarian to the king of France, and a celebrated writer of travels, was born at Paris in 1621, and had ſcarcely gone through his academical ſtudies, when he diſcovered a ſtrong paſſion for viſiting foreign countries. At firſt he ſaw only part of Europe; but then he took great care to procure very particular informations and memoirs from thoſe who had travelled over other parts of the globe, and out of thoſe compoſed his "Voyages and Travels."—He laid down, among other things, ſome rules, together with the invention of an inſtrument, for the better finding out of the longitude, and the declination of the needle; and ſome have thought that theſe are the beſt things in his works, ſince travels, related at ſecond-hand, can never be thought of any great authority or moment; not but Thevenot travelled enough to relate ſome things upon his own knowledge. Another paſſion in him, equally ſtrong with that for travelling, was to collect ſcarce books in all ſciences, eſpecially in philoſophy, mathematics, and hiſtory; and in this he may be ſaid to have ſpent his whole life. When he had the care of the King's library. though it was one of the beſt furniſhed in Europe, he found 2000 volumes wanting in it which he had in his own. Beſides printed books, he bought a great many manuſcripts in French, Engliſh, Spaniſh, Italian, Latin, Greek, Hebrew, Syriac, Arabic, Turkiſh, and Perſic. The marbles preſented to him by Mr Nointel, at his return from his embaſſy to Conſtantinople, upon which there are bas-reliefs and inſcriptions almoſt 2000 years old, may be reckoned among the curioſities of his library. He ſpent moſt of his time among his books, without aiming at any poſt of figure or profit: he had, however, two honourable employments; for he aſſiſted at a conclave held after the death of Pope Innocent X. and was the French king's envoy at Genoa. He was attacked with what is called a ſlow fever in 1692, and died October the ſame year, at the age of 71. According to the account given, he managed himſelf very improperly in this illneſs; for he diminiſhed his ſtrength by abſtinence, while he ſhould have increaſed it with hearty food and generous wines, which were yet the more neceſſary on account of his great age.—Thevenot's Travels into the Levant, &c. were publiſhed in Engliſh in the year 1687, folio; they had been publiſhed in French at Paris 1663, folio. He wrote alſo "L'Art de Nager," the Art of Swimming, 12mo, 1696.

THOMAS (Chriſtian) was born at Leipſic 1655, and was well educated, firſt under his father, and afterwards in the Leipſic univerſity. At firſt he acquieſced in the eſtabliſhed doctrines of the ſchools; but upon reading Puffendorf's "Apology for rejecting the Scholaſtic Principles of Morals and Law," light ſuddenly burſt upon his mind, and he determined to renounce all implicit deference to ancient dogmas. He read lectures upon the ſubject of Natural Law, firſt from the text of Grotius, and afterwards from that of Puffendorf, freely exerciſing his own judgment, and, where he ſaw reaſon, advancing new opinions. Whilſt his father was living, paternal prudence and moderation reſtrained the natural vehemence and acrimony of the young man's temper, which was too apt to break out, even in his public lectures. But when he was left to himſelf, the boldneſs with which he advanced unpopular tenets, and the ſeverity with which he dealt out his ſatirical cenſures, ſoon brought upon him the violent reſentment of theologians and profeſſors.

An "Introduction to Puffendorf," which Thomas publiſhed in the year 1687, wherein he deduced the obligation of morality from natural principles, occaſioned great offence. The following year he became ſtill more unpopular, by opening a monthly literary journal, which he intitled "Free Thoughts, or Monthly Dialogues on various Books, chiefly new;" in which he attacked many of his contemporaries with great ſeverity. The raillery of this ſatirical work was too provoking to be endured: complaints were lodged before the eccleſiaſtical court of Dreſden; the bookſeller was called upon to give up the author; and it was only through the intereſt of the Mareſchal that Thomas eſcaped puniſhment. The title of the work was now changed; but its ſpirit remained. A humorous and ſatirical life of Ariſtotle, and ſeveral other ſarcaſtic papers, kept alive the flame of reſentment, till at length it again burſt forth, on a charge brought againſt him before the ſame court by the clergy of Leipſic, for contempt of religion; but he defended himſelf with ſuch ability, that none of his adverſaries choſe to reply, and the matter was dropped.

A ſatirical review, which he wrote, of a treatiſe "On the Divine Right of Kings," publiſhed by a Daniſh divine; "A Defence of the Sect of the Pictiſts," and other eccentric and ſatirical publications, at laſt inflamed the reſentment of the clergy againſt Thomas to ſuch a degree, that he was threatened with impriſonment. To eſcape the ſtorm which thickened about him, he entreated permiſſion from the Elector of Brandenburg, in whoſe court he had ſeveral friends, that he might read private lectures in the city of Hall. This indulgence being obtained, Thomas became a voluntary exile from Leipſic. After a ſhort interval, he was appointed public profeſſor of juriſprudence, firſt in Berlin, and afterwards at Hall. In theſe ſituations, he found himſelf at full liberty to indulge his ſatirical humour, and to engage in the controverſies of the times: and as long as he lived, he continued to make uſe of this liberty in a manner which ſubjected him to much odium. At the ſame time, he perſevered in his endeavours to correct and ſubdue the prejudices of mankind, and to improve the ſtate of philoſophy. He died at Hall in the year 1728.

Beſides the ſatirical journal already mentioned, Thomas wrote ſeveral treatiſes on logic, morals, and juriſprudence; in which he advanced many dogmas contra-

Thomas, Thornton.

ry to received opinions. In his writings on phyſics, he leaves the ground of experiment and rational inveſtigation, and appears among the myſtics. His later pieces are in many particulars inconſiſtent with the former.—His principal philoſophical works are, "An Introduction to Aulic Philoſophy, or Outlines of the Art of Thinking and Reaſoning;" "Introduction to Rational Philoſophy;" "A Logical Praxis;" "Introduction to Moral Philoſophy;" "A Cure for Irregular Paſſions, and the Doctrine of Self-Knowledge;" "The new Art of diſcovering the ſecret Thoughts of Men;" "Divine Juriſprudence;" "Foundations of the Law of Nature and Nations;" "Diſſertation on the Crime of Magic;" "Eſſay on the Nature and Eſſence of Spirit, or Principles of Natural and Moral Science;" "Hiſtory of Wiſdom and Folly"

From the ſpecimen given by Dr Enfield of his more peculiar tenets (for we have read none of his books), Thomas appears to have been a man of wonderful inconſiſtency in his opinions; teaching on one ſubject rational piety and true ſcience, and on another abſurdity and atheiſm. "No other rule (he ſays) is neceſſary in reaſoning, than that of following the natural order of inveſtigation; beginning with thoſe things which are beſt known, and proceeding, by eaſy ſteps, to thoſe which are more difficult." This is perfectly conſiſtent with the foundation of the Baconian logic; and is indeed the only foundation upon which a ſyſtem of ſcience can poſſibly be built. Yet could the man, who profeſſes to proceed from a principle ſo well eſtabliſhed, gravely advance, as concluſions of ſcience, the following abſurdities: "Perception is a paſſive affection, produced by ſome external object, either in the intellectual ſenſe, or in the inclination of the will. God is not perceived by the intellectual ſenſe, but by the inclination of the will: for creatures affect the brain; but God, the heart. All creatures are in God: nothing is exterior to him. Creation is extenſion produced from nothing by the divine power. Creatures are of two kinds, paſſive and active; the former is matter, the latter ſpirit. Matter is dark and cold, and capable of being acted upon by ſpirit, which is light, warm, and active. Spirit may ſubſiſt without matter, but deſires a union with it. All bodies conſiſt of matter and ſpirit, and have therefore ſome kind of life. Spirit attracts ſpirit, and thus ſenſibly operates upon matter united to ſpirit. This attraction in man is called *love;* in other bodies, *ſympathy*. A finite ſpirit may be conſidered as a limited ſphere, in which rays, luminous, warm, and active, flow from a centre. Spirit is the region of the body to which it is united. The region of finite ſpirits is God. The human ſoul is a ray from the divine nature; whence it deſires union with God, who is love. Since the eſſence of ſpirit conſiſts in action, and of body in paſſion, ſpirit may exiſt without thought: of this kind are light, ether, and other active principles in nature." Fortunately, this jargon is as unintelligible as the categories of Kant, and the blaſphemies of Spinoza; for an account of which, the reader is referred to *Critical* PHILOSOPHY in this *Suppl.* and to SPINOZA in the *Encycl.*

Biographical Dictionary

THORNTON (Bonnel), a modern poet, the intimate friend of Lloyd and Colman, and juſtly claſſed with them in point of talents, was born in Maiden-lane, London, in the year 1724. He was the ſon of an apothecary; and being educated at Weſtminſter ſchool, was elected to Chriſt-Church, Oxford, in the year 1743. He was thus eight years ſenior to Colman, who was elected off in 1751. The firſt publication in which he was concerned was, "The Student, or Oxford and Cambridge Miſcellany," which appeared in monthly numbers; and was collected in two volumes 8vo, in 1748. Smart was the chief conductor of the work; but Thornton, and other wits of both univerſities, aſſiſted in it. He took his degree of maſter of arts in 1750; and as his father wiſhed him to make phyſic his profeſſion, he took the degree of bachelor of that faculty in 1754. In the ſame year he undertook the periodical paper called *The Connoiſſeur*, in conjunction with Colman, which they continued weekly to the 30th of September 1756. In the concluding paper, the different ages and purſuits of the two authors are thus jocularly pointed out, in the deſcription of the double author, Mr Town. "Mr Town is a fair, black, middle ſized, very ſhort man. He wears his own hair and a periwig. He is about thirty years of age (literally thirty-two), and not more than four-and-twenty. He is a ſtudent of the law and a bachelor of phyſic. He was bred at the univerſity of Oxford, where, having taken no leſs than three degrees, he looks down on many learned profeſſors as his inferiors: yet having been there but little longer than to take the firſt degree of bachelor of arts, it has more than once happened that the cenſor-general of all England has been reprimanded by the cenſor of his college, for neglecting to furniſh the uſual eſſay, or, in the collegiate phraſe, the theme of the week." Engaged in purſuits of this kind, Bonnel Thornton did not very cloſely follow the profeſſion to which his father deſtined him, but lived rather a literary life, employing his pen on various ſubjects. To the daily paper called the *Public Advertiſer*, then in high reputation, he was a frequent contributor: and he once had it in contemplation to treat with Mr Rich for the patent of Covent Garden theatre. In 1764, Mr Thornton married Miſs Sylvia Brathwaite, youngeſt daughter of Colonel Brathwaite, who had been governor of a fort in Africa. In 1766, encouraged, as he ſays himſelf, by the ſucceſs of his friend Colman's Terence, he publiſhed two volumes of a tranſlation of Plautus in blank verſe; propoſing to complete the whole if that ſpecimen ſhould be approved. Theſe volumes contained ſeven plays, of which the *Captive* was tranſlated by Mr Warner, who afterwards completed all that Thornton had left unfiniſhed; and the *Mercator* by Mr Colman. The remaining five are, the *Amphitryon*, *Miles Glorioſus*, *Trinummus*, *Aulularia*, *Rudens*. Some parts of the remaining plays which Thornton had tranſlated are preſerved by his continuator. There can be no doubt that this is the beſt way of tranſlating the old comedies, and that Thornton was well qualified for the taſk; but the work has never been in high favour with the public. Yet Warburton ſaid of it, that "he never read ſo juſt a tranſlation, in ſo pure and elegant a ſtyle." Thornton publiſhed in 1767, *The Battle of the Wigs*, as an additional canto to Garth's Diſpenſary; the ſubject of which was the diſputes then ſubſiſting between the fellows and licentiates.

The life of Thornton was not deſtined to attain any great extenſion: in the prime of his days, while he was ſurrounded by domeſtic felicity, the comforts of fortune, Thornton, Thunder.

tune, and the reſpect of ſociety, ill health came upon him; and medical aid proving inefficient, he died, of the gout in his ſtomach, May 9 1768, at only 44 years of age. His wife, a daughter, and two ſons, ſurvived him. Beſides the productions already mentioned, he wrote the papers in the Adventurer marked A; "An Ode to St Cecilia's day, adapted to the ancient Britiſh Muſic," a burleſque performance; "The Oxford Barber;" with many detached eſſays in the public papers. A few letters addreſſed to his Sylvia before they were married, diſplay great tenderneſs, expreſſed with frankneſs and eaſe. A ſmall edition of his works might, with much propriety, be preſented to the public, before it ſhall be too late to aſcertain them all. His character may be taken from his epitaph, written in Latin by his friend Dr Warton, and placed on his monument in Weſtminſter Abbey. It is to this effect: "His genius, cultivated moſt happily by every kind of polite literature, was accompanied and recommended by manners open, ſincere, and candid. In his writings and converſation he had a wonderful livelineſs, with a vein of pleaſantry peculiarly his own. In ridiculing the failings of men, without bitterneſs, and with much humour, he was ſingularly happy; as a companion, he was delightful."

1. THUNDER. There is not one of the appearances of nature which has ſo much engaged the attention of mankind as thunder. The ſavage, the citizen, and the philoſopher, have obſerved it with dread, with anxiety, and with curioſity; and the philoſopher of our times treats the others with a ſmile of condeſcenſion, while he here enjoys the fulleſt triumph of his ſuperiority.

> *Felix qui potuit rerum cognoſcere cauſas,*
> *Atque metus omnes et inevitabile fulmen*
> *Subjecit pedibus.*

But though this grand phenomenon has long engaged the curious attention of philoſophers, it is but very lately that they have been able to explain it; that is, to point out the more general law of nature of which it is a particular inſtance. Inflammable vapours had long furniſhed them with a ſort of explanation. The diſcovery of gunpowder, and ſtill more that of inflammable air, gave ſome probability to the exiſtence of extenſive ſtrata of inflammable vapours in the upper regions of the atmoſphere, which, being ſet on fire at one end, might burn away in rapid ſucceſſion, like a train of gunpowder. But the ſmalleſt inveſtigation would ſhew ſuch a diſſimilarity in the phenomena, and in the general effects, that this explanation can have no value in the eyes of a true naturaliſt. Horrid exploſion, and a blaſt which would ſweep every thing from the ſurface of the earth, muſt be the effects of ſuch inflammation. The very limited and capricious nature of the ravages made by thunder, render them altogether unlike exploſions of elaſtic fluids.

2
Thunder reſembles the electrical ſhock

No ſooner were the wonderful effects of the charged electrical phial obſerved, than naturaliſts began to think of this as exhibiting ſome reſemblance to a thunderſtroke (ſee Electricity, *Encycl.* n° 12.); but it was not till toward the year 1750 that this reſemblance was viewed in a proper light by the celebrated Franklin. In a diſſertation written that year, he delivers his opinion at large, and notices particularly the following circumſtances of ſimilarity.

Thunder in ſeveral remarkable particulars

1. The colour and crooked form of lightning, perfectly ſimilar to that of a vivid electrical ſpark between diſtant bodies, and unlike every other appearance of light. This angular, deſultory, capricious form of an electrical ſpark, and of forked lightning, is very ſingular. No two ſucceſſive ſparks have the ſame form. Their ſharp angles are unlike every appearance of motion through unreſiſting air: Such motions are always curvilineal. The ſpark is like the ſimultaneous exiſtence of the light in all its parts; and the fact is, that no perſon can poſitively ſay in which direction it moves.

2. Lightning, like electricity, always ſtrikes the moſt advanced objects—hills, trees, ſteeples.

3. Lightning affects to take the beſt conductors of electricity. Bell wires are very frequently deſtroyed by it. At Leven houſe in Fifeſhire, in 1733, it ran along a gilded moulding from one end of the houſe to the other, exploding it all the way, as alſo the tinfoil on the backs of ſeveral mirrors, and the gilding of ſcreens and leather hangings.

4. It burns, explodes, and deſtroys theſe conductors preciſely as electricity does. It diſſolves metals; melts wires; it explodes and tears to pieces bodies which contain moiſture. When a perſon is killed by lightning, his ſhoes are commonly burſt. When it falls on a wet ſurface, it ſpreads along it. The Royal William, in Louiſburgh harbour, in 1758, received a thunderſtroke, which diſſipated the maintop-gallant maſt in duſt, and came down on the wet decks in one ſpark, which ſpread over the whole deck as a ſpout of water would have done. This is quite according to electrical laws.

5. It has ſometimes ſtruck a perſon blind. Electricity has done the ſame to a chicken which it did not kill.

6. It affects the nervous ſyſtem in a way reſembling ſome of the known effects of electricity. The following is a moſt remarkable inſtance: —— Campbell, Eſq; of Succoth, in Dunbartonſhire, had been blind for ſeveral years. The diſorder was a gutta ſerena. He was led one evening along the ſtreets of Glaſgow by his ſervant Alexander Dick, during a terrible thunder ſtorm. The lightning ſometimes fluttered along the ſtreets for a quarter of a minute without ceaſing. While this fluttering laſted, Mr Campbell ſaw the ſtreet diſtinctly, and the changes which had been made in that part by taking down one of the city gates. When the ſtorm was over, his entire blindneſs returned.—We have from a friend another inſtance, no leſs remarkable. One evening in autumn he was ſitting with a gentleman who had the ſame diſorder, and he obſerved ſeveral lambent flaſhes of lightning. Their faces were turned to the parlour window; and immediately after a flaſh, the gentleman ſaid to his wife "Go, my dear, make them ſhut the white gate; it is open, you ſee." The lady did ſo, and returned; and, after a little, ſaid, "But how did you know that the gate was open?" He exclaimed, "My God! I ſaw it open, and two men look in, and go away again," (which our friend alſo had obſerved). The gentleman, on being cloſe queſtioned, could not recollect having had another glance, nor why it had not ſurpriſed him; but of the glimpſe itſelf he was certain, and deſcribed the appearance very exactly.

7. Lightning kills; and the appearances perfectly

reſemble thoſe of a mortal ſtroke of electricity. The muſcles are all in a ſtate of perfect relaxation, even in thoſe ſituations where it is uſually otherwiſe.

8. Lightning is well known to deſtroy and to change the polarity of the mariner's needle.

3
r Frank-
n diſco-
ered that
was the
me.

Dr Franklin was not contented with the bare obſervation of theſe important reſemblances. He availed himſelf of many curious diſcoveries which he had made of electrical laws. In particular, having obſerved that electricity was drawn off at a great diſtance, and without the leaſt violence of action, by a ſharp metallic point, he propoſed to philoſophers to erect a tall maſt or pole on the higheſt part of a building, and to furniſh the top of it with a fine metalline point, properly inſulated, with a wire leading to an inſulated apparatus for exhibiting the common electrical appearances. To the whole of this contrivance he gave the name of *thunder-rod*, which it ſtill retains. He had not a proper opportunity of doing this himſelf at the time of writing his diſſertation in a letter from Philadelphia to the Royal Society of London; but the contents were ſo ſcientific, and ſo intereſting, that in a few weeks time they were known over all Europe. His directions were followed in many places. In particular, the French academicians, encouraged by the preſence of their monarch, and the great ſatisfaction which he expreſſed at the repetition of Dr Franklin's moſt inſtructive experiments, which diſcovered and eſtabliſhed the theory of poſitive and negative electricity, as it is ſtill received, were eager to execute his orders, making his grand experiment, which promiſed ſo fairly to bring this tremendous operation of nature not only within the pale of ſcience, but within the management of human power.

But, in the mean time, Dr Franklin, impatient of delay, and perhaps incited by the honourable deſire of well-deſerved fame, put his own ſcheme in practice. His inventive mind ſuggeſted to him a moſt ingenious method of preſenting a point to a thunder cloud at a very great diſtance from the ground. This was by fixing his point on the head of a paper kite, which the wind ſhould raiſe to the clouds, while the wet ſtring that held it ſhould ſerve for a conductor of the electricity. We preſume that it was with a palpitating heart that Dr Franklin, unknown to the neighbours, and accompanied only by his ſon, went into the fields, and ſent up his meſſenger that was to bring him ſuch news from the heavens. He told a perſon, who repeated it in the hearing of the preſent writer, that when he ſaw the fibres of the cord raiſe themſelves up like hogs briſtles, he uttered a deep ſigh, and would have wiſhed that moment of joy to have been his laſt. He obtained but a few faint ſparks from his apparatus that day; but returned to his houſe in a ſtate of perfect happineſs, now feeling that his name was never to die. Thus did the ſoap bubble, and the paper kite, from being the playthings of children, become, in the hands of Newton, and of Franklin, the means of acquiring immortal honour, and of doing the moſt important ſervice to ſociety.

We may juſtly conſider this as one of the greateſt of philoſophical diſcoveries, and as doing the higheſt honour to the inventor; for it was not a ſuggeſtion from an accidental obſervation, but aroſe from a ſcientific compariſon of facts, and a ſagacious application of the doctrine of poſitive and negative electricity; a doctrine wholly Dr Franklin's, and the reſult of the moſt acute and diſcriminating obſervation. It was this alone that ſuggeſted the whole; and by explaining to his ſatisfaction the curious property of ſharp points, gave him the courage to handle the thunderbolt of Jove.

It is then a point fully aſcertained, that thunder and lightning are the electric ſnap and ſpark, as much ſuperior to our puny imitations as we can conceive from the immenſe extent of the inſtruments in the hands of Nature. If, ſays Dr Franklin, a conductor one foot thick and five feet long will produce ſuch ſnaps as agitate the whole human frame, what may we not expect from a ſurface of 10,000 acres of electrified clouds? How loud muſt be the exploſion? how terrible the effects?

4
Electrical
ſtates of the
atmoſ-
phere.

This diſcovery immediately directed the attention of philoſophers to the ſtate of the atmoſphere with reſpect to electricity; and in this alſo Dr Franklin led the way. He immediately erected his thunder rods; and they have been imitated all over the world, with many alterations or improvements, according to the different views and ſkill of their authors. It is needleſs to inſiſt here on their conſtruction. They have been deſcribed in the article ELECTRICITY (*Encycl.*); and any perſon well acquainted with its theory, as laid down in the *Supplementary* article ELECTRICITY, will be at no loſs to accommodate his own conſtruction to his ſituation and purpoſes.

Dr Franklin took the lead, as we have already obſerved, in this examination of the electrical ſtate of the atmoſphere. He ſeldom found it without giving ſigns of electricity, and this was generally negative. See *Phil. Tranſ.* Vol. XLVIII. p. 358. and 785.

Mr Canton repeated thoſe experiments, and found the ſame reſults; both, however, found that the electricity would frequently change from poſitive to negative, and from negative to poſitive, in very ſhort ſpaces of time, as different portions of clouds or air paſſed the thunder-rod.

5
Cautions to
be obſerved
in this exa-
mination
by a thun-
der rod.

We muſt here remark, that our acquaintance with the laws of electricity ſufficiently informs us, that the electricity of our thunder rod may frequently be of a different kind from that of the cloud which excites the appearances at our apparatus. We know that air, like glaſs, is a non-conductor; and that when it is brought into any ſtate of electricity, either by communication, or by mere induction, it will remain in that ſtate for ſome time, and that it always changes its electricity *per ſtratum*. A poſitive cloud, in the higher regions of the atmoſphere, will render the air immediately below it negative, and a ſtratum below that poſitive. If the thunder rod be in this poſitive ſtratum, it will exhibit poſitive electricity; but if the cloud be conſiderably nearer, the rod, by being in the adjoining negative ſtratum, may ſhow a negative electricity, which will exceed the poſitive electricity which the diſtant poſitive cloud would have induced on its lower end by mere poſition, had the intervening air been away. This exceſs of negative electricity muſt depend on the degree in which the ſurrounding ſtratum of air has been rendered negative. If this has been the almoſt inſtantaneous effect of the preſence of the poſitive cloud, it cannot be rendered ſo negative as to produce negative electricity in the lower

Thunder.

end of the thunder rod. But if the ſtratum of air has for ſome conſiderable time accompanied the poſitive cloud, its negative electricity has been increaſing, and ſome would remain, even if the cloud were removed. We muſt, at all times, conſider the thunder rod as affected by *all* the electricity in its neighbourhood. The diſtant poſitive cloud would at any rate render the lower end of the rod poſitive, without communication, by merely diſplacing the electricity in the rod itſelf, juſt as the north pole of a loadſtone would make the remote end of a ſoft iron rod a north pole. In like manner, the negative ſtratum of air immediately adjoining to the poſitive cloud would make the lower end of the rod negative, without communication. A poſitive ſtratum of air below this would have the contrary effect. The appearances, then, at the end of the rod, muſt be the reſult of the prevalence of one of theſe above the others; and many intervening circumſtances muſt be underſtood, before we can infer with certainty the ſtate of a cloud from the appearances at the lower end of the apparatus. It would, therefore, be a moſt inſtructive addition to a thunder rod to have an electroſcope at both ends. If they ſhew the ſame kind of electricity, we may be aſſured that it is by communication, and is the ſame with that of the ſurrounding ſtratum of air: But if they ſhew oppoſite electricities (which is generally the caſe), then we learn that it is by poſition or induction. We recommend this to the careful attention of the philoſopher.

In this way we perfectly explain an appearance which puzzled both of the above-mentioned obſervers. When a ſingle low cloud approached the rod, the electroſcope would ſhew poſitive electricity, but negative when the cloud was in the zenith, and poſitive again when it had paſſed by. We alſo learn from this the cauſe of Dr Franklin's diſappointment in his expectations of very remarkable phenomena by means of his kite. He imagined that it would be vaſtly ſuperior to the apparatus which he had recommended to the philoſophers of Europe. But the ſtring of the kite, traverſing ſeveral ſtrata in different ſtates of electricity, ſerved as a conductor between them, and he could only obtain the ſuperplus; which might be nothing, even when the clouds were ſtrongly electrified.

The moſt copious and curious obſervations on the electrical ſtate of the atmoſphere are thoſe by Profeſſor Beccaria of Turin. He had connected the tops of ſeveral ſteeples of the city by inſulated wires. He did the ſame thing at a monaſtery on a high hill in the neighbourhood. Each of theſe collected the electricity of a ſeparate ſtratum of conſiderable extent. He frequently found theſe two ſtrata in oppoſite ſtates of ſtrong electricity.

6
Beccaria's general laws of atmoſpheric electricity.

The following general obſervations are made out from a compariſon of a vaſt variety of more particular ones made in different places:

1. The air is almoſt always electrical, eſpecially in the day time and dry weather; and the electricity is generally poſitive. It does not become negative, unleſs by winds from places where it rains, ſnows, or is foggy.

2. The moiſture of the air is the conſtant conductor of its electricity in clear weather.

3. When dark or wet weather clears up, the electricity is always negative. If it has been very moiſt, and dries very faſt, the electricity is very intenſe, and diminiſhes when the air attains its greateſt dryneſs; and may continue long ſtationary, by a ſupply of air in a drying ſtate from diſtant places.

Thunde

4. If, while the ſky overcaſts in the zenith, only a high cloud is formed, without any ſecondary clouds under it, and if this cloud is not the extenſion of another which rains in ſome remote place, the electricity (if any) is always poſitive.

5. If the clouds, while gathering, are ſhaped like locks of wool, and are in a ſtate of motion among each other; or if the general cloud is forming far aloft, and ſtretches down like deſcending ſmoke, a frequent poſitive electricity prevails, more intenſe as the changes in the atmoſphere are quicker; and its intenſity predicts the great quantity of ſnow or rain which is to follow

6. When an extenſive, thin, level cloud forms, and darkens the ſky, we have ſtrong poſitive electricity.

7. Low thick fogs, riſing into dry air, carry up ſo much electricity as to produce ſparks at the apparatus. If the fog continues round the apparatus without riſing, the electricity fails.

8. When, in clear weather, a cloud paſſes over the apparatus, low and tardy in its progreſs, and far from any other, the poſitive electricity gradually diminiſhes, and returns when the cloud has gone over.

9 When many white clouds gather over head, continually uniting with and parting from each other, and thus form a body of great extent, the poſitive electricity increaſes.

10. In the morning, when the hygrometer indicates dryneſs equal to that of the preceding day, poſitive electricity obtains, even before ſunriſe.

11. As the ſun gets up, this electricity increaſes; more remarkably if the dryneſs increaſes. It diminiſhes in the evening.

12. The mid day electricity, of days equally dry, is proportional to the heat.

13. Winds always leſſen the electricity of a clear day, eſpecially if damp; therefore they do not electrify the air by friction on ſolid bodies.

14. In cold ſeaſons, with a clear ſky and little wind, a conſiderable electricity ariſes after ſunſet, at dew falling.

The ſame happens in temperate and warm weather.

If, in the ſame circumſtances, the general dryneſs of the air is leſs, the electricity is alſo leſs.

15. The electricity of dew, like that of rain, depends on its quantity. This electricity of dew may be imitated by electrifying the air of a cloſe room (not too dry), and filling a bottle with very cold water, and ſetting it in the upper part of the room. As the damp condenſes on its ſides, an electrometer will ſhew very vivid electricity.

Such a collection of obſervations, to be fit for inference, requires very nice diſcrimination. It is frequently difficult to diſcover electricity in damp air, though it is then generally ſtrongeſt; becauſe the inſulation of the apparatus is hurt by the dampneſs. To make the obſervation with accuracy, requires a portable apparatus, whoſe inſulation can be made good at all times. With ſuch apparatus we ſhall never miſs obſerving electricity in fogs, or during ſnow.

Curiou phenor non of ticklin fog.

There is a very curious phenomenon, which may be frequently obſerved in Edinburgh, and no doubt in other towns ſimilarly ſituated. In a clear day of the month

month of May, an eaſterly wind frequently brings a fog with it, which advances from the ſea in a denſe body; and when it comes up the High-ſtreet, it chills the body exceedingly, while it does not greatly affect the thermometer. Immediately before its gaining the ſtreet, one feels like a tickling on the face, as if a cobweb had fallen on it, and naturally puts up his hand, and rubs the face. We have never found this to fail, and have often been amuſed with ſeeing every perſon rubbing his face in his turn. The writer of this article has obſerved the ſame thing at St Peterſburgh, in a ſummer's evening, when a low fog came on about ten o'clock.

The general appearances of a thunder ſtorm are nearly as follow:

7
Phenomena of a thunder ſtorm.

For the moſt part the wind is gentle, or it is calm. A low denſe cloud begins in a place previouſly clear: this increaſes faſt in ſize; but this is only upwards, and in an arched form, like great bags of cotton. The lower ſurface of the cloud is commonly level, as if it reſted on a glaſs plane.

Soon after appear numberleſs ſmall ragged clouds, like flakes of cotton teazled out. Theſe are moving about in various uncertain directions, and continually changing their ragged ſhape. This change, however, is generally by augmentation. Whatever occaſions the precipitation of the diſſolved water ſeems to gain ground. As theſe clouds move about, they approach each other, and then ſtretch out their ragged arms toward each other. This is not by an augmentation, but by a real bending of theſe tatters towards the other cloud. They ſeldom come into contact; but after coming very near in ſome parts, they as plainly recede, either in whole, or by bending their arms away from each other.

But during this confuſed motion, the whole maſs of ſmall clouds approaches the great one above it: and when near it, the clouds of the lower maſs frequently coaleſce with each other before they finally coaleſce with the upper cloud: But as frequently the upper cloud increaſes without them. Its lower ſurface, from being level and ſmooth, now becomes ragged, and its tatters ſtretch down towards the others, and long arms are extended towards the ground. The heavens now darken apace, the whole maſs ſinks down; wind ariſes, and frequently ſhifts in ſqualls; ſmall clouds are now moving ſwiftly in various directions; lightning now darts from cloud to cloud. A ſpark is ſometimes ſeen co-exiſtent through a vaſt horizontal extent, of a crooked ſhape, and of different brilliancy in its different parts. Lightning ſtrikes between the clouds and the earth—frequently in two places at once. A continuation of theſe ſnaps rarifies the cloud; and in time it diſſipates. This is accompanied by heavy rain or hail; and then the upper part of the clouds is high and thin.

During this progreſs of the ſtorm, the thunder rod is ſtrongly electrified; chiefly when the principal cloud is over head. The ſtate of the electricity frequently changes from poſitive to negative—almoſt every flaſh, however diſtant, occaſions a ſudden ſtart of the electroſcope, and then a change of the electricity. When the cloud is more uniform, the electricity is ſo too.

8
Sources of atmoſpheric electricity.

The queſtion now is, In what manner does the air acquire this electricity? How come its different parts to be in different ſtates, and to retain this difference for a length of time? and how is the electric equilibrium reſtored with that rapidity, and to that extent, that we obſerve in a thunder ſtorm? For we know that air is a very imperfect conductor, and tranſmits electricity to ſmall diſtances only, and very ſlowly. We ſhall mention ſeveral circumſtances, which are known facts in electricity, and muſt frequently concur, at leaſt, with the other cauſes of this grand phenomenon.

Air is rendered electrical in a great variety of ways.

1. All operations which excite electricity in other bodies have the ſame effect on air. It is electrified by friction. When blown on any body, ſuch as glaſs, &c. that body exhibits electricity by a ſenſible electroſcope. We therefore conclude that the air has acquired the oppoſite electricity from this rubber. A glaſs veſſel, exhauſted of air, and broken in the dark, gives a loud crack, and a very ſenſible flaſh of light. An air-gun, diſcharged (without a ball) in the dark, does the ſame. Blowing on an electric with a pair of bellows never fails to excite it. In ſhort, the facts to this purpoſe are numberleſs.

2. Electricity is produced by a number of chemical operations, which are continually going on. The melting and freezing of electric bodies in contact with each other, ſuch as chocolate in its moulds, wax-candles in their moulds, ſealing-wax, &c. Nay, it is highly probable that any body, in paſſing from its fluid to its ſolid form, or the contrary, is electrical. This is the caſe when a ſolution of Glauber's ſalt, or of nitre, in water, is made to cryſtallize all at once by agitation.

The ſolution of bodies in their menſtrua is, in like manner, productive of electricity in many caſes Thus iron or chalk, while diſſolving in the ſulphuric acid, produce negative electricity in the mixture, and poſitive in the electric vapours which ariſe from them.

A moſt copious ſource of electricity is the converſion of water into elaſtic ſteam by violent heats. When this is done in a proper apparatus, the electricity of the liquid is negative, and the vapour is poſitive. But if this be accompanied by a decompoſition of the water, the liquid is ſometimes ſtrongly negative. Thus, when water evaporates ſuddenly from a red hot ſilver cup, the cup is ſtrongly negative; but if from clean red hot iron, ſo that the iron is calcined, and inflammable air produced, the iron is poſitive. If the decompoſition of the water is ſufficiently copious to do more than compenſate for the negative electricity produced by the mere expanſion of the water into ſteam, the electricity is poſitive: but not otherwiſe. Water expanded from a piece of red hot coal always gives negative electricity, and this frequently very ſtrong. Theſe experiments ſhould always be made in metalline veſſels. If made in glaſs veſſels, the glaſs takes a charge, which expends the produced electricity, and remains nearly neutral, ſo that the production of electricity is not obſerved. Theſe facts are to be found among many experiments of Mr Sauſſure. But there is here a very wide field of new inquiry, which cannot fail of being very inſtructive, and particularly in the preſent queſtion. We ſee ſome of the effects very diſtinctly in ſeveral phenomena of thunder and lightning. Thus, the great eruptions of Ætna and Veſuvius are always accompanied by forked lightnings, which are ſeen darting among the volumes of emitted ſmoke and ſteam. Here is a very copious converſion of water into elaſtic ſteam; and here alſo it is moſt reaſonable to expect a copious decompoſition of water, by the iron and coally matters, which are expoſed to the joint action of fire and water. Theſe two electricities will be oppoſite; or when not oppoſite, will not be equal: in either of which caſes, we have vaſt maſſes of ſteam in ſtates fit for flaſhing into each other.

A fact more to our purpoſe is, that if a ſilk or linen cloth, of a downy texture, be moiſtened or damped, and hung before a clear fire to dry, the fibres briſtle up, and on bringing the finger, or a metal knob, near them, they are plainly attracted by it. We found them negatively electric. This ſhews that the ſimple ſolution of water in air produces electricity. And this is the chief operation in Nature connected with the ſtate of the atmoſphere. It is thus that the watery vapours from all bodies, and particularly the copious exſudation of plants, diſappear in our atmoſphere. There can be no doubt but that the oppoſite electricity will be produced by the precipitation of this vapour; that is, by the formation of clouds in clear air. When damp, but clear air in one veſſel expands into an adjoining veſſel, from which the air has been exhauſted, a cloud appears in both, and a delicate electrometer is affected in both veſſels; but our apparatus was not fitted for aſcertaining the kind of electricity produced. Here then is another unexplored field of experiment. We got two veſſels made, having diaphragms of thin ſilk. Theſe were damped, and ſet into two tubs of water, of very different temperatures. Dry air was then blown thro' them, and came from their ſpouts ſaturated with water. The ſpouts were turned toward each other. Being of very different temperatures, the ſtreams produced a cloud upon mixing together, and a ſtrong negative electricity was produced. We even found that an electrometer, placed in a veſſel filled with condenſed air, was affected when this air was allowed to ruſh out by a large hole.

Laſtly, we know that the tourmaline, and many of the columnar cryſtals, are rendered electrical by merely heating and cooling. Nay, Mr Canton found that dry air became negative by heating, and poſitive by cooling, even when it was not permitted to expand or contract.

When water is precipitated, and forms a cloud, it is reaſonable to expect that it will have the electricity of the air from which it is precipitated. This may be various, but in general negative: For the heat by which the air was enabled to diſſolve the water made it negative; and much more the friction on the ſurface of the earth. But as heat cauſed it to diſſolve the water, cold will make it precipitate it; and we ſhould therefore expect that the air will be in the ſtate in which it was when it took up the water. But if it be cooled ſo faſt as to precipitate it in the form of rain, or ſnow, or hail, we may expect poſitive electricity. Accordingly, in ſummer, hail ſhowers always ſhew ſtrong poſitive electricity; ſo does ſnow when falling dry.

Here, then, are copious ſources of atmoſpheric electricity. The mere expanſion and condenſation of the air, and ſtill more the ſolution and precipitation of watery vapours in it, are perhaps ſufficient to account for all the inequality of electric ſtate that we obſerve in the atmoſphere.

The maſſes of air thus differently conſtituted are evidently diſpoſed in ſtrata The clouds are ſeen to be ſo. Theſe clouds are not the ſtrata, but the boundaries of ſtrata; which, from the very nature of things, are in different ſtates with reſpect to the ſuſception or precipitation of water. When two ſuch ſtrata are thus adjoining, they will ſlowly act on each other's temperature, and by mixing will form a thin ſtratum of cloud along their mutual confines. If the one ſtratum has any motion relative to the other, and be in the ſmalleſt degree diſturbed, they will mix to a greater depth in each; and this mixture will not be perfectly uniform. The extreme mobility of air will greatly increaſe this jumble of the adjoining parts of the two ſtrata, and will give the cloud a greater thickneſs. If the jumble has been very great, ſo as to puſh one of them through the other, we ſhall have great towering clouds, perhaps pervading the whole thickneſs of the ſtratum of air. We take theſe clouds to be like great foggy bladders, ſuperficially opaque where they have come into contact with the ſurrounding ſtratum of air, but tranſparent within.

9
Strata of the atmoſphere are in different ſtates of electricity, and are tranſparent.

When the wind, or ſtratum in motion, does not puſh all the quieſcent air before it, it generally gets over it, and then flows along its upper ſide, and, by a partial mixing, produces a fleecy cloud, as already deſcribed. We may obſerve here, by the way, that the motion of thoſe fleecy clouds is by no means a juſt indication of the motion of the ſtratum; it is nearly the motion compoſed of the half of the motions of the two.

10
Theſe ſtrata have ſtrata of clouds interpoſed.

This is in all probability the ſtate of the atmoſphere, conſiſting of ſtrata of clear air many hundred yards thick, ſeparated from each other by thin fleeces of clouds, which have been produced by the mixture of the two adjoining ſtrata. This is no fancy; for we actually ſee the ſky ſeparated by ſtrata of clouds at a great diſtance from each other. And we ſee that theſe ſtrata maintain their ſituations, without farther admixture, for a long time, the bounding clouds continuing all the while to move in different directions. In the year 1759, during the ſiege of Quebec, a hard gale blew one day from the weſtward, which made it almoſt impracticable to ſend a number of proviſion-boats to our troops ſtationed above the town. While the men were tugging hard at the oars againſt the wind, and hardly advancing, though the tide of flood favoured them, the French threw ſome bombs to deſtroy the boats. One of theſe burſt in the air, near the top of its flight, which was about a quarter of a mile high. The round ball of ſmoke produced by the exploſion remained in the ſame ſpot for above ſeven minutes, and diſappeared by gradual diffuſion. The lower air was moving to the eaſtward at leaſt 30 feet per ſecond.

In 1783, when a great fleet rendezvouſed in Leith Roads, the ſhips were detained by an eaſterly wind, which had blown for ſix weeks without intermiſſion. The ſky was generally clear; ſometimes there was a thin fleece of clouds at a great height, moving much more ſlowly in the ſame direction with the wind below. During the laſt eight days, the upper current was from the weſtward, as appeared by the motion of the upper clouds. High towering clouds came down the river, with a little rain; the ſtrata were jumbled, and the whole atmoſphere grew hazy and uniform; then came thunder, and heavy rain, and the wind below ſhifted to the weſtward.

Thus it is ſufficiently evinced, that the atmoſphere frequently conſiſts of ſuch ſtrata, well diſtinguiſhed from each other: their appearance and progreſs leave us no room to doubt but that they come from different quarters, and had been taken up or formed at different places, and in different circumſtances, and therefore differing in reſpect of their electrical ſtates.

11 The electric equilibrium is reſtored very ſlowly in general.

The conſequence of their continuing long together would be a gradual but ſlow progreſs of their electricity to a ſtate of equilibrium. The air is perhaps never in a perfectly dry ſtate, and its moiſture will cauſe the electricity to diffuſe itſelf gradually. It is not beyond the power of our mathematics to aſcertain the progreſs of this approximation to the electric equilibrium. We ſee ſomething very like it in the curious experiments of Beccaria with mirror plates laid together, and charged by means of a coating on the outer plates. Theſe plates were found to conſiſt of alternate ſtrata of poſitive and negative electricity, which gradually penetrated through the plates, and coaleſced till they were reduced to two ſtrata; perhaps in time the electricity would have diſappeared entirely by theſe two alſo coaleſcing. In the ſame manner there would be a ſlow transfuſion of ſenſible electricity through theſe ſtrata without any ſenſible appearances. If any collateral cauſes ſhould make a part more damp than the reſt, there would be a more briſk transference through it, accompanied with faint flaſhes of lambent lightning.

12 A rapid and extenſive reſtoration is a thunder clap.

But thunder requires a rapid communication, and a reſtoration of electric equilibrium in an inſtant, and to a vaſt extent. The means for this are at hand, furniſhed by Nature. The ſtrata of charged air are furniſhed with a coating of cloud. The lower ſtratum is coated on the underſide by the earth.

13 Manner in which this is effected by a coating of cloud.

When a jumble is made in any of the ſtrata, a precipitation of vapour muſt generally follow. Thus a conductor is brought between the electrical coatings. This will quickly enlarge, as we ſee that in our little imitations the knobs of our conductors inſtantaneouſly arrange any particles of duſt which chance to lie in the way, in ſuch a manner as to complete the line of conduct, and occaſion a ſpark to fly to a much greater diſtance than it would have leaped if no duſt had been interpoſed. We have often procured a diſcharge between two knobs which were too far aſunder, by merely breathing the damp air between them. In this manner the interpoſed cloud immediately attracts other clouds, grows ragged by the paſſage of electricity through clear air, where it cauſes a precipitation by altering the natural equilibrium of its electricity; for a certain quantity of electricity may be neceſſary for air's holding a certain quantity of vapour. Accordingly we ſee in a thunder ſtorm that ſmall clouds continually and ſuddenly form in parts formerly clear. Whatever cauſes thunder, does in fact promote this precipitation.

Theſe clouds have the electricity of the ſurrounding air, and muſt communicate it to others in an oppoſite ſtate, and within reach. They muſt approach them, and muſt afterwards recede from them, or from any that are in the ſame ſtate of electricity with themſelves. Hence their ragged forms, and the ſimilar form of the under ſurface of the great cloud; hence their continual and capricious ſhifting from place to place: they are carriers, which give and take between the other clouds, and they may become ſtepping ſtones for the general diſcharge.

If a ſmall cloud form a communication with the ground, and the great cloud be poſitive or negative, we muſt have a complete diſcharge, and all the electrical phenomena, with great violence; for this coating of vapour is abundantly complete for the purpoſe. It conſiſts of ſmall veſicles, which are ſufficiently near each other for diſcharging the whole air that is in their interſtices. A phial coated with amalgam is by no means fully coated. If we hold it between the eye and the light, we ſhall ſee that it is only covered with a number of detached points of amalgam, which looks like a cobweb. Yet this glaſs is almoſt completely diſcharged by a ſingle ſpark, the reſiduum being hardly perceptible.

14 The diſcharge is commonly between the clouds

The general ſcene of thunder is the heavens; and it is by no means a frequent caſe that a diſcharge is made into the earth. The air intervening between the earth and the loweſt coating is commonly very much confuſed in conſequence of the hills and dales, which, by altering the currents of the winds, toſs up the inferior parts, and mix them with thoſe above. This generally keeps the earth pretty much in the ſame electrical ſtate as the loweſt ſtratum of clouds.

15 Which are horizontally diſtant.

Nor are the great thunder ſtorms in general inſtances of the reſtoration of equilibrium between two ſtrata immediately incumbent on each other. They ſeem, for the moſt part, to be ſtrokes between two parcels of air which are horizontally diſtant. This, however, we do not affirm with great confidence. Our chief reaſon for thinking ſo is, that in theſe great ſtorms the ſpark or ſhaft of forked lightning is directed horizontally, and ſometimes is ſeen at once through an extent of ſeveral miles.

16 Particular account of forked lightning, and explanation of the long continued and rumbling noiſe of thunder.

The nature of this ſpark has not, we think, been properly conſidered. It is ſimply compared to a long electrical ſpark, which we conceive to be drawn thro' pure air, and is conſidered as marking the actual transference of electricity from one end to the other. But this we doubt very much. We are certain of having obſerved ſhafts of lightning at one and the ſame inſtant ſtretching horizontally, though with many capricious zigzags and lateral ſputterings, at leaſt five miles. We cannot conceive this to have been the ſtriking diſtance, becauſe the greateſt vertical diſtance of the ſtrata is not the half of this. We rather think that it is a ſimultaneous range of diſcharges, each accompanied with light, differently bright, according to the electrical capacity of the cloud into which it is made; and if there is a real transference of electric matter on this occaſion (which we do not affirm), it is only of a ſmall quantity from one cloud to the next adjoining. This we think confirmed by the ſound of thunder. It is not a ſnap, incomparably louder than our loudeſt ſnap from coated glaſs; but a long continued, rumbling, and *very unequable* noiſe. There is no doubt but that this ſnap was almoſt ſimultaneous through the whole extent of the ſpark; but its different parts are conveyed to our ear in time, and are therefore heard by us in ſucceſſion; and it is not an uniform roar, but a rumbling noiſe, unequally loud, according as the different parts of the ſnap are indeed differently loud. We ſhould hear a noiſe of the ſame kind if we ſtood at one end of a long line of ſoldiers, who diſcharged their muſquets (differently loaded) in the ſame inſtant. When any part of the ſpark is very near us, and is not very diffuſe, the ſnap begins with great ſmartneſs, and continues for ſome time, not unlike the violent tearing of a piece of ſtrong ſilk; after which it becomes more and more mellow as it comes from a greater diſtance. We do not, however, affirm, that the whole extenſive ſpark and ſnap are co-exiſtent or ſimultaneous. The cloud is, in all probability, but an indifferent conductor, and even a ſenſible time may elapſe during the propagation of the ſpark to a great diſtance. Beccaria obſerved this in a line of 250 feet of chain, lying looſely on the ground, and conſiſting of near 6000 links. He thought that it employed a full ſecond; but when the chain was gently ſtretched, the communication ſeemed inſtantaneous.

17
Obſervations on the electric ſpark.

We cannot help thinking that even the electrical ſnap between two metal knobs is of the ſame kind. Not a quantity of luminous matter which iſſues from the one and goes to the other, but a light that is excited or produced in different material interjacent particles of air or other interpoſed matter. The angular and ſputtering form is quite incompatible with the motion of a ſimple luminous point. Nay, our chemical knowledge here comes in aid, and obliges us to ſpeculate about the manner in which this light is produced. Whence does it come? It may be produced by two knobs of ice. We know that water conſiſts of vital and inflammable air, which have already emitted the light which made an ingredient of their compoſition. The ſpark therefore does not come from the ice. Is it then from the air? If ſo, perhaps water is produced, or rather ſomething elſe, for there is not always inflammable air at hand to compoſe water. Yet the transference of electricity has decompoſed the air, or has robbed it of part of its light. The remainder may not be water; but it is no longer air. Is not this confirmed by the peculiar ſmell which always accompanies electric ſparks? and the peculiar taſte, not unlike the taſte felt on the tongue when it is touched by the zinc in the experiments on GALVANISM? Even the fine pencil of light which flows from a point poſitively electrified, appears through a magnifying glaſs to conſiſt, not of luminous lines, but of lines of luminous points. And theſe points are of different brilliancy and different colour, both of which are inceſſantly changing. And be it farther obſerved, that theſe lines are curves, diverging from each other, and convex to the axis. This circumſtance indicates a mutual repulſion, ariſing, in all probability, from the expanſion of the air. And, laſtly, no ſpark nor light of any kind can be obtained in a ſpace perfectly void of air.

All theſe circumſtances concur in explaining the nature of the ſhaft of forked lightning. It is a ſeries of appearances excited in the intervening medium, and which produce ſome chemical change in it. Thunder, when it ſtrikes a houſe, always leaves a peculiar ſmell. Inflammable air has alſo a peculiar and very diſagreeable ſmell. The ſmell produced by electricity greatly reſembles the ſmell produced by ſtriking two pieces of quartz together.

18
Deluc's notion of thunder not probable.

Mr Deluc ſuppoſes that the electrical ſpark, as it is exhibited in thunder, is always accompanied by the decompoſition of air now ſo familiarly known, and that this is the origin of the deluge of rain which commonly finiſhes the ſtorm. But this is not in the ſmalleſt degree probable. The decompoſition extends ſurely no farther than where the light is ſeparated; and we ſhould no more expect a deluge of rain, even if we had inflammable air ready at hand, than we expect drops of water in our electrical experiments. Something different from water follows this decompoſition, total or partial, of the vital air; and the water which we do obſerve to accompany thunder, is no more than what we ſhould expect from the copious precipitation of water in a cloudy form. Mr Sauſſure's obſervations aſſure us, that the particles of a cloud are veſicles. Indeed no perſon who has looked narrowly at a fog, or has obſerved how large the particles are of the cloud which forms in a receiver when we ſuddenly diminiſh the denſity of the air, and who obſerves how ſlowly theſe particles deſcend, can doubt of their being hollow veſicles. We cannot perhaps explain their formation; but there they are. We can hardly conceive them receiving the commotion which accompanied the ſnap without collapſing by the agitation. Perhaps the very ceſſation of their electricity may produce this effect. They will therefore no longer float in the air, but fall, and unite, and come to the ground in rain. We may expect this rain to be copious, for it is the produce of two ſtrata of clouds. It greatly contributes to the putting an end to the ſtorm, by paſſing through the ſtrata, and helping to reſtore the equilibrium.

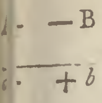
19
Why and how thunder may continue for ſome time.

One may at firſt expect that a ſingle clap of thunder will reſtore the equilibrium of any extent of clouds, and we require an explanation of their frequent repetition before this is accompliſhed. This is not difficult, and the fact is a confirmation of the above theory, which is conſiderably different from the generally received notions of the ſubject. We conſider the ſtratum of clear air as the charged electric; poſitive on one ſide, and negative on the other, and coated with conducting clouds. When the diſcharge is made, the ſtate of electricity is indeed changed through the whole ſtratum, but the equilibrium is by no means completed. The ſtratum is perhaps a quarter of a mile in thickneſs. The diſcharge does not immediately affect all this; but does it ſuperficially, leaving the reſt unbalanced. It is like the reſiduum which is left in a Leyden phial when the diſcharge has been made by means of a ſpark drawn at a diſtance. It is ſtill more like the reſiduum of the diſcharge of a Leyden phial that is coated only in patches on one ſide. Each of theſe patches diſcharge what is immediately under it and round it to a certain ſmall diſtance, but leaves a part beyond this ſtill charged. This redundant electricity gradually diffuſes itſelf into the ſpaces juſt now diſcharged; and, after ſome conſiderable time has elapſed, another diſcharge may be made. In like manner, the electricity remaining in the interior of the ſtratum diffuſes itſelf, comes within the action of the coating, and may be again diſcharged by a clap of thunder. We have a ſtill better parallel to this in Beccaria's experiments with two or more plates of glaſs laid together. After the firſt diſcharge, the internal ſurfaces will exhibit certain electricity. Lay the plates together, and, after ſome time, the electricity of the inner ſurfaces will be different, and another diſcharge may be obtained.

Magnetiſm affords the beſt illuſtration of this. If a magnet be brought near a piece of ſoft iron, lying below a paper on which iron filings are lightly ſtrewed, it will inſtantly induce a north pole on one end and a ſouth pole on the other; and this will be diſtinctly obſerved by the way in which theſe filings will arrange themſelves. But if, inſtead of ſoft iron, we place a bar of hard tempered ſteel, the ſouth pole will be but a ſmall matter removed from the north pole; but by continuing the magnet long in the ſame place, the diſtribution of magnetiſm in the piece of hard ſteel will gradually advance along the bar, and after a long time the neutral point will be almoſt in the middle of the bar, and the ſouth pole will be at the farther end. See Magnetism, in this *Suppl*

20 Moſt thun er ſtrokes re RE- URNING TROKES.

We ſaid that the clouds were the uſual ſcenes of the violent electric phenomena We imagine that the greateſt part of the thunder ſtrokes which have been felt have been of the kind which Lord Mahon, now Lord Stanhope, calls the returning ſtroke. If two clouds A and B are incumbent over the plain *a* and *b*; and if A be poſitive and B negative. the earth will be maintained in a negative ſtate at *a*, and a poſitive ſtate at *b*. If the diſcharge be now made between the clouds A and B, the electricity muſt inſtantly ruſh up through a conductor at *a*, and down through one at *b*. and each place will have a ſtroke. The ſame thing will happen if the negative cloud B is above the poſitive cloud A, but not in ſo great a degree; for the negative electricity at *a* will now be much leſs than in the other caſe, becauſe it is induced only by the prevalence of the poſitive cloud A over the more remote negative cloud B.



This returning ſtroke explains, much better than we can by any direct ſtroke, the capricious effects of thunder. A perſon at Vienna received a terrible ſhock by having his hand on a thunder-rod during a violent exploſion which he ſaw above three miles diſtant. Sparks are obſerved at thunder rods at every the moſt diſtant flaſh of lightning.

21 Beccaria's theory of thunder not juſt.

Beccaria has a different theory of thunder. He imagines that the different parts of the earth are in different ſtates of electricity, and that the clouds are the reſtoring conductors. But this does not accord with what we know of electricity. The earth is ſo good a conductor, that Dr Watſon could not obſerve any time loſt in communicating the electricity to the diſtance of more than four miles. It is very true, that the earth is almoſt always in a ſtate of very unequal, and even oppoſite, electricity in its different parts; but this ariſes from the variety of clouds ſtrongly electrified in the oppoſite way This induces electricity, or diſturbs the natural uniform diffuſion of electricity, juſt as the bringing magnets or loadſtones into the neighbourhood of a piece of iron, without touching it, renders it magnetical in its different parts. While they continue in their places, the piece of iron will be magnetical, and differently ſo in its different parts.

Such are the thoughts which occur to us on this ſubject. But we by no means affirm that we have given a full account of the procedure of Nature; we have only pointed out ſeveral neceſſary conſequences of the known laws of electricity, and of its production in the atmoſphere by means of natural operations which are continually going on. Theſe *muſt* operate, and produce an electrical ſtate of the atmoſphere greatly reſembling what we obſerve: and we have ſhewn, from the acknowledged doctrines of electricity, how this want of equilibrium may be removed, and muſt be removed, by the ſame operations of Nature. The equilibrium muſt be reſtored by means of the conducting coating furniſhed by the clouds. But theſe may be the leaſt conſiderable of Nature's reſources; and the ſubject is ſtill an unexplored field, in the examination of which we may hope to make great progreſs, in conſequence of our daily increaſing knowledge of the chemical ſtate of the atmoſphere.

22 Dr Franklin's invention of a guard againſt thunder.

Knowledge is valuable chiefly as it is uſeful. No man ever ſaw the propriety of this apothegm more ſtrongly than Dr Franklin, or more aſſiduouſly adhered to it in the courſe of a long and ſtudious life. However greatly we may admire his ſagacity, penetration, and logical diſcrimination, in the diſcoveries he has made in the ſcience of electricity, and his diſcovery of the identity of electricity and thunder, we muſt acknowledge infinitely greater obligations to him for putting it in our power to ward off the fatal, and formerly inevitable ſtroke, of this awful agent in the hands of Nature.

Dr Franklin conſiders the earth as performing the office of a conductor in reſtoring the electric equilibrium of the atmoſphere, which has been diſturbed by the inceſſant action of the unwearied powers of Nature.

He obſerves that the uſual preference will be given to the beſt conductors. In this reſpect, a metal rod far ſurpaſſes the brick, ſtone, timber, and other materials which compoſe our buildings, eſpecially when they are dry, as is uſually the caſe in the thundery ſeaſon. He therefore adviſes us to place metalline conductors in the way of the atmoſpherical electricity, in thoſe places where it is moſt likely to ſtrike, and to continue them down to the moiſt earth, at ſome depth under the ſurface. Nay, as it has been found that thunder has not in every inſtance ſtruck the higheſt parts of buildings, he adviſes to raiſe the metalline conductors to ſome conſiderable height above the building, the more certainly to invite the electricity to take this courſe.

23 Directions for conſtructing it.

To enſure ſucceſs, he obſerves that the electrical ſhock diſſipates water, and even metalline conductors, when too ſmall. He therefore adviſes to make the conductor at leaſt half an inch ſquare, none of that ſize having ever been deſtroyed, though ſmaller have, by the thunder; yet even theſe had conducted the thunder to the ground with perfect ſafety to the building.

No part of a conductor muſt terminate in the building; for the electricity accumulates exceedingly at the remote extremities of all long rods, and tends to fly off with great force, eſpecially if another conductor is near. This aids the accumulation, by acquiring at its upper end an electricity oppoſite to that of the lower end of the other: and this effect, produced by the influence of a poſitive cloud, makes the upper and negative end of the lower portion of a divided conductor draw more electricity to the lower end of the upper portion. This redundant electricity, ſtrongly attracted by the negative lower portion, flies off with great violence through the air; or if ſurrounded with any matter capable of converſion into elaſtic vapour by heat, burſts it with irreſiſtible force Thus the thunder, acting on the vane ſpindle of St Bride's ſteeple in London, ſprung from its lower end to the upper end of an iron window bar, and burſt the ſtone in which it was fixed, by expanding the moiſture into ſteam. In like manner it burſt the ſtone at the lower end of this bar, to make its way to an iron cramp which connected the oppoſite ſides of the ſteeple; from this it ſtruck to another cramp; and ſo from cramp

cramp to cramp, till it reached the gutter-leads of the church, burſting and throwing off the ſtonework in many places.

All interruptions muſt therefore be carefully avoided, and the whole muſt be made as much as poſſible one continued metal rod.

Farther, Dr Franklin, obſerving the ſingular property which ſharp points poſſeſs of drawing off the electricity in ſilence, adviſes us to finiſh our conductor with a fine point of gilt copper, which cannot be blunted by ruſt.

24
Is the thunder rod an effectual and ſafe contrivance?

But as thus raiſing the conductor, and pointing it, are ſo many invitations to the thunder to take this courſe; and as we cannot be certain that the quantity thus invited may not be more than what the rod can conduct with ſafety—it has appeared to Dr Wilſon, and other able electricians, that it will be ſafer to give abundance of conduct to what may unavoidably viſit us, without inviting what might otherwiſe have gone harmleſsly by.

This was attentively conſidered by Dr Franklin, Dr Watſon, Mr Canton, Dr Wilſon, and others, met as a committee of the Royal Society, at the deſire of the Board of Ordnance, to contrive a conductor for the powder magazine at Purfleet.

We think that the theory of induced electricity, founded on Dr Franklin's diſcoveries, and confirmed by all the later inventions of the electrophorus, condenſer, &c. will decide this queſtion in the moſt ſatisfactory manner.

25
Scientific account of the ſtate of electricity induced on a building by a thunder cloud,

When a cloud poſitively electrified comes over a building, it renders it negatively electrical in all its parts, if of conducting materials, and even the ground on which it ſtands. This effect is more remarkably produced if the ſtructure is of a tall and ſlender ſhape, like a ſteeple or a rod. Therefore the external electrical fluid is attracted by the building with greater force than if it had conſiſted of materials leſs conductive. A diſcharge will therefore be made through it in preference to any neighbouring building, becauſe it is more eminently negative. For the ſame reaſon, if there are two buildings equal and ſimilar, one of them being a good conductor, and the other being a leſs perfect one, the perfect conductor, becoming more powerfully negative, the cloud will become more ſtrongly poſitive over this houſe than over the other, and the ſtroke will be made through it.

26
And on the thunder rod.

The ſame thing muſt obtain in a perfect conductor continued from the top to the foundation of a houſe, built of worſe conducting materials. The conductor becoming more eminently negative than any other part of the building, the electric fluid will be more ſtrongly attracted by it, accumulated in its neighbourhood, and will all be diſcharged through it, ſo long as it is able to conduct.

If the building is of great extent, the proximity of one part of the building to the thunder cloud may produce an accumulation of electrical fluid in its neighbourhood, in preference to a more perfect, but remote, conductor. But when the diſtances from the cloud are not very unequal, the accumulation will always be in the neighbourhood of the perfect conductor; and this will determine the diſcharge that way. The accumulation in the neighbourhood of the rod will be ſmall indeed, when the rod is ſmall; but then it is denſe, and the whole of electric phenomena ſhew that it is the denſity, and not the quantity, of accumulation which produces the violent tendency to fly off: it is this alone which makes it impoſſible to confine electricity in a body which terminates in a ſharp point.

For the ſame reaſon, bodies of the ſame materials and ſhape will increaſe the accumulation in the adjoining part of the cloud in proportion as they are nearer to it, or more advanced beyond the reſt of the building.

And bodies of ſlender ſhape, and pointed, will produce this accumulation in their neighbourhood in a ſtill more remarkable degree, and determine the courſe of the diſcharge with ſtill greater certainty.

But it is evident that a metallic rod, no higher than the reſt of the building, may occaſion an accumulation in the adjoining part of a near thunder cloud ſufficient to produce a diſcharge, when the building itſelf, conſiſting of imperfect conductors, would not have provoked the diſcharge at all. It may therefore be doubted whether we have derived any advantage from the conductor.

27
Effect of all interruptions in the conductor.

To judge properly of this, we muſt conſider houſes as they really are, conſiſting of different materials, in very different ſhapes and ſituations; and particularly as having many large pieces of metal in their conſtruction, in various poſitions with regard to the cloud, the ground, and to each other. Suppoſe all the reſt of the building to be of non-conducting materials. When a poſitive thunder cloud comes overhead, every piece of metal in the building becomes electrical, without having received any thing as yet from the cloud; that end of each which is neareſt the cloud becoming negative, and the remote end poſitive. But, moreover, the electricity of one increaſes the electricity of its neighbour. Then the moſt elevated becomes more ſtrongly attractive at its upper end than it would have been had the others been away; and therefore produces a greater accumulation in the nearer part of the thunder cloud than it would otherwiſe have done, and it will receive a ſpark. By this its lower end becomes more overcharged, and this makes the upper end of the next more undercharged, and the ſpark is communicated to it, and ſo on to the ground; which would not have happened without this ſucceſſion of conductors. Thus it is eaſy to conceive, that the accumulation in the cloud is juſt inſufficient to produce a diſcharge—While things are in this ſtate, juſt ready to ſnap, ſhould a man chance to paſs under a bell wire, or under a luſtre hanging by a chain, his body will immediately augment the poſitive electricity of the lower end of the conductor above him, and thus will augment the negative electricity of its upper end. This again will produce the ſame effect in the conductor above it: and thus each conductor becomes more overcharged at its lower end, and more undercharged at the upper end. Before this, every thing was juſt ready to ſnap. All will now ſtrike at once. The cloud will be diſcharged through the houſe, and the man will be the ſacrifice, the whole diſcharge being made through his body. This needs no demonſtration for any well-informed electrician. Thoſe who have only ſuch a knowledge of the theory as can be gathered from the writings of Prieſtley, Cavallo, and other popular authors, may convince themſelves of the truth of what is here delivered in the following manner.

In dry weather, and the moſt favourable circumſtances for good electrical experiments, let a very large globe,

globe, ſmoothly covered with metal, and well inſulated, be as highly electrified as poſſible, without expoſing it to a rapid diſſipation. To enſure this circumſtance (which is important) let it be electrified till it begins to ſputter, and note the ſtate of the electrometer. Diſcharge this electricity, and electrify it to about half of this intenſity. Provide three or four inſulated metal conductors, about three inches long and an inch diameter, terminated by hemiſpheres, and all well poliſhed.

Having electrified the globe, as above directed, bring one of the inſulated conductors ſlowly up to it, and note its diſtance when it receives a ſpark. In doing this, take care that there be no conducting body near the remote end of the inſulated conductor. It will be beſt to puſh it gradually forward by means of a long glaſs rod. Withdraw the conductor, diſcharge its electricity, reſtore the globe to its former electricity, indicated by an electrometer, and repeat this experiment till the greateſt ſtriking diſtance is exactly diſcovered. Now ſet another of the inſulated conductors about half an inch behind the firſt, and puſh them forward together, by a glaſs rod, till a ſpark is obtained. The ſtriking diſtance will be found greater than before. Then repeat this laſt experiment, with this difference, that the two conductors are puſhed forward by taking hold of the remote one. The ſtriking diſtance will be found much greater than before. Laſtly, puſh forward the two conductors, the remote one having a wire communicating with the ground, till they are a ſmall matter *without* the ſtriking diſtance; and, leaving them in this ſituation, take any little conducting body, ſuch as a braſs ball fixed on the end of a glaſs rod, and paſs it briſkly through between the globe and the neareſt conductor, or through between the two conductors, taking care that it touch neither of them in the paſſage. It will be ſeen that, however ſwift the paſſage is made, there will be a diſcharge through all the four bodies. The inference from this is obvious and demonſtrative.

A very remarkable inſtance of this fact was ſeen at the chapel in Tottenham Court Road, London. A man, going into the chapel by the eaſt door, was killed by the thunder, which came down from the little bell-houſe, along the bell-wire, and the rod of the clock pendulum, from the end of which it leaped to ſome iron work above the door, and from thence, from nail to nail, till it reached the man's head.

This interruption of conduct, which is almoſt unavoidable in the conſtruction of any building, is the cauſe of moſt of the accidents that are recorded; for when the ends of thoſe communicating conductors are incloſed in materials of leſs conducting power, the electricity, in making its way to the next in a very denſe ſtate, never fails to explode every thing which can be converted into elaſtic vapour by heat. There is always a ſufficient quantity of moiſture in the ſtone or brickwork for this purpoſe; and moſt vegetable ſubſtances contain moiſture or other expanſible matter. The ſtone, brick, or timber, is burſt, and thrown to a conſiderable diſtance; or if kept together by a weight of wall, the wall is ſhattered. It is worth remarking that although no force whatever ſeems able to prevent this exploſion, the quantity of matter exploded is extremely ſmall; for the ſtones are never thrown to a greater diſtance than they would have been by two or three grains of gunpowder properly confined.

All theſe accidents will be prevented by giving a ſufficient uninterrupted conduct; and it is proper to make uſe of ſuch a conductor, although it may invite many diſcharges which would not otherwiſe happen. So long as the conductor is ſufficient for the purpoſe, there ſeems to be no doubt of the propriety of this maxim.

28
A thunder rod will protect even when it is not able to diſcharge the whole thunder.

But the moſt ſerious objection remains. As we are certain that theſe conductors, whether raiſed above the building or not, will produce diſcharges through them which otherwiſe would not have happened, and as we are quite uncertain whether the quantity contained in a thunder cloud may not greatly exceed what the thunder rod can conduct without being diſſipated in ſmoke, it ſeems very dangerous thus to invite a ſtroke which our conductor may not be able to diſcharge. In particular, it is reaſonable to believe that the ſtrata of electrified clouds which come near the earth loſe much of their electricity by paſſing over the ſharp points of trees, &c. while thoſe which are much higher may retain their electricity undiminiſhed, and paſs on. May it not therefore happen, that our conductor will invite a fatal ſtroke, which would have gone harmleſsly by?

The doubt is natural, and it is important.

Let us ſuppoſe a very extenſive and highly electrified cloud, in a poſitive ſtate, to come within ſuch a diſtance from a building as *juſt not to ſtrike it*, if unprovided with a conductor, but which will moſt certainly ſtrike the ſame building furniſhed with a conductor; and let the electricity be ſo great that the conductor ſhall be diſſipated in ſmoke before even a ſmall part of it is diſcharged—What will be the fate of the building? We believe that it will be perfectly ſafe.

However rapid we may ſuppoſe that motion by which electricity is communicated, it is ſtill motion, and time elapſes during the propagation. The cloud is diſcharged, not in a very inſtant, but in a very ſhort time. Part of the cloud is therefore diſcharged, while it explodes the conductor, and the electricity of the remainder is now too weak (by our ſuppoſition) to ſtrike the building no longer furniſhed with a conductor. This muſt be the caſe, however large and powerful the cloud may be, and however ſmall the conductor.

But ſuppoſe that the cloud has come ſo near as to ſtrike the building unprovided with a conductor. Then as much will be diſcharged through the building as it can conduct; and if the quantity be too great, the building will be deſtroyed: but let a conductor (tho' inſufficient) be added. The diſcharge will be made through it as long as it laſts, and the remainder only will be diſcharged through the houſe, ſurely with much leſs danger than before.

The truth of theſe concluſions from theory is fully verified by fact. When the church of Newbury in New England was ſtruck by lightning in 1755, a bell wire, no bigger than a knitting needle, conducted the thunder with perfect ſafety to the building as far down the ſteeple as the wire reached, though the ſtroke was ſo great that the wire had been exploded, and no part of it remained, but only a mark along the wall occaſioned by its ſmoke. From the termination of the wire to the ground the ſteeple was exceedingly ſhattered, and ſtones of great weight were thrown out from the foundation (where they were probably moiſter) to the diſtance of 20 and 30 feet.

Thunder.

Another remarkable inſtance happened in the ſummer palace at St Peterſburg. A Heyduk and a ſoldier of a foot regiment were ſtanding centinels at the door of the jewel-chamber: the Heyduk, with his ſcimitar reſting on his arm, was careleſsly leaning on the ſoldier, who had his muſket ſhouldered. Both were ſtruck down with lightning; and the ſoldier was killed, his left leg ſcorched, and his ſhoes burſt. The Heyduk had received no damage, but felt himſelf tripped up, as if a great dog had run againſt him. A narrow ſlip of gold lace, which was ſewed along the ſeam of his jacket and pantaloon breeches, reaching to his ſhoes, had been exploded on the left ſide. This ſeems to have been his protection. In all probability, the ſtroke came to both along the muſket (or perhaps to the Heyduk along the ſcimitar). The Heyduk had a complete, though inſufficient, conductor, and was ſafe. The ſoldier had not, and was killed. The puſh felt by the former probably aroſe from the exploſion of the lace.

It ſeems therefore plain that metalline conductors are always a protection; that advancing them above the building, increaſes their protection; and that pointing them may ſometimes enable them to diminiſh a ſtroke, by diſcharging part of the electricity ſilently.

Dr Franklin having formed all his notions of thunder from his pre-eſtabliſhed theory, and having ſeen the principal phenomena ſo conformable to it, was naturally led to expect this conformity in caſes which he could not eaſily examine preciſely by experiment. Accordingly, in his firſt diſſertation, he affirmed that a fine point always diſcharges a thunder cloud ſilently, and at a great diſtance. The analogous experiments in artificial electricity are ſo beautiful and ſo perſpicuous, that this confidence in the protecting power of fine points is not ſurpriſing: and this confidence was rendered almoſt complete by a moſt ſingular caſe which fell under his own obſervation He was awakened one night by loud cracks in his ſtair caſe, as if ſome perſon had been laſhing the wainſcoating with a great horſewhip. He thought it ſo, and got up in anger to chide the idle fool. On looking out at his chamber door, he ſaw that the diſturbance proceeded from electric exploſions at ſome interruptions of his conductor. He ſaw the electricity paſs, ſometimes in bright ſparks, producing thoſe loud thwacks, and ſometimes in a long continued ſtream of denſe white dazzling light as big as his finger, illuminating the ſtair-caſe like ſunſhine, and making a loud noiſe like a cutler's wheel. Had the cloud (ſays he) retained all this till it came within ſtriking diſtance, the conſequences would have been inconceivably dreadful. Yet not long after this he found that he had been in a miſtake; for the houſe of Mr Watt in Philadelphia, furniſhed with a finely pointed conductor, was ſtruck by a terrible clap of thunder, and the point of the conductor was melted down about two inches. This is perhaps the only inſtance on record of a finely-pointed *conductor* being ſtruck. The board room at the powder magazine at Purfleet was indeed ſtruck, though provided with a conductor; but the ſtroke was through another part of the building. St Peter's church, Cornhill, has been eight times ſtruck between 1772 and 1787; while St Michael's, in its neighbourhood, and much higher, has never had a ſtroke ſince 1772, when it was furniſhed with an excellent pointed conductor by Mr Nairne.

Thunder.

29
A pointed conductor may ſometimes be ſtruck.

Dr Franklin having ſeen the above exception to his rule, and reflected on it, acknowledges that there are caſes where a pointed conductor may be ſtruck, viz. when it ſerves as a ſtepping ſtone, to *complete* a canal of conveyance already near completed. A *ſmall* cloud may ſometimes ſerve as a ſtepping ſtone (like the man coming under a luſtre) for the electricity to come out of a great cloud, and diſcharge through the pointed conductor. Whenever it comes to the ſtriking diſtance from the conductor, it will explode at once; whereas the great cloud itſelf muſt have come nearer, and had its force gradually diminiſhed. It is remarkable that a point, employed in this way in artificial electricity, muſt be brought nearer to another body than a ball need be, before it can receive a ſtroke. The difference is about one third of the whole. Nairne found, that a ball one nine-tenths inches in diameter, exploded at the diſtance of nine inches, and a point at ſix inches diſtance.

We muſt alſo obſerve that a pointed conductor can have no advantage over a blunt one in the caſe of a returning ſtroke; which is perhaps the moſt common of any. This depends on another diſcharge, which is made perhaps at a great diſtance. This was moſt diſtinctly the caſe in the inſtance mentioned ſome time ago, of the perſon at Vienna who had a ſhock from a thunder rod by an exploſion far diſtant. This thunder rod was a very fine one, furniſhed with five gilt points.

30
Dr Franklin over-rated the protection of pointed conductors.

Still, however, this property of ſharp points was greatly over-rated by Dr Franklin, and thoſe who took all their notions of electricity from the ſimple diſcoveries of his ſagacious mind. Unfortunately Dr Franklin had not cultivated mathematical knowledge; and, ever eager after diſcovery, and ardent in all his purſuits, his wonderful penetration carried him through, and ſeldom allowed him to reſt long on falſe concluſions. He was certainly one of the greateſt *philoſophers*; and a little erudition would perhaps have brought him ſide by ſide with Newton. It was reſerved, however, for Lord C. Cavendiſh and for Æpinus, to ſubject the inveſtigations of Franklin to number and meaſure. By ſtudying what they have written on the ſubject, or even the view which we have given of their theory in the article ELECTRICITY *(Suppl.)*, the reader will be fully convinced, that a point has little or no advantage over a ball, with reſpect to a thunder cloud which is brought to the thunder rod by a briſk wind; although, when it comes ſlowly up during an almoſt perfect calm, it may diſcharge all that can be diſcharged without a ſnap. The conſtipation in a point is indeed very great, but the quantity conſtipated is moderate; and therefore its action, at any conſiderable diſtance, is but trifling. All this is fully verified by Dr Wilſon's judicious experiments in the Pantheon. He had a prodigious quantity of electrified ſurface ſuſpended there, and made a pointed apparatus come to its ſtriking diſtance with a motion which he could regulate and meaſure. And he found that with the very moderate velocity of twelve feet in a ſecond, he never failed of procuring a very ſmart ſtroke. The experiments made in the uſual way by the partiſans of ſharp points (for it became a matter of indecent party) were numberleſs, and decidedly in their favour. The great and juſt authority of Dr Franklin, who was one of the committee, procured them ſtill more conſideration, or at leaſt hindered people from ſeeing the force of Dr Wilſon's reaſoning. It is ſomewhat ſurpriſing, under.

priſing, that Dr Wilſon, a lover of mathematical learning, and a good judge, as appears from his publication of the papers of Mr Robins, did not himſelf ſee the full force of his own experiments. He had not ſurely ſtudied either Æpinus or Cavendiſh. He indeed frequently ſays, that the ſtate of the electricity in a thunder cloud, and in coated glaſs, is exceedingly different; and that the firſt extends its ſenſible influence much farther than the laſt, when both have the ſame quantity of electricity. But he ſeems not to have formed to himſelf any adequate notion of the difference. Had he done this, he would have ſeen that he has diſpoſed his great electrified ſurface very improperly. It ſhould have been collected much nearer his pointed apparatus, that this might, if poſſible, have been within the ſphere of attraction of every part of his artificial cloud. He would then have found reſults, ſome of which would have been much more favourable to his own general opinion, while others would have exhibited the peculiarities of the ſharp point in a more ſhowy manner than any thing we have ſeen.

31 hunder oud very like coat- glaſs;

Reaſoning from the true theory of coated glaſs, we ſhall learn that, when the glaſs is exceedingly thin, the accumulation of electricity, or the charge, will be exceedingly great; while the external appearance, or apparent energy, of the electricity may be hardly ſenſible, and will extend to a very ſmall diſtance. Thus, a circular plate of coated glaſs, ſix inches in diameter and one-twentieth thick, when electrified ſo as to make an electrometer diverge 50 degrees, contains about 60 times as much electricity as a braſs plate, of the ſame diameter, electrified to the ſame degree; and theſe two will have the ſame influence on an electrometer placed at a diſtance from them, and will give a ſpark nearly at the ſame diſtance. The ſpark from the coated glaſs will be bright, and will give a ſhock; while that from the braſs plate will be trifling. The cauſe of the equality of influence is, that the poſitive electricity of the one ſide of the coated glaſs is almoſt balanced by the negative electricity of the other ſide, and the unbalanced part is about $\frac{1}{59}$th of the whole. If we now take a braſs plate of 46½ inches in diameter, and electrify it to the ſame degree with the coated glaſs, we ſhall find that it will require the ſame number of turns of the machine to bring it to this ſtate, or to charge the coated glaſs. They contain the ſame quantity of electricity, and the ſpark of both will give the ſame ſhock. But this large plate will have a much wider influence: a perſon coming within ten feet of it will ſee his hair bend towards it, and feel like a cobweb on his face.

32 And the nfluence of harp points s trifling.

It may be farther demonſtrated that the power of a point to abſtract the electricity to a given degree from the large plate, is vaſtly ſmaller than its power to abſtract it to the ſame degree from the coated plate. This is different in the different degrees of the abſtraction, and cannot be expreſſed by any one number.

Thunder.

All theſe conſiderations taken together, ſhew us that the pointed conductor has little advantage over the ball in the circumſtance above-mentioned. It has, however, an advantage, and therefore ſhould be employed; and in the caſe of a calm, or very gentle progreſs of the thunder cloud, the advantage may be very great.

33 An extenſive and ſubſtantial metalline conductor is the chief ſecurity.

Thus we think the queſtion decided; and the only remaining conſideration is the quantity of metallic conduct that ſhould be given. Prudence teaches us not to ſpare, eſpecially in very lofty buildings. The conductor on the dome of St Paul's in London conſiſts of four iron ſtraps, each four inches broad and one half an inch thick. This conductor was once made red hot by a thunder ſtroke. No inſtance has been found of a rod one half an inch ſquare being exploded. The accident at Mr Watt's houſe in Philadelphia is curious. The braſs wire which terminated the rod had been ten inches long and one-fourth thick at the baſe, and two one-half inches were melted. It was unable, therefore, to conduct that ſtroke when its diameter was leſs than one-ſixteenth of an inch.

We recommend lead or copper in preference to iron. Iron waſtes by ruſt, and by exfoliating retains water, which may be dangerous by its expanſion. A ſtrap of lead, two inches broad and one fourth thick, ſtapled down to the roof or wall with braſs ſtaples, ſecures us from all riſks from neglect. An iron rod, or one faſtened with iron cramps, requires frequent inſpection, to ſee that nothing has failed or waſted by ruſt. The point or points ſhould ſurely be copper. It would be very proper to connect all the leads of the ridges, gutters, and ſpouts, with the conductor, by ſtraps of lead. This will greatly extend its protection.

A great extent of building is not ſufficiently ſecured by one conductor. And a powder magazine ſhould have ſome erected round it at a diſtance on maſts.

Maxims in a Thunder Storm.

Avoid being under trees—but be near them: do not avoid rain. When in a room, avoid the fire-ſide, which would bring you into the neighbourhood of the higheſt part of the houſe, viz. the ſtack of chimneys. The bell-wire, the grate, the fire irons – are bad neighbours. Nay, the ſoot of the chimney is not a good one, eſpecially if it has ever caked together by burning (A). Go to the middle of the room, and ſit down, if not near a luſtre, or any thing hanging from the ceiling. Avoid mirrors, or gilded mouldings.

Thunder Clouds, in phyſiology, are thoſe clouds which are in a ſtate fit for producing lightning and thunder. See the preceding article.

(A) In the terrible thunder ſtroke on Leven Houſe in Scotland, the two great ſtreams of electricity had taken the courſe of the vents which had been moſt in uſe, but not to get at the iron work, for it had branched off from the vents, at a great diſtance from the bottom. The chief conductors through the building had been various gilded mouldings, gilded leather hangings, gilded ſkreens, picture frames, and the foil of mirrors. In this progreſs the ſteps have been ſo many, and ſo capricious, that no line of progreſs can be traced, according to any principle. The thunder ſeems to have electrified at once the whole of the leaden roof, and, beſides the two main tracks along the vents, to have afterwards darted at every metal thing in its way. The loweſt point of the track was a leaden water ciſtern; which, however, received no damage; but a thick ſtone wall was burſt through to get at it.

THUS, in ſea language, a word uſed by the pilot in directing the helmſman or ſteerſman to keep the ſhip in her preſent ſituation when ſailing with a ſcant wind, ſo that ſhe may not approach too near the direction of the wind, which would ſhiver her ſails, nor fall to leeward, and run farther out of her courſe.

TIBERIAS (anc geog.), the laſt town of Galilee, ſituated on the ſouth ſide of the lake Tiberias; built by Herod the Tetrarch, and called *Tiberias* in honour of the Emperor Tiberius; diſtant 30 ſtadia from Hippus, 60 from Gadara, and 120 from Scythopolis: whence it appears to have been at no great diſtance from where the Jordan runs out of the lake. It is a number of times mentioned by St John the Evangeliſt. Pliny places it on the weſt extremity of the lake, commending the ſalubrity of its hot waters. Jerome ſays, the ancient name was *Chennereth;* which, if true, will account for the name of the lake.

TIERRA del Fuego, ſeveral iſlands at the ſouthern extremity of America. They take their name from a volcano on the largeſt of them. They are all very barren and mountainous; but from what Mr Forſter ſays, in his Voyage to the South Sea, the climate does not appear to be ſo rigorous and tempeſtuous as it is repreſented in Anſon's Voyage. Upon the lower grounds and iſlands, that were ſheltered by the high mountains, Mr Forſter found ſeveral ſorts of trees and plants, and a variety of birds. Among the trees was Winter's bark-tree, and a ſpecies of *arbutus*, loaded with red fruit of the ſize of ſmall cherries, which were very well taſted. In ſome places there is alſo plenty of celery. Among the birds was a ſpecies of duck, of the ſize of a gooſe, which ran along the ſea with amazing velocity, beating the water with its wings and feet. It had a grey plumage, with a yellow bill and feet, and a few white quill-feathers. At the Falkland iſlands it is called a *loggerhead-duck*. Among the birds are alſo plenty of geeſe and falcons. The rocks of ſome of the iſlands are covered with large muſcle-ſhells, the fiſh of which is well flavoured. The natives of this country are ſhort in their perſons, not exceeding five feet ſix inches at moſt, their heads large, their faces broad, their cheek bones prominent, and their noſes flat. They have little brown eyes, without life; their hair is black and lank, hanging about their heads in diſorder, and beſmeared with train-oil. On the chin they have a few ſtraggling ſhort hairs inſtead of a beard. The whole aſſemblage of their features forms the moſt loathſome picture of miſery to which human nature can poſſibly be reduced. Thoſe which Mr Forſter ſaw had no other clothing than a ſmall piece of ſeal ſkin, which hung from their ſhoulders to the middle of their back, being faſtened round the neck with a ſtring: the reſt of their body was perfectly naked. Their natural colour ſeems to be an olive brown, with a kind of gloſs, reſembling that of copper; but many of them diſguiſe themſelves with ſtreaks of red paint, and ſometimes, though ſeldom, with white. Their whole character is a ſtrange compound of ſtupidity, indifference, and inactivity. They have no other arms than bows and arrows; and their inſtruments for fiſhing are a kind of fiſh-gigs. They live chiefly on ſeals fleſh, and like the fat oily part moſt. There is no appearance of any ſubordination among them; and their mode of life approaches nearer to that of brutes than that of any other nation.

TILLANDSIA, the large barren WILD PINE of the Weſt Indies; a genus of the monogynia order, belonging to the hexandria claſs of plants. It is called *Caragatua* by Father Plumier, and is a paraſitic plant, and ought perhaps, in ſtrict propriety, to be denominated an *aquatic:* for although it is ſuſpended in the air among the branches of lofty trees, to whoſe boughs it is faſtened by its numerous roots; yet it is not indebted to thoſe boughs, like the miſletoe and other paraſitic plants, for nouriſhment, but merely for ſupport; provident Nature having, in a very extraordinary manner, ſupplied this with other means to preſerve its exiſtence: For the leaves, which much reſemble thoſe of the pine-apple, but are larger, ſurround this plant in a circular manner; each leaf being terminated near the ſtalk with a hollow bucket, which contains about half a pint of water. It is by theſe numerous ſmall reſervoirs of water that the roots, as well as every other part of this plant, are ſupplied with nouriſhment without the help of any earth. The flouriſhing condition of this plant, as well as the great growth of fig-trees, upon barren rocks, ſhews that water is of greater uſe to vegetation than earth.

One contrivance of Nature in this vegetable, ſays Dr Sloane, is truly admirable. The ſeed is crowned with many long downy threads, not only that it may be carried everywhere by the wind, but that by thoſe threads, when driven through the boughs, it may be held faſt, and ſtick to the arms and prominent parts of the barks of trees. So ſoon as it ſprouts or germinates, although it be on the under part of a bough, its leaves and ſtalks riſe perpendicular or erect: if they aſſumed any other direction, the ciſtern or reſervoir juſt mentioned, made of the hollow leaves, could not hold water, which is neceſſary to the life and nouriſhment of the plant. In ſcarcity of water this reſervoir is uſeful, not to the plant only, but to men, and even to birds and all ſorts of inſects, which come thither in troops, and ſeldom go away without refreſhment.

To the ſame purpoſe, Dampier, in his Voyage to Campeachy, relates, "that the wild pine has leaves that will hold a pint and a half or quart of rain-water, which refreſhes the leaves, and nouriſhes the roots. When we find theſe pines, we ſtick our knives into the leaves, juſt above the root; and the water guſhing out, we catch it in our hats, as I myſelf have frequently done, to my great relief."

TIMÆUS, a Greek hiſtorian, the ſon of Andronicus, who was eminent for his riches and excellent qualities, was born at Tauromenium in Sicily, and flouriſhed in the time of Agathocles. He wrote ſeveral books, and among the reſt an hiſtory of his own country; but they are all loſt.

TIMÆUS, a famous Pythagorean philoſopher, was born at Locres in Italy, and lived before Plato. There is ſtill extant a ſmall treatiſe of his on Nature and the Soul of the World, written in the Doric dialect. This treatiſe, which is to be found in the works of Plato, furniſhed that great philoſopher with the ſubject of his treatiſe intitled *Timæus*.

TINNING, the covering or lining of any thing with melted tin, or with tin reduced to a very fine leaf. Looking-glaſſes are foliated or *tinned* with thin plates of beaten tin, by a proceſs deſcribed under the title FOLIATING, *Encycl.*

Kettles, ſauce-pans, and other kitchen utenſils, which are uſually made of copper, are tinned by the following proceſs: The ſurface to be tinned, if of new copper, ſhould firſt be cleaned or ſcoured with ſalt and ſulphuric acid (vitriolic acid) diluted with water. This, however, is not always done; ſome workmen contenting themſelves with ſcouring it with ſand perfectly dry, or with ſcales of iron. Powdered roſin is then ſtrewed over it; and when the veſſel or utenſil is conſiderably heated, melted tin is poured into it, and rubbed with flax coiled hard over the ſurface to be coated. This tin may be either pure, ſuch as that known by the name of *grain-tin;* or a compoſition conſiſting of two parts of tin and one of lead. For very obvious reaſons, we ſhould certainly prefer the pure tin; but the generality of workmen give the preference to the compoſition, becauſe the ſurface coated with it appears more brilliant. The tin is not always put into the veſſel in a liquid ſtate; for ſome workmen ſtrew it in ſmall pieces over the ſurface to be coated, and then heat the veſſel till the tin melt, when they rub it as formerly.

In tinning old veſſels which have been tinned before, the proceſs is ſomewhat different. In theſe caſes, the ſurface is firſt ſcraped with an inſtrument proper for the purpoſe, or ſcoured with the ſcales of iron, which may be always found in a blackſmith's ſhop: it is then ſtrewed over with ſal ammoniac in powder, inſtead of roſin, or an infuſion of ſal ammoniac in ſtale urine is boiled in it till the urine be evaporated, and it is then tinned with pure tin; the compoſition of tin and lead being in this caſe never uſed. The tin, while liquid, is rubbed into the ſurface with a piece of ſal ammoniac, inſtead of a bundle of flax. When iron veſſels are to be tinned, they are firſt cleaned with muriatic acid, after which the proceſs is the ſame as in the tinning of old copper.

In the year 1785, Mr John Poulain of Mortlake, Surrey, obtained a patent for the diſcovery of a new compoſition for tinning veſſels, eſpecially ſuch as are uſed for culinary purpoſes. This compoſition conſiſts of grain tin one pound, good malleable iron one ounce and a half, platinum one drachm, ſilver one pennyweight, gold three grains: the whole muſt be well fuſed together in a crucible, with one ounce of pounded borax, and two ounces of pounded glaſs, and then caſt in ſmall ingots. The compoſition, to be fit for uſe, muſt be heated and put in a metal mortar, alſo heated over a fire, and well pounded with a heated metal peſtle; when it is well pounded, make an ingot of it, by putting it on the fire in a mould made of iron plate, in which mould the compoſition muſt be well ſtirred and let to cool; then it is fit for uſe. To apply the compoſition, firſt tin the utenſil or veſſel with grain-tin and ſal ammoniac, as is uſually done in the common way of tinning; clean well the tinned part of the metal utenſil or veſſel, and then apply a coat of the compoſition with ſal ammoniac, as is uſually done in the common way of tinning; and when the compoſition is well ſpread, let it cool; then make it a little red-hot in all its parts, to neal it, and plunge the metal utenſil or veſſel, while yet hot, in cold water; then, with a ſharp ſcraper, ſcrape and rub off the rough or grumous particles of the compoſition applied on the metal utenſil or veſſel, and ſcour it well with ſand. The ſame operation muſt be repeated for every coat of the compoſition that is applied; two coats of the compoſition are quite ſufficient for culinary utenſils or veſſels, and a thin coat of grain tin may be applied over the laſt coat of the compoſition, to ſmooth it. The author adds, that his compoſition may be employed for covering or plating the ſurfaces of all materials made of copper, braſs, iron, and other metals or mixtures of metals, and that it ſhould be applied with a charcoal fire in preference to any other fire. All this may be true, and it may be a very valuable coating to copper; but the ſcarcity, high price, and infuſibility of platinum, muſt for ever prevent it from coming into very general uſe.—We think that even the *Enamelling of Veſſels for the Kitchen* muſt be more common. See that article in this *Supplement.*

The following proceſs is leſs expenſive, whilſt the coating given by it is exceedingly durable, adds ſtrength to the copper veſſel, and ſecures it much longer than the common tinning from the action of acids:

When the veſſel has been prepared and cleaned in the uſual manner, it muſt be roughened on the inſide by being beat on a rough anvil, in order that the tinning may hold better, and be more intimately connected with the copper. The proceſs of tinning muſt then be begun with perfectly pure grained tin, having an addition of ſal ammoniac inſtead of the common colophonium or reſin. Over this tinning, which muſt cover the copper in an even and uniform manner throughout, a ſecond harder coat muſt be applied, as the firſt forms only a kind of medium for connecting the ſecond with the copper. For this ſecond tinning you employ pure grained tin mixed with zinc in the proportion of two to three, which muſt be applied alſo with ſal ammoniac ſmooth and even, ſo that the lower ſtratum may be entirely covered with it. This coating, which, by the addition of the zinc, becomes pretty hard and ſolid, is then to be hammered with a ſmoothing hammer, after it has been properly rubbed and ſcoured with chalk and water; by which means it becomes more ſolid, and acquires a ſmooth compact ſurface.

Veſſels and utenſils may be tinned in this manner on both ſides. In this caſe, after being expoſed to a ſufficient heat, they muſt be dipped in the fluid tin, by which means both ſides will be tinned at the ſame time.

As this tinning is exceedingly durable, and has a beautiful colour, which it always retains, it may be employed for various kinds of metal inſtruments and veſſels which it may be neceſſary to ſecure from ruſt.

TINPLATE, called in Scotland *White iron,* is a thin plate of iron covered with tin, to which it is united by chemical affinity. See Chemistry, n° 122. *Suppl.*

TIPRA, the name of certain mountainous diſtricts to the eaſtward of Bengal, inhabited by a people of very ſingular manners. As every thing which contributes a ſingle fact to the hiſtory of human nature is intereſting to the philoſopher, the reader will be pleaſed with the following account of the religion, laws, and manners of theſe people, taken from the 2d volume of the *Aſiatic Reſearches.*

Though they acknowledge one Creator of the univerſe, to whom they give the name of Pa'tiya'n, they believe that a deity exiſts in every tree, that the ſun and moon are gods, and that whenever they worſhip thoſe ſubordinate divinities Pátiyán is pleaſed. This is very ſimilar to the religious creed of ancient Greece and Rome, differing only with reſpect to creation, which, in the proper ſenſe of the word, the Greeks and Romans ſeem not to have admitted.

If any one of theſe mountaineers, called in the memoir Cucis, put another to death, the chief of the tribe, or other perſons who bear no relation to the deceaſed, have no concern in puniſhing the murderer; but if the murdered perſon have a brother or other heir, he may take blood for blood; nor has any man whatever a right to prevent or oppoſe ſuch retaliation.

When a man is detected in the commiſſion of theft or other atrocious offence, the chieftain cauſes a recompenſe to be given to the complainant, and reconciles both parties; but the chief himſelf receives a cuſtomary fine, and each party gives a feaſt of pork or other meat to the people of his reſpective tribe.

In ancient times, it was not a cuſtom among them to cut off the heads of the women whom they found in the habitations of their enemies; but it happened once that a woman aſked another, why ſhe came ſo late to her buſineſs of ſowing grain? ſhe anſwered, that her huſband was gone to battle, and that the neceſſity of preparing food and other things for him had occaſioned her delay. This anſwer was overheard by a man at enmity with her huſband; and he was filled with reſentment againſt her, conſidering, that as ſhe had prepared food for her huſband for the purpoſe of ſending him to battle againſt his tribe, ſo in general, if women were not to remain at home, their huſbands could not be ſupplied with proviſion, and conſequently could not make war with advantage. From that time it became a conſtant practice to cut off the heads of the enemy's women, eſpecially if they happen to be pregnant, and therefore confined to their houſes; and this barbarity is carried ſo far, that if a Cuci aſſail the houſe of an enemy, and kill a woman with child, ſo that he may bring two heads, he acquires honour and celebrity in his tribe, as the deſtroyer of two foes at once.

As to the marriages of this wild nation, when a rich man has made a contract of marriage, he gives four or five head of *gayáls* (the cattle of the mountains) to the father and mother of the bride, whom he carries to his own houſe: Her parents then kill the *gayáls;* and having prepared fermented liquors and boiled rice with other eatables, invite the father, mother, brethren, and kindred of the bridegroom to a nuptial entertainment. When a man of ſmall property is inclined to marry, and a mutual agreement is made, a ſimilar method is followed in a lower degree; and a man may marry any woman except his own mother. If a married couple live cordially together, and have a ſon, the wife is fixed and irremoveable; but if they have no ſon, and eſpecially if they live together on bad terms, the huſband may divorce his wife, and marry another woman.

They have no idea of heaven or hell, the reward of good, or the puniſhment of bad, actions; but they profeſs a belief, that when a perſon dies, a certain ſpirit comes and ſeizes his ſoul, which he carries away; and that whatever the ſpirit promiſes to give at the inſtant when the body dies, will be found and enjoyed by the dead; but that if any one ſhould take up the corſe and carry it off, he would not find the treaſure.

The food of this people conſiſts of elephants, hogs, deer, and other animals; of which if they find the carcaſes or limbs in the foreſts, they dry them, and eat them occaſionally.

When they have reſolved on war, they ſend ſpies, before hoſtilities are begun, to learn the ſtations and ſtrength of the enemy, and the condition of the roads; after which they march in the night, and two or three hours before daylight make a ſudden aſſault with ſwords, lances, and arrows: if their enemies are compelled to abandon their ſtation, the aſſailants inſtantly put to death all the males and females, who are left behind, and ſtrip the houſes of all their furniture; but ſhould their adverſaries, having gained intelligence of the intended aſſault, be reſolute enough to meet them in battle, and ſhould they find themſelves overmatched, they ſpeedily retreat and quietly return to their own habitations. If at any time they ſee a ſtar very near the moon, they ſay, "to-night we ſhall undoubtedly be attacked by ſome enemy;" and they paſs that night under arms with extreme vigilance. They often lie in ambuſh in a foreſt near the path, where their foes are uſed to paſs and repaſs, waiting for the enemy with different ſorts of weapons, and killing every man or woman who happens to paſs by: in this ſituation, if a leech, or a worm, or a ſnake, ſhould bite one of them, he bears the pain in perfect ſilence; and whoever can bring home the head of an enemy, which he has cut off, is ſure to be diſtinguiſhed and exalted in his nation. When two hoſtile tribes appear to have equal force in battle, and neither has hopes of putting the other to flight, they make a ſignal of pacific intentions, and, ſending agents reciprocally, ſoon conclude a treaty; after which they kill ſeveral head of *gayáls*, and feaſt on their fleſh, calling on the ſun and moon to bear witneſs of the pacification: but if one ſide, unable to reſiſt the enemy, be thrown into diſorder, the vanquiſhed tribe is conſidered as tributary to the victors; who every year receive from them a certain number of *gayáls*, wooden diſhes, weapons, and other acknowledgments of vaſſalage. Before they go to battle, they put a quantity of roaſted *álus* (eſculent roots like potatoes), and paſte of rice-flour, into the hollow of bamboos, and add to them a proviſion of dry rice with ſome leathern bags full of liquor: then they aſſemble, and march with ſuch celerity, that in one day they perform a journey ordinarily made by letter-carriers in three or four days, ſince they have not the trouble and delay of dreſſing victuals. When they reach the place to be attacked, they ſurround it in the night, and at early dawn enter it, putting to death both young and old, women and children, except ſuch as they chooſe to bring away captive: they put the heads, which they cut off, into leathern bags; and if the blood of their enemies be on their hands, they take care not to waſh it off When after this ſlaughter they take their own food, they thruſt a part of what they eat into the mouths of the heads which they have brought away, ſaying to each of them, "Eat, quench thy thirſt, and ſatisfy thy appetite; as thou haſt been ſlain by my hand, ſo may thy kinſmen be ſlain by my kinſmen!" During their journey, they have uſually two ſuch meals; and every watch, or two watches, they ſend intelligence of their proceedings to their families. When any one of them ſends word that he has cut off the head of an enemy, the people of his family, whatever be their age or ſex, expreſs great delight,

light, making caps and ornaments of red and black ropes; then filling ſome large veſſels with fermented liquors, and decking themſelves with all the trinkets they poſſeſs, they go forth to meet the conqueror, blowing large ſhells, and ſtriking plates of metal, with other rude inſtruments of muſic. When both parties are met, they ſhow extravagant joy, men and women dancing and ſinging together; and if a married man has brought an enemy's head, his wife wears a head-dreſs with gay ornaments, the huſband and wife alternately pour fermented liquor into each other's mouths, and ſhe waſhes his bloody hands with the ſame liquor which they are drinking. Thus they go revelling, with exceſſive merriment, to their place of abode; and having piled up the heads of their enemies in the court yard of their chieftain's houſe, they ſing and dance round the pile; after which they kill ſome *gayáls* and hogs with their ſpears; and having boiled the fleſh, make a feaſt on it, and drink the fermented liquor. The richer men of this race faſten the heads of their foes on a bamboo, and fix it on the graves of their parents, by which act they acquire great reputation. He who brings back the head of a ſlaughtered enemy, receives preſents from the wealthy of cattle and ſpirituous liquor; and if any captives are brought alive, it is the prerogative of thoſe chieftains, who were not in the campaign, to ſtrike off the heads of the captives. Their weapons are made by particular tribes; for ſome of them are unable to fabricate inſtruments of war.

In regard to their civil inſtitutions; the whole management of their houſehold affairs belongs to the women; while the men are employed in clearing foreſts, building huts, cultivating land, making war, or hunting game and wild beaſts. Five days (they never reckon by months or years) after the birth of a male child, and three days after that of a female, they entertain their family and kinſmen with boiled rice and fermented liquor; and the parents of the child partake of the feaſt. They begin the ceremony with fixing a pole in the court yard; and then killing a *gayál* or a hog with a lance, they conſecrate it to their deity; after which all the party eat the fleſh and drink liquor, cloſing the day with a dance and with ſongs. If any one among them be ſo deformed, by nature or by accident, as to be unfit for the propagation of his ſpecies, he gives up all thought of keeping houſe, and begs for his ſubſiſtence, like a religious mendicant, from door to door, continually dancing and ſinging. When ſuch a perſon goes to the houſe of a rich and liberal man, the owner of the houſe uſually ſtrings together a number of red and white ſtones, and fixes one end of the ſtring on a long cane, ſo that the other end may hang down to the ground; then, paying a kind of ſuperſtitious homage to the pebbles, he gives alms to the beggar; after which he kills a *gayál* and a hog, and ſome other quadrupeds, and invites his tribe to a feaſt: the giver of ſuch an entertainment acquires extraordinary fame in the nation, and all unite in applauding him with every token of honour and reverence.

When a *Cúci* dies, all his kinſmen join in killing a hog and a *gayál*; and, having boiled the meat, pour ſome liquor into the mouth of the deceaſed, round whoſe body they twiſt a piece of cloth by way of ſhroud: all of them taſte the ſame liquor as an offering to his ſoul; and this ceremony they repeat at intervals for ſeveral days. Then they lay the body on a ſtage, and kindling a fire under it, pierce it with a ſpit and dry it; when it is perfectly dried, they cover it with two or three folds of cloth, and, encloſing it in a little caſe within a cheſt, bury it under ground. All the fruits and flowers that they gather within a year after the burial they ſcatter on the grave of the deceaſed: but ſome bury their dead in a different manner; covering them firſt with a ſhroud, then with a mat of woven reeds, and hanging them on a high tree. Some, when the fleſh is decayed, waſh the bones, and keep them dry in a bowl, which they open on every ſudden emergence; and, fancying themſelves at a conſultation with the bones, purſue whatever meaſures they think proper; alleging that they act by the command of their departed parents and kinſmen. A widow is obliged to remain a whole year near the grave of her huſband; where her family bring her food: if ſhe die within the year, they mourn for her; if ſhe live, they carry her back to her houſe, where all her relations are entertained with the uſual feaſt of the *Cúcis*.

If the deceaſed leave three ſons, the eldeſt and the youngeſt ſhare all his property; but the middle ſon takes nothing: if he have no ſons, his eſtate goes to his brothers; and if he have no brothers, it eſcheats to the chief of the tribe.

TIRESIAS, a famous ſoothſayer of antiquity, was the ſon of Everes and the nymph Chariclo. Pherecydes ſays, that Minerva being accidentally ſeen by Tireſias, as ſhe was bathing with Chariclo in the fountain of Hippocrene, the goddeſs was enraged, and declared that he ſhould ſee nothing more: on which he inſtantly loſt his ſight; but afterwards received from the goddeſs ſuperior endowments. Others ſay, that Juno ſtruck him ſtone-blind for deciding a caſe between Jupiter and her, to her diſſatisfaction; for which Jupiter gave him the faculty of divination: He was the moſt celebrated prophet in the Grecian annals. Ulyſſes is ordered by Circe to conſult him in the ſhades.

> There ſeek the Theban bard depriv'd of ſight,
> Within irradiate with prophetic light.

But, beſides the honour done to him by Homer, Sophocles makes him act a venerable and capital part in his tragedy of Oedipus. Callimachus aſcribes to Minerva the gift of his ſuperior endowments; the pre-eminence of his knowledge is likewiſe mentioned by Tully in his firſt book of Divination. And not only Tireſias is celebrated by Diodorus Siculus, but his daughter Daphne, who, like her father, was gifted with a prophetic ſpirit, and was appointed prieſteſs at Delphos. She wrote many oracles in verſe, from whence Homer was reported to have taken ſeveral lines, which he interwove in his poems. As ſhe was often ſeized with a divine fury, ſhe acquired the title of *ſibyl*, which ſignifies "enthuſiaſt." She is the firſt on whom it was beſtowed: in aftertimes this denomination was given to ſeveral other females that were ſuppoſed to be inſpired, and who uttered and wrote their predictions in verſe; which verſe being ſung, their function may be juſtly ſaid to unite the prieſthood with prophecy, poetry, and muſic.

TISRI, or Tizri, in chronology, the firſt Hebrew month of the civil year, and the 7th of the eccleſiaſtical or ſacred year. It anſwered to part of our September and October.

Tithing-Men || Tombuctoo.

TITHING-MEN, are now a kind of petty conſtables, elected by pariſhes, and ſworn in their offices in the court-leet, and ſometimes by juſtices of the peace, &c. There is frequently a tithing-man in the ſame town with a conſtable, who is, as it were, a deputy to execute the office in the conſtable's abſence; but there are ſome things which a conſtable has power to do, that tithing men and head-boroughs cannot intermeddle with. When there is no conſtable of a pariſh, his office and the authority of a tithing man ſeems to be all one under another name.

TITHONUS, in fabulous hiſtory, the ſon of Laomedon king of Troy, and the brother of Priamus; was beloved by Aurora, who carried him to Delos, thence to Ethiopia, and at laſt to heaven, where ſhe prevailed on the Deſtinies to beſtow upon him the gift of immortality; but forgot to add that of youth, which could only render the preſent valuable. At length Tithonus grew ſo old that he was obliged to be rocked to ſleep like an infant; when Aurora, not being able to put an end to his miſery by death, transformed him into a graſshopper; which renews its youth by caſting his ſkin, and in its chirping retains the loquacity of old age.

TITLE FOR ORDERS, in the church of England, is an aſſurance of being employed and maintained as an officiating clergyman in ſome cathedral or parochial church, or other place of Divine worſhip. And, by the 33*d Canon*, "no one is to be ordained but in order to be a curate or incumbent, or to have ſome miniſter's place in ſome church, or except he be fellow, conduct, or chaplain, in ſome college in one of the univerſities, or be maſter of arts of five years ſtanding, and live there at his own coſt." By the ſame canon, the biſhop who ordains a clerk without title, is bound to keep him till he prefer him to ſome eccleſiaſtical living.

TOD OF WOOL, is mentioned in the ſtatute 12 Carol. II. c. 32. as a weight containing 2 ſtone, or 28 pounds.

TOMBUCTOO, a large city in North Africa, and capital of a kingdom of the ſame name. It has for ſome years paſt been the great object of European reſearch, being one of the principal marts for that extenſive commerce which the Moors carry on with the Negroes. The hopes of acquiring wealth in this purſuit, and zeal for propagating their religion, have filled this extenſive city with Moors and Mahomedan converts; the king himſelf, and all the chief officers of ſtate are Moors; and they are ſaid to be more ſevere and intolerant in their principles than any other of the Mooriſh tribes in this part of Africa. Mr Park was informed, by a venerable old Negro, that when he firſt viſited Tombuctoo, he took up his lodging at a ſort of public inn, the landlord of which, when he conducted him into his hut, ſpread a mat on the floor, and laid a rope upon it; ſaying, "if you are a Muſſulman, you are my friend, ſit down; but if you are a Kafir, you are my ſlave; and with this rope I will lead you to market." The reigning ſovereign of Tombuctoo, when Mr Park was in Africa, was named *Abu Abrahima*. He was reported to poſſeſs immenſe riches, and his wives and concubines were ſaid to be clothed in ſilk, and the chief officers of ſtate live in conſiderable ſplendour. The whole expence of his government is defrayed by a tax upon merchandize, which is collected at the gates of the city.

Tomſook, Tooth-ache.

Of that city very little is known with accuracy, as it has never been viſited by any European. It is the largeſt on the Niger, Houſſa only excepted; and probably contains from 60,000 to 80,000 inhabitants In ſome of the Gazetteers, its houſes are ſaid to be built in the form of bells; but they are probably ſuch buildings as thoſe of SEGO, which ſee in this *Supplement*. Tombuctoo, according to Major Rennel, is in 16° 30′ N Lat. and 1° 33′ E. Long. from Greenwich.

TOMSOOK, in the language of Bengal, a bond.

TOOTH-ACHE, a well known-excruciating pain (ſee *Encycl.*), for the alleviation, and even the cure of which, many ſpecifics have been offered to the public. Of one of the moſt extraordinary of theſe, there is an account, in a ſmall work publiſhed at Florence in 1794, by profeſſor Gerbi, who gives the deſcription of an inſect, a kind of *curculio*, which, from its property of allaying the tooth-ache, has received the epithet of *antiodontalgicus*, and which is found on a ſpecies of thiſtle, *carduus ſpinoſiſſimus*. The flowers of this thiſtle, when analyſed, gave the acid of galls, the muriatic acid, oxalat of lime, extractive matter, and a very little reſin. On the bottom of the calyx, which ſupports the flowers, there are often found excreſcences like the gall nut, which are at firſt ſpheroidal, afterwards cylindric, and at length aſſume the figure of two hemiſpheres: they conſiſt of the like component parts with the flowers, but contain more reſin, and far more oxalat of lime; as the gall apple of the oak, according to the experiments of M. Branchi, which are here mentioned, contains more of the acid of galls than the bark and other parts of the oak, in which he could diſcover no ſulphuric acid. The inſect, according to the author's obſervations, eats not only the parenchyma, but alſo the veſſels and fibres of the leaves. The egg, before the worm makes its appearance, is nouriſhed by the ſap of the plant, and of the above excreſcences, in which it reſides, by means of the attractive power that the egg poſſeſſes for certain vegetable juices and ſubſtances. The excreſcences ariſe by the accumulation of a ſolid ſubſtance, which is precipitated from the nouriſhing juices of the thiſtle, diminiſhed by nouriſhing the egg and the worm. This inſect, the eggs of which are depoſited in theſe excreſcences, is, together with the *curculio* of the centaury, a new ſpecies. It is of a longiſh figure; covered below with ſhort yellow hair, and above with golden yellow velvety ſpots. Its corſlet is variegated with ſpecks; and the covering of its wings with ſpecks and ſtripes. It has a ſhort proboſcis, and ſhews ſome likeneſs to the *curculio villoſus* of Geoffroy. Its larva repreſents a ſort of ichneumon. By chemical analyſis it exhibits ſome traces of common ſalt; by diſtillation with a ſtrong dry heat, ſome volatile lixivious ſalts; and it contains, beſides theſe, ſome gelatinous, and a little ſebaceous and ſlimy extractive matter. If about a dozen or fifteen of theſe inſects, when in the ſtate of larva, or even when come to perfection, be bruiſed and rubbed ſlowly between the fore-finger and the thumb, until they have loſt their moiſture, and if the painful tooth, where it is hollow, be touched with that finger, the pain ceaſes, ſometimes inſtantaneouſly. This power or property the finger will retain for a year, even though it be often waſhed and uſed. A piece of ſhamoy leather will ſerve equally well with the finger. Of 629 experiments, 401 were attended with complete ſucceſs. In two of theſe caſes, the hollow teeth aroſe from ſome fault in the juices: in the reſt they were merely local. If the gums are inflamed, the remedy is of no avail.

To the truth of this tale the reader will give what credit he pleaſes; but it is ſurely very difficult to believe, that a living finger, continually perſpiring, can retain for a year the moiſture imbibed from this inſect. But it ſeems there are other inſects which have the property of curing the tooth ache; ſuch as the *carabus chryſocephalus* of Roſſi; the *carabus ferrugineus* of Fabricius; the *coccinella ſeptem punctata* (the lady bird); the *chryſomela populi*, and the *chryſomela ſanguinolenta*. It would appear, therefore, that this property belongs to various kinds of the *coleoptera*.

The idea of theſe inſects being endowed with the property of curing the tooth-ache is not confined to Italy; for Dr Hirſch, dentiſt to the court of Weimar, aſſerts (*Verkundiger*, September 24, 1798) that he employed them with the happieſt effect, except in ſome caſes where his patients were females. He ſays, that he took that ſmall inſect, found commonly among corn, *coccinella ſeptem punctata*, and bruiſed it between his fingers. He then rubbed the fingers with which he had bruiſed it, till they became warm at the points, and touched with them the unſound parts of the gums, as well as the diſeaſed tooth. Dr Hirſch adds, that he made the ſame experiment a few days after with equal ſucceſs, though he had not bruiſed a new inſect with his fingers. He ſeems to think that, to inſure the efficacy of the proceſs, the inſect ſhould be alive; becauſe, when dead, its internal parts, in which he preſumes the virtue chiefly reſides, become dried up, leaving only the wings and an empty ſhell; and therefore propoſes to phyſicians to turn their attention to the finding out of ſome method for preſerving the virtue of the inſect, ſo that its efficacy may be in full vigour throughout the year.

Beſides theſe beetles, charcoal has been recommended as an anodyne in the tooth-ache; but whether it operates merely by filling the hollow of the tooth, and thereby preventing the acceſs of atmoſpheric air to the nerve, or by any of its ſingular and hitherto unknown qualities, ſeems not to have been well aſcertained.

TOR, a town of Aſia, in Arabia Petræa, ſeated on the Red Sea, with a good harbour, defended by a caſtle. There is a handſome Greek convent, in whoſe garden are fountains of bitter water, which they pretend are thoſe rendered ſweet by Moſes, by throwing a piece of wood into them. Some think that this town is the ancient Elana. E. Long. 31. 25. N. Lat. 28. 0.

TORELLI (Joſeph), was born at Verona on the 4th of November 1721. His father Lucas Torelli, who was a merchant, dying while young Torelli was but an infant, he was left entirely to the care of his mother Antonia Albertini, a Venetian lady of an excellent character. After receiving the firſt rudiments of learning, he was placed under the Ballerini, who, obſerving the genius of the boy, prevailed upon his mother to ſend him to complete his education at Patavia. Here he ſpent four years entirely devoted to ſtudy, all his other paſſions being abſorbed by his thirſt for knowledge.

The unſullied innocence of his life, and the prudence and gravity of his conduct, ſoon attracting the attention of his maſters, they not only commended him with eagerneſs, but performed to him the part of parents, converſed with him familiarly about their reſpective ſciences, and read over to him privately the lectures which they had to deliver. This was the caſe particularly with Hercules Dondinus, under whom Torelli ſtudied juriſprudence. But he by no means confined himſelf to that ſcience alone. The knowledge which he acquired was ſo general, that upon whatever ſubject the converſation happened to turn, he delivered his ſentiments upon it in ſuch a manner that one would have thought he had beſtowed upon it his whole attention.

After receiving the degree of Doctor, he returned home to the enjoyment of a conſiderable fortune; which putting it into his power to chooſe his own mode of living, he determined to devote himſelf entirely to literary purſuits. He reſolved, however, not to cultivate one particular branch to the excluſion of every other, but to make himſelf maſter of one thing after another, as his humour inclined him; and he was particularly attentive to lay an accurate and ſolid foundation. Tho' he declined practiſing as a lawyer, he did not, on that account, relinquiſh the ſtudy of law. The Hebrew, Greek, Latin, and Italian languages, occupied much of his time. His object was to underſtand accurately the two firſt, and to be able to write and ſpeak the two laſt with propriety and elegance. Beſides theſe languages, he learned French, Spaniſh, and Engliſh. On the laſt, in particular, he beſtowed uncommon pains; for he was peculiarly attached to the Britiſh nation, and to Britiſh writers, whom he peruſed with the greateſt attention; not merely to acquire the language, but to imbibe alſo that force and loftineſs of ſentiment for which they are ſo remarkable. Nay, he even began an Italian tranſlation of Paradiſe Loſt.

He likewiſe made himſelf acquainted with ethics, metaphyſics, and polemical divinity; to which laſt ſubject he was induced to pay attention by the cuſtom of his country. With ancient hiſtory he was very familiarly acquainted, calling in to his aſſiſtance, while engaged in that ſtudy, the aids of chronology, geography, and criticiſm. This laſt art, indeed, by means of which what is counterfeit may be diſtinguiſhed from what is genuine, what is interpolated from what is uncorrupted, and what is excellent from what is faulty, he carried about with him as his counſellor and his guide upon all occaſions.

The theory of *muſic* he ſtudied with attention, preferring thoſe powerful airs which make their way into the ſoul, and rouſe the paſſions at the pleaſure of the muſician. His knowledge of *pictures* was held in high eſtimation by the artiſts themſelves, who were accuſtomed to aſk his opinion concerning the fidelity of the deſign, the harmony of colours, the value of the picture, and the name of the painter. He himſelf had a collection, not remarkably ſplendid indeed, but exceedingly well choſen. *Architecture* he ſtudied with ſtill greater attention, becauſe he conſidered it as of more real utility. Nor did he neglect the purſuits of the *antiquarian*, but made himſelf familiarly acquainted with coins, gems, medals, engravings, antique veſſels, and monuments. Indeed ſcarce any monumental inſcriptions were engraved at Verona which he had not either compoſed or corrected. With the *antiquities* of his own country he was ſo intimately acquainted, that every perſon of eminence, who viſited Verona, took care to have him in their company when they examined the curioſities of the city.

But theſe purſuits he conſidered merely as amuſements; mathematics and the belles lettres were his ſerious ſtudies. Theſe ſtudies are, in general, conſidered as incompatible; but Torelli was one of the few who could combine the gravity of the mathematician with the amenity of the muſes and graces, and who handle the compaſs and the plectrum with equal ſkill. Of his progreſs in mathematics, ſeveral of his treatiſes, and eſpecially his edition of Archimedes, publiſhed ſince his death by the univerſity of Oxford, are ſufficient proofs. Nor was his progreſs in the more pleaſing parts of literature leſs diſtinguiſhed. In both theſe ſtudies he was partial to the ancients, and was particularly hoſtile to the poetry and the literary innovations of the French.

Nothing could be purer or more elegant than his Latin ſtyle, which he had acquired at the expence of much time and labour. His Latin tranſlation of Archimedes is a ſufficient proof of this, and is indeed really wonderful, if we conſider that the Romans, being far inferior to the Greeks in mathematical knowledge, their language was of neceſſity deſtitute of many neceſſary words and phraſes. He wrote the Italian language with the claſſic elegance of the 14th and 15th centuries. Witneſs his different works in that language, both in proſe and verſe. He tranſlated the whole of Æſop's Fables into Latin, and Theocritus, the *Epithalamium* of Catullus, and the *comedy* of Plautus, called *Pſeudolus*, into Italian verſe. The two firſt books of the Æneid were alſo tranſlated by him with ſuch exactneſs, and ſo much in the ſtyle of the original, that they may well paſs for the work of Virgil himſelf.

His life, like his ſtudies, was drawn after the model of the ancient ſages. Frugal, temperate, modeſt, he exhibited a ſtriking contraſt to the luxurious manners of his age. In religion he adhered ſtrictly, though not ſuperſtitiouſly, to the opinions of his anceſtors. He was firm to his reſolutions, but not fooliſhly obſtinate; and ſo ſtrict an obſerver of equity, that his probity would have remained inviolate, even though there had been no law to bind him to juſtice. He never married, that he might have leiſure to devote himſelf, with leſs interruption, to his favourite ſtudies. Every one readily found admiſſion to him, and no man left him without being both pleaſed and inſtructed; ſuch was the ſweetneſs of his temper, and the readineſs with which he communicated information. He adhered with great conſtancy to his friendſhips. This was particularly exemplified in the caſe of Clemens Sibiliatus, who has favoured the world with the life of Torelli. With him he kept up the cloſeſt connection from a ſchool boy till the day of his death. He was peculiarly attached likewiſe to many men of diſtinction, both in Italy and Britain. He died in Auguſt 1781, in the 70th year of his age.

The following is a complete liſt of his works, his edition of Archimedes excepted, which was not publiſhed till after his death:

1. "Lucubratio Academica, ſivi Somnium Jacobi Pindemontii, &c." Patavii, 1743.—2. "Animadverſiones in Hebraicum Exodi Librum et in Græcum lxx Interpretationem;" Veronæ, 1744.—3. "De principe Gulæ incommodo, ejuſque remedio, Libri duo;" Coloniæ Agrippinæ, 1744.—4. "De Probabili Vitæ Morumque Regula;" Coloniæ, 1747.—5. "Li due primi Canti dell' Iliade (di Scipione Maffei) e li due primi dell' Eneide di Giuſeppe Torelli tradotti in verſi Italiani;" Verona, 1749.—6. "Gli ſteſſi due canti dell' Eneide riſtampati ſoli lo ſteſſo anno per lo ſteſſo Ramanzini."—7. "Scala de Meriti a capo d'anno Trattato Geometrico;" Verona, 1751.—8. "De Nihilo Geometrico, lib. 2.;" Veronæ, 1758.—9. "Lettera intorno a due paſſi del Purgatorio di Dante Alighiero;" *ib.* 1760.—10. "Della Denominazione del corrente anno volgarmente detto 1760 in Bologna per Lelio della Volpe."—11. "Il pſeudolo. Comedia, &c. e ſi aggiunge la traduzione d'alcuni Idilli di Teocrito e di Moſco;" Firenze, 1765.—12. "Inno a Maria Virgine nella Feſtivita della ſua Concezione;" Verona, 1766.—13. "Lettera a Miladi Vaing-Reit premeſſa al libro che ha per titalo xii. lettere Ingleſi, con altra lettera all'autore della ſuddetta;" Verona, 1767.—14. TORPEDO, or Cramp-fish, has been deſcribed under the generic title Raja; and an attempt made to explain its electrical phenomena in the article Electricity, n° 258, &c. (Both theſe articles are in the *Encyclopædia*). From ſome late diſcoveries, however, of Volta and others, the ſhock given by the torpedo appears much more analogous to the ſhock of Galvaniſm than to that of common electricity; and even the electrical organs of the fiſh ſeem to reſemble the apparatus with which thoſe diſcoveries in galvaniſm were made.

In the 63d volume of the Philoſophical Tranſactions, Mr Hunter deſcribes the electric organ of the torpedo as conſiſting of a number of columns, varying in their length from an inch and a half to a quarter of an inch, with diameters about two-tenths of an inch. The number of columns in each organ of the torpedo which he preſented to the Royal Society was about 470; but in a very large torpedo which he diſſected, the number of columns in one organ was 1182. Theſe columns were compoſed of films parallel to the baſe of each; and the diſtance between each partition of the columns was $\frac{1}{150}$th of an inch. From theſe facts, the reader will find the anomalies of torpedinal electricity (ſuppoſing it the ſame with common electricity) accounted for in a very ingenious and philoſophical manner by Mr Nicholſon, at p. 358 of the firſt volume of his valuable Journal. We paſs on, however, to point out the reſemblance between it and the lately diſcovered phenomena in galvaniſm.

Take any number of plates of copper, or, which is better, of ſilver, and an equal number of tin, or, which is much better, of zinc, and a like number of diſcs, or pieces

pieces of card, or leather, or cloth (A), or any porous ſubſtance capable of retaining moiſture. Let theſe laſt be ſoaked in pure water, or, which is better, ſalt and water, or alkaline leys. The ſilver or copper may be pieces of money. Build up a pile of theſe pieces; namely, a piece of ſilver, a piece of zinc, and a piece of wet card: then another piece of ſilver, a piece of zinc, and a piece of wet card: and ſo forth, in the ſame order (or any other order, provided the pieces ſucceed each other in their turn), till the whole number intended to be made uſe of is builded up. The inſtrument is then completed.

In this ſtate it will afford a perpetual current of the galvanic influence through any conductor communicating between its upper and lower plates; and if this conductor be an animal, it will receive an electrical ſhock as often as the touch is made, by which the circuit is completed. Thus if one hand be applied to the lower plate, and the other to the upper, the operator will receive a ſhock, and that as often as he pleaſes to lift his finger and put it down again.

This ſhock reſembles the weak charge of a battery of immenſe ſurface; and its intenſity is ſo low that it cannot make its way through the dry ſkin. It is therefore neceſſary that a large ſurface of each hand ſhould be well wetted, and a piece of metal be graſped in each, in order to make the touch; or elſe that the two extremities of the pile ſhould communicate with ſeparate veſſels of water, in which the hands may be plunged.

The commotion is ſtronger the more numerous the pieces. Twenty pieces will give a ſhock in the arms, if the above precautions be attended to. One hundred pieces may be felt to the ſhoulders. The current acts on the animal ſyſtem while the circuit is complete, as well as during the inſtant of commotion, and the action is abominably painful at any place where the ſkin is broken.

That this influence, whatever it may be, has a ſtriking reſemblance to the repeated ſhocks given by the torpedo, is obvious; but what it really is in itſelf muſt be aſcertained, if it can be aſcertained at all, by future experiments. Mr Nicholſon indeed, from whoſe Journal we have taken this account of Volta's apparatus and its effects, ſeems confident that theſe effects proceed from an electrical ſtream or current; but this mode of operation is quite foreign from all the laws of electricity known to us. The galvanic influence in this apparatus appears to move perpetually in a circle; to which we are acquainted with no fact in electricity that is at all ſimilar. Galvaniſm, too, ſeems capable of accumulation, even while ſurrounded by conducting ſubſtances, which is quite inconſiſtent with all that we *diſtinctly* know of electricity and its laws.

That the energy of the apparatus, however, is the effect of an electric ſtream or current, our ingenious author thinks proved by the condenſer with which Sig. Volta aſcertained the kind of the electricity, and obtained its ſpark. He finds the action ſtrongeſt, or moſt pungent, on wounds on the minus ſide of the apparatus, or where the wounds give out electricity; a fact alſo obſervable in the common electric ſpark.

The theory of the learned inventor ſeems to be, that it is a property of ſuch bodies as differ in their power of conducting electricity, that when they are brought into contact they will occaſion a ſtream of the electric matter. So that if zinc and ſilver be made to communicate immediately by contact, there will be a place of good conducting energy; and if they be made to communicate mediately by means of water, there will be a place of inferior conducting energy: and wherever this happens, there will be a ſtream or current produced in the general ſtock of electricity. This is not deduced as the conſequence of other more ſimple facts; but is laid down as a general or ſimple principle grounded on the phenomena. If ſo, is it not a *petitio principii?* That ſuch bodies as zinc and ſilver, when properly diſpoſed, produce a ſtream or current, or ſomething analogous to a ſtream or current, in the galvanic fluid, follows indeed indiſputably from the phenomena; but it by no means follows from the ſame phenomena that galvaniſm is electricity; for electricity ſeems ſubject to different laws. See ELECTRICITY and THUNDER, both in this *Supplement*.

It muſt be acknowledged that the diſcovery of the galvanic ſhock and ſpark, and of the apparent exiſtence of two oppoſite ſtates of galvaniſm correſponding to poſitive and negative electricity, conſiderably increaſe the analogy; which, in the article GALVANISM, *Suppl.* we have admitted to be very ſtriking: but ſuppoſing no fallacy in any of Volta's experiments, we do not think that theſe diſcoveries amount to any thing like a demonſtration of the concluſions which have been drawn from them. It is by no means certain that light is eſſentially connected with the electric fluid; for we know that it is not eſſentially connected with heat: (See *THERMOMETRICAL Spectrum*, in this *Suppl.*) The flaſh, for example, of lightning may be merely an extrication of light, in conſequence of the action of electricity upon the atmoſphere in its paſſage, or on the bodies upon which it impinges; and there are many inſtances of a ſimilar extrication, as in the colliſion of two pieces of flint, where neither electricity nor galvaniſm were ever ſuſpected to have any ſhare in producing the phenomenon. Why may not the progreſs of the galvanic fluid have a ſimilar effect in this inſtance with that of electricity, though the two fluids be eſſentially different between themſelves? But we have more to ſay on this ſubject.

Meſſrs Nicholſon and Carliſle conſtructed an apparatus ſimilar to that of Volta, which gave them a ſhock as before deſcribed, and a very acute ſenſation wherever the ſkin was broken. Their firſt reſearch was directed to aſcertain that the ſhock they felt was really an electrical phenomenon. For this purpoſe the pile was placed upon Bennett's gold leaf electrometer, and a wire was then made to communicate from the top of the pile to the metallic ſtand or foot of the inſtrument; ſo that the circuit of the ſhock would have been thro' the leaves, if they had diverged; but no ſigns of electricity appeared. Recourſe was then had to the revolving doubler; of which the reader will find an account in our Supplementary article ELECTRICITY,

---

(A) Woollen or linen cloth appear to be more durable, and more ſpeedily ſoaked, than card.

nº 203. The doubler had been previouſly cleared of electricity by twenty turns in connection with the earth. The negative divergence was produced in the electrometer. Repeated experiments of this kind ſhewed that the ſilver end was in the minus, and the zinc end in the plus ſtate.

Here a pile of 17 half crowns, with a like number of pieces of zinc, and of paſteboard ſoaked in ſalt water, though it gave a ſevere ſhock, exhibited no ſymptoms of electricity till aſſiſted by the doubler. Will it be ſaid that this aroſe from want of intenſity in the galvanic ſhock? We can only reply, that a much leſs intenſe ſhock of electricity would have produced a ſenſible divergence in the inſtrument without the doubler. What was the cauſe of this difference? We have, however, no doubt but that electricity was concerned in this phenomenon; for we have ſhewn elſewhere (ſee Thunder, *Suppl.)*, that either *electricity* is produced, or the equilibrium of the electrical fluid diſturbed, by every chemical ſolution; and we ſhall ſee immediately that chemical ſolutions are perpetually going on in Volta's apparatus.

Very early in the courſe of this experiment, the contacts being made ſure by placing a drop of water upon the upper plate, Mr Carliſle obſerved a diſengagement of gas round the touching wire. This gas, though very minute in quantity, evidently ſeemed to have the ſmell afforded by hydrogen when the wire of communication was ſteel. This, with ſome other facts, led Mr Nicholſon to propoſe to break the circuit by the ſubſtitution of a tube of water between two wires. They therefore inſerted a braſs wire through each of two corks inſerted in a glaſs tube of half an inch internal diameter. The tube was filled with New River water, and the diſtance between the points of the wires in the water was one inch and three quarters. This compound diſcharger was applied ſo that the external ends of its wire were in contact with the two extreme plates of a pile of 36 half crowns, with the correſpondent pieces of zinc and paſteboard. A fine ſtream of minute bubbles immediately began to flow from the point of the lower wire in the tube which communicated with the ſilver, and the oppoſite point of the upper wire became tarniſhed, firſt deep orange, and then black. On reverſing the tube, the gas came from the other point, which was now loweſt; while the upper, in its turn, became tarniſhed and black. Reverſing the tube again, the phenomena again changed their order. In this ſtate the whole was left for two hours and a half. The upper wire gradually emitted whitiſh filmy clouds, which, towards the end of the proceſs, became of a pea-green colour, and hung in perpendicular threads from the extreme half inch of the wire, the water being rendered ſemiopaque by what fell off, and in a great part lay, of a pale green, on the lower ſurface of the tube, which, in this diſpoſition of the apparatus, was inclined about forty degrees to the horizon. The lower wire, of three quarters of an inch long, conſtantly emitted gas, except when another circuit, or complete wire, was applied to the apparatus; during which time the emiſſion of gas was ſuſpended. When this laſt mentioned wire was removed, the gas re-appeared as before, not inſtantly, but after the lapſe of four beats of a half ſecond clock ſtanding in the room. The product of gas, during the whole two hours and a half, was two-thirtieths of a cubic inch. It was then mixed with an equal quantity of common air, and exploded by the application of a lighted waxed thread.

Meſſrs Nicholſon and Carliſle had been led, by their reaſoning on the firſt appearance of hydrogen, to expect a decompoſition of the water; but it was with no little ſurprize that they found the hydrogen extricated at the contact with one wire, while the oxygen fixed itſelf, in combination with the other wire, at the diſtance of almoſt two inches. This new fact ſtill remains to be explained, and ſeems, ſays Mr Nicholſon, to point at ſome general law of the agency of electricity in chemical operations. Does it not as naturally ſuggeſt a ſuſpicion that galvaniſm is not electricity; eſpecially as we are informed, by Mr Cruickſhank of Woolwich, that Meſſrs Nicholſon and Carliſle diſcovered, that "galvaniſm decompoſes water with much greater facility than electricity, and with phenomena ſomewhat different?" What the particular differences are, he does not ſay; but we learn from Mr Nicholſon himſelf, that from the general tenor of his experiments, it appears to be eſtabliſhed, that the decompoſition of water by galvaniſm is more effectual the leſs the diſtance is between the wires, but that it ceaſes altogether when the wires are in contact.

Mr Nicholſon concludes his memoir with mentioning conciſely the effects of a pile of 100 half crowns, and a chemical incident, which appears to be the moſt remarkable of thoſe which he has yet obſerved.

The pile was ſet up with pieces of green woollen cloth ſoaked in ſalt water. It gave ſevere ſhocks, which were felt as high as the ſhoulders. The tranſition was much leſs forcible through a number of perſons, but it was very perceptible through nine. The ſpark was frequently viſible when the diſcharge was made in the dark, and a gleam of light was alſo, in ſome inſtances, ſeen about the middle of the column at the inſtant of the exploſion. The aſſiſtants were of opinion that they heard the ſnap.

The extrication of the gaſes was rapid and plentiful by means of this apparatus. When copper wires were uſed for the broken circuit, with muriatic acid diluted with 100 parts of water in the tube, no gas, nor the leaſt circulation of the fluid was perceived, when the diſtance of the wires was two inches. A ſhort tube, with two copper wires very near each other in common water, was made part of the circuit, and ſhewed, by the uſual phenomena, that the ſtream of electricity was rapidly paſſing. The wires in the muriatic acid were then ſlided within the third of an inch of each other. For the ſake of brevity he avoids enumerating the effects which took place during ſeveral hours, and ſimply ſtates, that the minus wire gave out ſome hydrogen during an hour; while the plus wire was corroded, and exhibited no oxyd; but a depoſition of copper was formed round the minus, or lower wire, which began at its lower end: that no gas whatever appeared in this tube during two hours, though the depoſition was going on, and the ſmall tube ſhewed the continuance of the electric ſtream; and that the depoſition, at the end of four hours, formed a ramified metallic vegetation, nine or ten times the bulk of the wire it ſurrounded.

In this experiment, it appeared that the influence of electricity increaſing the oxydability of the upper wire, and affording naſcent hydrogen from the lower, cauſed the latter to act as the precipitant of a ſolution of one and the ſame metal.

Mr Nicholſon, we ſee, continues to call it electricity with the utmoſt confidence, as if it could not poſſibly be any thing elſe; and yet he ſays that the galvanic ſhock is much leſs forcible when paſſed through a number of perſons than when paſſed only through one. This, we believe, does not hold in the ſhocks of common electricity; and the difference probably ariſes from the cuticle obſtructing the paſſage of the one and not of the other. Volta himſelf ſays, that *this* electricity, for he too is deſirous to prove it electricity, does not diffuſe itſelf through the air. It is ſo univerſally known that very dry air is no conductor of electricity, that he muſt mean, on this occaſion, air not uncommonly dry; otherwiſe the non-diffuſion of *this* electricity through air would not diſtinguiſh it, as he ſeems to admit it does, from common electricity. But what occaſions this diſtinction, if the two electricities be the ſame?

Lieutenant-colonel Haldane, well known in the ſcientific world, made experiments with Volta's pillar, both in a horizontal and in a vertical poſition. With a large pillar, placed vertically, he obtained very weak ſigns of electricity. He connected the apparatus with the conductor of an electrical machine, and found the effect rather impeded than aſſiſted by the common electric ſtream. He placed the plate of Bennet's electrometer in the circuit, without producing electric ſigns. He found that the galvanic apparatus, placed between the outſide and inſide of a jar, prevented its charging, and that it is alſo capable of conducting the charge, though not rapidly: and, on the whole, from the very minute exhibition of the attractive and repellent powers, while the cauſticity, the ſhock, and the oxydation, are ſo very powerful, he cannot be perſuaded that electricity is the principal agent, though ſome might be generated, or diſengaged, during the operation of the apparatus.

This is exactly our own opinion, which is ſtrongly corroborated by the reſults of ſome very curious experiments made by Mr Cruickſhank of Woolwich. Theſe experiments our limits permit us not to detail. They were made with a view to aſcertain the nature and relative proportions of the gaſes obtained from water and other fluids by this influence; and the author thinks himſelf authoriſed to conclude from them:

1. That hydrogen gas, mixed with a very ſmall proportion of oxygen and ammonia, is ſomehow diſengaged at the wire connected with the ſilver extremity of the machine; and that this effect is equally produced, whatever the nature of the metallic wire may be, provided the fluid operated upon be pure water.

2. That where metallic ſolutions are employed inſtead of water, the ſame wire which ſeparates the hydrogen revives the metallic calx, and depoſits it at the extremity of the wire in its pure metallic ſtate; in this caſe no hydrogen gas is diſengaged. The wire employed for this purpoſe may be of any metal.

3. That of the earthy ſolutions, thoſe of magneſia and argil only are decompoſed by the ſilver wire; a circumſtance which ſtrongly favours the production of ammonia.

4. That when the wire connected with the zinc extremity of the pile conſiſts either of gold or platinum, a quantity of oxygen gas, mixed with a little azote and nitrous acid, is diſengaged; and the quantity of gas thus obtained is a little better than $\frac{1}{3}$d of the hydrogen gas ſeparated by the ſilver wire at the ſame time.

5. That when the wire connected with the zinc is ſilver, or any of the imperfect metals, a ſmall portion of oxygenous gas is likewiſe given out; but the wire itſelf is either oxydated or diſſolved, or partly oxydated and partly diſſolved: indeed, the effect in this caſe produced upon the metal is very ſimilar to that of the concentrated nitrous acid, where a great deal of the metal is oxydated, and but a ſmall quantity held in ſolution.

6. That when the gaſes obtained by gold or platinum wires are collected together and exploded over mercury, the whole nearly diſappears and forms water, with probably a little nitrous acid; for there was always a thick white vapour perceived for ſome time after the exploſion. The reſiduary gas, in this caſe, appeared to be azote.

In reflecting on theſe experiments, it would appear that in ſome of them the water muſt be decompoſed: but how this can be effected is by no means ſo eaſily explained. For example, it ſeems extremely myſterious how the oxygen ſhould paſs ſilently from the extremity of the ſilver wire to that of the zinc wire, and there make its appearance in the form of gas. It is to be obſerved, likewiſe, that this effect takes place which ever way the wires are placed, and whatever bends may be interpoſed between their extremities, provided the diſtance be not too great. On conſidering theſe facts more minutely, it appeared to Mr Cruickſhank that the eaſieſt and ſimpleſt mode of explanation would be, to ſuppoſe that the galvanic influence (whatever it may be) is capable of exiſting in two ſtates, that is, in an oxygenated and deoxygenated ſtate; that when it paſſes from metals to fluids containing oxygen, it ſeizes their oxygen, and becomes oxygenated; but when it paſſes from the fluid to the metal again, it aſſumes its former ſtate, and becomes deoxygenated. Now when water is the fluid interpoſed, and the influence enters it from the ſilver ſide deoxygenated (and we ſuppoſe that it always paſſes from the deoxygenated to the oxygenated ſide), it ſeizes the oxygen of the water, and diſengages the hydrogen, which accordingly appears in the form of gas*; but when the influence enters the zinc wire, it parts with the oxygen, with which it had formerly united; and this either eſcapes in the form of gas, unites with the metal to form an oxyd, or, combined with a certain portion of water, &c. may, according to the German chemiſts, form nitrous acid. When a metallic ſolution is the interpoſed fluid, the effect produced may be explained in two ways; but the ſimpleſt is to ſuppoſe that the influence, in paſſing from the ſilver wire, ſeizes the oxygen of the metallic calx, and afterwards depoſits it on entering the zinc one. In this caſe no gas ſhould appear at the ſilver wire; but when a perfect metal is employed, oxygen ſhould be diſengaged from the zinc wire: and this, as has been already mentioned, is exactly what takes place.

What our author conſiders as the ſtrongeſt argument in favour of this hypotheſis, and what we conſider as an argument equally ſtrong to prove that galvaniſm differs eſſentially from electricity, is, that all fluids which do not contain oxygen, are incapable of tranſmitting the galvanic fluid, ſuch as alcohol, æther, the fat, and eſſential oils, as he has proved by direct experiment ; but on the contrary, that all thoſe which do contain oxygen conduct it more or leſs readily, as all aqueous fluids, metallic ſolutions, and acids, more eſpecially the concentrated ſulphuric acid ; which it decompoſes. In this laſt inſtance, the oxygen produced can hardly be aſcribed to the decompoſition of water ; for this acid, when properly concentrated, does not contain any ſenſible quantity. By this theory alſo we can readily explain the oxydation of the zinc plates in the machine ; where the fluid in paſſing from the different pairs of plates appears to be alternately oxygenated and deoxygenated. Although I am not (ſays Mr Cruikſhank) by any means entirely ſatisfied with this hypotheſis, yet as it is the only one by which I can explain the different phenomena, it was thought adviſable to throw it out, merely with a view to induce others to reaſon upon the ſubject, and to incite them to make experiments, by which alone truth can be aſcertained.

We approve heartily of his conduct. It is for the ſame reaſon, and not to maintain at all hazards any preconceived opinion of our own, that we have urged every objection that occurs to us againſt the hypotheſis of the identity of galvaniſm and electricity. Theſe fluids or influences appear to us to differ eſſentially ; but ſtill we admit that future experiments and future reaſonings *may remove* our objections, which, however, ought never to be loſt ſight of *till* they be removed. If ingenious men, adopting implicitly the hypotheſis of Volta and Mr Nicholſon, ſhall inſtitute a ſet of experiments to aſcertain the laws of the galvanic influence, they will be very apt to make their experiments ſupport their hypotheſis, inſtead of employing them as guides to the temple of truth. Mr Nicholſon ſays, that in all the experiments made by him and Mr Carliſle, the action of the inſtrument was freely tranſmitted through the uſual conductors of electricity (meaning, we ſuppoſe, metals and watery fluids), but that it was ſtopped by glaſs and other non-conductors. We have experienced the ſame thing, and ſo far we acknowledge a ſtriking reſemblance between galvaniſm and electricity ; but, on the other hand, we have never been able to make any accumulation of galvaniſm by means of coated electrics, whilſt Mr Cruickſhank found that the galvanic influence cannot be tranſmitted through alcohol, ether, or eſſential oils. In theſe inſtances, the difference between galvaniſm and electricity ſeems to be as ſtriking as the reſemblance is in the others. Indeed theſe differences between the one and the other are ſo many and ſo great, that M. Fabbroni attributes the phenomena of galvaniſm not to electricity, but to a chemical operation ; to the tranſition of oxygen into a combination, and to the formation of a new compound. He had obſerved, in repeating the common experiment, that if he wiped his tongue as accurately as poſſible, the ſenſation of taſte excited by the two metals was ſo diminiſhed as to be hardly diſtinguiſhed. The ſaliva, or ſome other moiſture, muſt therefore be of ſome importance in this phenomenon. He afterwards inſtituted a ſet of very proper experiments; from which it appeared to him that an evident chemical action takes place in the operations of galvaniſm, and that it is unneceſſary to ſeek farther for the nature of the new ſtimulus. Galvaniſm (he ſays) is manifeſtly a combuſtion or oxydation of the metals ; and the ſtimulating principle may be either the caloric which is diſengaged, or the oxygen which paſſes into new combinations ; or the new metallic ſalt ; but which of theſe he has not aſcertained.

Without adopting or rejecting theſe concluſions, we recommend them to the attention of our chemical readers ; for it is only by expert and ſcientific chemiſts that we expect the nature and properties of galvaniſm to be aſcertained. In the mean time, it is proper to obſerve, that the pile of Volta continues in order for about three days, and ſcarcely three ; and that on account of the corroſion of the fæces of the zinc, it is neceſſary to renew them previous to each conſtruction of the pile. This may be done by ſcraping or grinding, or by cleaning them with diluted muriatic acid.

To avoid the trouble of conſtantly repiling the pieces of ſilver and zinc, Mr Cruickſhank conſtructed a kind of trough of baked wood, 26 inches in length, 1.7 inches deep, and 1.5 inches wide ; in the ſides of this trough grooves were made oppoſite to each other, about the tenth of an inch in depth, and ſufficiently wide to admit one of the plates of zinc and ſilver when ſoldered together ; three of theſe grooves were made in the ſpace of one inch and three tenths, ſo that the whole machine contained 60 pair of plates. A plate of zinc and ſilver, each 1.6 inches ſquare, well cemented together, were introduced into each of theſe grooves or notches, and afterwards cemented into the trough by a compoſition of roſin and wax, ſo perfectly that no water could paſs from one cell to the other, nor between the plates of zinc and ſilver. This circumſtance muſt be ſtrictly attended to, elſe the machine will be extremely imperfect. When all the plates were thus ſecured in the trough, the interſtices or cells formed by the different pairs of plates were filled with a ſolution of the muriat of ammonia, which here ſupplied the place of the moiſtened papers in the pile, but anſwered the purpoſe much better. It is hardly neceſſary to obſerve, that in fixing the zinc and ſilver plates, they muſt be placed regularly, as in the pile, *viz.* alternately zinc and ſilver, the ſilver plate being always on the ſame ſide. When a communication was made between the firſt and laſt cell, a ſtrong ſhock was felt in the arms, but ſomewhat different from that given by the pile, being quicker, leſs tremulous, and bearing a greater reſemblance to the common electrical ſhock. He conſtructed two of theſe machines, which contained in all 100 pair of plates ; theſe when joined together gave a very ſtrong ſhock, and the ſpark could be taken in the day-time at pleaſure ; but what ſurpriſed him not a little, was the very ſlender power which they poſſeſſed in decompoſing water : in this reſpect they were certainly inferior to a pile of 30 pair, although ſuch a pile would not give a ſhock of one third the ſtrength.

This apparatus retained its power for many days, and would in all probability have retained it much longer, had not the fluid got between the dry ſurfaces of the metals. To remedy this defect, he ſoldered the zinc and ſilver plates together, and found that this method anſwers very well. The zinc plates may be cleaned at any time, by filling the different cells for a few minutes with the dilute muriatic acid. Although this apparatus may not entirely ſuperſede the pile, eſpecially if it ſhould be found to decompoſe water, &c. but ſlowly, yet in other reſpects it will no doubt be found very convenient and portable.

If this article be thought long, and if we appear to have loſt ſight of our original ſubject, the *Torpedo*, we have

have only to plead in excuſe for our conduct, that whilſt we could not avoid pointing out the reſemblance between the ſhock given by the torpedo and that by Volta's apparatus, we felt it a kind of duty to embrace the only opportunity that we ſhall have of laying before our readers the additional information reſpecting the phenomena of GALVANISM which we have received ſince the publication of that article. Theſe phenomena are yet new, and they are unqueſtionably important; indeed ſo very important, that to us it appears neither impoſſible, nor even improbable, that to the galvanic agency of metals and minerals may be attributed volcanoes and earthquakes.

TOUCAN, or AMERICAN GOOSE, is one of the modern conſtellations of the ſouthern hemiſphere, conſiſting of nine ſmall ſtars.

TRACTORS, METALLIC. See PERKINISM in this *Suppl.*

TRACTRIX, in geometry, a curve line, called alſo CATENARIA; which ſee, *Encycl.* and ARCH, *Suppl.*

TRADESCANT (John), an ingenious naturaliſt and antiquary, was, according to Anthony Wood, a Fleming or a Dutchman. We are informed by Parkinſon, that he had travelled into moſt parts of Europe, and into Barbary; and from ſome emblems remaining upon his monument in Lambeth church yard, it plainly appears that he had viſited Greece, Egypt, and other eaſtern countries. In his travels, he is ſuppoſed to have collected, not only plants and ſeeds, but moſt of thoſe curioſities of every ſort which, after his death, were ſold by his ſon to the famous Elias Aſhmole, and depoſited in his muſeum at Oxford. When he firſt ſettled in this kingdom cannot, at this diſtance of time, be aſcertained. Perhaps it was at the latter end of the reign of Queen Elizabeth, or the beginning of that of King James I. His print, engraven by Hollar before the year 1656, which repreſents him as a perſon very far advanced in years, ſeems to countenance this opinion. He lived in a great houſe at South Lambeth, where his muſeum was frequently viſited by perſons of rank, who became benefactors thereto: among theſe were King Charles I. (to whom he was gardener), Henrietta Maria his Queen, Archbiſhop Laud, George Duke of Buckingham, Robert and William Cecil, Earls of Saliſbury, and many other perſons of diſtinction. John Tradeſcant may therefore be juſtly conſidered as the earlieſt collector (in this kingdom) of every thing that was curious in natural hiſtory, viz. minerals, birds, fiſhes, inſects, &c. He had alſo a good collection of coins and medals of all ſorts, beſides a great variety of uncommon rarities. A catalogue of theſe, publiſhed by his ſon, contains an enumeration of the many plants, ſhrubs, trees, &c. growing in his garden, which was pretty extenſive. Some of theſe plants are, if not totally extinct, at leaſt become very uncommon, even at this time: though this able man, by his great induſtry, made it manifeſt, in the very infancy of botany, that there is ſcarce any plant extant in the known world that will not, with proper care, thrive in this kingdom.

When his houſe at South Lambeth, then called *Tradeſcant's Ark*, came into Aſhmole's poſſeſſion, he added a noble room to it, and adorned the chimney with his arms, impaling thoſe of Sir William Dugdale, whoſe daughter was his third wife; where they remain to this day.

It were much to be wiſhed, that the lovers of botany had viſited this once famous garden before, or at leaſt in the beginning of the preſent century. But this ſeems to have been totally neglected till the year 1749, when Dr Watſon and the late Dr Mitchell favoured the Royal Society with the only account now extant of the remains of Tradeſcant's garden.

When the death of John Tradeſcant happened is not known; no mention being made thereof in the regiſter-book of Lambeth church.

TRAJECTORY, a term often uſed, generally for the path of any body, moving either in a void, or in a medium that reſiſts its motion; or even for any curve paſſing through a given number of points. Thus Newton, Princip. lib. 1. prop. 22. propoſes to deſcribe a trajectory that ſhall paſs through five given points.

TRAITOR's ISLAND, one of the Archipelago called *NAVIGATOR's Iſlands*, in the South Sea (See that article, *Suppl.*). It is low and flat, with only a hill of ſome height in the middle; and is divided into two parts by a channel, of which the mouth is about 150 toiſes wide. It abounds with bannanas, yams, and the fineſt cocoa nuts, which Perouſe ſays he ever ſaw. About twenty canoes approached the French ſhips without dread, traded with a good deal of honeſty, and never refuſed, like the natives of the archipelago of Navigators, to give their fruit before they were paid for it; nor, like them, did they give a preference to beads over nails and pieces of iron. They ſpoke, however, the ſame language, and had the ſame ferocious look; their dreſs, their manner of tatowing, and the form of their canoes, were the ſame; nor could we (ſays the author) doubt that they were one and the ſame people: they differed, indeed, in having univerſally two joints cut off from the little finger of the left hand; whereas, in the iſlands of Navigators, I only perceived two individuals who had ſuffered that operation. They were alſo of much lower ſtature, and far leſs gigantic make; a difference proceeding, no doubt, from the ſoil of theſe iſlands, which being leſs fertile, is conſequently leſs favourable to the expanſion of the human frame.

TRAMMELS, in mechanics, an inſtrument uſed by artificers for drawing ovals upon boards, &c. One part of it conſiſts of a croſs with two grooves at right angles; the other is a beam carrying two pins, which ſlide in thoſe grooves, and alſo the deſcribing pencil. All the engines for turning ovals are conſtructed on the ſame principles with the trammels: the only difference is, that in the trammels the board is at reſt, and the pencil moves upon it; in the turning engine, the tool, which ſupplies the place of the pencil, is at reſt, and the board moves againſt it. See a demonſtration of the chief properties of theſe inſtruments by Mr Ludlam, in the *Phil. Tranſ.* vol. lxx. p. 378, &c.

TRANSFORMATION, in geometry, is the changing or reducing of a figure, or of a body, into another of the ſame area, or the ſame ſolidity, but of a different form. As, to tranſform or reduce a triangle to a ſquare, or a pyramid to a parallelopipedon.

TRANSFORMATION of Equations, in algebra, is the changing equations into others of a different form, but of equal value. This operation is often neceſſary, to prepare equations for a more eaſy ſolution.

TRANSLATION, in literature, is a matter of ſo much importance, that no other apology can be made for the very imperfect manner in which it is treated in the *Encyclopædia*, than a candid declaration that it was impoſſible to enter at all upon the ſubject within the narrow limits to which we were then reſtricted by the proprietors of the work. The fundamental laws of tranſlation, which we gave from Dr Campbell of Aberdeen, we believe indeed to be unexceptionable; but the queſtion is, how are theſe laws to be obeyed?

In order that a tranſlator may be enabled to give a complete tranſcript of the ideas of the original work, it is almoſt needleſs to obſerve, that he muſt poſſeſs a perfect knowledge of both languages, *viz.* that of his author, and that into which he is to tranſlate; and that he muſt have a competent acquaintance with the ſubject of which his author treats. Theſe propoſitions we conſider as ſelf evident; but if any of our readers ſhall be of a different opinion, we refer them to an *Eſſay on the Principles of Tranſlation*, publiſhed 1797 by Cadell and Davies, London, where they will find our doctrine very clearly illuſtrated. It may be proper to add, that ſuch a knowledge of the Greek and Latin languages as merely enables a man to read them with eaſe and entertainment to himſelf, is by no means ſufficient to qualify him for tranſlating every Greek and Latin book, even though it treats of a ſubject with which he has a general acquaintance. The religious rites and ceremonies of the Greeks and Romans, as well as the radical words of their language, were derived from the Eaſt; and he who is an abſolute ſtranger to oriental literature, will be very liable to miſtake occaſionally the ſenſe of Greek and Roman authors who treat of religious ſubjects. We could illuſtrate the truth of this poſition by quotations from ſome of the moſt admired modern tranſlations of the Greek Scriptures, which we have no heſitation to ſay fall very ſhort of the authoriſed verſion in accuracy as well as in elegance. The divines employed by King James to tranſlate the Old and New Teſtaments were profoundly ſkilled in the learning, as well as in the languages, of the Eaſt; whilſt ſome of thoſe who have preſumed to improve their verſion ſeem not to have poſſeſſed a critical knowledge of the Greek tongue, to have known ſtill leſs of the Hebrew, and to have been abſolute ſtrangers to the dialect ſpoken in Judea in the days of our Saviour, as well as to the manners, cuſtoms, and peculiar opinions of the Jews ſects. Neither metaphyſical acuteneſs, nor the moſt perfect knowledge of the principles of tranſlation in general, will enable a man who is ignorant of theſe things to improve the authoriſed verſion either of the Goſpels or the Epiſtles; for ſuch a man knows not accurately, and therefore cannot give a complete tranſcript of the ideas of the original work.

But ſuppoſing the tranſlator completely qualified with reſpect to knowledge, it becomes a queſtion, whether he may, in any caſe, add to or retrench the ideas of his author? We are ſtrongly inclined to think, that, in no caſe, it is allowable to take ſuch liberties; but the ingenious and elegant eſſayiſt, whoſe work on the principles of tranſlation we muſt always quote with reſpect, is of a different opinion. "To give a general anſwer (ſays he) to this queſtion, I would ſay, that this liberty may be uſed, but with the greateſt caution. It muſt be further obſerved, that the ſuperadded idea ſhall have the moſt neceſſary connection with the original thought, and actually increaſe its force. And, on the other hand, that whenever an idea is cut off by the tranſlator, it muſt be only ſuch as is an acceſſory, and not a principle, in the clauſe or ſentence. It muſt likewiſe be confeſſedly redundant, ſo that its retrenchment ſhall not impair or weaken the original thought. Under theſe limitations, a tranſlator may exerciſe his judgment, and aſſume to himſelf, in ſo far, the character of an original writer"

Of the judicious uſe, as he thinks it, of this liberty, the author quotes many examples, of which we ſhall ſelect three, as well calculated to illuſtrate our own ideas of the ſubject.

In the firſt book of the Iliad, Achilles, having reſolved, though indignantly, to give up Briſeis, deſires Petroclus to deliver her to the heralds of Agamemnon:

> Ὡς φατο· Πατροκλης δε φιλω επεπειθεθ' ἑταιρῳ·
> Εκ δ' αγαγε κλισιης Βρισηιδα καλλιπαρηον,
> Δωκε δ' αγειν· τω δ' αυτις ιτην παρα νηας Αχαιων·
> Ἡ δ' ακεους' ἁμα τοισι γυνη κιεν· *Ilias*, A. 345.

> Patroclus now th' unwilling beauty brought;
> She in ſoft ſorrows, and in penſive thought,
> Paſt ſilent, as the heralds held her hand,
> And oft look'd back, ſlow moving o'er the ſtrand.
> POPE.

Our author thinks, and we heartily agree with him, that the amplification in the three laſt lines of this verſion highly improves the effect of the picture; but we cannot conſider this amplification as a new idea ſuperadded. It was the object of Homer to inform his countrymen, that Briſeis went with the heralds *unwillingly*. This he does by the words ἡ δ' ακευσ' ἁμα τοισι γυνη κιεν· and it is by no means improbable, that the rhythmical movement of the verſe may have preſented to the ancient Greeks the image of the lady walking ſlowly and reluctantly along. This image, we are ſure, is not produced by a literal tranſlation of the Greek words into Engliſh; and therefore it was Pope's duty, not to add to the ideas of the original, but, by amplification, to preſent to his own countrymen the picture which Homer, by the ſuperiority of the Greek language and rhythm, had preſented to his.

In the ninth book of the Iliad, where Phœnix reminds Achilles of the care he had taken of him while an infant, one circumſtance, extremely mean, and even diſguſting, is found in the original:

> ——— ὁτε δη σ' επ' εμοισιν εγω γουνασσι καθισσας
> Οψου τ' ασαιμι προταμων, και οινον επισχων·
> Πολλακι μοι κατεδευσας επι στηθεσσι χιτωνα,
> Οινου αποβλυζων εν νηπιεη αλεγεινη.

The literal verſion of theſe lines is indeed very groſs: "When I placed you before my knees, I crammed you with meat, and gave you wine, which you often vomited upon my boſom, and ſtained my clothes, in your troubleſome infancy:" but we cannot agree with our author, that the Engliſh reader is obliged to Pope for having altogether ſunk this nauſeous image. What is, or ought to be, our object in reading Homer? If it be merely to delight our ear with ſonorous lines, and pleaſe our fancy with grand or ſplendid images, the tranſlator certainly did right in keeping out of view this diſguſting picture of ſavage life; but when he did ſo, he cannot be ſaid to have given a complete tranſcript of his author's ideas. To pleaſe ourſelves, however, with ſplendid images, is not our only object when ſtudying the

the works of the ancient poets. Another, and in our opinion a more important object, is to acquire a lively notion of ancient manners; and if ſo, Pope groſsly miſleads the mere Engliſh reader, when, inſtead of the beaſtly image of Homer, he preſents him with the following ſcene, which he may daily meet with in his own family, or in the families of his friends:

> Thy infant breaſt a like affection ſhow'd,
> Still in my arms, an ever pleaſing load;
> Or at my knee, by Phœnix would'ſt thou ſtand,
> No food was grateful but from Phœnix hand:
> I paſs my watchings o'er thy helpleſs years,
> The tender labours, the compliant cares.

This is a picture of the domeſtic manners of Great Britain in the 18th century, and not of Greece in the heroic ages.

In the beginning of the eighth book of the Iliad, Homer puts into the mouth of Jove a very ſtrange ſpeech, ſtuffed with braggart vaunting and ludicrous images. This, as our author obſerves, is far beneath the dignity of the thunderer; but it is only beneath the dignity of the thunderer as our habits and modes of thinking compel *us* to conceive ſuch a being. The thunderer of the Greeks was a notorious adulterer and ſodomite, whoſe moral character ſinks beneath that of the meaneſt of our bravos; and as he had dethroned his father, and waged for ſome time a doubtful war with certain *earthly* giants, it does not appear to us that the boaſting ſpeech which Homer puts into his mouth is at all unſuitable to his acknowledged attributes. But whether it be or not, was not the tranſlator's concern. Homer, when he compoſed it, certainly thought it not unworthy of the thunderer; and whatever Pope's opinion might be, he had no right to ſubſtitute his own notions of propriety for thoſe of his author. The mythological tales of the poets, and more eſpecially of Homer and Heſiod, conſtituted, as every one knows, the religious creed of the vulgar Greeks (ſee POLYTHEISM, n° 33. *Encycl.*); and this circumſtance makes it doubly the duty of a tranſlator to give, on ſuch ſubjects, a fair tranſcript of his author's ideas, that the mere Engliſh reader, for whom he writes, may know what the ancients really thought of the objects of their idolatrous worſhip. This Pope has not done in the ſpeech under conſideration; and has therefore, in our opinion, deviated widely from the firſt and moſt important of the three general laws of tranſlation. Johnſon has apologized, we think ſufficiently, for many of Pope's embelliſhments of his author; but he has not attempted to make an apology for ſuch embelliſhments as alter the ſenſe. We cannot indeed conceive a pretence upon which it can ever be allowable in a tranſlator to add to the ideas of his author, to retrench, or to vary them. If he be tranſlating hiſtory, and find his author advancing what he *believes* to be falſe, he may correct him in a note; but he has no right to make one man utter, as his own, the belief or the ſentiments of another, when that belief, and thoſe ſentiments, are *not* his own. If he be tranſlating a work of ſcience, he may likewiſe correct the errors of his author in notes, as Dr Clerke corrected thoſe of Rohault; but no man has a right to give to a Rohault the ſcience of a Newton. The tranſlator of a poem may certainly employ amplification to place in a ſtriking light the images or the ſentiments of the original work; but he muſt not alter thoſe images or ſentiments ſo as to make that appear grand or elegant in the verſion, which is mean or diſguſting in the original. On every occaſion on which he takes ſuch liberties as theſe, he ceaſes to be a tranſlator, and becomes a faithleſs paraphraſt.

The ſecond general law of tranſlation, though certainly leſs important, is perhaps more difficult to be obſerved than the firſt. We have ſtated it in theſe words: (See TRANSLATION, *Encycl.*) "The ſtyle and manner of the original ſhould be preſerved in the tranſlation;" but it is obvious, that this cannot be done by him who poſſeſſes not ſufficient taſte and judgment to aſcertain with preciſion to what claſs the ſtyle of the original belongs. "If a tranſlator fail in this diſcernment, and want this capacity, let him be ever ſo thoroughly maſter of the ſenſe of his author, he will preſent him through a diſtorting medium, or exhibit him in a garb that is unſuitable to his character." It would obviouſly be very improper to tranſlate the elegantly ſimple language of Cæſar into rounded periods like thoſe of *The Rambler*, or the Orations of Cicero into the language of Swift.

The chief characteriſtic of the hiſtorical ſtyle of the ſacred Scriptures is its ſimplicity; and that ſimplicity is, for the moſt part, well preſerved in the authoriſed verſion. It is, however, loſt in many of the modern verſions. Caſtalio's, for inſtance, though intitled to the praiſe of elegant latinity, and though, in general, faithful to the ſenſe of the original, yet exhibits numberleſs tranſgreſſions of the law which is now under conſideration. Its ſentences are formed in long and intricate periods, in which many ſeparate members are artfully combined; and we obſerve a conſtant endeavour at claſſical phraſeology and ornamented diction, inſtead of the beautiful ſimplicity of the original.

The verſion of the Scriptures by Arias Montanus is, in ſome reſpects, a contraſt to that of Caſtalio. By adopting the literal mode of tranſlation, Arias undoubtedly intended to give as faithful a picture as he could, both of the ſenſe and of the manner of the original. Not attending to the peculiar idioms of the Hebrew, Greek, and Latin tongues, which, in ſome reſpects, are very different from each other, he has, by giving to his Latin the combination and idioms of the two firſt of theſe languages, ſometimes made the ſacred writers talk abſurdly. In Latin, as every ſchool-boy knows, two negatives make an affirmative, whilſt in Greek they add force to the negation. χωρις εμου ου δυνασθε ουδεν ſignifies, "Without me ye can do nothing," or, "Ye cannot *poſſibly* do any thing;" but Arias has tranſlated the words *ſine me non poteſtis facere nihil*, *i. e.* "without me ye cannot do nothing," or, "ye *muſt* do ſomething," which is directly contrary to the meaning of our Lord. It is not therefore by tranſlating literally or verbally that we can hope to preſerve the ſtyle and manner of the original.

To expreſs in florid or elevated language the ideas of an author who writes himſelf in a ſimple ſtyle, is not to give in the verſion a juſt picture of the original; but to attempt, for the ſake of verbal accuracy, to introduce into one language the peculiar idioms or conſtruction of another, is ſtill worſe, as in this mode of tranſlation the ſenſe, as well as the manner of the original, is loſt. The rule obviouſly is to uſe, in the verſion, the words and phraſeology which we have reaſon to believe that the author would himſelf have uſed, had he been maſter of the language into which we are tranſlating his ideas. Thus, if we are to tranſlate into Engliſh a piece of elegantly ſimple Greek or Latin, we muſt make ourſelves completely maſter of the author's meaning, and, neglecting the Greek or Latin *idioms*, expreſs that meaning in elegantly ſimple Engliſh. We need not add, that when the language of the original is florid or grand, if that ſtyle be ſuited to the ſubject, the language of the tranſlation ſhould be florid or grand likewiſe; but care muſt always be taken that perſpicuity be not ſacrificed to ambitious ornaments of any kind; for ornaments which obſcure the ſenſe are worſe than uſeleſs.

If theſe reflections be juſt, it is obvious that a poem cannot be properly tranſlated into proſe. The mere ſenſe may doubtleſs be thus transferred from one language into another, as has generally been done by Macpherſon in his hobbling verſion of the Iliad, and perhaps more completely by a late tranſlator of Anacreon; but in ſuch a verſion, the ſtyle and manner of the original muſt neceſſarily be loſt. Of this the following accurate proſe tranſlation of Anacreon's ninth ode (on a dove) is a ſtriking inſtance:

"O lovely Pigeon! whence, whence do you fly? Whence, ſpeeding through the air, do you breathe, and diſtil ſo many perfumes? Who is your maſter? For it concerns me to know. 'Anacreon ſent me to a youth, —to Bathyllus, at preſent the prince, and diſpoſing of all things Venus ſold me, receiving a little hymn in return. And I ſerve Anacreon in ſuch tranſactions as theſe: and now I carry his letters, ſuch as you ſee: and he affirms, that he will immediately make me free. But I will remain a ſervant with him although he may diſmiſs me: For wherefore does it behove me to fly, both over mountains, and fields, and to perch on trees, devouring ſome ruſtic food? Now indeed I eat bread, ſnatching it from the hands of Anacreon himſelf; and he gives to me the wine to drink which he drinks before me; and having drunk, I perhaps may dance, and cover my maſter with my wings: then going to reſt, I ſleep upon the lute itſelf. You have it all;—begone: you have made me more talkative, O mortal! than even a jay *."

How inferior is the general effect of this piece of proſe to that of the well-known poetical verſions of Addiſon and Johnſon? and yet the mere *ideas* of the original are perhaps more faithfully tranſcribed by this anonymous writer than by either of thoſe elegant tranſlators. The emotions indeed excited by the original are not here brought into view.

The third general law of tranſlation is ſo nearly allied to the ſecond, that we have very few directions to give for the obſervation of it. He who, in his verſion, preſerves the ſtyle and manner of the original, as we have endeavoured to ſhew that they *ought* to be preſerved, will, of courſe, give to the tranſlation the eaſe of original compoſition. The principal difficulty that he has to encounter in this part of his taſk, will occur in the tranſlating of idiomatical and proverbial phraſes. Hardly any two languages are conſtructed preciſely in the ſame way; and when the ſtructure of the Engliſh language is compared with that of the Greek and Latin, a remarkable difference between the ancient and modern tongues is found to pervade the whole. This muſt occaſion very conſiderable difficulty; but it is a difficulty which will be removed by a due obſervance of the former law, which directs the tranſlator to make his author ſpeak Engliſh in ſuch a ſtyle to Engliſhmen as he ſpoke his own tongue to his own countrymen, and of courſe to uſe the Engliſh idiom with Engliſh words. But what is to be done with thoſe proverbial phraſes of which every language has a large collection, and which allude to local cuſtoms and manners?

The ingenious author of the Eſſay ſo often quoted, very properly obſerves, in anſwer to this queſtion, that the tranſlation is perfect when the tranſlator employs, in his own language, an idiomatic phraſe correſponding to that of the original. "It is not (ſays he) poſſible perhaps to produce a happier inſtance of tranſlation by correſponding idioms, than Sterne has given * in the tranſlation of Slawkenbergius's tale. *Nihil me penitet hujus naſi*, quoth Pamphagus; that is, "My noſe has been the making of me." *Nec eſt cur pœniteat*; that is, "How the deuce ſhould ſuch a noſe fail?" *Miles peregrini in faciem ſuſpexit!* "The centinel looked into the ſtranger's face. Never ſaw ſuch a noſe in his life!"

"As there is nothing (continues our author) which ſo much conduces both to the eaſe and ſpirit of compoſition as a happy uſe of idiomatic phraſes, there is nothing which a tranſlator, who has a moderate command of his own language, is ſo apt to carry to an extreme." Of this he gives many ſtriking examples from Echard's tranſlations of Terence and Plautus, for which we muſt refer the reader to the Eſſay itſelf. He obſerves, likewiſe, that in the uſe of idiomatic phraſes, a tranſlator frequently forgets both the country of his original author, and the age in which he wrote; and while he makes a Greek or Roman ſpeak French or Engliſh, he unwittingly puts into his mouth alluſions to the manners of modern France or England. This, to uſe a phraſe borrowed from painting, may be termed an offence againſt the *coſtume*. The proverbial expreſſion βατραχῳ ὑδωρ, in Theocritus, is of ſimilar import with the Engliſh proverb, *to carry coals to Newcaſtle*; and the Scotch, *to drive ſalt to Dyſart*; but it would be a groſs impropriety to uſe either of theſe expreſſions in the tranſlation of an ancient claſſic. Of ſuch improprieties our author points out many inſtances both in French and Engliſh tranſlations of the claſſics; and he might have increaſed the number by quotations from Blackwell's Memoirs of the Court of Auguſtus, where, inſtead of Roman ſenators and their wives, we meet with modern gentlemen and ladies, with *ſecretaries at war*, *paymaſters*, *commiſſary generals*, and *lord high admirals*. It is true the memoirs of the court of Auguſtus is no tranſlation; but with reſpect to coſtume, it is neceſſarily ſubject to the laws of tranſlation.

Offences againſt coſtume are often committed by the uſe of improper words as well as of improper phraſes. To introduce into dignified and ſolemn compoſition words aſſociated with mean and ludicrous ſubjects, is equally a fault in an original author and in a tranſlator; and it is obviouſly improper, in the tranſlation of works of very high antiquity, to make uſe of words which have but lately been admitted into the language of the tranſlator. Faults of this kind are very frequent in Dr Geddes's tranſlation of the Bible, as when the *paſſover* is called the *ſkipover*; the tabernacle of the congregation,

---

* The Odes of Anacreon, tranſlated into Engliſh proſe, printed at York, 1796.

* Triſtram Shandy.

tion, the *convention-tent;* and a burnt-offering, a *holocauſt.* The firſt of theſe expreſſions preſents to the imagination an image profanely ludicrous; the ſecond, brings into our view the French Convention, which, we ſuſpect, occupied no ſmall portion of the Doctor's thoughts, when they ſhould have been wholly employed on the ſacred text; and the word *holocauſt,* which muſt be unintelligible to the mere Engliſh reader, is, in the mind of every man of letters, cloſely aſſociated with the abominable rites performed at the ſacrifices of the ancient heathens. But it is needleſs to point out faults of this kind in a work which is open to more ſerious objections, and which, we truſt, ſhall never be generally read. We are ſorry that truth compels us to ſay, that the novel expreſſions introduced by Dr Campbell into his verſion of the goſpels—ſuch as *confluence* for multitude, and *reign* for kingdom—are, to ſay the beſt of them, no improvements of the authoriſed verſion. We will not rank them with Dr Geddes's innovations, becauſe we will not claſs the great author of the *Diſſertation on Miracles* with a paradoxical Chriſtian of no communion; but we do not think that Dr Campbell's laurels were freſhened on his brow by the tranſlation of the Goſpels.

We ſhall conclude this article with the following reflections, taken from the Eſſay which has been ſo often quoted:

"If the order in which we have claſſed the three general laws of tranſlation be their juſt and natural arrangement, which, we preſume, will hardly be denied, it follows, that, in every caſe where it is neceſſary to make a ſacrifice of one of theſe laws to another, a due regard ought to be paid to their rank and comparative importance. When the genius of the original language differs much from that of the tranſlation, it is often neceſſary to depart from the author's manner in order to convey a faithful picture of his ſenſe; but it would be highly prepoſterous to depart, in any caſe, from the ſenſe, for the ſake of imitating the manner. Equally improper would it be, to ſacrifice either the ſenſe or manner of the original, if theſe can be preſerved conſiſtently with purity of expreſſion, to a fancied eaſe or ſuperior gracefulneſs of compoſition; and it is certain that the ſenſe may always be preſerved, though to purity of expreſſion the manner of the original muſt ſometimes be ſacrificed."

TRAPEZOID, ſometimes denotes a trapezium that has two of its ſides parallel to each other; and ſometimes an irregular ſolid figure, having four ſides not parallel to each other.

TRAVERSE, in gunnery, is the turning a piece of ordnance about, as upon a centre, to make it point in any particular direction.

TRAVERSE, in fortification, denotes a trench with a little parapet, ſometimes two, one on each ſide, to ſerve as a coverfrom the enemy that might come in flank.

TRAVERSE, in a wet foſs, is a ſort of gallery, made by throwing ſauciſſons, joiſts, faſcines, ſtones, earth, &c. into the foſs, oppoſite the place where the miner is to be put, in order to fill up the ditch, and make a paſſage over it.

TRAVERSE alſo denotes a wall of earth, or ſtone, raiſed acroſs a work, to ſtop the ſhot from rolling along it.

TRAVERSE alſo ſometimes ſignifies any retrenchment, or line fortified with faſcines, barrels, or bags of earth, or gabions.

TRAVESTY, or burleſque tranſlation, is a ſpecies of writing which, as it partakes, in a great degree, of original compoſition, is not to be meaſured by the laws of ſerious tranſlation. It conveys neither a juſt picture of the ſentiments, nor a faithful repreſentation of the ſtyle and manner of the original; but pleaſes itſelf in exhibiting a ludicrous caricatura of both. It diſplays an overcharged and groteſque reſemblance, and excites our riſible emotions by the incongruous aſſociation of dignity and meanneſs, wiſdom and abſurdity. This aſſociation forms equally the baſis of traveſty and of ludicrous parody, from which it is no otherwiſe diſtinguiſhed than by its aſſuming a different language from the original. In order that the mimickry may be underſtood, it is neceſſary that the writer chooſe, for the exerciſe of his talents, a work that is well known, and of great reputation. Whether that reputation is deſerved or unjuſt, the work may be equally the ſubject of burleſque imitation. If it has been the ſubject of general, but undeſerved praiſe, a parody or a traveſty is then a fair ſatire on the falſe taſte of the original author and his admirers, and we are pleaſed to ſee both become the objects of a juſt caſtigation. The *Rehearſal*, *Tom Thumb*, and *Crononhotonthologos*, which exhibit ludicrous parodies of paſſages from the favourite dramatic writers of the times, convey a great deal of juſt and uſeful criticiſm. If the original is a work of real excellence, the traveſty or parody detracts nothing from its merit, nor robs the author of the ſmalleſt portion of his juſt praiſe. We laugh at the aſſociation of dignity and meanneſs; but the former remains the excluſive property of the original, the latter belongs ſolely to the copy. We give due praiſe to the mimical powers of the imitator, and are delighted to ſee how ingeniouſly he can elicit ſubjects of mirth and ridicule from what is grave, dignified, pathetic, or ſublime.

But this ſpecies of compoſition pleaſes only in a ſhort ſpecimen. We cannot bear a lengthened work in traveſty. The incongruous aſſociation of dignity and meanneſs excites riſibility chiefly from its being unexpected. Cotton's and Scarron's Virgil entertain but for a few pages: the compoſition ſoon becomes tedious, and at length diſguſting. We laugh at a ſhort exhibition of buffoonery; but we cannot endure a man who, with good talents, is conſtantly playing the fool.

TREACLE (ſee *Encycl.*) or MELASSES, is a ſubſtance very wholeſome, but of a taſte diſagreeably ſweet. Methods have accordingly been propoſed for purifying it, ſo as that it may, on many occaſions, ſupply the place of refined ſugar, which has long been at a price which a great number of poor perſons cannot afford to pay for what muſt now be conſidered as a neceſſary of life. The following is the proceſs for purifying treacle, given by the M. Cadet (Devaux) in the *Feuille du Cultivateur*, founded upon experiments made by Mr Lowitz of Peterſburgh:

Take of treacle 24 lbs. of water 24 lbs. of charcoal, thoroughly burnt, 6 lbs. Bruiſe the charcoal groſsly, mix the three ſubſtances in a caldron, and let the mixture boil gently upon a clear wood-fire. After it has boiled for half an hour, pour the liquor through a ſtraining-bag, and then replace it upon the fire, that the ſuperfluous water may be evaporated, and that the treacle may be brought to its original conſiſtence. There is little or no loſs by this operation, as 24 lbs. of treacle give nearly the ſame quantity of ſyrup.

This proceſs has been repeated in the large way, and has ſucceeded: the treacle is ſenſibly ameliorated, ſo that it may be uſed for many diſhes; nevertheleſs, thoſe with milk, and the fine or aromatic *liqueurs*, are not near ſo good as with ſugar.

TREBISOND, a large, populous, and ſtrong town of Turkey in Aſia, in the province of Jenich, with a Greek archbiſhop's ſee, a harbour, and a caſtle. It is ſeated at the foot of a very ſteep hill. The walls are ſquare and high, with battlements; and are built with the ruins of ancient ſtructures, on which are inſcriptions not legible. The town is not populous; for there are more woods and gardens in it than houſes, and theſe but one ſtory high The caſtle is ſeated on a flat rock, with ditches cut therein. The harbour is at the eaſt end of the town, and the mole built by the Geneoſe is almoſt deſtroyed. It ſtands on the Black Sea, 104 miles north weſt of Erzerum, and 440 eaſt of Conſtantinople. E. Lon. 40° 25′. N. lat. 40° 45′.

TREE. Under this title (*Encycl.*) we gave an account of the method recommended by Meſſrs Forſyth and Hitt for curing injuries and defects in trees. The actual cautery is employed in Cevennes, and in the department de l'Allier, in France, for ſtopping the progreſs of rottenneſs in large trees. When they perceive that this very common and deſtructive diſeaſe begins to make ſome progreſs in the cheſnut-tree, by excavating its trunk, they collect heath, and other combuſtible vegetables, and burn them in the very cavity, till the ſurface is completely converted into a coal. It ſeldom happens that the tree periſhes by the effect of this operation, and it is always found that this remedy ſuſpends the progreſs of the decay. It is practiſed in the ſame manner, and with ſimilar ſucceſs, on the white oak. When we compare the effects of the actual cautery on the animal ſyſtem, in ſimilar diſeaſes, a new reſemblance is ſeen between the diſeaſes which affect the organic beings of both kingdoms, as well as between the remedies by which they may be oppoſed.—*Nicholſon's Journal.*

TRIANGLE, Arithmetical, a kind of numeral triangle, or triangle of numbers, being a table of certain numbers diſpoſed in form of a triangle. It was ſo called by Paſcal; but he was not the inventor of this table, as ſome writers have imagined, its properties having been treated of by other authors ſome centuries before him, as is ſhewn in Dr Hutton's Mathematical Tracts, vol. i. p. 69. &c.

The form of the triangle is as follows:

1					
1	1				
1	2	1			
1	3	3	1		
1	4	6	4	1	
1	5	10	10	5	1
1	6	15	20	&c.	
1	7	21	&c.		
1	8	&c.			
1	9				
1					

And it is conſtructed by adding always the laſt two numbers of the next two preceding columns together, to give the next ſucceeding column of numbers.

The firſt vertical column conſiſts of units; the ſecond, a ſeries of the natural numbers 1, 2, 3, 4, 5, &c.; the third, a ſeries of triangular numbers 1, 3, 6, 10, &c.; the fourth, a ſeries of pyramidal numbers, &c. The oblique diagonal rows, deſcending from left to right, are alſo the ſame as the vertical columns. And the numbers taken on the horizontal lines are the co-efficients of the different powers of a binomial. Many other properties and uſes of theſe numbers have been delivered by various authors, as may be ſeen in the Introduction to Hutton's Mathematical Tables, pages 7, 8, 75, 76, 77, 89, ſecond edition.

TRIANGULAR Compasses, are ſuch as have three legs or feet, by which any triangle, or three points, may be taken off at once. Theſe are very uſeful in the conſtruction of maps, globes, &c.

Triangular Numbers, are a kind of polygonal numbers; being the ſums of arithmetical progreſſions, which have 1 for the common difference of their terms.

Thus, from theſe arithmeticals 1 2 3 4 5 6,
are formed the triangular numbers 1 3 6 10 15 21,
or the third column of the arithmetical triangle abovementioned.

The ſum of any number n of the terms of the triangular numbers, 1, 3, 6, 10, &c. is =

$$\frac{n^3}{6}+\frac{n^2}{2}+\frac{n}{3}, \text{ or } \frac{n}{1}\times\frac{n+1}{2}\times\frac{n+2}{3}$$

which is alſo equal to the number of ſhot in a triangular pile of balls, the number of rows, or the number in each ſide of the baſe, being n.

The ſum of the reciprocals of the triangular ſeries, infinitely continued, is equal to 2; viz.

$$1+\frac{1}{3}+\frac{1}{6}+\frac{1}{10}+\frac{1}{15}, \text{ \&c.} = 2.$$

For the rationale and management of theſe numbers, ſee *Malcolm's Arith.* book 5. ch. 2.; and *Simpſon's Algeb.* ſec. 15.

TRIESTE, a ſmall, but ſtrong and ancient ſeaport of Italy, in Iſtria, on the gulph of Venice, with a biſhop's ſee. It is beautifully ſituated on the ſide of a hill, about which the vineyards form a ſemicircle. The ſtreets are narrow; but there is a large ſquare, where they keep the annual fair. The harbour is ſpacious, but not good; becauſe it is open to the W. and S. W. winds. The inhabitants have a good trade in ſalt, oil, almonds, iron, &c. brought from Laubach; and they make good wines. The cathedral, and the late Jeſuits church, are the two beſt buildings. It belongs to the Houſe of Auſtria, and is eight miles north of Capo d'Iſtria, and 80 north-eaſt of Venice. E. Long. 14. 4. N Lat. 45. 56.

TRINITARIANS (Order of), was inſtituted at Rome in the year 1198, under the pontificate of Innocent III. the founders whereof were John de Matha and Felix de Valois. His Holineſs gave them permiſſion to eſtabliſh this order for the deliverance of captives, who groaned under the tyranny of the infidels: he gave them as a habit a white gown, ornamented with a red and blue croſs. After the death of the two founders, Pope Honorious III. continued the order; and their rule was approved by his ſucceſſor Clement IV. in 1367. At firſt they were not permitted to eat fleſh; and when they travelled, were to ride only upon aſſes. But their rule was corrected and mitigated by the biſhop of Paris, and the abbots of St Victor and St Genevieve, who allowed them to eat any kind of food, and to uſe horſes. This order poſſeſſed, at one time, about 250 convents in 13 different provinces: ſix of which were in France; namely, France, Normandy, Picardy, Champaine, Languedoc, and Provence; three in Spain, viz. New Caſtile, Old Caſtile, and Arragon; one in Italy, and one in Portugal. There was formerly the province of England, where this order had 43 houſes; that of Scotland, where it had nine; and that of Ireland, where it had 52; beſides a great number of monaſteries in Saxony, Hungary, Bohemia, and other countries. The convent of Cerfroy in France was head of the order. It is impoſſible for us to ſay what is now the ſtate of the order, which can have no viſible exiſtence in France, and is probably ſuppreſſed even in Italy.

TRIONES, in aſtronomy, a ſort of conſtellation, or aſſemblage of ſeven ſtars in the Urſa Major, popularly called *Charles's Wain.*—From the *ſeptem triones* the north pole takes the denomination *ſeptentrio*.

TRIPOLI of Syria is, according to Mr Browne, by no means ſo populous a place as we were led to repreſent it in the *Encyclopædia*. It is indeed, he ſays, a city of ſome extent, ſituated about a mile and a half from the ſea; but inſtead of ſixty, he eſtimates its population at about ſixteen thouſand. The air is rendered unwholeſome by much ſtagnant water. The town is placed on a ſlight elevation, the length conſiderably exceeding the breadth. On the higheſt ground, to the ſouth, is the caſtle, formerly poſſeſſed by the earls of Tripoli; it is large and ſtrong. Hence is viſible a part of mount Libanus, the ſummit of which is covered with ſnow. The gardens in the vicinity are rich in mulberry and other fruit trees. The city is well built, and moſt of the ſtreets are paved.

Here is found a number of Mohammedan merchants, ſome of the richeſt and moſt reſpectable in the empire. Silk is the chief article of commerce.

The *miri*, or fixed public revenue paid by Tripoli to Conſtantinople, is only about L.1000 Sterling, 20 purſes, a-year. Syria at preſent contains only four Paſhaliks, Damaſcus, Aleppo, Acré, and Tripoli; the laſt of which is the ſmalleſt in territory and power. Our author obſerved no antiquities at Tripoli; but the country round it is noted for producing the beſt tobacco in Syria.

TRISECTION, the dividing a thing into three equal parts. The term is chiefly uſed in geometry, for the diviſion of an angle into three equal parts. The *triſection of an angle* geometrically, is one of thoſe great problems, whoſe ſolution has been ſo much ſought for by mathematicians for 2000 years paſt; being, in this reſpect, on a footing with the famous quadrature of the circle, and the duplicature of the cube.

TRISTAN d'Acunha, the largeſt of three iſlands which were viſited by Lord Macartney and his ſuite on the 31ſt of December 1792. The other two are diſtinguiſhed by the names of *Inacceſſible* and *Nightingale* iſlands. "Inacceſſible (as Sir Eraſmus Gower obſerved) ſeems to deſerve that name, being a high, bluff, as well as apparently barren plain, about nine miles in circumference, and has a very forbidding appearance. There is a high rock detached from it at the ſouth end. Its latitude is 37° 19′ ſouth; its longitude 11° 50′ weſt from Greenwich. This rude-looking ſpot may be ſeen at 12 or 14 leagues diſtance. Nightingale iſland is irregular in its form, with a hollow in the middle, and is about ſeven or eight miles in circumference, with ſmall rocky iſles at its ſouthern extremity. It is deſcribed as having anchorage on the north-eaſt ſide. Its latitude is 37° 29′ ſouth; and longitude 11° 48′ weſt from Greenwich. It may be ſeen at ſeven or eight leagues diſtance. The largeſt of theſe three iſlands, which comparatively may be called the great iſle of *Triſtan d'Acunha*, is very high, and may be ſeen at 25 leagues diſtance. It ſeems not to exceed in circumference 15 miles. A part of the iſland towards the north riſes perpendicularly from the ſea to a height apparently of a thouſand feet or more. A level then commences, forming what among ſeamen is termed *table land*, and extending towards the centre of the iſland; from whence a conical mountain riſes, not unlike in appearance to the Peak of Teneriffe, as ſeen from the bay of Santa Cruz. Boats were ſent to ſound and to examine the ſhore for a convenient place to land and water. In conſequence of their report, the Lion (a ſhip of 64 guns) ſtood in, and came to anchor in the evening on the north ſide, in 30 fathoms water, one mile from the ſhore; the bottom black ſand with ſlime; a ſmall rock, off the weſt point, bearing ſouth weſt by ſouth, juſt open with the weſtern extremity of the iſland; a caſcade, or fall of water, emptying itſelf upon the beach, ſouth by eaſt. All the ſhore, from the ſouthern point to the eaſtern extremity, appears to be clear of danger, and ſteep, except the weſt point, where there are breakers about two cables length, or near 500 yards from the ſhore. The ſhip, when anchored, was overſhadowed by the dark maſs of that portion of the iſland whoſe ſides ſeemed to riſe, like a moſs grown wall, immediately from the ocean. On the right the elevation was leſs rapid, and between the riſing part and the ſea was left a flat, of ſome extent, covered with ſedge-graſs, interſperſed with ſmall ſhrubs, which, being perfectly green, looked from the ſhip like a pleaſant meadow, watered by a ſtream that fell, afterwards, from its banks upon the beach. The officers, who went aſhore, reported, that the caſks might be filled with freſh water by means of a long hoſe, without moving them from the boats. The landing place thereabouts was alſo deſcribed as being ſafe, and ſuperior to any other that had been examined. From the plain, the land roſe gradually towards the central mountain, in ridges covered with trees of a moderate ſize and height. The coaſt abounded with ſea lions and ſeals, penguins and albatroſſes. One of the latter was brought on board, his wings meaſuring ten feet from tip to tip; but others are ſaid to have been found much larger. The coaſt was covered with a broad ſea-weed, ſeveral fathoms long, and deſervedly by naturaliſts termed *gigantic fucus*. Some good fiſh was caught with the hook and line.

"The accident of a ſudden guſt, by which the anchor was in a few hours driven from its hold, and the ſhip forced out to ſea, prevented the iſland from being explored, as was intended. It is probable that had the Lion anchored in 20, inſtead of 30 fathoms water, the anchor would have held firmly. Some advantage was obtained, however, from coming to this place. The juſt poſition of thoſe iſlands, in reſpect to their longitude, was aſcertained, by the mean of ſeveral time-pieces, to be about two degrees to the eaſtward of the place where they are laid down in charts, taken from obſervations made at a period when the inſtruments for this purpoſe were leſs accurate than at preſent. The ſpot where the Lion anchored was determined, by good meridional obſervations, and by accurate time-pieces, to be 37° 6′ ſouth latitude, and 11° 43′ weſt longitude from Greenwich. The compaſs had ſeven degrees of variation weſtward from the pole. Fahrenheit's thermometer ſtood at 67 degrees. It was uſeful alſo to have aſcertained, that a ſafe anchorage, and plenty of good water, were to be found here. Theſe iſlands are certainly worthy of a more particular inquiry; for they are not 50 leagues from the general track of veſſels bound to China, and to the coaſt of Coromandel, by the outer paſſage. In war time, an excellent rendezvous might be ſettled there, for ſhips that wanted no other ſupply but that of water. When circumſtances require particular diſpatch, it is practicable to come from England to Triſtan d'Acunha without ſtopping in the way, and afterwards to the end of the voyage to India or China."

Theſe iſlands are ſeparated by a ſpace of about fifteen hundred miles from any land to the weſtward or northward of them. They are ſituated in that part of the ſouthern hemiſphere, in the neighbourhood of which a continent, to balance the quantity of land in the northern hemiſphere, was once expected to be found, but where it has been ſince diſcovered that there is none. Of what extent, however, the baſes of theſe iſlands are under the ſurface of the ſea, cannot be aſcertained ; or whether they may, or may not,' be ſufficient to make up for the defect of land appearing above water. Navigators report, that to the eaſtward of them are other ſmall iſlands, differing not much in latitude, ſuch as Gough and Alvarez iſlands, and the Marſouines ; as well as extenſive ſhoals, lying due ſouth of the moſt ſoutherly point of Africa, and extending eaſterly ſeveral degrees. That all theſe together form a chain, ſome of ſubaqueous, and ſome of ſuperaqueous mountains, but all connected by their roots, is perhaps a conjecture leſs improbable, than that they ſhould ſeparately ariſe, like tall columns, from the vaſt abyſs.

A ſettlement in Triſtan d'Acunha is known to have been twice in the contemplation of adventurers, but not as yet to have been carried into execution. One had the project of rendering it a mart for the change of the light manufactures of Hindoſtan, ſuited to hot climes, for the ſilver of the Spaniſh ſettlements in South America ; in the route between which places it is conveniently ſituated. The other plan meant is only as a ſuitable ſpot for drying and preparing the furs of ſea lions and ſeals, and for extracting the ſpermaceti of the white or long-noſed whale, and the whale-bone and oil of the black ſpecies. Whales of every kind were ſeen ſporting about Triſtan d'Acunha, particularly near the ſetting of the ſun; and the ſword-fiſh likewiſe made its appearance occaſionally.—*Sir George Staunton's Account of the Embaſſy to China.*

TRITON, in zoology, a genus belonging to the order of vermes molluſca. The body is oblong ; the tongue is ſpiral ; it has twelve tentacula, ſix on each ſide, the hindmoſt ones having claws like a crab. There is but one ſpecies, found in holes of rocks about the ſhore.

TROTTER (Mrs Catharine), was the daughter of Captain David Trotter, a Scotch gentleman. He was a commander in the royal navy in the reign of Charles II. and at his death left two daughters, the youngeſt of whom, Catharine, our celebrated author, was born in London, Auguſt 1679. She gave early marks of her genius ; and learned to write, and alſo made herſelf miſtreſs of the French language, by her own application and diligence, without any inſtructor ; but ſhe had ſome aſſiſtance in the ſtudy of the Latin grammar and logic, of which latter ſhe drew up an abſtract for her own uſe. The moſt ſerious and important ſubjects, and eſpecially religion, ſoon engaged her attention.—But notwithſtanding her education, her intimacy with ſeveral families of diſtinction of the Romiſh perſuaſion, expoſed her, while very young, to impreſſions in favour of that church ; which not being removed by her conferences with ſome eminent and learned members of the church of England, ſhe embraced the Romiſh communion, in which ſhe continued till the year 1707. In 1695, ſhe produced a tragedy called *Agnes de Caſtro*, which was acted at the theatre-royal when ſhe was only in her 17th year. The reputation of this performance, and the verſes which ſhe addreſſed to Mr Congreve upon his Mourning Bride, in 1697, were probably the foundation of her acquaintance with that celebrated writer. Her ſecond tragedy, *Fatal Friendſhip*, was acted in 1698, at the new theatre in Lincoln's-Inn-Fields. This tragedy met with great applauſe, and is ſtill thought the moſt perfect of her dramatic performances. Her dramatic talents not being confined to tragedy, ſhe brought upon the ſtage, in 1701, a comedy called *Love at a loſs*, or *Moſt votes carry it.* In the ſame year ſhe gave the public her third tragedy, entitled the *Unhappy Penitent*, acted at the theatre royal in Drury-lane. But poetry and dramatic writing did not ſo far engroſs the thoughts of our author but that ſhe ſometimes turned them to ſubjects of a very different nature ; and diſtinguiſhed herſelf in an extraordinary manner in defence of Mr Locke's writings ; a female metaphyſician being a remarkable phenomenon in the republic of letters.

She returned to the exerciſe of her dramatic genius in 1703, and fixed upon the revolution of Sweden, under Guſtavus Erickſon, for the ſubject of a tragedy. This tragedy was acted, in 1706, at the Queen's theatre in the Hay-Market. In 1707, her doubts concerning the Romiſh religion, which ſhe had ſo many years profeſſed, having led her to a thorough examination of the grounds of it, by conſulting the beſt books on both ſides of the queſtion, and adviſing with men of the beſt judgment, the reſult was a conviction of the falſeneſs of the pretenſions of that church, and a return to that of England, to which ſhe adhered during the remainder of her life. In 1708, ſhe was married to the Rev. Mr Cockburn, then curate of St Dunſtan's in Fleet-ſtreet, but he afterwards obtained the living of Long-Horſely, near Morpeth in Northumberland. He was a man of conſiderable abilities ; and, among ſeveral other things, wrote an account of the Moſaic Deluge, which was much approved by the learned.

Mrs Cockburn's remarks upon ſome writers in the controverſy concerning the foundation of moral duty and moral obligation, were introduced to the world, in Auguſt 1743, in the Literary Journal, intitled *The Hiſtory of the Works of the Learned.* The ſtrength, clearneſs, and vivacity ſhewn in her remarks upon the moſt abſtract and perplexed queſtions, immediately raiſed the curioſity of all good judges about the concealed writer ; and their admiration was greatly increaſed when her ſex and advanced age were known. Dr Rutherforth's Eſſay on the Nature and Obligations of Virtue, publiſhed in May 1744, ſoon engaged her thoughts ; and notwithſtanding the aſthmatic diſorder which had ſeized her many years before, and now left her ſmall intervals of eaſe, ſhe applied herſelf to the confutation of that elaborate diſcourſe, and finiſhed it with a ſpirit, elegance, and perſpicuity equal, if not ſuperior, to all her former writings.

The loſs of her huſband in 1748, in the 71ſt year of his age, was a ſevere ſhock to her ; and ſhe did not long ſurvive him, dying on the 11th of May 1749, in her ampet arine.

71ſt year, after having long ſupported a painful diſorder with a reſignation to the Divine will, which had been the governing principle of her whole life, and her ſupport under the various trials of it.

Her works are collected into two large volumes 8vo, by Dr Birch; who has prefixed to them an account of her life and writings.

TRUMPET Marine, or Marigny. This is a ſtringed inſtrument, invented in the 16th century by an Italian artiſt Marino or Marigni, and called a *trumpet*, becauſe it takes only the notes of the trumpet, with all its omiſſions and imperfections, and can therefore execute only ſuch melodies as are fitted for that inſtrument. It is a very curious inſtrument, though of ſmall muſical powers, becauſe its mode of performance is totally unlike that of other ſtringed inſtruments; and it deſerves our very particular attention, becauſe it lays open the mechaniſm of muſical ſounds more than any thing we are acquainted with; and we ſhall therefore make uſe of it in order to communicate to our readers a philoſophical theory of muſic, which we have already treated in detail as a liberal or ſcientific art.

Plate XLV.

The trumpet marine is commonly made in the form of a long triangular pyramid, ABCD, fig. A. on which a ſingle ſtring EFG is ſtrained over a bridge F by means of the finger pin L. At the narrow end are ſeveral frets 1, 2, 3, 4, 5, &c. between E and K, which divide the length EF into aliquot parts. Thus E 1 is $\frac{1}{32}$ of EF, E 2 is $\frac{1}{31}$, and ſo on. The bow is drawn lightly acroſs the cord at H, and the ſtring is ſtopped by preſſing it with the finger immediately above the frets, but not ſo hard as to make it touch the fret. When the open ſtring is ſounded, it gives the fundamental note. If it be ſtopped, in the way now deſcribed, at $\frac{1}{3}$d of its length from E, it yields the 12th of the fundamental; if ſtopped at $\frac{1}{4}$th, it gives the double octave; if at $\frac{1}{5}$th, it gives the 17th major, &c. In ſhort, it always gives the note correſponding to the length of the part between the fret and the nut E. The ſounds reſemble thoſe of a pipe, and are indeed the ſame with thoſe known by the name *harmonics*, and now executed by every performer on inſtruments of the viol or violin ſpecies. But in order to increaſe the noiſe, the bridge F is conſtructed in a very particular manner. It does not reſt on the ſound-board of the inſtrument through its whole breadth, but only at the corner *a*, where it is firmly fixed. The other extremity is detached about $\frac{1}{100}$ of an inch from the ſound-board; and thus the bridge, being made to tremble by the ſtrong vibration of the thick cord, rattles on the ſound-board, or on a bit of ivory glued to it. The uſual way in which this motion is procured, is to have another ſtring paſſing under the middle of the bridge in ſuch a manner that, by ſtraining it tight, we raiſe the corner *b* from the ſound-board to the proper height. This contrivance increaſes prodigiouſly the noiſe of the inſtrument, and gives it ſomewhat of the ſmart ſound of the trumpet, tho' very harſh and coarſe. But it merits the attention of every perſon who wiſhes to know any thing of the philoſophy of muſical ſounds, and we ſhall therefore ſay as much on the ſubject as will conduce to this effect.

Galileo, as we have obſerved in the article Temperament, *Suppl.* was the firſt who diſcovered the real connection between mathematics and muſic, by demonſtrating that the times of the vibrations of elaſtic cords of the ſame matter and ſize, and ſtretched by equal weights, are proportional to the lengths of the ſtrings. He inferred from this that the muſical pitch of the ſound produced by a ſtretched cord depended ſolely on the frequency of the vibrations. Moreover, not being able to diſcover any other circumſtance in which thoſe ſounds phyſically reſembled each other, and reflecting that all ſounds are immediately produced by agitations of air acting on the ear, he concluded that each vibration of the cord produced a ſonorous pulſe in the air, and therefore that the pitch of *any* ſound whatever depended on the frequency of the aerial pulſes. In this way alone the ſound of a ſtring, of a bell, of an organ pipe, and the bellow of a bull, may have the ſame pitch. He could not, however, demonſtrate this in any caſe but the one above mentioned. But he was encouraged to hope that mathematicians would be able to demonſtrate it in all caſes, by his having obſerved that the ſame proportions obtained in organ pipes as in ſtrings ſtretched by equal weights. But it required a great progreſs in mechanical philoſophy, from the ſtate in which Galileo found it, before men could ſpeculate and reaſon concerning the pulſes of air, and diſcover any analogy between them and the vibrations of a ſtring. This analogy, however, was diſcovered, and its demonſtration completed, as we ſhall ſee by and by. In the mean time, Galileo's demonſtration of the vibrations of elaſtic cords became the foundation of all muſical philoſophy. It muſt be thoroughly underſtood before we can explain the performance of the trumpet marine.

Trumpet Marine.

The demonſtration of Galileo is remarkable for that beautiful ſimplicity and perſpicuity which diſtinguiſh all the writings of that great mechanician, and it is the elementary propoſition in all mechanical treatiſes on muſic. Few of them indeed contain any thing more; but it is extremely imperfect, and is juſt only on the ſuppoſition that all the matter of the ſtring is collected at its middle point, and that the reſt of it has elaſticity without *inertia*. This did not ſuit the accurate knowledge of the laſt century, after Huyghens and Newton had given the world a taſte of what might be done by proſecuting the Galilean mechanics. When a muſical cord has its middle point drawn aſide, and it is ſtrained into the ſhape of two ſtrait lines, if it be let go, it will be obſerved not to vibrate in this form. It may eaſily be ſeen in the extremity of its excurſions, where it reſts, before it return by its elaſticity. The reaſon is this (ſee fig. B.) When the middle point C of the cord is drawn aſide, and the cord has the form of two ſtraight lines AC, CB, this point C, being pulled in the directions CA, CB, at once, is really accelerated in the direction CD, which biſects the angle ACB; and if it were then detached from the reſt of the material cord, it would move in that direction. But any other point *f* between C and B has no accelerating force whatever acting on it. It is equally pulled in the directions *f* C and *f* B. The particle C therefore is obliged to drag along with it the inert matter of the reſt of the cord; and when it has come to any intermediate ſituation *c*, the cord cannot have the form of two ſtraight lines A *c*, *c* B, with the particle *f* ſituated in *f*. This particle will be left ſomewhat behind, as in φ, and the cord will have a curved form A *c* φ B; and in this form it will vibrate, going to the other ſide, and aſſuming, not the rectilineal form ADB, but the curved form

A δ B.

A *f* B. That every particle of the curve A $e\,c'f$ B is now accelerated toward the axis AB is evident, becauſe every part is curved, and the whole is ſtrained toward A and B, which tends to ſtraighten every part of it. But in order that the whole may arrive at the axis in one moment, and conſtitute a ſtraight line AB, it is evidently neceſſary that the accelerating force on every particle be as the diſtance of the particle from that point of the axis at which it arrives. It is well known to the mathematician that the accelerating force by which any particle is urged towards a rectilineal poſition, with reſpect to the adjoining particles, is proportional to the curvature. Our readers who are not familiar with ſuch diſcuſſions, may ſee the truth of this fundamental propoſition by conſidering the whole of A c B as only a particle or minute portion of a curve, magnified by a microſcope. The force which ſtrains the curve may be repreſented by c A or AE. Now it is well known (and is the foundation of Galileo's demonſtration) that the ſtraining force is to the force with which c is accelerated in the direction c E as A c to c D, or as AE to c D, or as AE to twice c E. Now c E is the meaſure of the curvature of A c B, being its deflection from a right line. Therefore when the ſtraining force is the ſame all over the curve, the accelerating force, by which any portion of it tends to become ſtraight, is proportional to the curvature of that portion. And if r be the radius of a circle paſſing through A, c, and B, and coinciding with this element of a curve, it is plain that $c\text{D} : c\text{A} = c\text{A} : r$, or that the radius of curvature is to the element c A as the extending force to the accelerating force; and $c\text{D} = \frac{c\text{A}^2}{r}$; and is inverſely as r, or directly as the curvature.

Hence we ſee the nature of that curve which a muſical chord muſt have, in order that all its parts may arrive at the axis at once. The curvature at c muſt be to the curvature at f as E c to $g\,f$. But this may not be enough. It is farther neceſſary that when c has got half way to E, the curvature in the different points of the new curve into which the cord has now arranged itſelf, be alſo, in every point, proportional to the diſtance from the axis. Now this *will* be the caſe if the extreme curve has been ſuch. For, taking the cord in any other ſucceſſive ſhape, the diſtance which each point has gone in the ſame moment muſt be proportional to the force which impelled it; therefore the remaining diſtances of all the points from the axis will have the ſame proportions as before. And the geometrical and evident conſequence of this is, that the curvatures will alſo be in the ſame proportion.

Therefore a cord that is once arranged in this form will always preſerve it, and will vibrate like a cycloidal pendulum, performing its oſcillations in equal times, whether they be wide or narrow. Therefore ſince this perfect iſochroniſm of vibrations is all that is wanted for preſerving the ſame muſical pitch or tone, this cord will always have the ſame note.

This propoſition was the diſcovery of Dr Brooke Taylor, one of the ornaments of our country *, and is publiſhed in his celebrated work *Methodus Incrementorum*. The inveſtigation, however, and the demonſtration in that work, are ſo obſcure and ſo tedious that few had patience to peruſe them. It was more elegantly treated afterwards by the Bernoullis and others. The curve got the name of the *Taylorean curve;* and is conſidered by many eminent mathematicians as a trochoid, *viz.* the curve deſcribed by a point in the nave or ſpoke of a wheel while the wheel rolls along a ſtraight line. But this is a miſtake, although it is allied to the trochoid in the ſame manner that the figure of ſines is allied to the cycloid. Its phyſical property intitles it to the name of the HARMONICAL CURVE. As this curve is not only the foundation of all our knowledge of the vibration of elaſtic cords, but alſo furniſhes an equation which will lead the mathematician through the whole labyrinth of aereal undulations, and be of uſe on many other occaſions; and as the firſt mathematicians have, through inattention, or through enmity to Dr Taylor, affected to conſider it as the trochoid already well known to themſelves—we ſhall give a ſhort account of its conſtruction and chief properties, ſimplified from the elegant deſcription given by Dr Smith in his Harmonics.

Let SDTV, QERP (fig. C.), be circles deſcribed round the centre C. Draw the diameters QCR, ECP, cutting each other at right angles. From any point G in the exterior circle draw the radius GC, cutting the interior circle in F, draw KHFI parallel to QCR, and make HI, HK, each equal to the arch EG. Let this be done for every point of the quadrantal arch EGR. The points I, K, are in the harmonic curve; that is, the curve AKDIB paſſing through the points K and I, determined by this conſtruction, has its curvature in every point K proportional to the diſtance KN from the baſe AB.

To demonſtrate this, draw FL perpendicular to the axis, and join EL. Take another point g in the outer circle indefinitely near to G. Draw $g\,c$, cutting the inner circle in f, and $f\,h$ and $f\,l$ perpendicular to DC, CT, and join E l. Then ſuppoſe two lines K m', K m' perpendicular to the curve in K and k. They muſt meet in m, the centre of the equicurve circle. Draw KN n' perpendicular to the baſe, and $m'\,n'$ parallel to it, and join $k\,n$ Laſtly, draw XL x perpendicular to EL.

It is plain that k O, the difference of HK and $h\,k$, is equal to G g, the difference of GE and g E, and that KO is equal to F r, and L l to $r\,f$. Alſo, becauſe ELX is a right angle, $\text{EX} = \frac{\text{EL}^2}{\text{EC}}$.

We have $\text{F}r : \text{F}f = \text{CL} : \text{CF}, = \text{CL} : \text{CD}.$
$\text{F}f : \text{G}g = \text{CD} : \text{CE}.$
Therefore $\text{F}r : \text{G}g$, or $\text{KO} : \text{O}k = \text{CL} : \text{CE}.$

The triangles ECL and kOK are therefore ſimilar, as are alſo kOK and K$n\,m$, and conſequently ECL and K$n\,m$; and becauſe EC is parallel to Kn, EL is parallel to Km. For the ſame reaſon $k\,m$ is parallel to El, and the triangles E$l\,x$ and mKk are ſimilar, and

$\text{L}x : \text{K}k = \text{LE} : \text{K}m,$
and $\text{L}x : \text{K}k = \text{EC} : \text{K}n.$ But farther,
$\text{L}x : \text{L}l = \text{CE} : \text{CL}$
$\text{L}l : \text{F}f = \text{KN} : \text{CD}$, being $= \text{FL} : \text{FC}$
$\text{F}f : \text{G}g = \text{CD} : \text{CE}$, being $= \text{F}f : k\text{O}$
$\text{G}g : \text{K}k = \text{CE} : \text{CL}$, being $= \text{KO} : \text{K}k.$
Therefore $\text{L}x : \text{K}k = \text{KN} \times \text{CE} : \text{EL}^2, = \text{KN} : \text{EX}.$
Therefore $\text{KN} : \text{EX} = \text{LE} : \text{K}m$, and $\text{K}m = \frac{\text{EX} \cdot \text{LE}}{\text{KN}}$,
and $\text{KN} : \text{EX} = \text{CE} : \text{K}n$, and $\text{K}n = \frac{\text{EX} \cdot \text{CE}}{\text{KN}}$.

In

---

* See his Life, Encycl

In the very narrow vibrations of muſical cords, CD is exceedingly ſmall in compariſon with CE, ſo that EX·EL, or EX·CE, may, without ſenſible error, be taken for CE^2, and then we obtain K*m* or K*n* (which hardly differ) $= \frac{CE^2}{KN}$, and therefore the curvature is proportional to KN. The ſmall deviation from this ratio would ſeem to ſhew that this conſtruction does not give the harmonic curve with accuracy. But it is not ſo. For it will be found that although the curvature is not as KN, it is ſtill proportional to the ſpace which any particle K muſt really deſcribe in order to arrive at the axis. Theſe paths are lines whoſe curvatures diminiſh as they approach to DC.

We ſee, *1ſt*, that the baſe ACB of the curve is equal to the ſemicircular arch QER.

2d, Alſo that the tangent KZ in any point K is perpendicular to EL.

3d. We learn that the curvature at A and B is nothing, for in theſe two points KN is nothing.

4th, The radius of curvature at D is preciſely $= \frac{CE^2}{CD}$.

Therefore, as the ſtring approaches the axis, and CD diminiſhes, the curvature diminiſhes in the ſame proportion. The vibrations therefore are performed like thoſe of a pendulum in a cycloid, and are iſochronous, whether wide or narrow, and therefore the muſical pitch is conſtant.

This is not ſtrictly true, becauſe in the wide vibrations the extenſion or extending force is ſomewhat greater. Hence it is that a ſtring when violently twanged ſounds a little ſharper at the beginning. Dr Long made a harpſichord whoſe ſtrings were ſtretched by weights, by which this imperfection was removed.

It is proper to exhibit the curvature at D in terms of the length AB, and of the greateſt excurſion *c* D. Therefore let *c* be the circumference of a circle whoſe diameter is 1. Let AB the length of the cord be = L, and let CD the $\frac{1}{2}$ breadth of the vibration be B.

We had a little ago $Dm = \frac{CE^2}{CD}$, but $c : 1 = AB : CE$, and $CE = \frac{AB}{c}$, and $cE^2 = \frac{ABc}{c^2}$. Therefore $Dm = \frac{AB^2}{c^2 \times CD}, = \frac{L^2}{9{,}87CD}$ nearly.

We can now tell the number of vibrations made in a ſecond by a ſtring. This we obtain by comparing its motion, when impelled by the accelerating force which acts on it, with its motion when acted on by its weight only. Therefore let L be the length of a ſtring, and W its weight, and let E be the ſtraining weight, or extending force. Let *f* be the force which accelerates the particle D *d* of the cord, and *w* the weight of that particle, while W is the weight of the whole cord. Let *z* be the ſpace which the particle D *d* would deſcribe during the time of one vibration by the uniform action of the force *f*, and let S be the ſpace which it would deſcribe in the ſame time by its weight *w* alone. Then (DYNAMICS, *Suppl.* n° 103. cor. 6) the time in which *f* would impel the particle D *d* along $\frac{1}{2}$ DC, is to the time of one vibration as $1 : c$. And $\frac{1}{2}$ DC is to *z* as the ſquare of the time of deſcribing $\frac{1}{2}$ DC, is to the ſquare of the time of deſcribing *z*; that is, $1 : c^2 = \frac{1}{2} DC : 2z$, and $c^2 . DC = 2z$.

Trumpet Marine.

Now, by the property of the harmonic curve,

$$AB : Dm = 2z : AB$$

But $Dm : Dd = E : f$

And $Dd : AB = w : W$

Therefore $2z \cdot E \cdot w = AB \cdot f \cdot W$

And $f : w = 2z \times E : AB \times W$

But $w : f = 2S : 2z$

Therefore $2S \times E = AB \times W$

And $2E : W = AB : S$.

That is, a muſical cord, extended by a force E, performs one vibration DCV in the time that a heavy body deſcribes a ſpace S, which is to the length of the cord as its weighr is to twice the extending force.

Now let *g* be the ſpace through which a heavy body falls in one ſecond, and ſet the time of a vibration (eſtimated in parts of a ſecond) be T. We have

$$AB : S = 2E : W$$

$$S : g = T^2 : 1^2$$

Therefore $AB : g = 2E \cdot T^2 : W$

And $AB \times W = T^2 \times 2E \times g$

Therefore $T^2 = \frac{AB \times W}{2g.E}$, and $T = \sqrt{\frac{AB \times W.}{2g.E}}$

Let *n* be the number of vibrations made in a ſecond,

$$n = \frac{1}{T}, = \sqrt{\frac{2g.E}{AB.W}} = \sqrt{\frac{2gE}{L.W}}.$$

If the length of the cord be meaſured in feet, 2 *g* is very nearly 32. If in inches, 2 *g* is 386, more nearly. Therefore $n = \sqrt{\frac{32E}{L \cdot W}}$ or $\sqrt{\frac{386E}{L \cdot W}}$. This may eaſily be compared with obſervation. Dr Smith hung a weight of 7 pounds, or 49,000 grains, on a braſs wire ſuſpended from a finger pin, and ſhortened it till it was in perfect uniſon with the double octave below the open ſtring D of a violin. In this ſtate the wire was 35,55 inches long, and it weighed 31 grains.

Now $\sqrt{\frac{384 \times 49000}{35{,}55 \times 31}} = 130{,}7 = n$. This wire, therefore, ought to make 130,7 vibrations in a ſecond. Dr Smith proceeded to aſcertain the number of aereal pulſes made by this ſound, availing himſelf of the theory of the beats of tempered conſonances invented by himſelf. On his fine chamber organ he tuned upwards the perfect fifths DA, A *e*, *e b*, and then tuned downward the perfect 6th *e d*. Thus he obtained an octave to D, which was too ſharp by a comma, and he found that it beat 65 times in 20 ſeconds. Therefore the number of vibrations was $\frac{65}{20}$ 81, or 263,25. Theſe were complete pulſes or motions from D to V and back again, and therefore contained $526\frac{1}{2}$ ſuch vibrations as we have now been conſidering. The double octave below ſhould make $\frac{1}{4}$th of this, or 131,6, which is not a complete vibration more than the above theory requires: more accurate coincidence is needleſs.

This theory is therefore very completely eſtabliſhed, and it may be conſidered as one of the fineſt mechanical problems which has been ſolved in this century. We mention it with the greater minuteneſs, becauſe the merit of Dr Taylor is not ſufficiently attended to. Mr Rameau, and the other great theoriſts in muſic, make no mention of him; and ſuch as have occaſion to ſpeak of the abſolute number of vibrations made by any muſical note, always quote Mr Sauveur of the French academy,

demy. This gentleman has written ſome very excellent diſſertations on the theory of muſic, and Sir Iſaac Newton in his *Principia* often quotes his authority. He has given the actual determination of the number of vibrations of the note C, obtained in a manner ſimilar to that practiſed by Dr Smith on his chamber organ, and which agrees extremely well with that meaſure. But Mr Sauveur has alſo given a mechanical inveſtigation of the problem, which gives the ſame number of vibrations that he obſerved. We preſume that Rameau and others took the demonſtration for good; and thus Mr Sauveur paſſes on the Continent for the diſcoverer of this theorem. But it was not publiſhed till 1716, though read in 1713; whereas Dr Taylor's demonſtration was read to the Royal Society in May 1714. But this demonſtration of Mr Sauveur is a mere paralogiſm, where errors compenſate errors; and the aſſumption on which he proceeds is quite gratuitous, and has nothing to do with the ſubject. Yet John Bernoulli, from enmity to Taylor and the Engliſh mathematicians, takes not the leaſt notice of this ſophiſticated demonſtration, accommodated to the experiment, and ſo devoid of any pretenſions to argument that this ſevere critic could not but ſee its falſity.

Sauveur was one of the firſt who obſerved diſtinctly that remarkable fact which Mr Rameau made the foundation of his muſical theory, *viz.* that a full muſical note is accompanied by its octave, its twelfth, and its ſeventeenth major. It had been caſually obſerved before, by Marſennus, by Perrault, and others; but Sauveur tells diſtinctly how to make the obſervation, and affirms it to be true in all deep notes. Rameau aſſerts it to be univerſally and neceſſarily true in all notes, and the foundation of all muſical pleaſure.

It had been diſcovered before this time, that not only a full note cauſed its uniſon to reſound, but alſo that a 12th, being ſounded near any open ſtring, the ſtring *reſounded* to this 12th. It does the ſame to a 15th, a 17th major, a 22d, &c.

Dr Wallis added a very curious circumſtance to this obſervation. Two of his pupils, Mr Noble and Mr Pigott, in 1673, amuſing themſelves with theſe reſonnances, obſerved, that if a ſmall bit of paper be laid on the ſtring of a violin which is made to reſound to its uniſon, the paper is thrown off: a proof that the ſtring reſounded by really vibrating, and that it is thrown into theſe vibrations by the pulſes of the air produced by the other ſtring. In like manner the paper is thrown off when the ſtring reſounds to its octave. But the young gentlemen obſerved, that when the paper was laid on the middle point of the ſtring, it remained without agitation, although the ſtring ſtill reſounded. They found the ſame thing when they made the ſtring reſound to its 12th: papers laid on the two points of diviſion lay ſtill, but were thrown off when laid on any other place. In ſhort, they found it a general rule, that papers laid on any points of diviſion correſponding to the note which was reſounded, were not agitated.

Dr Wallis (the greateſt theoriſt in muſic of the laſt century) juſtly concluded that theſe points of the reſounding ſtring were at reſt, and that the intermediate parts were vibrating, and producing the notes correſponding to their lengths.

From this Mr Sauveur, with great propriety, deduced the theory of the performance of the trumpet marine, the vielle, the clavichord, and ſome other inſtruments.

When the ſtring of the trumpet marine is gently ſtopped at $\frac{1}{2}$, and the bow drawn lightly acroſs it at H (fig. A), the full vibration at the finger is ſtopped; but the ſtring is thrown into vibrations of ſome kind, which will either be deſtroyed or may go on. It is of importance to ſee what circumſtance will permit their continuance.

Suppoſe an elaſtic cord put into the ſituation ABCDE (fig. D), ſuch that AB, BC, CD, DE, are all equal, and that BCD is a ſtraight line. Let the point C be made faſt, and the two points B and D be let go at once. It is evident that the two parts will immediately vibrate in two harmonical curves A*b*C and CDE, which will change to ABC and C*d*E, and ſo on alternately. It is alſo evident that if a line FCG be drawn touching the curve ABC, it will alſo touch the curve CDE; and the line which touches the curve A*b*C in C, will alſo touch the curve C*d*E. In every inſtant the two halves of the cord will be curves which have a common tangent in the point C. The undoubted conſequence of this is, that the point C will not be affected by theſe vibrations, and its fixure may be taken away. The cord will continue to vibrate, and will give the ſound of the octave to its fundamental note.

The condition, then, which muſt be implemented, in order that a ſtring may reſound to its octave, or take the ſound of its octave, is ſimply this, that its two parts may vibrate equally in oppoſite directions. This is evidently poſſible; and when the bow is drawn acroſs the ſtring of the trumpet marine at H, and irregular vibrations are produced in the whole ſtring, thoſe which happen to be in one direction on both ſides of the middle point, where it is gently ſtopped by the finger, will deſtroy each other, and the conſpiring ones will be inſtantly produced, and then every ſucceeding action of the bow will increaſe them.

The ſame thing muſt happen if a ſtring is gently ſtopped at one-third of its length; for there will be the ſame equilibrium of forces at the two points of diviſion, ſo that the fixures of theſe points may be removed, and the ſtring will vibrate in three parts, ſounding the 12th of the fundamental.

We may obſerve, by the way, that if the bow be drawn acroſs the ſtring at one of the points of diviſion, correſponding to the ſtopping at the other end of the ſtring, it will hardly give any diſtinct note. It rattles, and is intolerably harſh. The reaſon is plain: The bow takes ſome hold of the point C, and drags it along with it. The cord on each ſide of C is left behind, and therefore the two curves cannot have a common tangent at C. The vibrations into which it is thus jogged by the bow deſtroy each other.

We now ſee why the trumpet marine will not ſound every note. It will ſound none but ſuch as correſpond to a diviſion of the ſtring into a number of equal parts, and its note will be in uniſon with a ſtring equal to one of thoſe parts. Therefore it will *firſt* of all ſound the fundamental, by its whole length;

2. Its octave, correſponding to - $\frac{1}{2}$ its length
3. The 12th, - - - $\frac{1}{3}$
4. The 15th, or double octave, - $\frac{1}{4}$
5. The 17th, - - - $\frac{1}{5}$
6. The 19th, - - - $\frac{1}{6}$

7. The

7. The 21ſt, which is not in the diatonic ſcale of our muſic, - $\frac{1}{7}$ its length.
8. The triple octave, or 22d, - $\frac{1}{8}$
9. The 23d, or 2d in the ſcale of the triple octave - - - $\frac{1}{9}$
10. The 24th, or 3d in this ſcale, $\frac{1}{10}$
11. The 25th, a falſe 4th of this ſcale, $\frac{1}{11}$
12. The 26th, a perfect 5th of this ſcale, $\frac{1}{12}$
13. The 27th, a falſe 6th of ditto, $\frac{1}{13} = \frac{3}{39}$ or $\frac{3}{40}$
14. The 28th, a falſe 7th minor, - $\frac{1}{14}$
15. The 28th, a perfect 7th major, $\frac{1}{15}$
16. The quadruple octave, - $\frac{1}{16}$

Thus we ſee that this inſtrument will not execute all muſic, and indeed will not complete any octave, becauſe it will neither give a perfect 4th nor 6th. We ſhall preſently ſee that theſe are the very defects of the trumpet.

This ſingular ſtringed inſtrument has been deſcribed in this detail, chiefly with the view of preparing us for underſtanding the real trumpet. The **Vielle, Savoyarde**, or **Hurdygurdy**, performs in the ſame manner. While the wheel rubs one part of the ſtring like a bow, the keys gently preſs the ſtrings, in points of aliquot diviſion, and produce the harmonic notes.

It is to prevent ſuch notes that the part of harpſichord wires, lying between the bridge and the pins, are wrapped round with liſt. Theſe notes would frequently diſturb the muſic.

Laſtly on this head, the Æolian harp derives its vaſt variety of fine ſounds from this mode of vibration. Seldom do the cords perform their fundamental or ſimple vibrations. They are generally ſounding ſome of the harmonies of their fundamentals, and give us all this variety from ſtrings tuned in uniſon.

Trumpet, Muſical, is a wind inſtrument which ſounds by preſſing the cloſed lips to the ſmall end, and forcing the wind through a very narrow aperture between the lips. This is one of the moſt ancient of muſical inſtruments, and has appeared in all nations in a vaſt variety of forms. The conch of the ſavage, the horn of the cowherd and of the poſtman, the bugle horn, the lituus and tuba of the Romans, the military trumpet, and the trombone, the *cor de chaſſe* or French horn—are all inſtruments winded in the ſame manner, producing their variety of tones by varying the manner and force of blowing. The ſerpent is another inſtrument of the ſame kind, but producing part of its notes by means of holes in the ſides.

Although the trumpet is the ſimpleſt of all muſical inſtruments, being nothing but a long tube, narrow at one end and wide at the other, it is the moſt difficult to be explained. To underſtand how ſonorous and regulated undulations can be excited in a tube without any previous vibration of reeds to form the waves at the entry, or of holes to vary the notes, requires a very nice attention to the mechaniſm of aereal undulations, and we are by no means certain that we have as yet hit on the true explanation. We are certain, however, that theſe aereal undulations do not differ from thoſe produced by the vibration of ſtrings; for they make ſtrings reſound in the ſame manner as vibrating cords do. Galileo, however, did not know this argument for his aſſertion that the muſical pitch of a pipe, like that of a cord, depended on the frequency alone of the aereal undulations; but he thought it highly probable, from his obſervations on the ſtructure of organs, that the notes of pipes were related to their lengths in the ſame manner as thoſe of wires, and he expreſsly makes this remark. Newton, having diſcovered that ſound moved at the rate of about 960 feet per ſecond, obſerved that, according to the experiments of Mr Sauveur, the length of an open pipe is half the length of an aereal pulſe. This he could eaſily aſcertain by dividing the ſpace deſcribed by ſound in a ſecond by the number of pulſes.

Daniel Bernoulli, the celebrated promoter of the Newtonian mechanics, diſcovered, or at leaſt was the firſt who attentively marked, ſome other circumſtances of reſemblance between the undulations of the air in pipes and the vibrations of wires. As a wire can be made, not only to vibrate in its full length, ſounding its fundamental note, but can alſo be made to ſubdivide itſelf, and vibrate like a portion of the whole, with points of reſt between the vibrating portions, when it gives one of its harmonic notes; ſo a pipe cannot only have ſuch undulations of air going on within it as are competent to the production of its fundamental note, but alſo thoſe which produce one of its harmonic notes. Every one knows that when we force a flute, by blowing too ſtrongly, it quits its proper note, and gives the octave above. Forcing ſtill more, produces the 12th. Then we can produce the double octave or 15th, and the 17th major, &c. In ſhort, by attending to ſeveral circumſtances in the manner of blowing, all the notes may be produced from one very long pipe that we produce from the trumpet marine, and in preciſely the ſame order, and with the ſame omiſſions and imperfections. This alone is almoſt equivalent to a proof that the mechaniſm of the undulations of air in a pipe are analogous to that of the vibrations of an elaſtic cord. Having with ſo great ſucceſs inveſtigated the mechaniſm of the partial vibrations of wires, and alſo another kind of vibrations which we ſhall mention afterwards, incomparably more curious and more important in the philoſophy of muſical ſounds, Mr Bernoulli undertook the inveſtigation of thoſe more myſterious motions of air which are produced in pipes; and in a very ingenious diſſertation, publiſhed in the Memoirs of the Academy of Paris for 1762, &c. he gives a theory of them, which tallies in a wonderful manner with the chief phenomena which we obſerve in the wind inſtruments of the flute and trumpet kind. We are not, however, ſo well ſatisfied with the truth of his *aſſumptions* reſpecting the ſtate of the air, and the preciſe form of the undulations which he aſſigns to it; but we ſee that, notwithſtanding a probability of his being miſtaken in theſe circumſtances (it is with great deference that we preſume to ſuppoſe him miſtaken), the chief propoſitions are ſtill true; and that the changes from note to note muſt be produced in the order, tho' perhaps not in the preciſe manner, aſſigned by him.

It is by no means eaſy to conceive, with clearneſs, the way in which muſical undulations are excited in the various kinds of trumpets. Many who have reputation as mechanicians, ſuppoſe that it is by means of vibrations of the lips, in the ſame manner as in the hautboy, clarionette, and reed pipes of the organ, where the air, ſay they, is put in motion by the trembling reed. But this explanation is wrong in all its parts; even in the reed-pipes of an organ, the air *is not* put in motion by the reeds. They are indeed the *occaſions* of its muſical undulation, but they do not *immediately impel* it into thoſe waves. This method (and indeed all methods but the vibrations of wires, bells, &c.) of producing ſound is little underſtood, though it is highly worthy of notice, being the origin of animal voice, and becauſe a knowledge of it would enable the artiſts to entertain us with ſounds hitherto unknown, and thus add conſiderably to this gift of our Bountiful Father, who has ſhewn, in the ſtructure of the larynx of the human ſpecies, that he intended that we ſhould enjoy the pleaſures of muſic as a *laborum dulce lenimen*. He has there placed a micrometer apparatus, by which *after* the other muſcles have done their part in bringing the glottis nearly to the tenſion which the intended note requires, we can eaſily, and inſtantly, adjuſt it with the utmoſt nicety.

We truſt, therefore, that our readers will indulge us while we give a very curſory view of the manner in which the tremulous motion of the glottis, or of a reed in an organ pipe, produces the ſonorous undulations with a conſtant or uniform frequency, ſo as to yield a muſical note.

If we blow through a ſmall pipe or quill, we produce only a whizzing or hiſſing noiſe. If, in blowing, we ſhut the entry with our tongue, we hear ſomething like a ſolid blow or tap, and it is accompanied with ſome faint perception of a muſical pitch, juſt as when we tap with the finger on one of the holes of a flute when all the reſt are ſhut. We are then ſenſible of a difference of pitch according to the length of the pipe; a longer pipe or quill giving a graver ſound. Here, then, is like the *beginning* of a ſonorous undulation. Let us conſider the ſtate of the air in the pipe: It was filled by a column of air, which was moving forward, and would have been ſucceeded by other air in the ſame ſtate. This air was therefore nearly in its ſtate of natural denſity. When the entry is ſuddenly ſtopped by the tongue, the included air, already in motion, continues its motion. This it cannot do without growing rarer, and then it is no longer a balance for the preſſure of the atmoſphere. It is therefore retarded in its motion, totally ſtopped (being in a rarefied ſtate), and is then preſſed back again. It comes back with an accelerated motion, and recovers its natural denſity, while the ſtate of rarefaction goes forward through the open air like any other aereal pulſe. Its motions are ſomewhat, but not altogether, like that of a ſpiral wire, which has been in like manner moving uniformly along the pipe, and has been ſtopped by ſomething catching hold of its hindermoſt extremity. This ſpring, when thus catched behind, ſtretches itſelf a little, then contracts *beyond* its natural ſtate, and then expands again, quivering ſeveral times. It can be demonſtrated that the column of air will make but one quiver. Suppoſe this accompliſhed in the hundredth part of a ſecond, and that at that inſtant the tongue is removed for the hundredth part of a ſecond, and again applied to the entry of the pipe. It is plain that this will produce ſuch another pulſe, which will join to the former one, and force it out into the air, and the two pulſes together will be like two pulſes produced by the vibration of a cord. If, inſtead of the tongue, we ſuppoſe the flat plate of an organ-reed to be thus alternately applied to the hole and removed, at the exact moments that the renewals of air are wanted, it is plain that we ſhall have *ſonorous* undulations of *uniform* frequency, and therefore a muſical note. This is the way in which reeds produce their effect, not by *impelling* the air into alternate ſtates of motion to and fro, and alternate ſtrata of rarefied and condenſed air, but by giving them time to acquire this ſtate by the combination of the air's elaſticity with its progreſſive motion.

The adjuſtment of the ſucceeding puff of air to the pulſe which precedes it, ſo that they may make one ſmooth and regular pulſe, is more exact than we have yet remarked; for the ſtoppage of the hole not only *occaſions* a rarefaction *before it*, but by checking the air which was juſt going to enter, makes a condenſation *behind the door* (ſo to ſpeak); ſo that, when the paſſage is again opened, the two parcels of air are fitted for ſupporting each other, and forming one pulſe.

Suppoſe, in the next place, that the reed, inſtead of completely ſhutting the hole each time, only half ſhuts it. The ſame thing muſt ſtill happen, although not in ſo remarkable a degree. When the paſſage is contracted, the ſupply is diminiſhed, and the air now in the pipe muſt rarefy, by advancing with its former velocity. It muſt therefore retard; by retarding, regain its former denſity; and the air, not yet got into the pipe, muſt condenſe, &c. And if the paſſage be again opened or enlarged in the proper time, we ſhall have a complete pulſe of condenſed and rarefied air; and this muſt be accompanied by the beginning of a muſical note, which may be continued like the former.

This will be a ſofter or more mellow note than the other; for the condenſed and rarefied air will not be ſo ſuddenly changed in their denſities. The difference will be like the difference of the notes produced by drawing a quill along the teeth of a comb, and that produced by the equally rapid vibrations of a wire. For let it be remarked here, that muſical notes are by no means confined, as theoriſts commonly ſuppoſe, to the regular cycloidal agitations of air, ſuch as are produced by the vibrations of an elaſtic cord; but that any crack, ſnap, or noiſe whatever, when repeated with ſufficient frequency, becomes *ipſo facto* a muſical ſound, of which we can tell the pitch or note. What can be leſs muſical than the ſolitary cracks or ſnaps made by a ſtiff door when very ſlowly opened? Do this briſkly, and the creak changes to a chirp, of which we can tell the note. The ſounds will be harſh or ſmooth, according as the ſnaps of which they are compoſed are abrupt or gradual.

This diſtinction of ſounds is moſt ſatisfactorily confirmed by experiment. If the tongue of the organ reed is quite flat, and if, in its vibrations, it apply itſelf to the whole margin of the hole at once, ſo as completely to ſhut it (as is the caſe in the oldfaſhioned regal ſtop of the organ), the note is clear, ſmart, and harſh or hard: but if the lips of the reed are curved, or the tongue properly bent backward, ſo that it applies itſelf to the edges of the hole *gradatim*, and never completely ſhuts the paſſage, the note may have any degree of mellow ſweetneſs. This remark is worth the attention of the inſtrument-makers or organ builders, and enables them to vary the VOICE of the organ at pleaſure. We only mention it here as introductory to the explanation of the ſounds of the trumpet.

We truſt that the reader now perceives how the air, proceeding along a pipe, may be put in the ſtate of alternate ſtrata of condenſed and rarefied air, the particles, in the mean time, proceeding along the pipe with a very moderate velocity; while the *ſtate of undulation* is propagated at the rate of eleven or twelve hundred feet in a ſecond; juſt as we may ſometimes ſee a ſtream of water gliding gently down a canal, while a wave runs along its ſurface with much greater rapidity.

It will greatly aſſiſt the imagination, if we compare theſe aërial undulations with the undulations of water in an open canal. While the water is flowing ſmoothly along, ſuppoſe a ſluice to be thruſt up from the bottom quite to the ſurface, or beyond it. This will immediately cauſe a depreſſion on the lower ſide of the ſluice, by the water's going along the canal, and a heaping up of the water on the other ſide. By properly timing the motion of this ſluice up and down, we can produce a ſeries of connected waves. If the ſluice be not puſhed up to the ſurface but only one-half way, there will be the ſame ſucceſſion of waves, but much ſmoother, &c. &c.

It is in this ſtate, though not by ſuch means, that the air is contained in a ſounding trumpet. It is not brought into this ſtate by any tremor of the lips. The trumpeter ſometimes feels ſuch a tremor; but whenever he feels it, he can no longer ſound his note. His lips are painfully tickled, and he muſt change his manner of winding.

When blowing with great delicacy and care, the deepeſt notes of a French horn, or trombone, we ſometimes can feel the undulations of the air in the pipe diſtinctly fluttering and beating againſt the lips; and it is difficult to hinder the lips from being affected by it: but we feel plainly that it is not the lips which are fluttering, but the air before them. We feel a curious inſtance of this when we attempt to whiſtle in concert. If our accompanier intonates with a certain degree of incorrectneſs, we feel ſomething at our own lips which makes it impoſſible to utter the intended note. This happens very freqnently to the perſon who is whiſtling the upper note of a greater third. In like manner, the undulations in a pipe react on the reed, and check its vibrations. For if the dimenſions of a pipe are ſuch that the undulations formed by the reed cannot be kept up in the pipe, or do not ſuit the length of the pipe, the reed will either not play at all, or will vibrate only in ſtarts. This is finely illuſtrated by a beautiful and inſtructive experiment. Take a ſmall reed of the *vox humana* ſtop of an organ, and ſet it in a glaſs foot, adapted to the windbox of the organ. Inſtead of the common pipe above it, fix on it the ſliding tube of a ſmall teleſcope. When all the joints are thruſt down, touch the key, and look attentively to the play of the reed. While it is ſounding, draw out the joints, making the pipe continually longer. We ſhall obſerve the reed thrown into ſtrange fits of quivering, and ſometimes quite motionleſs, and then thrown into wide ſonorous vibrations, according as the *maintainable* pulſe is commenſurate or not with the vibrations of the reed. This plainly ſhews that the air is not impelled into its undulations by the reed, but that the reed accommodates itſelf to the undulations in the pipe.

We acknowledge that we cannot explain with diſtinctneſs in what manner the air in a trumpet is firſt put into muſical undulations. We ſee that it is only in very long and ſlender tubes that this can be done. In ſhort tubes, of conſiderable diameter, like the cowherd's horn, we obtain only one or two very indiſtinct notes, of which it is difficult to name the pitch; and this requires great force of blaſt; whereas, to bring out the deep notes of the French horn, a very gentle and well regulated blaſt is neceſſary. The form of the lips, combined with the force of the blaſt, form all the notes. But this is in a way that cannot be taught by any deſcription. The performer learns it by habit, and *feels* that the inſtrument leaps into its note without him, when he gradually varies his blaſt, and continues ſounding the ſame note; although he, in the mean time, makes ſome ſmall change in his manner of blowing. This is owing to what Mr Bernoulli obſerved. The tube is ſuited only to ſuch pulſes, and can only maintain ſuch pulſes as correſpond to aliquot parts of its length; and when the embouchure is very nearly, but not accurately, ſuited to a particular note, that note *forms itſelf* in the tube, and, reacting on the lips, brings them into the form which can maintain it with eaſe. We have a proof of this when we attempt to ſound the note correſponding to one ſeventh of the length. Not having a diſtinct notion of this note, which makes no part of our ſcale of melody, we cannot eaſily prepare for it in the way that habit teaches us to prepare for the others: whereas, from what we ſhall ſee preſently, the notes *one-ſixth* and *one eighth* are both familiar to the mind, and eaſily produced. When, therefore, we attempt to produce the note *one-ſeventh*, we ſlide, againſt our will, into the *one ſixth* or *one-eighth*.

Nor can we completely illuſtrate the formation of muſical pulſes by waves in water. A canal is equally ſuſceptible of every height and length of progreſſive waves; whereas we ſee that a certain length of tube will maintain only certain determined pulſes of air.

We muſt therefore content ourſelves for the preſent with having learned, by means of the reed pipes, how the air may exiſt progreſſively in a tube, in an alternate ſtate of condenſation and rarefaction; and we ſhall now proceed to conſider how this ſtate of the air is related to the length of the tube. And here we can do no more than give an outline of Mr Bernoulli's beautiful theory of flutes and trumpets, but without a mathematical examination of the particular motions. We can, however, ſhew, with ſufficient evidence, how the different notes are produced from the ſame tube. It requires, however, a very ſteady attention from the reader to enable him to perceive how the different portions of this air act on each other. We truſt that this will now be given.

The conditions which muſt be implemented, in order to maintain a muſical pulſe, are two: 1. That the vibrations of the different plates of air be performed in equal times, otherwiſe they would all mix and confound each other. 2. That they move all together, all beginning and all ending at the ſame inſtant. It does not appear that any other ſtate of vibration can exiſt and be maintained.

The column of air in a tube may be conſidered as a material ſpring (having weight and inertia). This ſpring is compreſſed and coiled up by the preſſure of the atmoſphere. But in this coiled ſtate it can vibrate in its different parts, as a long ſpiral wire may do, though preſſed a little together at the ends. It is evident that the air within a pipe, ſhut at both ends, may be placed in ſuch a ſituation, *in a variety of ways*, that it will vibrate in every part, in the ſame manner as a chord of the ſame length and weight, ſtrained by a force equal to the preſſure of the atmoſphere. Thus, in the ſhut pipe AB (fig. 1.), ſuppoſe a harmonic curve ACB, or

Plate XLV.

a wire of the ſame weight with the air, throwing itſelf into the form of this curve. The force which impels the point C to the axis is to that which impels the point c as CE to $c\,e$. Now, ſuppoſe the air in this pipe divided into parallel ſtrata or plates, croſſing the tube like diaphragms. In order that theſe may vibrate in the ſame manner (not acroſs the tube, but in the direction of its axis), all that is neceſſary for the moment is, that the exceſs of the preſſure of the ſtratum $d\,d$ above that of the ſtratum $f\,f$ may be to the exceſs of the preſſure of DD above that of FF as $c\,e$ to CE. In this caſe, the ſtratum $c\,e$ will be accelerated in the direction $e\,f$, and the ſtratum EE is accelerated in the ſame direction, and in the due proportion. Now this may be done in an infinite variety of ways for a ſingle moment. It depends, not on the abſolute denſity, but on the *variation* of denſity; becauſe the preſſure by which a particle of air is urged in any direction ariſes from the *difference* of the diſtances of the adjoining particles on each ſide of it. But in order to *continue* this vibration, or in order that it may obtain at once in the whole pipe, this variation of denſity muſt continue, and be according to ſome connected law. This circumſtance greatly limits the ways in which the vibration may be kept up. Mr Bernoulli finds that the iſochroniſm and ſynchroniſm can be maintained in the following manner, and in no other that he could think of:

Let AB (fig. 2.) be a cylindrical pipe, ſhut at A, and open at B. Then, in whatever manner the ſound is produced in the pipe, the undulations of the contained air muſt be performed as follows: Let $a\,a$ be a plate of air. This plate will approach to, and recede from, the ſhut end A, vibrating between the ſituations $b\,b$ and $c\,c$, the whole vibration being $b\,c$, and the plate will vibrate like a pendulum in a cycloid. The greater we ſuppoſe the excurſions $a\,b$, $a\,c$, the louder will the ſound be; but the duration of them all muſt be the ſame, to agree with the fact that the tone remains the ſame. The motion will be accelerated in approaching to $a\,a$ from either ſide, and retarded in the receſs from it. Let us next conſider a plate $\alpha\,\alpha$, more remote from A. It muſt make ſimilar vibrations from the ſituation $\beta\,\beta$ to the ſituation $\gamma\,\gamma$. But theſe vibrations muſt be greater in proportion as the plate is farther from A. It cannot be conceived otherwiſe: For ſuppoſe the plate $\alpha\,\alpha$ to make the *ſame* excurſions with $a\,a$, and that the reſt do the ſame. Then they will all retain the ſame diſtances from each other; and thus there will be no force whatever acting on any particles to make them vibrate. But if every particle make excurſions proportional to its diſtance from A, the *variation* of denſity will, in any inſtant, be the ſame through the whole pipe, and each particle in the vibrating plate $\beta\,\beta$ will be accelerated or retarded in proportion to its diſtance from A; while the accelerations and retardations over all will, in any inſtant, be proportional to the diſtance of each particle from its place of reſt. All this will appear to the mathematician, who attentively conſiders any momentary ſituation of the particles. In this manner all the particles will ſupport each other in their vibrations.

It follows from this deſcription that the air in the tube is alternately rarefied and condenſed. But theſe changes are very different in different parts of the tube. They muſt be greateſt of all at A; becauſe, while all the plates approach to A, they concur in condenſing the air immediately adjoining to A; while the air in $a\,a$ and $\alpha\,\alpha$ is leſs condenſed by the action of the plates beyond it. The air at B is always of its natural denſity, being in equilibrio with the ſurrounding air. At B, therefore, there is a ſmall parcel of air, of its natural denſity, which is alternately going in and out.

This account is confirmed by many facts. If the bottom of the pipe be ſhut by a fine membrane, ſtretched acroſs it like a drum-head, with a wire ſtretched over it, either externally or internally, in the ſame manner as the catgut is ſtretched acroſs the bottom of a drum, it will be thrown into ſtrong vibrations, making a very loud noiſe, by rattling againſt the croſs wire. The ſame thing happens if the membrane be paſted over a hole cloſe to the bottom, leaving a ſmall ſpace round the edge of the hole without paſte, ſo that the membrane may play out and in, and rattle on the margin of the hole. This alſo makes a prodigious noiſe. Now, if the membrane be paſted on a hole far from the bottom, the agitations will be much fainter; and when the hole is near the mouth of the pipe, there will be none.—When a pipe has its air agitated in this manner, it is giving the loweſt note of which it is ſuſceptible.

Let us next conſider a pipe open at both ends. Let CB (fig. 3.) be this pipe. It is plain that, if there be a partition A in the middle, we ſhall have two pipes AB, AC, each of which may undulate in the manner now deſcribed, if the undulations in each be in oppoſite directions. It is evidently poſſible, alſo, that theſe undulations may be the ſame in point of ſtrength in both, and that they may begin in the ſame inſtant. In this caſe, the air on each ſide of the partition will be in the ſame ſtate, whether of condenſation or rarefaction, and the partition A itſelf will always be in equilibrio. It will perfectly reſemble the point C of the muſical cord BFCGH (fig. 6.), which is in equilibrio between the vibrating forces of its two parts. In the pipe, the plates of air on each ſide are either both approaching it, or both receding from it, and the partition is either equally ſqueezed from both ſides, or equally drawn outwards. Conſequently this partition may be removed, and the parcels of air on each ſide will, in any inſtant, ſupport each other. There ſeems no other way of conceiving theſe vibrations in open pipes which will admit of an explanation by mechanical laws. The vibrations of all the plates muſt be obtained without any mutual hinderance, in order to produce the tone which we really hear; and therefore ſuch vibrations are impreſſed by Nature on each plate of air.

But if this explanation be juſt, it is plain that this pipe CB muſt give the ſame note with the pipe AB (fig. 2.) of half the length, ſhut at one end. But the ſound, being doubled, with perfect conſonance, muſt be clear, ſtrong, and mellow. Now this is perfectly agreeable to obſervation; and this fact is an unequivocal confirmation of the juſtneſs of the theory. If we take a ſlender pipe, about ſix inches long and one half of an inch wide, ſhut at one end, and ſound it by blowing acroſs its mouth, as we whiſtle on the pipe of a key, or acroſs a hole that is cloſe to the mouth, and formed with an edge like the ſound-hole of a German flute, we ſhall get a very diſtinct and clear tone from it. If we now take a pipe of double the length, open at both ends, and blow acroſs its mouth, we obtain the ſame note, but more clear and ſtrong. And the note produced by blowing acroſs the mouth is not changed by a hole made exactly in the middle, in reſpect of its muſical pitch, although it is greatly hurt in point of clearneſs and ſtrength. Alſo a membrane at this hole is ſtrongly agitated. All this is in perfect conformity to this mechaniſm.

Thus we have, in a great meaſure, explained the effect of an open and a ſhut pipe. The ſhut pipe is always an octave graver than an open pipe of the ſame length; becauſe the open pipe is in uniſon with a ſhut pipe of half the length.

Let AC (fig. 4.) be a pipe ſhut at both ends. We may conſider it as compoſed of two pipes AB, BC, ſtopped at A and C, and open at B. Undulations may be performed in each half, preciſely as in the pipe AB of fig. 2.; and they will not, in the ſmalleſt degree, obſtruct each other, if we only ſuppoſe that the plates in each half are vibrating at once in the *ſame* direction. The condenſation in AB will correſpond with the rarefaction in BC, and the middle parcel B will maintain its natural denſity, vibrating to, and again acroſs the middle; and two plates $a\,a$, $\alpha\,\alpha$, which are equally diſtant from B, will make equal excurſions in the ſame direction.

We may produce ſound in this pipe by making an opening at B. Its note will be found to be the ſame with that of BC of fig. 2. or of AB of fig. 2.

In the next place, let a pipe, ſhut at one end, be conſidered as divided into any odd number of equal parts, and let them be taken in pairs, beginning at the ſtopped end, ſo that there may be an odd one left at the open end. It is plain that each of theſe pairs may be conſidered as a pipe ſtopped at both ends, as in fig. 4.

For the partitions will, of themſelves, be in equilibrio, and may be removed, and vibrations may be maintained in the whole, conſiſtent with the vibration of the odd part at the open end; and theſe vibrations will all ſupport each other, and the plates of air which are at the points of diviſion will remain at reſt. Conceive the pipe AB of fig. 2. to be added to the pipe AC of fig. 4. the part A of the firſt being joined to A of the other. Now, ſuppoſe the vibrations to be performed in both, in ſuch a manner that the ſimultaneous undulations on each ſide of the junction may be in oppoſite directions. It is plain that the partition will be in equilibrio, and may be removed; and the plate of air will perform the ſame office, being alternately the middle plate of a condenſed and of a rarefied parcel of air. The two pipes CA, AB will together give the ſame note that AB would have given alone, but louder.

In like manner may another pipe, equal to AC, be joined to the ſhut end of this compound pipe, as in fig. 5. and the three will ſtill give the ſame note that AB would have done alone.

And in the ſame manner may any number of pipes, each equal to AC, be added, and the whole will give ſtill the ſame note that AB would have given alone.

Hence it legitimately follows, that if the undulations can be once begun in this manner in a pipe, it may give either the ſound competent to it, as a ſingle pipe AB (fig. 2.); or it may give the ſound competent to a pipe of $\frac{1}{3}$d, $\frac{1}{5}$th, $\frac{1}{7}$th, &c. of its length; the undulations in each part AB, BC, CD, maintaining themſelves in the manner already deſcribed. This ſeems the only way in which they can be preſerved, both iſochronous and ſynchronous.

It is known that the graveſt tones of pipes are as the lengths of the pipes, or the frequency of the undulations are inverſely as their lengths. (This will be *demonſtrated* preſently). Therefore theſe acceſſory tones ſhould be as the odd numbers 3, 5, 7, &c. and the whole tones, including the fundamental, ſhould form the progreſſion of the odd numbers 1, 3, 5, 7, &c.

This is abundantly confirmed by experiment. Take a German flute, and ſtop all the finger-holes. The flute, by gradually forcing the blaſt, will give the fundamental, the 12th, the 17th, the 21ſt, &c. (A).

Again, let AD (fig. 6.) repreſent the length of a pipe. Conſtruct on AD an harmonic curve AEBFCGHD, in ſuch a manner that HD may be $\frac{1}{2}$ AB, $= \frac{1}{2}$ BC, $= \frac{1}{2}$ CH. The ſmall ordinates $m\,n$ will expreſs the total excurſion of the plates of air at the points m, m, &c. and thoſe ordinates which are above the axis will expreſs excurſions on one ſide of the place of reſt, and the ordinates below will mark the excurſions in the oppoſite directions, in the ſame manner as if this harmonic curve were really a vibrating cord. Theſe excurſions are nothing in the points A, B, C, H, and are greateſt at the points E, F, G, D, where the little maſs of air retains its natural denſity, and travels to and again, condenſing the air at B, or rarefying it, according as the parcels E and F are approaching to or receding from each other. The points A, B, C, H, may be called NODES, and the parts E, F, G, D, may be called BIGHTS or LOOPS. This repreſents very well to the eye the motion of the plates of air. The denſity and velocity need not be minutely conſidered at preſent. It is enough that we ſee that when the denſity is increaſing at A, by the approach of the parcel E, it is diminiſhing at B by the receſs of E and F; and increaſing at C, by the approach of F and G, and diminiſhing at H, by the receſs of G. In the next vibration it will be diminiſhing at A and C, and increaſing at B and H. And thus the alternate nodes will be in the ſame ſtate, and the adjoining nodes in oppoſite ſtates.

The reader muſt carefully diſtinguiſh this motion from

(A) A little reflection will teach us that theſe tones will not be perfectly in the ſcale. A certain proportion between the diameter and length of the pipe produces a certain tone. Making the pipe wider or ſmaller flattens or ſharpens this tone a little, and alſo greatly changes its clearneſs. Organ builders, who have tried every proportion, have adopted what they found beſt. This requires the diameter to be about $\frac{1}{11}$th or $\frac{1}{12}$th of the length. Therefore, when we cauſe the ſame pipe to ſound different notes, we neglect this proportion; and the notes are falſe, and even very coarſe, when we produce one correſponding to a very ſmall portion of the pipe. For a ſimilar reaſon, Mr Lambert found that, in order to make his pitch pipe ſound the octave to any of its notes, it was not ſufficient to ſhorten its capacity one-half by puſhing down the piſton; he found that the part remaining muſt be leſs than the part taken off by a fixed quantity $1\frac{5}{11}$ inches. Or, the length which gave any note being x, the length for its octave muſt be $\frac{x - 1\frac{5}{11}}{2}$.

Muſical Trumpet.

from the undulatory motion of a pulſe, inveſtigated by Newton, and deſcribed in the article ACOUSTICS, *Encycl.* That undulation is going on at the ſame time, and is *a reſult* of what we are now conſidering, and the cauſe of our hearing this undulation. The undulation we are now conſidering is the original agitation, or rather it is the SOUNDING BODY, as much as a vibrating ſtring or bell is; for it is not the trumpet that we hear, but the air trembling in the trumpet. The trumpet is performing the office, not of the ſtring, but of the pin and bridge on which the ſtring is ſtrained. This is an important remark in the philoſophy of muſical ſounds.

There is yet another ſet of notes producible from a pipe beſides thoſe which follow in the order of frequency 1, 3, 5, 7, &c.

Suppoſe a pipe open at both ends, ſounding by blowing acroſs the end, and undulating, as already deſcribed, with a node in the middle A (fig. 3.) If we ſtill expreſs the fundamental note of the pipe AB of fig. 2. by 1, it is plain that the fundamental of an open pipe of the ſame length will have the frequency of its undulations expreſſed by 2; becauſe an open pipe of twice the length of AB (fig 2.) will be 1, the two pipes AB (fig. 2.), and CB (fig. 3.), being in uniſon.

But this open pipe may be made to undulate in another manner; for we have ſeen that AB of fig. 2. joined to CA of fig. 4. may ſound altogether when the partition A is removed, ſtill giving the note of AB (fig. 2.) Let ſuch another as AB (fig. 2.) be added to the end C, and let the partition be removed. The whole may ſtill undulate, and ſtill produce the ſame note; that is, a pipe open at both ends may ſound a note which is the fundamental of a pipe like AB (fig. 2.), but only one-fourth of its length. The pipe CB of fig. 3. may thus be ſuppoſed to be divided into four equal parts, CE, EA, AF, FB, of which the extreme parts EC and FB contain undulations ſimilar to thoſe in AB (fig. 2.); and the two middle parts contain undulations like thoſe in CA (fig. 4.) The partitions at E and F may be removed, becauſe the undulations in EC and EA will ſupport each other, if they are in oppoſite directions; and thoſe in FB and FA may ſupport each other in the ſame manner.

It muſt here be remarked, that in this ſtate of undulation the direction of the agitations at the two extremities is the ſame; for in the middle piece EF the particles are moving one way, condenſing the air at E, while they rarefy it at F. Therefore, while the middle parcel is moving from E towards F, the air at B muſt be moving towards F, and the air at C muſt be moving from E. In ſhort, the air at the two extremities muſt, in every inſtant, be moving in the oppoſite direction to that of the air in the middle.

In like manner, if the pipe CB of fig. 3. be divided into ſix parts, the two extreme parts may undulate like AB of fig. 2. and the four inner parts may undulate like two pipes, ſuch as CA of fig. 4. and the whole will give the ſound which makes the fundamental of a pipe of one-ſixth of the length, or having the frequency 6.

We may remark here, that the ſimultaneous motion of the air at the extremities is in oppoſite directions, whereas in the laſt caſe it was in the ſame direction. This is eaſily ſeen; for as the partition which is between the two middle pieces muſt always be in equilibrio, the air muſt be coming in or going out at the extremities together. This circumſtance muſt give ſome ſenſible difference of character to the ſounds 4 and 6. In the one, the agitations at each end of the tube are in the ſame direction, and in the other they are in the oppoſite. Both produce pulſes of ſound which are conveyed to the ear. Thus we ſee that the air in a pipe open at both ends may undulate in two ways. It may undulate with a node in the middle, giving the note of AB (fig. 2.), or of its 3d, 5th, 7th, &c. paſt; and it may undulate with a loop or bight in the middle, ſounding like $\frac{1}{2}$, $\frac{1}{4}$, $\frac{1}{6}$, &c of AB, fig. 2.

Muſical Trumpet.

In like manner may this pipe produce ſounds whoſe frequency are expreſſed by 8, 10, &c. and proceed as the even numbers

This ſtate of agitation may be repreſented in the ſame way that we repreſented the ſounds 1, 3, 5, &c. by conſtructing on AM (fig. 7.) an harmonic curve, with any number of nodes and loops. Divide the parts AF, FD, DE, EM, equally in C, O, P, B. CB will correſpond to the pipe, and the ordinates to the curve GFHDLEN will expreſs the excurſions of the plates of air.

If the pipe gives its fundamental note, its length muſt be repreſented by CO, and the undulations in it will reſemble the vibrations of part CO of a cord, whoſe length AD is equal to 2CO, and which has a node in F.

If the pipe is ſounding its octave, it will be repreſented by CP, and its undulations will reſemble the vibrations of a cord CP, whoſe length AE is $\frac{1}{2}$ of CP, having nodes at F and D, &c. &c.

We can now ſee the poſſibility of ſuch undulations exiſting in a pipe as will be permanent, and produce all the variety of notes by a mere change in the manner of blowing, and why theſe notes are in the order of the natural numbers, preciſely as we obſerve to happen in winding the trumpet or French horn. We have, *1ſt*, the fundamental expreſſed by 1; then the octave 2; then the 12th, 3; the double octave 4; then the third major of that octave 5, or 17th of the fundamental; then the octave of the 12th, or the 5th of this double octave, = 6. We then jump to the triple octave 8, without producing the intermediate ſound correſponding to $\frac{1}{7}$th of the pipe. With much attention we can hit it; and it is a fact that a perſon void of muſical ear ſtumbles on it as eaſily as on any other. But the muſician, finding this ſound begin with hum, and his ear being grated with it, perhaps thinks that he is miſtaking his embouchure, and he ſlides into the octave. After the triple octave, we eaſily hit the ſounds correſponding to $\frac{1}{9}$ and $\frac{1}{10}$, which are the 2d and 3d of this octave. The next note $\frac{1}{11}$ is ſharper than a juſt 4th. We eaſily produce the note 12, which is a juſt 5th; 13 is a falſe 6th; 14 is a ſound of no uſe in our muſic, but eaſily hit; 15 and 16 give the exact 7th and 8th of this octave.

Thus, as we aſcend, we introduce more notes into every octave, till at laſt we can nearly complete a very high octave; but in order to do this with ſucceſs, and tolerable readineſs, we muſt take an inſtrument of a very low pitch, that we may be able nearly to fill up the ſteps of the octave in which our melody lies. Few players can make the French horn or trombone ſound its real fundamental, and the octave is generally miſtaken for it. The proof of this is, that moſt players can give uſical umpet.

give the 5th of the loweſt note that they are able to produce; whereas the 5th of the real fundamental cannot be uttered. Therefore that loweſt note is not the fundamental, but the octave to the fundamental.

Few performers can ſound even this ſecond octave on a ſhort inſtrument, ſuch as the ordinary military trumpet; and what they imagine to be the fundamental ſound of this inſtrument is the double octave above it. This appears very ſtrange; and it may be aſked, how we know what is really the fundamental note of a trumpet? The anſwer to this is to be obtained only by demonſtrating, on mechanical principles, what is the frequency of undulation correſponding to a given length of pipe. This is a propoſition equally fundamental with its correſponding one in the theory of muſical cords; but we have reſerved it till now, becauſe many readers would ſtop ſhort at ſuch an inveſtigation, who are able to underſtand completely what we have now delivered concerning the muſic of the trumpet.

Suppoſe therefore a pipe ſhut at both ends, and that the whole weight of the contained air is concentrated in its middle point, the reſt retaining its elaſticity without inertia; or (which is a more accurate conception), let the middle point be conceived as extending its elaſticity to the two extremities of the pipe, being repelled from each by a force inverſely as the diſtance. Let the length of this pipe be L. This may alſo expreſs the weight of the middle plate of air, which will always be proportional to the length of the pipe, becauſe all is ſuppoſed to be concentrated there. Let E be the elaſticity of the air. This muſt be meaſured by the preſſure of the atmoſphere, or by the weight of the column of mercury in the barometer. Perhaps the rationale of this will be better conceived by ſome readers by conſidering E as the height of a homogeneous atmoſphere. Then it is plain that E is to L as the weight of this atmoſpheric column to the weight of the column of the ſame air which fills the pipe whoſe length is L. Then it is alſo plain that E is to L as the external preſſure; and conſequently, as the elaſticity which ſupports that preſſure is to the weight or inertia of the matter to be moved. Let this middle plate or diaphragm be withdrawn from its place of reſt to the very ſmall diſtance a. The elaſticity or repulſion will be augmented on one ſide and diminiſhed on the other; and the difference between them is the only force which impels the diaphragm toward the middle point, and cauſes it to vibrate, or produces the undulation. It is plain that the repulſion on one ſide is $\frac{\frac{1}{2}L}{\frac{1}{2}L-a}\times E$, or $\frac{L}{L-2a}E$ $\left(\text{for } \frac{1}{2}L-a:\frac{1}{2}L=E:\frac{\frac{1}{2}LE}{\frac{1}{2}L-a}\right)$, and the repulſion on the other ſide is $\frac{\frac{1}{2}L}{\frac{1}{2}L+a}\times E$, or $\frac{L}{L+2a}E$. The difference of theſe repulſions is $E\times L\times\frac{4a}{L^2-4a^2}$. But as we ſuppoſe a exceedingly ſmall in compariſon with L, this difference, or the accelerating force, may ſafely be expreſſed by $E\frac{4a}{L}$, or $4a\frac{E}{L}$.

Hence we deduce, in the firſt place, that the undulations will be iſochronous, whether wide or narrow; becauſe the accelerating force is always proportional to the diſtance a from the middle point.

Muſical Trumpet.

Now, let a pendulum, whoſe quantity of matter is L, and length a, be ſuppoſed to vibrate in a cycloid by the force $\frac{4a}{L}E$, or $\frac{4E}{L}a$. It muſt perform its vibrations in the ſame time with the plate of air; becauſe the moving force, the matter to be moved, and the ſpace along which they are to be ſimilarly impelled, are the ſame in both caſes. Let another pendulum, having the ſame quantity of matter L, vibrate by its weight L alone. In order that theſe two pendulums may vibrate in equal times, their lengths muſt be as the accelerating forces. Therefore we muſt have $\frac{4E}{L}a:L=a:\frac{aL^2}{4Ea}$, $=\frac{L^2}{4E}$, which is therefore the length of the ſynchronous pendulum.

Now, a cord without weight and inertia, but loaded with the weight L at its middle point, and ſtrained by a weight E, and drawn from the axis to the diſtance a, is preciſely ſimilar in its motion to the diaphragm we are now conſidering, and muſt make its oſcillations in the ſame time.

This is applicable to any number of plates of air, by ſubſtituting in the cord a loaded point for each of the plates; for when the caſe is thus changed, both in the pipe and the cord, the ſpace to be paſſed over by the plate of air bears the ſame proportion to a, which is paſſed over by the whole air concentrated in the middle point, which the ſpace to be paſſed over by the correſponding loaded point of the cord bears to that paſſed over by the whole matter of the cord concentrated in the middle point; and the ſame equality of ratios obtains in the accelerating forces of the plate of air and the correſponding loaded point of the cord. Suppoſe, then, a pipe divided into 2, 3, 4, &c. equal parts, by 1, 2, 3, diaphragms, each of which contains the air of the intervening portion of the pipe, the whole weight L being equally divided among them. If there be but one diaphragm, its weight muſt be L; if two, the weight of each muſt be $\frac{1}{2}$ L; if three, the weight of each muſt be $\frac{1}{3}$ L; and ſo on for any number.

By conſidering this attentively, we may infer, without farther inveſtigation, what will be the undulations of all the different plates of air in a pipe ſtopped at both ends. We have only to compare it with a cord ſimilarly divided and loaded. Increaſe the number of loaded points, and diminiſh the load on each, continually—it is evident that this terminates in the caſe of a ſimple cord, with its matter uniformly diffuſed; and a ſimple pipe, with its air alſo uniformly diffuſed over its whole length.

Therefore, if we take an elaſtic cord, and ſtretch it by ſuch a weight that the extending weight may bear the ſame proportion to the accelerating force acting on the whole matter concentrated in its middle point, which the elaſticity of the air bears to its accelerating force acting on the whole matter concentrated at the mouth of an open pipe, ſounding its fundamental note, the cord and the air will vibrate in the ſame time. Moreover, ſince the proportion between the vibrations of a cord ſo conſtituted, and thoſe of a cord having its matter uniformly diffuſed, is the ſame with the proportion between the undulations in a pipe ſo conſtituted, and thoſe of a pipe in which the air is uniformly diffuſed—it is plain that the vibrations of the cord and of the pipe

pipe in their natural ſtate will alſo be performed in equal times.

We look on this as the eaſieſt way of obtaining a diſtinct perception of the authority on which we reſt our knowledge of the abſolute number of undulations of the air in a pipe of given length. It may be obtained directly; and Daniel Bernoulli, Euler, and others, have given very elegant ſolutions of this problem, without having recourſe to the analogy of the vibrations of cords and undulations of a column of air. But it requires more mathematical knowledge than many readers are poſſeſſed of who are fully able to follow out this analogical inveſtigation.

Let us therefore compare this theory with experiment. What we call an open pipe of an organ is the ſame which we, in this theory, have conſidered as a pipe open at both ends; for the opening at the foot, which the organ builders call the VOICE of the pipe, is equivalent to a complete opening. The aperture, and the ſharp edge which divides the wind, may be continued all round, and the wind admitted by a circular ſlit, as is repreſented in fig. 10. We have tried this, and it gives the moſt brilliant and clear tones we ever heard, far exceeding the tones of the organ. An open organ pipe, therefore, when ſounding its fundamental note, undulates with one node in its middle, and its undulations are analogous, in reſpect of their mechaniſm, with the vibrations of a wire of the ſame length, and the ſame weight, with the column of air in the pipe, and ſtretched by a weight equal to that of a column of the ſame air, reaching to the top of a homogeneous atmoſphere, or equal to the weight of a column of mercury as high as that in the barometer.

Dr Smith (ſee *Harmonics*, 2d edit. p. 193) found that a braſs wire, whoſe length was 35,55 inches, and weight 31 troy grains, and ſtretched by 7 pounds avoirdupois, or 49000 grains, was in perfect uniſon with an open organ pipe whoſe length was 86,4 inches.

Now 86,4 inches of this wire weighs 75,34 grains. When the barometer ſtands at 30 inches, and the thermometer at 55° (the temperature at the time of the experiment), the height of a homogeneous atmoſphere is 332640 inches. This has the ſame proportion to the length of the pipe which the preſſure of the atmoſphere has to the weight of the column of air contained in the pipe.

Now 86,4 : 332640 = 75,34 : 290060. This wire, therefore, ſhould be ſtretched (if the theory be juſt) by 290060 grains, in order to be uniſon with the other wire, and we ſhould have $35,55^2 : 86,4^2 = 49000 : 290060$
But, in truth, - $35,55^2 : 86,4^2 = 49000 : 289430$
The difference is - - - - - 630
The error ſcarcely exceeds $\frac{1}{300}$, and does not amount to an error of one vibration in a ſecond.

We muſt therefore account this theory as accurate, ſeeing that it agrees with experiment with all deſirable exactneſs.

We may alſo deduce from it a very compendious rule for determining the abſolute number of aereal pulſes made by an open pipe of any given length. When conſidering the vibrations of cords, we found that the number of vibrations made in a ſecond is $\sqrt{\frac{386E}{LW}}$, where E is the extending weight, W the weight of the cord, and L its length. Let H be the height of a homogeneous atmoſphere. We have its weight $= \frac{HW}{L}, = E$. Therefore ſubſtituting $\frac{HW}{L}$ for E in the above formula, we have the number of aereal pulſes made per ſecond $= \sqrt{\frac{386H}{L^2}}$, or $= \frac{\sqrt{386H}}{L}$. Now $\sqrt{386H}$, computed in inches, is 11331. Therefore, if we alſo meaſure the length of the pipe L in inches, the pulſes in a ſecond are $= \frac{11331}{L}$. Thus, in the caſe before us, $\frac{11331}{86,4} = 131,12$, or this pipe produces 131 pulſes in a ſecond. Dr Smith found by experiment that it produced 130,9, differing only about $\frac{1}{6}$th of a pulſe.

We ſee that the pitch of a pipe depends on the height of the homogeneous atmoſphere. This may vary by a change of temperature. When the air is warmer it expands, and the weight of the induced column is leſſened, while it ſtill carries the ſame preſſure. Therefore the pitch muſt riſe. Dr Smith found his organ a full quarter tone higher in ſummer than in winter. The effect of this is often felt in concerts of wind inſtruments with ſtringed inſtruments. The heat which ſharpens the tone of the firſt flattens the laſt. The harpſichord ſoon gets out of tune with the horns and flutes.

Sir Iſaac Newton, comparing the velocity of ſound with the number of pulſes made by a pipe of given length, obſerved that the length of a pulſe was twice the length of the open pipe which produced it. Divide the ſpace paſſed over in a ſecond by the number of pulſes, and we obtain the length of each pulſe. Now it was found that a pipe of 21,9 inches produced 262 pulſes. The velocity of ſound (as computed by the theory on which our inveſtigation of the undulations in pipes proceeds) is 960 feet. Now $\frac{960 \times 12}{262} = 44$ inches very nearly, the half of which is 22, which hardly differs from 21,9. The difference of this theoretical velocity of ſound, and its real velocity 1142 feet per ſecond, remains ſtill to be accounted for. We may juſt obſerve here, that when a pipe is meaſured, and its length called 21,9, we do really allow it too little. The voice-hole is equivalent to a portion, not inconſiderable of its length, as appears very clearly from the experiments of Mr Lambert on a variable pitch pipe, and on the German flute, recorded in the Berlin Memoirs for 1775. He found it equivalent to $\frac{1}{8}$th; and this is ſufficient for reconciling theſe meaſures of a pulſe with the real velocity of ſound.

The determination which we have given of the undulations of air in an organ pipe is indirect, and is but a ſketch of the beautiful theory of Daniel Bernoulli in which he ſtates with accuracy the preciſe undulation of each plate of air, both in reſpect of poſition, denſity, velocity, and direction of its motion. It is a pleaſure to obſerve how the different equations coincide with thoſe which expreſs the vibrations of an elaſtic cord. But this would have taken up much room, and would not have been ſuited to the information of many curious readers, who can eaſily follow the train of reaſoning which we have employed.

Mr Bernoulli applies the ſame theory to the explanation

nation of the undulations in flutes, or inſtruments whoſe ſounds are modified by holes in the ſides of the pipe. But this is foreign to our purpoſe of explaining the muſic of the trumpet. We ſhall only obſerve, that a hole made in that part of a pipe where a node ſhould form itſelf, in order to render practicable the undulations competent to a particular note, prevents its formation, and in its place we only get ſuch undulations (and their correſponding ſounds) as have a loop in that place. The intelligent reader will perceive that this ſingle circumſtance will explain almoſt every phenomenon of flutes with holes; and alſo the effects of holes in inſtruments with a reed voice, ſuch as the hautboy or clarionette.

We now ſee that the ſound or muſical pitch of a pipe is inverſely as its length, in the ſame manner as in ſtrings. And we learn, by comparing them, that the ſound of a trumpet has the ſame pitch with an open organ pipe of the ſame length. A French horn, 16 feet long, has the ſound C *fa ut*, which is alſo the ſound of an open flute-pipe of that length.

The TROMBONE, great trumpet, or SACKBUT, is an old inſtrument deſcribed by Merſennus and other authors of the laſt century. It has a part which ſlides (air-tight) within the other. By this contrivance the pitch can be altered by the performer as he plays. This is a great improvement when in good hands; becauſe we can thus correct all the falſe notes of the trumpet, which are very offenſive, when they occur in an emphatical or holding note of a piece of muſic. We can even employ this contrivance for filling up the blanks in the lower octaves.

We muſt not take leave of this ſubject without taking notice of another diſcovery of Mr Bernoulli's, which is exceedingly curious, and of the greateſt importance in the philoſophy of muſic.

Artiſts had long ago obſerved that the deep notes of muſical inſtruments are ſometimes accompanied by their harmonic ſounds. This is moſt clearly perceived in bells, ſome of which give theſe harmonics, particularly the 12th, almoſt as ſtrong as the fundamental. Muſicians, by attending more carefully to the thing, ſeem now to think that this accompaniment is univerſal. If one of the fineſt ſounding ſtrings of the baſes of a harpſichord be ſtruck, we can hear the 12th very plainly as the ſound is dying away, and the 17th major is the laſt ſound that dies away on the ear This will be rendered much more ſenſible, if we divide the wire into five parts, and at the points of diviſion tie round it a thread with a faſt knot, and cut the ends off very ſhort. This makes the ſtring falſe indeed by the unequal loading; but, by rendering thoſe parts ſomewhat leſs moveable by this additional matter, the portions of the wire between theſe points are thus jogged, as it were, into ſecondary vibrations, which have a more ſenſible proportion to the fundamental vibration. This is ſtill more ſenſible in the ſound of the ſtrings of a violincello when ſo loaded; but we muſt be careful not to load them too much, becauſe this would ſo much retard the fundamental vibration, without retarding the ſecondary vibrations, that both cannot be maintained together. (*N. B.* This experiment always produces a beat in the ſound).—Liſtening to a fine ſounding flute-pipe of the organ, we can alſo very often perceive the ſame thing. Mr Rameau, and moſt other theoriſts in muſic, now aſſert that this is the eſſence of a muſical ſound, and *neceſſarily* exiſts in all of them, diſtinguiſhing them from harſh noiſes. Rameau has made this the foundation of his ſyſtem of muſic, aſſerting that the pleaſure of harmony reſults from the ſucceſsful imitation of this harmony of Nature. (ſee MUSIC, *Encycl.*). But a little logic ſhould convince theſe theoriſts that they muſt be miſtaken. If a note is muſical becauſe it has theſe accompaniments, and by this compoſition alone is a muſical note, what are theſe harmonics? Are they muſical notes? This is granted. Therefore they have the ſame compoſition; and a muſical note muſt conſiſt at once of every poſſible ſound; yet we know that this would be a jarring noiſe. A little mathematics, too, or mechanics, would have convinced them. A ſimple vibration is ſurely a moſt poſſible thing, and therefore a ſimple ſound. No, ſay the theoriſts; for though the vibration of the cord may be ſimple, it produces ſuch undulations in the air as excite in us the perception of the harmonics. But this is a mere aſſertion, and leaves the queſtion undecided. Is not a ſimple undulation of the air as poſſible as the ſimple vibration of a cord?

It is, however, a very curious thing, that almoſt all muſical ſounds really have this accompaniment of the octave, 12th, double octave, and 17th major; for theſe are the harmonics that we hear.

The jealouſy of Leibnitz and of John Bernoulli, and their unfriendly thoughts reſpecting all the Britiſh mathematicians, made John Bernoulli do every thing in his power to leſſen the value of Dr Taylor's inveſtigation of the vibration of a muſical cord. Taylor gave him a good opportunity. Perhaps a little vain of his inveſtigation of this abſtruſe matter, he thought too much of it. He affirmed that the harmonic curve was the eſſential form of a ſtring giving a muſical note. This was denied, without knowing at firſt whether it was true or falſe. But as the analytic mathematics improved, it was at length found that there are an infinity of forms into which an elaſtic cord can be thrown, which are conſiſtent both with iſochronous vibrations, whether wide or narrow, and alſo with the condition of the whole cord becoming a ſtraight line at once. Euler, D'Alembert, and De la Grange, have proſecuted this matter with great ingenuity, and it is one of the fineſt problems of the preſent day.

Daniel Bernoulli, of a very different caſt of mind from his illuſtrious friends, admired both Newton and Taylor; and ſo far from wiſhing to eclipſe Dr Taylor by the additions he had made to his theory, tried whether he could not extend Taylor's doctrine as far as the author had ſaid. When he took a review of what he had done while explaining the partial vibrations of muſical cords, he thought it very poſſible that while a cord is vibrating in three portions, with two nodes or points of reſt, and ſounding the 12th to its fundamental, it might at the ſame time be alſo vibrating as a ſimple cord, and ſounding its fundamental note. It was poſſible, he thought, that the three portions might be vibrating between the four points with a triple frequency, while the two middle nodes were vibrating acroſs the ſtraight line between the two pins; and thus the vibrating cord might be a moveable axis, to which the rapid vibrations of the three parts might always be referred. This was very ſpecious; and when a little more attentively conſidered, became more probable: for if the cord ApBqCrD (fig. 8.) be vibrating as a 12th to its fundamental AD, the points B and C are in equilibrio. If therefore theſe two points be laid hold of by hooks, and be drawn aſide to β and γ, while the ſtring is yet vibrating, this ſhould not hinder the vibrations. If the hooks be annihilated in an inſtant, the whole ſhould vibrate between A and D; and this ſhould be in a way very different from the ſimple vibration. The queſtion now is, will the cord *continue* to vibrate with the loops $\beta s \gamma$, $\beta q \gamma$, &c. in the 900th part of a ſecond (for inſtance), while the whole ſtring vibrates from A$\beta\gamma$D to A$\beta'\gamma'$D in the 300th part of a ſecond? or will it at once acquire the form of the ſimple harmonic curve? The caſe in which it is moſt likely to take the latter mode of vibration is when the points β and γ are let go at the inſtant that each portion of the ſtring is in the middle of its vibration, and therefore forms the line A$\beta\gamma$D. But a moment's conſideration will ſhew us that it cannot do this; for at that inſtant the point v, for inſtance, which had come from q, is moving outwards with a moſt rapid motion, and therefore will continue to go outward, while β and γ are approaching the axis. The point w, on the contrary, is at this moment approaching the axis with a motion equally rapid. They cannot therefore all come to the axis at once, and the vibration muſt differ greatly from a ſimple one. On the other hand, let it be ſuppoſed that both ſpecies of vibrations can be preſerved, and that, at the moment of letting go the points β and γ, the cord has the form A$m\beta q\gamma n$D. Then, when β and γ have come to B and C, having made $\frac{1}{2}$ a vibration, the point m will be in the axis, having made a vibration downward, and a half vibration upwards. q, in like manner, is in the axis, having made a whole vibration upwards, and half a vibration downwards. n is like m. Thus the whole comes to the axis at once; and in ſuch a manner, that if the points B and C were inſtantly ſtopped, the three portions would continue their partial vibrations without any new effort. The reſult of this compound vibration muſt be a compound pulſe of air, which will excite in us the perception of the fundamental ſound and of its 12th. The conſequence will be the ſame if the points β and γ are ſtopped any where ſhort of the axis; and therefore (ſaid Bernoulli) the ſtring will really vibrate ſo if not ſtopped at all.

But this was refuſed by Euler, who obſerved that in the points β and γ of contrary flexure, having no curvature, there can be no accelerating force. This cauſed Bernoulli to attempt a direct inveſtigation, examining minutely the curvatures and accelerating forces in the different points.

He had the pleaſure of finding that the accelerating forces ariſing from the curvature in every point, were preciſely ſuch as would produce the accelerations neceſſary in thoſe points for performing the motion that was required. And he exhibited the equations expreſſive of the ſtate of the cord in all theſe points. And, on the faith of theſe equations, he reſtored the Taylorean curve to the rank which its inventor had given it; and he aſſerted that in every muſical vibration the cord was diſpoſed in a harmonical curve either ſimple or compound. He farther ſhewed that the equations which Euler and D'Alembert had given for the muſical cord (at leaſt in the caſes which they had publiſhed) were included in his equations, and that their equations only exhibited its momentary ſtates, while his own equations ſhewed the phyſical connection of them all; which is, that the whole cord forms a harmonic curve between the two fixed pins, while its different portions form ſubordinate harmonic curves on the firſt as an axis. Euler and D'Alembert, although they acknowledge this in the particular caſes which they had taken as examples, on account of their ſimplicity, ſtill inſiſt that no ſubordinate harmonic vibrations can correſpond to all the ſtates of an elaſtic cord which their equations exhibit as iſochronous and permanent. Mr Bernoulli's death put an end to the controverſy, and the queſtion (conſidered as a general theory) is perhaps ſtill undecided. It may very probably be true, that as a ſimple vibration may be permanent which never has the form of the ſimple harmonic deſcribed by Dr Taylor, ſo a vibration may exiſt compounded of ſuch vibrations, and therefore not expreſſible by any equation deduced from the Taylorean curve.

But, in the mean time, Mr Bernoulli has made the moſt beautiful diſcovery in mechanics which has appeared in the courſe of the preſent century, and has explained the moſt curious phenomenon of continued ſounds, *viz.* the *almoſt univerſal* accompaniment of the harmonic notes of any fundamental ſound. For this *ſuſceptibility* of compounded variation is not confined to a 12th, but is equally demonſtrable of every other harmonic. Nay, it is evident that the ſame ſimple vibration of a cord may furniſh a moveable axis to more than one harmonic. For as the ſimple vibration can have a ſubordinate harmonic vibration ſuperinduced upon it, ſo may this compounded vibration have another ſuperinduced on it, and ſo on to any degree of compoſition. And farther, as Mr Bernoulli has ſhewn the complete analogy between the accelerations of the different points of an elaſtic cord and of the correſponding plates of a column of air, it legitimately follows that all the conſequences which we can eaſily deduce, reſpecting the vibrations of an elaſtic cord, may be affirmed reſpecting the undulations of a column of air in a pipe. Therefore this accompaniment of the harmonics muſt not be confined to the muſic of ſtrings and bells, but equally obtains in the muſic of wind inſtruments. And thus the doctrine becomes univerſal.

Mr Bernoulli did not think it enough to ſhew that theſe compound vibrations are poſſible. He endeavours to ſhew that this accompaniment muſt be frequent. He illuſtrates this very prettily, by ſuppoſing that a toothed wheel is turned round, and rubs with its teeth on an elaſtic cord. If the ſucceſſive dropping of the teeth keep exactly pace with ſuch vibrations as the cord can take and maintain by its elaſticity, theſe will certainly be formed on it. If the intervals do not *exactly* correſpond, a little reflection will ſhew that the agitation which the cord acquires will approximate to thoſe which it can maintain; and, if when they are exactly ſo in any place of it, and the wheel be in that inſtant removed, this vibration will remain and diffuſe itſelf throught he reſt of the cord; ſo that the very laſt dying quiver (ſo to ſpeak) will be a harmonic. Every *harmonic* agitation tends, by the very nature of the thing, to continue, while thoſe that are incompatible really *do* deſtroy each other; and the very laſt muſt be the remainder or ſuperplus of ſuch as could continue,

over thoſe which deſtroyed each other. Accordingly, the harmonic notes of wires are always moſt diſtinctly heard as the ſound is dying away.

There is no occaſion now to ſay any thing about the fallacy of Rameau's *Generation Harmonique* as a theory of muſical pleaſure. Our harmonies pleaſe us, not becauſe a ſound is accompanied by its harmonics, but becauſe harmonics pleaſe. His principle is therefore a tautology, and gives no inſtruction whatever. His theory is a very *forced* accommodation of this principle to the practice of muſicians, and taſte of the Public. He is exceedingly puzzled in the caſe of the *ſousdominante*, or 4th of the ſcale, and the 6th where there is no reſonnance. He ſays that theſe notes, "fremiſſent, quoiqu' elles ne reſonnent pas." But this miſleads us. They do not reſound; becauſe a 4th and a 6th cannot be produced at all by dividing the cord. They tremble; becauſe the falſe 4th and falſe 6th are very near the true ones, and the true 4th and 6th would both tremble and reſound if they were made falſe. A ſtring will both tremble and reſound, if very nearly true, as any one obſerves the 12th and 17th on a harpſichord tremble and reſound very ſtrongly, though they are tempered notes. The whole theory is overturned at once by tuning the 4th falſe, ſo as to correſpond to an aliquot diviſion of the cord. It will then reſound; and if this had happened to be agreeable, it would have been catched at as the ſouſdominant.

The phyſical cauſe of the pleaſure of harmonic ſounds is yet to ſeek, as much as our choice of thoſe notes for melody which give us the beſt harmony (ſee TEMPERAMENT, *Suppl.*). We have no heſitation in ſaying that, with reſpect to our choice, the two are quite independent. Thouſands enjoy the higheſt pleaſure from melody who never heard a harmonious ſound. All the untaught ſingers, and all ſimple nations, are examples. They not only fix on certain intervals as the ſteps of their tunes, but are diſguſted when other ſteps are taken. Nor do we heſitate, for the very ſame reaſons, to ſay that the rules of accompaniment are dependent on the cantus or air, and by no means on the fundamental baſs of Rameau. The dependence aſſumed by him, as the rule of accompaniment, would, if properly adhered to, according to his own notions of the comparative values of the harmonics, lead to the moſt fantaſtic airs imaginable, always jumping by large intervals, and altogether incompatible with graceful muſic. The rules of modulation which he has ſqueezed out of his principle, are nothing but forced, very forced, accommodations of a very vague principle to the current practice of his contemporaries. They do not ſuit the primitive melodies of many nations, and they have cauſed theſe national muſics to degenerate. This is acknowledged by all who are not perverted by the prevailing habits. We have heard, and could write down, ſome moſt enchanting lullabies of ſimple peaſant women, poſſeſſed of muſical ſenſibility, but far removed, in the cool ſequeſtered vale of life, from all opportunities of ſtealing from our great compoſers. Some of theſe lullabies never fail to charm, even the moſt erudite muſician, when ſung by a fine flexible voice: but it would puzzle Mr Rameau to accompany them *ſecundum artem*.

We conclude this ſubject by deſcribing a moſt beautiful and inſtructive experiment.

Mr Watt, the celebrated engineer, was amuſing himſelf (about the year 1765) with organ building, and invented a monochord of continued ſound, by which he could tune an organ with mathematical preciſion, according to any propoſed ſyſtem of temperament. It conſiſted of a covered ſtring of a violincello, ſounding by the friction of an ivory wheel. The inſtrument did not anſwer Mr Watt's purpoſe, by reaſon of the dead harſhneſs of its tone, and a flutter in the ſtring by the unequal action of the wheel. But Mr Watt was amuſed by obſerving the ſtring frequently taking, of its own accord, points of diviſion, which remained fixed, while the reſt was in a ſtate of ſtrong vibration. The inſtrument came into the poſſeſſion of the writer of this article. He ſoon ſaw that it gave him an opportunity of making all the experiments which Bernoulli could only relate. When the ſtring was kept in a ſtate of ſimple vibration, by a very uniform and gentle motion of the wheel, if its middle point was then gently touched with a quill, this point immediately ſtopped, but the ſtring continued to vibrate in two parts, ſounding the octave: And this it continued to do, however ſtrong the vibrations were rendered afterwards by increaſing the preſſure and velocity of the wheel. The ſame thing happened if the ſtring was gently touched at one third. It inſtantly divided itſelf into three parts, with two nodes, and ſounded the 12th. In the ſame manner the double octave, the 17th, and all other harmonics, were produced and maintained.

But the prettieſt experiment was to put ſomething ſoft, ſuch as a lock of cotton, in the way of the wide vibrations of the cord, at one third and two-thirds of its length, ſo as to diſturb them when they became very wide. When this was done, the ſtring inſtantly put on the appearance of fig. 8. performing at once the full vibration competent to its whole length, and the three ſubordinate vibrations, correſponding to one-third of its length, and ſounding the fundamental and the 12th with equal ſtrength. In this manner all the different accompaniments were produced at pleaſure, and could be continued, even with ſtrong ſounds. And it was amuſing to obſerve, when the wheel was ſtrongly preſſed to the ſtring, and the motion violent, the nodes would form themſelves on various parts of the ſtring, running from one part to another. This was always accompanied with all the jarring ſounds which correſponded to them.

When the ſtring was making very gentle, ſimple vibrations, and the wheel hardly touching it, if a violincello was made to ſound the 12th very ſtrongly in its neighbourhood, the ſtring inſtantly divided itſelf, and vibrated in uniſon, frequently retaining its ſimple vibration and fundamental tone. We recommend this experiment to every perſon who wiſhes to make himſelf well acquainted with the mechaniſm of muſical ſounds. He will ſee, in a moſt ſenſible and convincing manner, how a ſingle ſtring of the Æolian harp gives us all the changes of harmony, ſliding from one ſound to another, according as it is affected in its different parts by an irregular breeze of wind. The writer of this article has attempted to regulate theſe ſweet harmonic notes, and to introduce them into the organ. His ſucceſs has been very encouraging, and the ſounds far exceed in pathetic ſweetneſs any that have yet been produced by that noble inſtrument. But he has not yet brought them fully under command, nor made them ſtrong enough for any thing but the ſofteſt chamber muſic. Other

Muſical Trumpet, Tſchirnhaus.

neceſſary occupations prevent him from giving the attention to this ſubject that it deſerves. He recommends it therefore to the muſical inſtrument makers as richly deſerving their notice. His general method was this: A wooden pipe is made, whoſe ſection is a double ſquare. A partition in the middle divides it into two pipes, along ſide of each other. One of them communicates with the foot and wind cheſt, and is ſhut at the upper end. The other is open at the upper, and ſhut at the lower end. In the partition there is a ſlit almoſt the whole length, and the ſides of this ſlit are brought to a very ſmooth chamfered or feather edge. A fine catgut is ſtrained in this ſlit, ſo as almoſt to touch the ſides. It is evident that when the wind enters one pipe by the foot, it paſſes through the ſlit into the other, and eſcapes at the top, which is open. In its paſſage it forces the catgut into motion, and produces a muſical note, having all the ſweetneſs of the Æolian harp. The ſtrength of ſound may be increaſed by increaſing the body of air which is made to undulate. This was done by uſing, inſtead of catgut, very narrow ſilk tape or ribband varniſhed: but the unavoidable raggedneſs of the edges made the ſounds coarſe and wheeſing. Flat ſilver wire was not ſufficiently elaſtic; flat wire, uſed for watch balance ſprings, was better, but ſtill very weak ſounded. Other methods were tried, which promiſed better. A thin round plate of metal, properly ſupported by a ſpring, was ſet in a round hole, made in another plate not ſo thin, ſo as juſt not to touch the ſides. The air forced through this hole made the ſpring plate tremble, dancing in and out, and produced a very bold and mellow ſound.—This, and ſimilar experiments, are richly worth attention, and promiſe great additions to our inſtrumental muſic.

TSCHIRNHAUS (Ehrenfred Walther Von), a name well known in the republic of letters, and one of the ornaments of the laſt century, was born April 10. 1651, at Kiſlingſwald near Gorlitz in Upper Luſatia. His father was Erneſt Chriſtopher Von Tſchirnhaus, Baron Kiſlingſwald and Stoltzberg, and Obernſchonfeld, privy counſellor, and in various offices of rank under the Electors George I. and II. of Saxony, the firſt of whom honoured him with the diſtinction of the gold chain and portrait, as a mark of his ſenſe of his merits and ſervices. The mother of the young Von Tſchirnhaus was Maria Stirling, daughter of *Baro a Stirling et Achil*, Stirling of Achil, or Achyle, in Scotland, an old and reſpectable family, as appears by an epitaph which the Duke Chriſtian, brother of the Elector George II. inſcribed on the tomb of Johan Albert Stirling of Achil, in the cathedral of Marckſburg. This gentleman had been preſident of the ſenate of the electorate, privy counſellor, director of the impoſts, and maſter of horſe to the Prince, and had, by his faithful and uſeful ſervices, acquired his higheſt eſteem.

E. W. Von Tſchirnhaus was born, as has been obſerved, at Kiſlingſwald, the uſual reſidence of the family, and poſſeſſed by it during more than 300 years. The family came originally from Bohemia, and appears to have been conſiderable, ſeeing that, from the earlieſt accounts of it in Luſatia, the Barons of Kiſlingſwald are generally found in the moſt reſpectable civil offices.

The figure which Baron Von Tſchirnhaus, the ſubject of this relation, has made in the ſcientific and political world, makes it ſuperfluous to ſay that his early years were well employed. Quick apprehenſion, a clear perception of the ſubject of his thoughts, and the moſt ardent and inſatiable thirſt for knowledge, diſtinguiſhed him during his academical education. When 17 years of age, he was ſent to Leyden. In 1672 all ſtudy was interrupted in Holland by the din of war; and Mr Von Tſchirnhaus left the univerſity for the camp. His knowledge in mathematics, mechanics, and all phyſical ſcience, found ample room in the military ſervice for ſhewing the importance of thoſe ſciences; and Tſchirnhaus ſo diſtinguiſhed himſelf by his ſervice in this way, that Baron Nieuland, a general officer of great merit, and at the ſame time an accompliſhed ſcholar, took delight in puſhing him into every ſervice where he could ſhew himſelf and his talents.

Tſchirnhaus.

After two years ſervice, he returned to his father's; but finding little to intereſt him in the life of a mere country gentleman, and ſtill burning with the ſame thirſt of knowledge, he prevailed on his father to allow him to travel. His younger brother George Albrecht Von Tſchirnhaus, Baron Obernſchonfeld, which he inherited from his grandfather Stirling, loved him with the warmeſt affection, and ſupplied him liberally with what was required for his appearance everywhere in a manner becoming his rank, and for fully gratifying his curioſity. He uſed often to ſay, "Sorry was I to loſe the company of my dear brother, and I ſometimes wiſhed to accompany him; but not having his thirſt for knowledge, I knew that his love for me would debar him of much happineſs, which I ſhould thus have obſtructed." *Felices animæ!* He went to Holland, from thence into England, France, Italy, Sicily, Malta, Greece.—Returning through the Tyrol, he met his brother at Vienna, where both were in great favour at the court of Leopold Wherever he went, he made himſelf acquainted with the moſt eminent in all departments of ſcience, living with them all in the mutual exchange of diſcoveries and of kind offices. In Holland he was intimate with Huyghens and Hudde; in England, with Newton, Wallis, Halley, and Oldenburgh; in France, among a people who more ſpeedily contract acquaintance, there was not a man of note with whom he did not cultivate an active acquaintance—and, fortunately, Leibnitz then lived at Paris: in Italy, he was particular careſſed by Michaeli, ſoon after Cardinal; and was in the cloſeſt correſpondence with Kircher. His enjoyments, however, were derived ſolely from the communications of the moſt eminent; his curioſity was directed to every thing, and wherever he ſaw an ingenious artiſan, he was eager to learn from him ſomething uſeful. In 1682, when at Paris for the third time, he communicated to his friends his celebrated theory of the cauſtic curves, which marked him out as a valuable acquiſition, and he was elected a member of the Royal Academy of Sciences, which was then reformed by the great miniſter Colbert, and the moſt illuſtrious in all nations were picked out for its ornaments. There he found himſelf ſeated with Leibnitz, Huyghens, John Bernoulli, &c.

After twelve years employed in viſiting Europe, he returned home: but after a ſhort ſtay, went to Flanders, and prepared to publiſh his work, intitled *Medicina Mentis*; of which the ſubject may almoſt be gueſſed, from the way in which he had exerciſed his own mind. Having the moſt exalted notions of the intellectual and moral

moral nature of man, he thought that the continual ſupply of information was as neceſſary as the continual ſupply of food. And his great principle was TO ENLIGHTEN. This work was committed to the care of ſome friends, and did not appear till 1687, at Amſterdam. A ſecond edition appeared at Leipſic in 1695.

Finding now that his moderate fortune was inſufficient for the great public projects he had in view, he ſought for aſſiſtance, and endeavoured to make friends by frequenting the court of the Elector at Dreſden. He ſoon became a favourite of his Princes, George the II. and III. and was appointed to active offices of great reſponſibility. By the orders and encouragement of the Elector, then king of Poland, he introduced into his native country the firſt manufacture of glaſs; and his project ſoon throve to ſuch a degree, that not only Saxony was ſupplied, but they even began to export the finer kinds of white glaſs for windows; in which manufacture Saxony ſtill excels. It was in the courſe of experiments for improving this manufacture that Tſchirnhaus made the celebrated great burning glaſſes which ſtill bear his name. He made two of theſe lenſes, and gave one to the Emperor, and the other to the Academy of Paris. He was eager to improve the art of forming and poliſhing optical glaſſes; and in the proſecution of the theory on which their performance depends, he made ſome beautiful diſcoveries in the department of pure geometry. It is well known that all the ſciences are allied, and of a family, and that eminence in one is ſeldom attainable without the aſſiſtance of others. His preſent purſuits led him to the ſtudy of chemiſtry, which he proſecuted with the ſame ardour which he exhibited in every thing he undertook. But all the while, mathematics, and eſpecially geometry, was his favourite ſtudy; and he was anxious to make the ſame advances in the general paths of mathematical inveſtigation which he thought he had made in the general laws of material nature. He apprehended that only bye paths were yet known, and that many things were yet inacceſſible; becauſe we had not yet found out the great roads from which thoſe branches were derived. He was of Des Cartes's opinion, that the true road in mathematics muſt be an eaſy one, except in caſes which were, in their own nature, complicated. Very early, therefore, he began writing on mathematical ſubjects, always continuing his general views of the ſcience, and his endeavours to ſyſtematiſe the ſtudy; but, at the ſame time, beſtowing a very particular attention on any branch which chanced to intereſt him: each of theſe his epiſodical ſtudies in mathematics deſerves the name of a department of the ſcience. This is the caſe with his theory of cauſtic curves, with his method of tangents, and his attempt to free Leibnitz's calculus from all conſideration of infiniteſimal quantities. Mr Tſchirnhaus ſeldom gave himſelf any trouble with a particular problem. In all his mathematical performances, there is an evident connection with ſomething which he conſidered as the great whole of the ſcience; and the manner of treating the different queſtions is plainly accommodated to a ſyſtem in his thoughts. This he intended as the third part of the Medicina Mentis; and, having nearly completed the ſecond, he had propoſed theſe as the occupation of the enſuing winter (1708-9). But his death, which may be called premature, has deprived the world of theſe, and other beneficent and uſeful labours.

Mr Von Tſchirnhaus was of the moſt mild and gentle diſpoſition, as was well known to all who enjoyed his acquaintance. This diſpoſition was ſo eminent in him, that ſcarcely any perſon ever ſaw him angry, or even much ruffled in his temper. He forgave injuries frankly and heartily, and often ſtood the friend (unknown) of thoſe who had wronged him. By ſuch conduct, he changed ſome enmities into the moſt ſteady and affectionate friendſhips. As an inquirer and an inventor, he had contentions with other claimants, and ſome diſputes about the legitimacy of his methods; as, for example, with Nicholas Fatio Duiller, who attacked Tſchirnhaus's method of tangents; and Preſtet and Rolle, who found fault with his expreſſion of equations of the third degree. But theſe were all friendly debates, and never carried him beyond the limits of gentlemanly behaviour. He began to diſpute with Ozanam about a quadratrix; but on being merely told that he was miſtaken, by P. Souciet, he immediately acknowledged his error, and corrected it.

Many original and important mathematical performances of Mr Von Tſchirnhaus are to be ſeen in the Leipſic Acts, in the Memoirs of the Academy of Sciences at Paris, and other literary journals. His happy generaliſation of Dr Barrow's theorem for the focus of a ſlender pencil of rays after reflection or refraction, and the theory of cauſtic curves, in which this terminates, both conſtitutes one of the moſt elegant branches of optical ſcience, and affords a rich harveſt of very curious and unexpected geometrical truths. The manner in which he notices the rough way in which his firſt and ſole miſtake in this theory was pointed out, is perhaps incomparable as an example of gentlemanlike reprehenſion, and is a leſſon for literati of all deſcriptions, highly valuable on account of the ſoft way in which it falls, while it is convincing as a mathematical theorem.

Tſchirnhaus was the diſcoverer of the ſubſtance of which the celebrated Saxon porcelain is made, and of the manner of working it up; by which he eſtabliſhed a manufacture highly profitable to his country, and has given us the fineſt pottery in the world. He never wearied in ſpreading uſeful knowledge; and the ſhops of our artiſans of almoſt all kinds were ſupplied with books of inſtructions and patterns, many of them written by Mr Von Tſchirnhaus, or under his inſpection. Uſeful books of all kinds were tranſlated out of foreign languages at his expence. Men of genius in the arts were enabled, through the encouragement of himſelf and his friends, and often by his pecuniary aſſiſtance, to bring their talents before the public eye. In ſhort, he ſeemed at all times to prefer the public good to his own; and never felt ſo much pleaſure as when he could promote ſcience or the uſeful arts. He was as it were ſtimulated to this by an innate propenſity. And as he was more deſirous of *being* than of *appearing* the accompliſhed man, he was in no concern what notice others took of his ſervices to the public. He even repreſents the deſire of fame as hoſtile to the improvement either of ſcience or morality, in his *Medicina Mentis*; a work which is acknowledged by all who knew him to be a picture of his own amiable mind. He lightly eſteemed riches; and knew not what

Tſchirnhaus.

uſe they were of, except for providing the neceſſaries of life, and the means of acquiring knowledge. In perfect conformity to this maxim, he modeſtly, and with elegant reſpect, refuſed the ample preſents made him by his affectionate ſovereign; and when he was added to his cabinet council, he received the diploma, but begged and obtained to be free from the title. And when he preſented his great burning glaſs to the Emperor, and got from him the dignity and inſignia of Baron of the Empire, he pleaded for leave to decline it, requeſting to keep the chain and portrait, which he always wore under his veſt. He expended a very great portion of the ample revenue left him by his father in the ſervice of his country, by promoting the uſeful arts and ſciences.

Mr Von Tſchirnhaus venerated truth above all things; ſaying, that thoſe who thought any thing comparable with it were not the ſons of God, but ſtep-children, and that the love of truth is the ruling affection in every man of a worthy heart. In a letter to an intimate friend, he ſaid that, by the age of five-and-twenty, he had completely ſubdued the love of glory, of riches, and of worldly pleaſures; and that at no time he had found it difficult to repreſs vanity, becauſe he was every day conſcious of having acted worſe than he was certain that he might and ſhould have done. He felt himſelf humbled in the ſight of the All-perfect Judge.

Nor was all this the vain boaſt of a man averſe to buſineſs, and poſſeſſed of an ample fortune, which permitted him, without inconvenience, to pleaſe his fancy in ſtudy, and in helping others with what to himſelf was ſuperfluous. Such a character, though rare, may exiſt, without being the object of much reſpect. No: Mr Tſchirnhaus was really a philoſopher of the true ſtoïc ſect, in reſpect of fortitude of mind, while a good Chriſtian in modeſty and diffidence. In the laſt five years of his life he bore up under troubles, and embarraſſments, and misfortunes in his family, which would have tried the mind of Cato himſelf. But in the midſt of theſe ſtorms he was unſhaken, and preſerved his ſerenity of mind. He was even ſenſible of this being a rare gift of Providence, and uſed frequently to expreſs his thankfulneſs for a treaſure ſo precious. He felt deeply his relation to the Author of Nature, and rejoiced in thinking himſelf ſubject to the providence of God. He ſaid that he was fully perſuaded that he would meet with perfect juſtice, and would therefore ſtrive to perform his own part to the utmoſt of his power, that his future condition might be the more happy, and that he might in the mean time enjoy more ſatisfaction on reflecting on his own conduct. His lot, he ſaid, was peculiarly fortunate: having ſuch thirſt for novelty, he would have been unhappy without an affluent fortune; and his own enjoyments encouraged neither vice nor idleneſs in himſelf or in the miniſters to his pleaſures.

This amiable perſon was of a conſtitution not puny, but not robuſt, and he had hurt it by too conſtant ſtudy. He feared no diſeaſe; thinking that he had a cure or an alleviation for all but one, namely, the ſtone and gravel. He had a dread of this, and laboured to find a preventative or a remedy. He thought that he had alſo done a great deal here; and deſcribes in his *Medicina Corporis* a preparation of whey, which he ſaid he uſed with great advantage to his health. But his precautions were in vain: He was attacked with the gravel, which, after three months ſuffering, brought on a ſuppreſſion of urine. The phyſicians ſaw that his end approached; and finding him diſregard their preſcriptions, they quitted him. He treated himſelf (it is ſaid judiciouſly) for ſome time, and with ſome appearance of ſucceſs; but at laſt he ſaw death not far off. He dictated a letter to his Sovereign, thanking him for all his favours and kindneſs, and recommended his children to his protection. He never fretted nor complained; but frequently, with gliſtening eyes, expreſſed his warmeſt thanks to Providence for the wonderful track of good fortune and of happineſs that he had enjoyed; and ſaid that he alſo felt ſome ſatisfaction in the conſciouſneſs that ſome of this was owing to his own prudent conduct. He poſſeſſed his entire faculties to the laſt moment; and when he felt his ſpirit juſt about to depart, his laſt words were, "*Iö triumphé—Victoria!*" No longer able to ſpeak, he made ſigns for what he wanted; and a little after, ſhutting his eyes, as if to ſleep, he gently, and without a groan, yielded up his ſpirit, about four o'clock in the morning of the 11th of October 1708, aged 56.

His funeral was performed in a manner becoming his rank, and the body conveyed to the family vault. The Elector (King of Poland) defrayed the expence; for he would not allow his family to have any thing to do with the funeral of a man of ſo public a character, and ſo univerſally beloved.

The account of ſuch a life as that of Baron Von Tſchirnhaus would, at all times, make a pleaſant and uſeful impreſſion. In theſe our times, in the end of the 18th century, after ſociety has availed itſelf of all the acquiſitions in ſcience and art, furniſhed by that ardent age of the world which this gentleman contributed to adorn; in an age when we boaſt of illumination unparalleled in hiſtory, and of improvements almoſt amounting to perfection; and in particular, of an emancipation from the prejudices which had obſcured our view of the chief good, and ſtifled public ſpirit—now, when we are ſo full of knowledge that it is running over on all hands, in volumes of inſtruction, how to make the world one happy family; in theſe bright days of philanthropiſm, can the public records of Europe exhibit a ſuperior character to that of Mr Von Tſchirnhaus, either in reſpect of wiſdom or of diſpoſition? Was he not a philanthropiſt, a ſincere lover of mankind? Was he not wiſe, in employing his great acquired knowledge as the means of direct and active beneficence, by limiting his exertions to the extent of thoſe circles where his own efforts would be effective? He did not write books, teaching others how to do good: he taught it by example; being determined that his own wiſhes to ſee men happier ſhould not fail by the want of ſuch wiſhes in others, even after he ſhould inſtruct them. He never allowed his inſatiable curioſity for freſh diſcoveries to interfere with the immediate turning to the good of his own country the knowledge he had already acquired. He probably never thought of improving the ſituation of the Chineſe or the Mexicans, finding that it required all his ample fortune, and all the intereſt and influence he could acquire, to do the good he wiſhed in Saxony. We doubt not but that he was equally attentive to the

ſtill

Tſchirnhaus, Tſhamie.

ſtill narrower circle of duties formed by his own family. We ſee that he was a dearly beloved brother; which could hardly be without his alſo being a loving brother and a dutiful ſon. The nature of the diſtreſſes which he experienced in his family, and the manner in which he behaved under them, ſhew him to have been an eminent Chriſtian moraliſt. With a modeſty that is unmatched by any one of the thouſands who have poured out inſtructions uponus during the laſt ten years, and a gracefulneſs which characteriſes the gentleman, his *Medicina Mentis* is offered to public notice, merely as an experimental proof that a certain way of thinking and acting is productive of internal quiet of mind; of great mental enjoyment, both moral and intellectual; and of peace, and the good will of thoſe around us: and that it did, in fact, produce a dutiful and comfortable reſignation to the unavoidable trials of human life. He pretends not to be greatly ſuperior in wiſdom to his neighbours, but merely tells how things ſucceeded with himſelf. He did not ſcruple, however, to publiſh to the world diſcoveries in ſcience, in which he had got the ſtart of others during that buſy period of ſcientific occupation: and theſe diſcoveries in mathematics were highly prized by the firſt men of the age; nor will the name of Tſchirnhaus, or his cauſtic curves, ever be forgotten.

We felt ourſelves obliged to the friend who took notice of the omiſſion of this gentleman's name, ſo eminent in the mathematical world, in the courſe of our alphabet; but when we looked into the Memoirs of the Academy of Paris for 1709 for ſome account of him, what we there ſaw appeared ſuch a continual panegyric, that we could not take it as a fair picture of any real character. Looking about for more impartial information, we found in the *Acta Eruditorum*, Leipſ. 1709, the account of which the foregoing is an abſtract, except a particular or two which we have copied from an account in the Literary Journal of Breſlaw, by Count Herberſtein, whom we can ſcarcely ſuſpect of undue partiality, becauſe he had ſome diſputes with Mr Von Tſchirnhaus on mathematical ſubjects. May we not ſay, "the memory of this man is ſweet!"

TSHAMIE, the Indian name of a tree in the Northern Circars of Hindoſtan. It grows, ſays Dr Roxburgh, to be a pretty large tree, is a native of moſt parts of the coaſt, chiefly of low lands at a conſiderable diſtance from the ſea, and may be only a variety of *proſopis ſpicigera*, for the thorns are in this ſometimes wanting; flowers during the cold and beginning of the hot ſeaſons. *Trunk* tolerably erect, bark deeply cracked, dirty aſh colour. *Branches* irregular, very numerous, forming a pretty large ſhady head. *Prickles* ſcattered over the ſmall branches; in ſome trees wanting. *Leaves* alternate, generally bipinnate, from two to three inches long; pinnæ from one to four, when in pairs oppoſite, and have a gland between their inſertions. *Leaflets* oppoſite, from ſeven to ten pair, obliquely lanced, ſmooth, entire, about half an inch long, and one-ſixth broad. *Stipules* none. *Spikes* ſeveral, axillary, filiform, nearly erect. *Bracts* minute, one-flowered, falling. *Flowers* numerous, ſmall, yellow, ſingle, approximated. *Calyx* below, five-toothed. *Filaments* united at the baſe. *Anthers* incumbent, a white gland on the apex of each, which falls off ſoon after the flower expands. *Style* crooked. *Stigma* ſimple. *Legume* long, pendulous, not inflated. *Seeds* many, lodged in a brown meally ſubſtance.

Tucker.

The pod of this tree is the only part uſed. It is about an inch in circumference, and from ſix to twelve long; when ripe, brown, ſmooth, and contains, beſides the ſeeds, a large quantity of a brown meally ſubſtance, which the natives eat; its taſte is ſweetiſh and agreeable; it may therefore be compared to the Spaniſh *algaroba*, or locuſt tree. (*Ceratonia ſiliqua*, Linn.)

In compliance with Dr Kœnig's opinion, Dr Roxburgh calls this tree a *proſopis*; but as he thinks the antheral glands give it a claim to the genus *adenanthera*, we have retained the Indian name till its botanical claſſification ſhall be aſcertained by thoſe who have greater authority in the ſcience than we lay claim to.

TUCKER (Abraham), Eſq; a curious and original thinker, was a gentleman of affluent fortune, and author of "The Light of Nature purſued," 9 vols 8vo; of which the five firſt volumes were publiſhed by himſelf in 1768, under the aſſumed name of "Edward Search, Eſq;" and the four laſt after his death, in 1777, as "The poſthumous Work of Abraham Tucker, Eſq; publiſhed from his manuſcript as intended for the preſs by the author." Mr Tucker lived at Betchworth-caſtle, near Dorking, in Surrey; an eſtate which he purchaſed in the early part of his life. He married the daughter of Edward Barker, Eſq; by whom he had two daughters; one of whom married Sir Henry St John, and died in his lifetime; the other ſurvived, and now lives at Betchworth-caſtle. He loſt his eyeſight a few years before his death, which happened in 1775. To deſcribe him as a neighbour, landlord, father, and magiſtrate, it would be neceſſary to mention the moſt amiable qualities in each. It is unneceſſary to add, that he was very ſincerely regretted by all who had the pleaſure of his acquaintance, and who ſtood connected with him in any of thoſe relations.

Tucker (Joſiah, D. D.), well known as a political and commercial writer, was born at Langhorn, in Caermarthenſhire, in the year 1712. His father was a farmer, and having a ſmall eſtate left him at or near Aberyſtwith, in Cardiganſhire, he removed thither; and perceiving that his ſon had a turn for learning, he ſent him to Ruthin ſchool, in Denbighſhire, where he made ſo reſpectable a progreſs in the claſſics, that he obtained an exhibition at Jeſus College, Oxford. It is generally underſtood that ſeveral of his journeys to and from Oxford were performed on foot, with a ſtick on his ſhoulder, and bundle at the end of it. Thus it might be ſaid by him, as by Simonides, "*Omnia mea mecum porto.*"

At the age of 23 he entered into holy orders, and ſerved a curacy for ſome time in Glouceſterſhire. About 1737 he became curate of St Stephen's church in Briſtol, and was appointed minor-canon in the cathedral of that city. Here he attracted the notice of Dr Joſeph Butler, then Biſhop of Briſtol, and afterwards of Durham, who appointed Mr Tucker his domeſtic chaplain. By the intereſt of this prelate Mr Tucker obtained a probendal ſtall in the cathedral of Briſtol; and on the death of Mr Catcott, well known by his treatiſe on the Deluge, and a volume of excellent ſermons, he became rector of St Stephen. The inhabitants of that pariſh conſiſt

conſiſt chiefly of merchants and tradeſmen; a circumſtance which greatly aided his natural inclination for commercial and political ſtudies.

When the famous bill was brought into the Houſe of Commons for the naturalization of the Jews, Mr Tucker, conſidering the meaſure rather as a merchant or politician than as a Chriſtian divine, wrote in defence of it with a degree of zeal which, to ſay no more, was at leaſt indecent in a man of his profeſſion. As ſuch it was viewed by his brethren of the clergy, and by his pariſhioners; for, while the former attacked him in pamphlets, newſpapers, and magazines, the latter burnt his effigy dreſſed in canonicals, together with the letters which he had written in defence of the naturalization.

In the year 1753 he publiſhed an able pamphlet on the "Turkey Trade;" in which he demonſtrates the evils that reſult to trade in general from chartered companies. At this period Lord Clare (afterward Earl Nugent) was returned to Parliament for Briſtol; which honour he obtained chiefly through the ſtrenuous exertions of Mr Tucker, whoſe influence in his large and wealthy pariſh was almoſt deciſive on ſuch an occaſion. In return for this favour, the Earl procured for him the deanery of Glouceſter, in 1758, at which time he took his degree of doctor in divinity. So great was his reputation for commercial knowledge, that Dr Thomas Hayter, afterwards Biſhop of London, who was then tutor to his preſent majeſty, applied to Dr Tucker to draw up a diſſertation on this ſubject for the peruſal of his royal pupil. It was accordingly done, and gave great ſatisfaction. This work, under the title of "The Elements of Commerce," was printed in quarto, but never publiſhed.

Dr Warburton, who became Biſhop of Glouceſter in the year 1760, thinking very differently from Dr Tucker of the proper ſtudies of a clergyman, as well as of the project for naturalizing the Jews, ſaid once to a perſon who was praiſing the Elements of Commerce, that "his Dean's trade was religion, and religion his trade." This ſarcaſm, though not perhaps groundleſs, was certainly too ſevere; for ſome of the Dean's publications evince him to have devoted part of his time at leaſt to the ſtudy of theology, and to have been a man of genuine benevolence.

In the year 1771, when a ſtrong attempt was made to procure an abolition of ſubſcription to the 39 articles, Dr Tucker came forward as an able and moderate advocate of the church of England. About this time he publiſhed "Directions for Travellers;" in which he lays down excellent rules, by which gentlemen who viſit foreign countries may not only improve their own minds, but turn their obſervations to the benefit of their native country.

The Dean was an attentive obſerver of the American conteſt. He examined the affair with a very different eye from that of a party man, or an intereſted merchant; and he diſcovered, as he conceived, that both ſides would be better off by an abſolute ſeparation. Mr Burke's language in the Houſe of Commons, in conſequence of his publiſhing this opinion, was harſh, if not illiberal. In his famous ſpeech on the American taxation bill, April the 13th, 1774, he called the Dean of Glouceſter the advocate of the court faction, though it is well known that the court diſapproved of the propoſal as much as the oppoſition. This attack rouſed the Dean to reſentment; and he publiſhed a letter to Mr Burke; in which he not only vindicates the purity of his own principles, but retorts upon his adverſary in very forcible and ſarcaſtic terms. He afterwards ſupported Lord Nugent's intereſt in Briſtol againſt that of Mr Burke, and was certainly very inſtrumental in making the latter loſe his election.

When the terrors of an invaſion were very prevalent in 1779, Dr Tucker circulated, in a variety of periodical publications, ſome of the moſt ſenſible obſervations that were ever made on the ſubject, in order to quiet the fears of the people. In 1781 he publiſhed, what he had printed long before, "A Treatiſe on Civil Government," in which his principal deſign is to counteract the doctrines of Locke and his followers. The book made a conſiderable noiſe, and was very ſharply attacked by ſeveral writers on the democratic ſide of the queſtion, particularly by Dr Towers and Dr Dunbar of Aberdeen. This laſt gentleman acted a part which, if not diſhonourable, was at leaſt uncommon. The Dean had thrown off thirty copies of his work long before he publiſhed it; and theſe he ſent to different men of eminence, that he might avail himſelf of their animadverſions before he ſhould ſubmit it to the public at large. Principal Campbell of Aberdeen received one copy for this purpoſe; and Dr Dunbar having by him been favoured with a peruſal of it, inſtead of ſending his objections privately to the author, publiſhed ſevere remarks on it in a work which he had then in the preſs. Thus was the anſwer to the Dean of Glouceſter's Treatiſe on Government publiſhed before that treatiſe itſelf; but Dr Dunbar was no match for Dr Tucker.

In the year 1782 our author cloſed his political career with a pamphlet intitled "*Cui Bono?*" in which he balances the profit and loſs of each of the belligerent powers, and recapitulates all his former poſitions on the ſubject of war and colonial poſſeſſions. His publications ſince that period conſiſted of ſome tracts on the commercial regulations of Ireland, on the exportation of woollens, and on the iron trade. In 1777 he publiſhed ſeventeen practical ſermons, in one volume octavo. In the year 1778, one of his pariſhioners, Miſs Pelloquin, a maiden lady of large fortune and moſt exemplary piety, bequeathed to the Dean her dwelling houſe in Queen Square, Briſtol, with a very handſome legacy, as a teſtimony of her great eſteem for his worth and talents. In the year 1781 the Dean married a lady of the name of Crowe, who reſided at Glouceſter.

It ſhould be recorded to his praiſe, that though enjoying but very moderate preferment (for to a man of no paternal eſtate, or other eccleſiaſtical dignity, the Deanery of Glouceſter is no very advantageous ſituation), he was notwithſtanding a liberal benefactor to ſeveral public inſtitutions, and a diſtinguiſhed patron of merit. The celebrated John Henderſon of Pembroke-college, Oxford, was ſent to the univerſity, and ſupported there, at the Dean's expence, when he had no means whatever of gratifying his ardent deſire for ſtudy. We ſhall mention another inſtance of generoſity in this place, which reflects the greateſt honour upon the Dean. About the year 1790 he thought of reſigning his rectory in Briſtol, and, without communicating his deſign to any other perſon, he applied to the Chancellor, in whoſe

whoſe gift it is, for leave to quit it in favour of his curate, a moſt deſerving man, with a large family. His Lordſhip was willing enough that he ſhould give up the living, but he refuſed him the liberty of nominating his ſucceſſor. On this the Dean reſolved to hold the living himſelf till he could find a fit opportunity to ſucceed in his object. After weighing the matter more deliberately, he communicated his wiſh to his pariſhioners, and adviſed them to draw up a petition to the Chancellor in favour of the curate. This was accordingly done, and ſigned by all of them, without any exception, either on the part of the diſſenters or others. The Chancellor being touched with this teſtimony of love between a clergyman and his people, yielded at laſt to the application; in conſequence of which the Dean cheerfully reſigned the living to a ſucceſſor well qualified to tread in his ſteps. Since that time he reſided chiefly at Glouceſter, viewing his approaching diſſolution with the placid mind of a Chriſtian, conſcious of having done his duty both to God and man. He died in November 1799. The following we believe to be a tolerably correct liſt of his works.

Theological and Controverſial.—1. A Sermon, preached before the Governors of the Infirmary of Briſtol, 1745. 2. Letters in behalf of the Naturalization of the Jews. 3. Apology for the Church of England, 1772. 4. Six Sermons, 12mo, 1773. 5. Letter to Dr Kippis on his Vindication of the Proteſtant Diſſenting Miniſters. 6. Two Sermons and Four Tracts. 7. View of the Difficulties of the Trinitarian, Arian, and Socinian Syſtems, and Seventeen Sermons, 1777.

Political and Commercial.—8. A pamphlet on the Turkey Trade. 9. A brief View of the Advantages and Diſadvantages which attend a Trade with France. 10. Reflections on the Expediency of Naturalizing foreign Proteſtants, and a Letter to a Friend on the ſame Subject. 11. The Pleas and Arguments of the Mother Country and the Colonies ſtated. 12. A Letter to Mr Burke. 13. Quere, Whether a Connection with, or Separation from, America, would be for national Advantage? 14. Anſwers to Objections againſt the Separation from America. 15. A Treatiſe on Civil Government. 16. *Cui Bono?* 17. Four Letters on national Subjects. 18. Sequel to Sir William Jones on Government. 19. On the Diſpute between Great Britain and Ireland. 20. Several Papers under the Signature of Caſſandra, &c. on the Difficulties attendant on an Invaſion. 21. A Treatiſe on Commerce (Mr Coxe, in his Life of Sir Robert Walpole, ſays that this was printed, but never publiſhed.)

Miſcellaneous.—22. Directions for Travellers. 23. Cautions againſt the Uſe of Spirituous Liquors. 24. A Tract againſt the Diverſions of Cock-fighting, &c.

TULIPOMANIA, the very proper name given to a kind of gambling traffic in *tulip roots*, which prevailed in Holland and the Netherlands during ſome part of the 17th century. It was carried on to the greateſt extent in Amſterdam, Haerlem, Utrecht, Alkmaar, Leyden, Rotterdam, Hoorn, Enkhuyſen, and Meedenblick; and roſe to the greateſt height in the years 1634, 1635, 1636, and 1637. Munting, who, in 1696, wrote a book of 1000 pages folio on the ſubject, has given a few of the moſt extravagant prices, of which we ſhall preſent the reader with the following For a root of that ſpecies called the *Viceroy*, the after-mentioned articles, valued as below, were agreed to be delivered.

		Florins.
2	laſts of wheat	448
4	ditto rye	558
4	fat oxen	480
8	fat ſwine	240
12	fat ſheep	120
2	hogſheads of wine	70
4	tons beer	32
2	ditto butter	192
1000	pounds of cheeſe	120
	a complete bed	100
	a ſuit of clothes	80
	a ſilver beaker	60
	Sum	2500

Theſe tulips afterwards were ſold according to the weight of the roots. Four hundred perits* of Admiral Lieſken coſt 4400 florins; 446 ditto of Admiral Von der Eyk, 1620 florins; 106 perits Schilder coſt 1615 florins; 200 ditto Semper Auguſtus, 5500 florins; 410 ditto Viceroy, 3000 florins, &c. The ſpecies Semper Auguſtus has been often ſold for 2000 florins; and it once happened that there were only two roots of it to be had, the one at Amſterdam and the other at Haerlem. For a root of this ſpecies, one agreed to give 4600 florins, together with a new carriage, two grey horſes, and a complete harneſs. Another agreed to give twelve acres of land for a root: for thoſe who had not ready money, promiſed their moveable and immoveable goods, houſe and lands, cattle and clothes. A man, whoſe name Munting once knew, but could not recollect, won by this trade more than 60,000 florins in the courſe of four months. It was followed not only by mercantile people, but alſo by the firſt noblemen, citizens of every deſcription, mechanics, ſeamen, farmers, turf-diggers, chimney-ſweeps, footmen, maid-ſervants, and old clothes-women, &c. At firſt, every one won and no one loſt. Some of the pooreſt people gained in a few months houſes, coaches, and horſes, and figured away like the firſt characters in the land. In every town ſome tavern was ſelected which ſerved as a change, where high and low traded in flowers, and confirmed their bargains with the moſt ſumptuous entertainments. They formed laws for themſelves, and had their notaries and clerks.

To get poſſeſſion of fine flowers was by no means the real object of this trade, though many have ſaid that it was, and though we have known ſome individuals in Scotland, who, led away by what they thought the faſhion, have given ten guineas for a tulip root. During the time of the tulipomania, a ſpeculator often offered and paid large ſums for a root which he never received, and never wiſhed to receive. Another ſold roots which he never poſſeſſed or delivered Oft did a nobleman purchaſe of a chimney-ſweep tulips to the amount of 2000 florins, and ſold them at the ſame time to a farmer; and neither the nobleman, chimney ſweep, or farmer, had roots in their poſſeſſion, or wiſhed to poſſeſs them Before the tulip ſeaſon was over, more roots were ſold and purchaſed, beſpoke, and promiſed to be delivered, than in all probability were to be found in the gardens of Holland; and when Semper Auguſtus

---

* A *perit* is a ſmall weight leſs than a grain.

was not to be had, which happened twice, no ſpecies perhaps was oftener purchaſed and ſold. In the ſpace of three years, as Munting tells us, more than ten millions were expended in this trade in only one town of Holland.

To underſtand this gambling traffic, it may be neceſſary to make the following ſuppoſition. A nobleman beſpoke of a merchant a tulip root, to be delivered in ſix months, at the price of 1000 florins. During theſe ſix months the price of that ſpecies of tulip muſt have riſen or fallen, or remained as it was. We ſhall ſuppoſe that, at the expiration of that time, the price was 1500 florins; in that caſe, the nobleman did not wiſh to have the tulip, and the merchant paid him 500 florins, which the latter loſt and the former won. If the price was fallen when the ſix months were expired, ſo that a root could be purchaſed for 800 florins, the nobleman then paid to the merchant 200 florins, which he received as ſo much gain; but if the price continued the ſame, that is, 1000 florins, neither party gained or loſt. In all theſe circumſtances, however, no one ever thought of delivering the roots or of receiving them. Henry Munting, in 1636, ſold to a merchant at Alkmaar, a tulip root for 7000 florins, to be delivered in ſix months; but as the price during that time had fallen, the merchant paid, according to agreement, only 10 *per cent.* "So that my father (ſays the ſon) received 700 florins for nothing; but he would much rather have delivered the root itſelf for 7000." The term of theſe contracts was often much ſhorter, and on that account the trade became briſker. In proportion as more gained by this traffic, more engaged in it; and thoſe who had money to pay to one, had ſoon money to receive of another; as at faro, one loſes upon one card, and at the ſame time wins on another. The tulip dealers often diſcounted ſums alſo, and transferred their debts to one another; ſo that large ſums were paid without caſh, without bills, and without goods, as by the Virements at Lyons. The whole of this trade was a game at hazard, as the Miſſiſſippi trade was afterwards, and as ſtock jobbing is at preſent. The only difference between the tulip trade and ſtock-jobbing is, that at the end of the contract the price in the latter is determined by the Stock Exchange; whereas in the former it was determined by that at which moſt bargains were made. High and low priced kinds of tulips were procured, in order that both the rich and the poor might gamble with them; and the roots were weighed by perits, that an imagined whole might be divided, and that people might not only have whole, but half and quarter lots. Whoever is ſurpriſed that ſuch a traffic ſhould become general, needs only to reflect upon what is done where lotteries are eſtabliſhed, by which trades are often neglected, and even abandoned, becauſe a ſpeedier mode of getting fortunes is pointed out to the lower claſſes.

At length, however, this trade fell all of a ſudden. Among ſuch a number of contracts many were broken; many had engaged to pay more than they were able; the whole ſtock of the adventurers was conſumed by the extravagance of the winners; new adventurers no more engaged in it; and many becoming ſenſible of the odious traffic in which they had been concerned, returned to their former occupations. By theſe means, as the value of tulips ſtill fell, and never roſe, the ſellers wiſhed to deliver the roots *in natura* to the purchaſers at the prices agreed on; but as the latter had no deſire for tulips at even ſuch a low rate, they refuſed to take them or to pay for them. To end this diſpute, the tulip-dealers of Alkmaar ſent, in the year 1637, deputies to Amſterdam; and a reſolution was paſſed on the 24th of February, that all contracts made prior to the laſt of November 1636 ſhould be null and void; and that, in thoſe made after that date, purchaſers ſhould be free on paying ten *per cent.* to the vender.

The more diſguſted people became with this trade, the more did complaints increaſe to the magiſtrates of the different towns; but as the courts there would take no cognizance of it, the complainants applied to the States of Holland and Weſt Frieſland. Theſe referred the buſineſs to the determination of the provincial council at the Hague; which, on the 27th of April 1637, declared that it would not deliver its opinion on this traffic until it had received more information on the ſubject; that in the mean time every vender ſhould offer his tulips to the purchaſer; and, in caſe he refuſed to receive them, the vender ſhould either keep them, or ſell them to another, and have recourſe on the purchaſer for any loſs he might ſuſtain. It was ordered alſo, that all contracts ſhould remain in force till farther enquiry was made. But as no one could foreſee what judgment would be given reſpecting the validity of each contract, the buyers were more obſtinate in refuſing payment than before; and venders, thinking it much ſafer to accommodate matters amicably, were at length ſatisfied with a ſmall profit inſtead of exorbitant gain: and thus ended this extraordinary traffic, or rather gambling. *Beckmann's Hiſtory of Inventions*, vol. i.

TUMAR, in Bengal, rent-roll or aſſeſſment.

TUMBREL, is a kind of carriage with two wheels, uſed either in huſbandry for dung, or in artillery to carry the tools of the pioneers, &c. and ſometimes likewiſe the money of an army.

TUNGSTEN (ſee CHEMISTRY, n° 178, &c. in this *Suppl.*) when well fuſed, is, according to Guyton *alias* Morveau, of no higher ſpecific gravity than 8.3406. This is very different from the ſpecific gravity which has hitherto been aſſigned to it. The ſame eminent chemiſt concludes, from its extreme brittleneſs and difficulty of fuſion, that it affords little promiſe of utility in the arts, except in metallic alloys, or by virtue of the property which its oxyd poſſeſſes, of affording fixed colours, or giving fixity to the colours of vegetables.

TURNSOL, a dye-ſtuff manufactured in Holland, the preparation of which was long kept a profound ſecret. In order to miſlead foreigners, the Dutch pretended that turnſol was made from rags dyed with the juice of the ſun-flower (*Helianthus*), from which it obtained its name. Since the late revolution, however, in Holland, the true method employed by the Dutch for preparing this colour has been diſcovered, and the proceſs is as follows:—That kind of lichen called orchil (LICHEN-*Rocella*. See that article in this *Suppl.*), or, when that cannot be procured, the large oak-moſs, after being dried and cleaned, is reduced to powder, and by means of a kind of oil-preſs the powder is forced thro' a braſs ſieve, the holes of which are ſmall. The ſifted powder is then thrown into a trough and mixed with an alkali called *vetas*, which is nothing elſe than the

aſhes

aſhes of wine lees, in the proportion of half a pound of aſhes to one pound of powder. This mixture is moiſtened with a little human urine, for that of other animals contains leſs ammonia, by which a fermentation is produced; and the moiſtneſs is ſtill kept up by the addition of more urine. As ſoon as the mixture aſſumes a red colour, it is poured into another trough; is again moiſtened with urine, and than ſtirred round in order that the fermentation may be renewed. In the courſe of a few days it acquires a bluiſh colour, and is then carefully mixed with a third part of very pure pulveriſed potaſh; after which the mixture is put into wooden pails, three feet in height, and about half a foot broad. When the third fermentation takes place, and the paſte has acquired a conſiderably dark blue colour, it is mixed with chalk or pulveriſed marble, and ſtirred well round that the whole may be completely united. This laſt ſubſtance gives the colour no higher quality, and is intended merely to add to the weight. The blue, prepared in this manner, is poured into oblong ſquare iron moulds; and the cakes, when formed, are placed upon fir boards on an airy floor in order to dry, after which they are packed up for ſale.

TURPENTINE, a well known ſubſtance extracted from the pine. Under the article PINUS (*Encycl.*), we have given an account of one proceſs by which this extract is made; but the following, which is taken from the 31ſt volume of the *Journal de Phyſique*, is very different, and probably better. The pine from which turpentine is extracted, is never fit for this operation till it be thirty years of age. The extraction is begun in February and continued to the end of October. Inciſions are made with an hatchet, beginning at the foot of the tree on one ſide, and riſing ſucceſſively: they are repeated once or twice a week, the ſize about one finger's breadth acroſs, and three or four inches long. During the four years in which it is continued, the inciſions have riſen to about eight or nine feet. Then the inciſions are begun on the other ſide; and during this time the old ones fill up, and may be again opened after ſome years, ſo that a tree on a good ſoil, and well managed, may yield turpentine for a century. At the bottom of the tree, under the inciſion, a hole is dug in the ground to receive the reſin which flows from the tree. This reſin is called *terebinthine brut*, is of a milky colour, and is that which flows during the three ſummer months; it requires further purification.

The winter crop is called *barras galipot*, or white reſin: it ſticks to the bark of the tree, when the heat has not been ſtrong enough to let it flow into the trough in the ground. It is ſcraped off with iron knives.

Two methods are practiſed for purifying theſe reſins. That which is followed at Bayonne is to have a copper cauldron which will hold 300lb. of materials fixed over a fire, and the flame circulating at the bottom of the copper. The turpentine is put in, melted with a gentle heat, and, when liquid, it is ſtrained through a ſtraw-baſket made for the purpoſe, and ſtretched over a barrel, which receives the ſtrained turpentine. This purification gives it a golden colour, and may be performed at all times of the year.

The ſecond manner, which is practiſed only in the mountain of De Buch, near Bourdeaux, conſiſts in having a large tub, ſeven or eight feet ſquare, and pierced with ſmall holes at the bottom, ſet upon another tub to catch the liquor. This is expoſed to the hotteſt ſun for the whole day, filled two-thirds with turpentine, which as it melts falls through the holes, and leaves the impurities behind. This pure turpentine is leſs golden-coloured, and is much more eſteemed than the other. This proceſs can only be done in the ſummer.

To make *oil* of turpentine, an alembic, with a worm like what is uſed by the diſtillers, is employed here. It generally contains 250lb. of turpentine, which is boiled gently, and kept at the boiling point till no more oil paſſes, when the fire is damped. This generally gives 60lb. of oil, and the operation laſts one day.

The boiling turpentine, when it will give no more oil, is tapped off from the ſtill and flows into a tub, and from thence into a mold of ſand, which it fills, and is ſuffered to cool for at leaſt two days without diſturbing it. This reſidue is known under the name of *colophony*. It is of a brown colour, and very dry. It may be made clearer and nearer in colour to that of the reſin, by adding hot water to it before it is tapped off the ſtill, and ſtill boiling and ſtirring the water well with it, which is done with a beſom of wet ſtraw; and it is then ſold for roſin, but is little eſteemed, as it contains no eſſential oil.

TUSCULANUM, a villa belonging to Cicero, near Tuſculum, where he wrote his *Quæſtiones Tuſculanæ*, ſo named from the place; thus become famous as well for the productions of genius as of nature. Formerly the villa of Sylla: now called *Grotta Ferrata*.—Another *Tuſculanum* (inſcription), a town of the Tranſpadana, ſituated on the weſt ſide of the Lacus Benatus. Now ſaid to be called *Toſcolano*, in the territory of Breſcia, ſubject to Venice. Here many monuments of antiquity are dug up.

TUSCULUM (anc. geog.), a town of Latium, to the north of Alba; ſituated on an eminence, and therefore called *Supernum* (Horace, Strabo). In ſight of Rome, at about the diſtance of 100 ſtadia, or 12 miles. Adorned with plantations and princely edifices: The ſpot remarkable for the goodneſs of the ſoil, and its plenty of water. Built by Telegonus, who ſlew his father Ulyſſes (Ovid, Horace); called the grandſon of Ulyſſes in Silius Italicus. A municipium (Cicero); the birth-place of the elder Cato (Nepos, Cicero). Now *Freſcati*, in the Campania of Rome.

TUTENAG, according to Sir George Staunton, is, properly ſpeaking, zinc extracted from a rich ore, or calamine. The ore is powdered and mixed with charcoal-duſt, and placed in earthen jars over a ſlow fire, by means of which the metal riſes in the form of vapour, in a common diſtilling apparatus, and afterwards is condenſed in water. The calamine from which tutenag is thus extracted, contains very little iron, and no lead or arſenic, ſo common in the calamine of Europe (See CALAMINE, *Encycl.*) Hence it is that tutenag is more beautiful than our zinc, and that the white copper of the Chineſe takes ſo fine a poliſh. See *White Copper*, in this *Supplement*.

TYERS (Thomas), an author both in poetry and proſe, the friend of Johnſon, and well known to moſt of the eminent characters of the preſent time, was a ſtudent of the Temple in 1753. His father intended him for the law, but the young man it ſeems penned a ſonnet when he ſhould engroſs. He was an accompliſhed, but not a profound man; and had taſte and elegance of mind, ſlightly tinged with gleams of genius. He wrote ſome paſtorals and political tracts, which probably will not ſurvive the partiality of his particular friends.

TYPOGRAPHY, as the word imports, is the art of printing by types; but it is likewiſe uſed to ſignify the multiplying of copies by any mechanical contrivance. Of the art of printing by types, and the many improvements from time to time either made or attempted in it, a pretty full account will be found in the *Encyclopædia*, under the titles Letter, Logography, and Printing; and in this *Supplement* under the word Printing. Of typography, in the other and larger ſenſe, ſome account may likewiſe be found in the *Encyclopædia* under the title *Method of Copying Writings*; but to almoſt all theſe articles there is ample room for ſome additions here.

The *ſtereotype* printing of *Didot* and *Herhan*, being conſidered in France as a great improvement, muſt not be paſſed over wholly without notice. The term *ſtereotype* is derived from the Greek words ϛερεος and τυπος, becauſe in this method the types are fixed and immoveable in the form, ſo that none of them can be pulled or diſplaced by the preſſman. We need hardly obſerve, to thoſe who are at all acquainted with the hiſtory of printing, that the project of ſoldering a whole form together, or of caſting a ſolid form from an impreſſion made by a general ſyſtem of types, or page ready compoſed, is not new. It was realiſed 70 years ago by William Ged, a goldſmith in Edinburgh; for an account of whoſe method we refer the reader to his life in the *Encyclopædia*. Didot now follows nearly the ſame proceſs as Ged. He does not indeed caſt his types in a maſs, but after the form is compoſed and carefully corrected, he cements or ſolders the types together ſo firmly that none of them is liable to be looſened by the action of the preſs or the adheſion of the balls. How far this method of printing is of value with regard to books which are altered and improved in every ſubſequent edition, may, perhaps, be queſtioned; but on a looſe conſideration of the ſubject, it ſeems as if it would, in every caſe, be advantageous to a bookſeller to print a few copies of a work, and keep the types ſtanding to print others as they may be wanted; —we ſay it would be advantageous, if it were not for the immenſe value in types, which would, by that means, be locked up. To form ſome judgment of this, it may be ſtated, that the works of Virgil, printed by Didot, in 18mo, form a beautiful volume of 418 pages, of 35 lines each. The character ranges line for line with that called burgeois, N° 2. in Caſlon's book of ſpecimens, the face of the letter being rather ſmaller; and we are told * that the price of the plates of this work is twelve hundred franks, or 50l. ſterling. From this fact ſome judgment may be formed of the commercial queſtion. We have caſually looked at different books printed by Didot, but can ſay nothing of their correctneſs: the page is very pretty.

For multiplying copies of any writing, or of a book of ordinary ſize, Rochon, of the French National Inſtitute, and now Director of the Marine Obſervatory at the port of Breſt, invented, about the year 1781, a machine for engraving, with great celerity and correctneſs, the pages of the book or manuſcript on ſo many plates of copper. It was ſubmitted to the examination of a committee of the Royal Academy of Sciences, whoſe report of its utility was given in the following words:

"This machine appears to us to unite ſeveral advantages. 1*ſt*, Engraved editions of books may be executed, by this means, ſuperior to thoſe which can be made by the hand of the engraver, however ſkilful; and theſe engraved originals will be made with much more ſpeed, and much leſs expence. 2*d*, As this machine is portable, and of no conſiderable bulk, it may become very uſeful in armies, fleets, and public-offices, for the impreſſion of orders, inſtructions, &c. 3*d*, It poſſeſſes the advantage which, in a variety of circumſtances, is highly valuable, of being capable of being uſed by any man of intelligence and ſkill, without requiring the aſſiſtance of any profeſſional workman. And, *laſtly*, It affords the facility of waiting for the entire compoſition and engravings of a work before any of the copies are pulled off; the expence of plates, even for a work of conſiderable magnitude, being an object of little charge; and this liberty it affords to authors, may prove highly beneficial in works of which the chief merit conſiſts in the order, method, and connection of ideas."

Rochon's machine conſiſts of two braſs wheels *, placed on the ſame axis above each other, and ſeparated by a number of pillars, each two inches in length. Theſe two wheels, with the interval which ſeparates them, are equivalent to a ſingle wheel about three inches thick. In order therefore to ſimplify the deſcription, they are conſidered as a ſingle wheel which moves freely on its axis.

This wheel is perforated near its circumference with a number of ſquare holes, which are the ſheaths or ſockets through which a like number of ſteel punches, of the ſame ſhape, are inſerted, and are capable of moving up and down. They are very well fitted; and from this circumſtance, as well as the thickneſs of the double wheel, they have no ſhake, or ſide motion, independent of the motion of the wheel itſelf. Every punch is urged upwards by a ſeparate ſpring, in ſuch a manner, that the wheel armed with its characters, or ſteel types (the lower faces of the punches being cut into the figures of the ſeveral letters), may turn freely on its axis; and if it be moved, the ſeveral punches will paſs in ſucceſſion beneath an upright ſcrew, for preſſure. The ſcrew is fixed in a very firm and ſolid frame, attached to the ſupports of the machine; and by this arrangement a copperplate, diſpoſed on the table, or bed of the apparatus, will receive the impreſſion of all the punches in ſucceſſion, as they may be brought beneath the vertical preſſing ſcrew, and ſubjected to its action.

But as the preſs is fixed, it would neceſſarily follow that each ſucceſſive impreſſion would, in part, deſtroy or mutilate the previous impreſſions, unleſs the plate itſelf were moveable. It therefore becomes neceſſary that the plate ſhould be moveable in two directions: the firſt, to determine the interval between the letters and words, and form the lines; and the other motion, which is more ſimple, becauſe its quantity may remain the ſame through the whole of a book, ſerves to give the interval between line and line, and to form the pages.

It will eaſily be conceived that it would be a tedious operation to ſeek, upon the circumference of the wheel, each ſeveral character, as it might be required to come

---

* *La Decade Philoſophique.*

* See Plate XLVI.

beneath the preſs, becauſe it is neceſſary to repeat this operation as many times as there are characters in a work. The author has conſiderably diminiſhed the time and trouble of this operation, by fixing upon the axis of the great wheel, which carries the punches, another ſmall wheel, about four inches in diameter, the teeth of which act upon a rack, which carries a rule moving between two ſliders. This rule, or ſtraight line, will therefore repreſent the developement, or unfolding of the circumference of the wheel which cauſes it to move, and will ſhew the poſition of the great wheel, which carries the punches. For theſe two wheels being concentric, the developement of the ſmall toothed wheel, of about two inches radius, will exhibit, in a ſmall ſpace (for example, that of a foot), an accurate regiſter of the relative poſitions of the punches with regard to the preſſing-ſcrew. To obtain this effect, nothing more is neceſſary than to place a fixed index oppoſite to the moveable rule, which laſt is divided in the following manner:

The punch on which the firſt letter of the alphabet is engraved, muſt be brought under the centre of the preſſing-ſcrew; and a line of diviſion then drawn upon the moveable rule, to which the letter itſelf muſt be added to diſtinguiſh it. The index, already mentioned, being placed oppoſite, and upon this firſt diviſion, will ſerve to place immediately beneath the preſſing-ſcrew the punch, or rather the character, correſponding with the diviſion upon the rule, without its being afterwards neceſſary to inſpect the place either of the punch or the ſcrew, with regard to each other. Conſequently, as ſoon as the diviſions which correſpond with all the punches inſerted in the wheel are engraved upon the ſtraight rule, the fixed index will immediately determine the poſition into which that wheel muſt be brought, in order to place the punches under the preſſing-ſcrew in the order which the work may require.

This regiſter, for this name diſtinguiſhes the rule and its index, has no other function in the machine than to guide the hand of the operator, and to ſhew when the punch is very near its proper poſition beneath the preſſing-ſcrew. When this is the caſe, the required poſition is accurately obtained by means of a detent or catch.

The detent which he uſes for this operation is a lever with two tails, one of which is urged toward the circumference of the wheel by a ſpring. To this extremity of the lever is fixed a piece of hardened ſteel, of the figure of a wedge, which, by means of a ſpring, is preſſed towards the axis of the great wheel, but may be relieved, or drawn back, by preſſure on the oppoſite tail of the lever, ſo as to permit the great wheel to revolve at liberty.

In the next place, it muſt be explained how this detent takes hold of the wheel, ſo as to retain it preciſely in the ſituation neceſſary to cauſe any one of the punches, at pleaſure, to give its impreſſion to the plate. For this purpoſe there are a number of notches cut in the circumference of the wheel, for the purpoſe of receiving the detent. Theſe notches may be about half an inch deep, wider towards the circumference than elſewhere, and it will be of advantage that this outer width ſhould be as great as the circumference of the wheel can conveniently allow. By this contrivance, the wedge will not fail to preſent itſelf oppoſite to one of the notches into which it will fall, and draw the wheel exactly to its due ſituation, even though the index of the regiſter ſhould not be brought preciſely to the line of diviſion appropriated to any particular letter. For if this laſt degree of preciſion were required in working the machine, it would be very prejudicial to the requiſite ſpeed which, above all things, is required in its uſe. When the wedge is therefore left at liberty, it not only enters immediately into its place, and moves the wheel till its two ſides apply fairly to the interior ſurfaces of the notch, but retains the wheel in this ſtate with the neceſſary degree of ſtability.

The method of giving the proper figure to theſe notches is very eaſy. For this purpoſe it is neceſſary, in the firſt place, to impreſs all the characters contained in the wheel on a plate of copper or pewter. The ſupport on which the plate is fixed muſt be moved in a right line, after each ſtroke of the punch, through ſuch a ſpace that the characters may be arranged one after the other without touching. Now, as the perfect linear arrangement (ſuppoſing every other part to be true) muſt depend on the notches, it might ſeem ſufficient to cut theſe according to the method uſed for the wheels of clock-work: but as it is very difficult to avoid ſome obliquity on the face of the punch, and perhaps in the hole through which it paſſes, it is in almoſt every caſe neceſſary to retouch the notch itſelf. The requiſite degree of preciſion may be eaſily obtained, when, upon examining with attention the print of the characters engraved upon the plate, the inequalities ſhall have been aſcertained by a very fine line paſſing exactly under the baſe of two ſimilar letters, aſſumed as objects of compariſon: for the irregularity of linear poſition may, by this means, be determined with great exactneſs, and remedied to the moſt extreme nicety. In this operation, the workman muſt file away part of that ſurface of the notch which is oppoſite to the direction of the motion the character requires. Great care muſt be taken to file only a ſmall portion at a time, in order that the inſtant may be ſeized at which the wedge, by entering into the notch, brings the character to its due ſituation.

Theſe details, reſpecting the right-lined arrangement on the characters, muſt not divert our attention from the very great celerity with which any letter is brought to its place under the preſs by means of the regiſter and detent. This celerity is an object of ſo much importance in the engraving of a great work, that every means ought to be purſued which may tend to increaſe it. For this reaſon it is, that inſtead of following the alphabetic order in the arrangement of punches on the ſurface of the wheel, we ought to prefer that in which the ſum of the different motions to be given to the wheel, for engraving an entire work, ſhall be the leaſt poſſible. This tedious enquiry may well be diſpenſed with, by obſerving the order in which printers diſpoſe their caſes of characters, that the letters of the moſt frequent recurrence may be moſt immediately under the hand of the workman.

If all the characters afforded an equal reſiſtance to impreſſion in a plate of metal, a conſtant force would never fail to drive the punches to the ſame depth. But the faces of the letters are very unequal, and conſequently it will be neceſſary to uſe a variable force. Moſt workmen uſe the hammer, and not a ſcrew, as in this

this machine, for ſtamping. If the hammer had been uſed in this machine, it is evident, that if we ſuppoſed it to have fallen from the ſame height upon every one of the punches, the force of the ſtroke could be rendered variable according to the nature of the characters, by placing a capital, or head, upon each, of an height properly adjuſted to receive the hammer after paſſing through a greater or leſs ſpace. But the heads of our punches are variable at pleaſure, becauſe they are ſcrewed on; and thus it is that, by experimentally adjuſting the heads of all the punches, a ſet of impreſſions are obtained of equal depths from every one of them. When, for example, the letter *i* is placed under the hammer, the upper part of its head is at a ſmall diſtance from the head of the hammer, in order that its fall, which begins always at the ſame place, may ſtrike this letter weakly; but when the letter M is brought under the hammer, the upper part of its head being much leſs elevated than that of the letter *i*, will receive a much ſtronger blow. The impreſſions of the letters M and *i* will therefore always be equally deep, if the heads of the punches be once properly fixed by experiment.

Inſtead of the ſtroke of a hammer, however, our author makes uſe of the preſſure of a ſcrew, of which the threads are ſo inclined that it runs through its female ſocket, and would fall out merely by its own weight. This conſtruction affords the double advantage of preſerving the impreſſions from the effects of the circular motion, and of affording a fall in the ſcrew of nearly nine lines for each revolution. The head of this ſcrew is ſolidly fixed in the centre of a braſs wheel, of which the poſition is horizontal. The diameter of this wheel muſt be ſufficiently large, that its motion may not be perceptibly affected by the irregularities of friction in the ſcrew. This conſiderable diameter is alſo requiſite, becauſe the preſſure of the ſcrew depends, not only upon the force which is applied, but the diſtance of the place of application from the centre of movement.

It is eſſential that this wheel ſhould have very little ſhake; for which reaſon it is adviſeable that the axis of the ſcrew ſhould be prolonged above the wheel itſelf, that it may ſlide in a ſocket firmly fixed to the frame of the machine. In this ſituation, the wheel, which is fixed on the prolongation of the ſcrew, will have its plane conſtantly preſerved in a ſituation parallel to itſelf, without any libration, notwithſtanding the riſe and fall of near nine lines, or three quarters of an inch, which it undergoes for each revolution on its axis.

It has been ſtated, as a requiſite condition, that the ſcrew ſhould conſtantly fall from the ſame fixed point, or elevation, upon the heads of every one of the punches. To accompliſh this eſſential purpoſe, a lever is firmly fixed to the ſupport of the ſcrew; which lever reſembles the beam of a balance, having one of its extremities armed with a claw, and the other ſerving to give it motion through a ſmall vertical ſpace. The claw falls into a notch in the upper ſurface of the wheel attached to the ſcrew, as ſoon as that wheel has riſen to the deſired elevation; and the lever itſelf is ſo far limited in its motion, that it cannot take hold of the wheel, excepting when it has reached that height. The wheel, therefore, remains confined and immoveable, by means of this detent, and cannot deſcend until it is delivered by preſſure upon the oppoſite tail of the lever. In this machine, the wheel which has the preſſing ſcrew for its axis does not perform an entire revolution. It was with a view that there might never be any fall capable of ſhaking and diſturbing the machine that the author determined to uſe only two-thirds of a revolution to ſtrike thoſe punches, which afford the ſtrongeſt reſiſtance. The ſcrew conſequently falls only through ſix lines upon thoſe heads which are leaſt elevated, and about two lines upon thoſe which ſtand higheſt. Whence the difference between the extreme heights does not exceed four lines.

It is obvious, that ſo ſmall a difference is not ſufficient to ſtrike all the characters from M to the letter *i*, when the wheel which governs the ſcrew is put in motion by a conſtant weight, of which the impulſe, like that of a hammer, is increaſed only by the acceleration of its fall. It is evident that this requiſite variation of force might be had by changing the weight; but it is equally clear, that the numberleſs and inceſſant changes which the engraving of an entire work would demand, would be incompatible with that degree of ſpeed which forms one of the firſt requiſites. He was therefore obliged to render the force of the weight, which turns the ſcrew, variable, by cauſing it to act upon levers of greater or leſs lengths, according to the different quantities of impulſe required by the ſeveral punches. For this purpoſe he adopted the following conſtruction: He connected by a ſteel chain to the wheel, which moves the ſcrew, another wheel, having its axis horizontal, ſo that the two wheels reſpectively command each other. They are of equal diameter, and the chain is no longer than to make an entire turn round each wheel. This ſecond wheel, or leading pulley, is intended to afford the requiſite variations of force, which it does by means of a ſnail fixed upon its axis. The ſnail is acted upon by a cord paſſing over its ſpiral circumference, or groove, and bearing a weight which is only to be changed when a new ſet of punches for characters of a different ſize are put into the great wheel. The ſpiral is ſo formed, that when the weight deſcends only through a ſmall ſpace, the part of the cord, which is unwound, acts at a very ſhort diſtance from the centre of the pulley; but when the fall is greater, the part of the ſnail upon which it acts is ſo far enlarged as to afford a much longer lever, and, conſequently, to give a proportionally greater effect to the ſtroke. This conſtruction, therefore, by giving the advantage of a longer lever to a greater fall of the ſcrew, affords all the power which the nature of the work, and the different ſpaces of the letters demand.

The ſupport on which the plate is fixed muſt, as has before been remarked, move ſo as to form ſtrait lines. This motion, which ſerves to ſpace the different characters with preciſion, is obtained by means of a ſcrew, the axis of which remains fixed, and carries a female ſcrew or nut. The nut itſelf is attached to the ſupport of the metallic plate, which receives the letters, and carries it in the right lined direction without any deviation; becauſe it is confined in a groove formed between two pieces of metal. The ſcrew is moved by a lever, which can turn it in one direction only, becauſe it acts by a click upon a ratchet-wheel, which is fixed to the head of the ſcrew. The action of this lever always begins from a fixed ſtop; but the ſpace through which it moves is variable, according to the reſpective breadths of the letters. This new conſideration induced M. Rochon to fix upon the rule or plate of the regiſter, a

number

ROCHON'S MACHINE FOR ENGRAVING METALLIC PLATES.

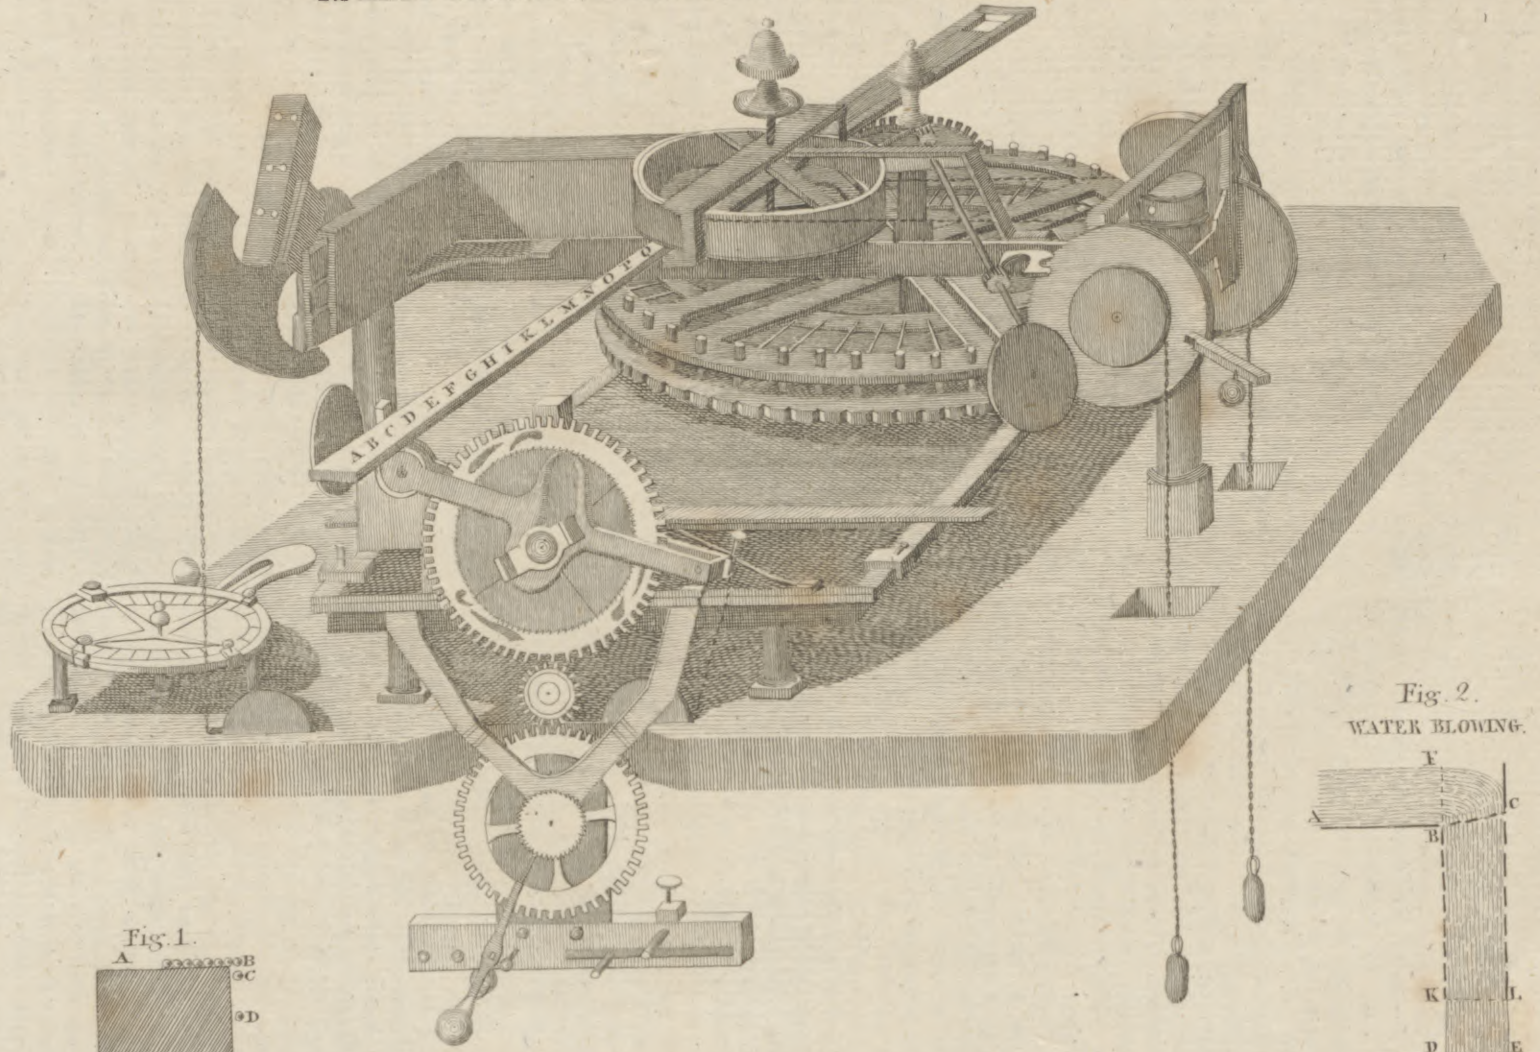

Fig. 1.

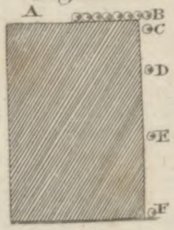

Fig. 2.

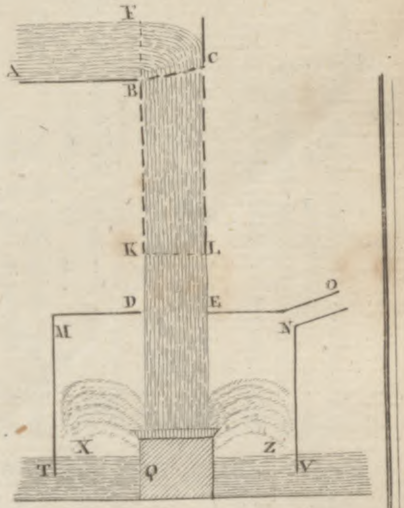
WATER BLOWING.



D Lizars Sculp^t

number of pins, correſponding with the different diviſions which anſwer to each punch: theſe pins determine the diſtance to which the lever can move. It therefore becomes a condition, that its poſition in the machine ſhould be oppoſite to the fixed index which determines the character at any time beneath the preſſing-ſcrew. The lever and its pin are therefore the ſole agents employed to ſpace the characters. If the plate were not moved by the lever, the impreſſions would fall upon each other; and thus, for example, the letter *i* would be totally obliterated by the impreſſion of the letter *l*.

Whenever, therefore, it is required to diſpoſe the letters *i* and *l* beſide each other, the plate muſt be moved after ſtriking the letter *i* through a ſpace equal to the quantity of the deſired operation. Suppoſe this to be one fourth of a line, and that the lever ſhould run through an arc of ten degrees to move the plate thro' this quantity; as ſoon as the pin of the letter *l* ſhall be adjuſted to the neceſſary length to enable the lever to deſcribe an arc of ten degrees, the operation of ſpacing the two letters *i* and *l* will be reduced to that of placing the laſt letter beneath the fixed index, and moving the plate till the lever ſhall be ſtopped by the pin belonging to the letter *l*. All the other letters will be equally ſpaced, if the diſpoſition of the punches in the wheel be ſuch, that the laſt ſtroke of any letter ſhall conſound itſelf with any letter of a ſingle ſtroke, ſuppoſing them to be impreſſed one after the other, without moving the lever between ſtroke and ſtroke. This arrangement deſerves to be very ſeriouſly attended to, becauſe the proceſs could not be performed without it.

Many well-informed perſons are of opinion, that the perfect equality which this machine for engraving affords in the formation of letters and ſigns the moſt difficult to be imitated, may afford a means of remedying the dangers of forgery. It is certain that the performance exhibits a ſimple and ſtriking character of preciſion, which is ſuch, that the leaſt experienced eyes might flatter themſelves, in certain caſes, to diſtinguiſh counterfeits from originals. Lavoiſier, whom the friends of ſcience and the arts will not ceaſe to regret, made ſome experiments of this kind for the *caiſſe de'ſcompte*, which were attended with perfect ſucceſs. Artiſts appointed for that purpoſe endeavoured in vain to imitate a vignette, formed by the ſucceſſive and equal motion of a character of ornament.

TYRTÆUS, an Athenian general and muſician, is celebrated by all antiquity for the compoſition of military ſongs and airs, as well as the performance of them. He was called to the aſſiſtance of the Lacedæmonians in the ſecond war with the Meſſenians, about 685 B. C.; and a memorable victory which they obtained over that people is attributed by the ancient ſcholiaſts upon Horace to the animating ſound of a new military flute or clarion, invented and played upon by Tyrtæus. Plutarch tells us that they gave him the freedom of their city; and that his military airs were conſtantly ſung and played in the Spartan army to the laſt hour of the republic. And Lycurgus the orator, in his oration againſt Leocrates, ſays, "The Spartans made a law, that whenever they were in arms, and going out upon any military expedition, they ſhould all be firſt ſummoned to the king's tent to hear the ſongs of Tyrtæus;" thinking it the beſt means of ſending them forth in a diſpoſition to die with pleaſure for their country. Fragments of his poetry, in elegiac verſe, are preſerved in Stobæus, Lycurgus Orat. in Fulvius Urſinus, at the end of Poems by illuſtrious Women: and in the Oxford edition of *Eleg. & Lyric. Frag. & Scholia.* printed 1759. Εκ Στοβαιου, &c.

TYTLER (William, Eſq;), ſo well known in the literary world as one of the ableſt, and certainly the moſt gentlemanly, of the defenders of the fame of Mary Queen of Scots, was born at Edinburgh, October 12. 1711. He was the ſon of Mr Alexander Tytler, writer (or attorney) in Edinburgh, by Jane, daughter of Mr William Leſlie, merchant in Aberdeen, and granddaughter of Sir Patrick Leſlie of Idan, provoſt of that city. He received his education at the grammar ſchool (or, as it is there called, the High School) and the univerſity of his native city, and diſtinguiſhed himſelf by an early proficiency in thoſe claſſical ſtudies, which, to the lateſt period of his life, were the occupation of his leiſure hours, and a principal ſource of his mental enjoyments.

In the year 1731, he attended the academical lectures of Mr Alexander Bayne, Profeſſor of municipal law in the univerſity of Edinburgh, a gentleman diſtinguiſhed alike for his profeſſional knowledge, his literary accompliſhments, and the elegance of his taſte. The Profeſſor found in his pupil a congenial ſpirit; and their connection, notwithſtanding the diſparity of their years, was ſoon ripened into all the intimacy of the ſtricteſt friendſhip. So ſtrong indeed became at length that tie of affection, that the worthy Profeſſor, in his latter years, not only made him the companion of his ſtudies, but when at length the victim of a lingering diſeaſe, choſe him as the comforter of thoſe many painful and melancholy hours which preceded his death.

At the age of 31, Mr Tytler was admitted into the Society of Writers to his Majeſty's Signet, and continued the practice of that profeſſion with very good ſucceſs, and with equal reſpect from his clients and the public, till his death, which happened on the 12th of September 1792. He married, in September 1745, Anne Craig, daughter of Mr James Craig of Dalnair, writer to the ſignet, by whom he has left two ſons, Alexander Fraſer Tytler, his Majeſty's Judge advocate for Scotland, and Profeſſor of civil hiſtory in the univerſity of Edinburgh; and Patrick Tytler, Lieutenant colonel of a regiment of fencible infantry, and Fort major of the caſtle of Stirling; together with one daughter, Miſs Chriſtina Tytler. His wife died about nine years before him; and, previouſly to that period, he had loſt a ſon and a daughter, both grown to maturity.

The moſt remarkable feature of Mr Tytler's character was an ardour and activity of mind, prompted always by a ſtrong ſenſe of rectitude and honour. He felt with equal warmth the love of virtue and the hatred of vice; he was not apt to diſguiſe either feeling, nor to compromiſe, as ſome men more complying with the world might have done, with the faſhion of the time, or the diſpoſition of thoſe around him. He ſeldom waved an argument on any topic of hiſtory, of politics, or literature; he never retreated from one on any ſubject that touched thoſe more important points on which he had formed a decided opinion. Decided opinions he always formed on ſubjects of importance; for on ſuch ſubjects he formed no opinions raſhly; and what he firmly believed he avowed with confidence, and ſometimes with warmth.

Nor was it in opinion or argument only that this warmth and ardour of mind were conſpicuous. They prompted him equally in action and conduct. His affection to his family, his attachment to his friends and companions, his compaſſion for the unfortunate, were alike warm and active. He was in ſentiment alſo what Johnſon (who felt it ſtrongly in himſelf, and mentions it as the encomium of one of his friends) calls a *good hater*; but his hatred or reſentment went no further than opinion or words, his better affections only roſe into action. In his opinions, or in his expreſſion of them, there was ſometimes a vehemence, an appearance of acrimony, which his friends might regret, and which ſtrangers might cenſure; but he had no aſperity in his mind to influence his actual conduct in life. He indulged oppoſition, not enmity; and the world was juſt to him in return. He had opponents; but two of his biographers, who knew him well, as well as the people with whom he moſt aſſociated, declare their belief that he had not a ſingle enemy. His conteſts were on opinions, not on things; his diſputes were hiſtorical and literary. In converſation, he carried on theſe with uncommon intereſt and vivacity; and the ſame kind of impulſe which prompted his converſation (as is juſtly obſerved by an author, who publiſhed ſome notices of his life and character in the periodical work intitled *The Bee*) induced him to become an author. He wrote not from vanity or vain-glory, which Rouſſeau holds to be the only inducement to writing; he wrote to open his mind upon paper; to ſpeak to the public thoſe opinions which he had often ſpoken in private; opinions on the truth of which he had firmly made up his own conviction, and was ſometimes ſurpriſed when he could not convince others: it was fair to try, if, by a fuller expoſition of his arguments, he could convince the world.

With this view, he publiſhed, in 1759, his “Inquiry, hiſtorical and critical, into the Evidence againſt *Mary Queen of Scots*, and an Examination of the Hiſtories of Dr Robertſon and Mr Hume with reſpect to that Evidence;” in which he warmly eſpouſed the cauſe of that unfortunate Princeſs, attacked with ſeverity the conduct of her enemies, and expoſed the fallacy, in many parts the fabrication, of thoſe proofs on which the charges againſt her had been founded.

This was a cauſe worthy of an advocate who loved truth better than popular applauſe; and Mr Tytler evinced himſelf to be ſuch an advocate. The problem of Mary's guilt or innocence, if conſidered merely as a detached hiſtorical fact, would appear an object which, at this diſtance of time, ſeems hardly to merit that laborious and earneſt inveſtigation to which it has given riſe; though, even in this point of view, the mind is naturally ſtimulated to ſearch out the truth of a dark myſterious event, diſgraceful to human nature; and our feelings of juſtice and moral rectitude are intereſted to fix the guilt upon its true authors. But when we conſider that this queſtion involves a diſcuſſion of the politics of both England and Scotland during one of the moſt intereſting periods of their hiſtory, and touches the characters, not only of the two ſovereigns, but of their miniſters and ſtateſmen, it muſt then be regarded in the light of a moſt important hiſtorical inquiry, without which our knowledge of the hiſtory of our own country muſt be obſcure, confuſed, and unſatisfactory. In addition to theſe motives of inquiry, this queſtion has exerciſed ſome of the ableſt heads both of earlier and of latter times; and it is no mean pleaſure to engage in a conteſt of genius and of talents, and to try our ſtrength in the deciſion of a controverſy which has been maintained on both ſides with conſummate ability.

As we have elſewhere (ſee Mary, *Encycl.*) given an abſtract of the arguments on both ſides of this diſputed queſtion, it would be altogether improper to repeat them here; but juſtice to the ſubject of this memoir requires us to ſay, that by his manner of diſcuſſing it he acquired high reputation in the republic of letters. Before the appearance of the Inquiry, ſays an ingenious writer, it was the faſhion for literary diſputants to attack each other like miſcreants and banditti. The *perſon* was never ſeparated from the *cauſe*; and whatever attached the *one*, was conſidered as equally affecting the *other*; ſo that ſcurrility and abuſe bloated the pages even of a Bentley and a Ruddiman. The Hiſtorical Inquiry was free from every thing of that ſort: and though the higheſt name produced not a mitigation of the force of any argument, the meaneſt never ſuffered the ſmalleſt abuſe. He conſidered it as being greatly beneath the dignity of a man contending for truth, to overſtretch even an argument in the ſmalleſt degree, far more to pervert a fact to anſwer his purpoſe on any occaſion. In the courſe of his argument, he had too often occaſion to ſhew that this had been done by others; but he diſdained to imitate them. His reaſoning was forcible and elegant; impartially ſevere, but always polite, and becoming the gentleman and the ſcholar.

When this book appeared, it was univerſally read in Britain, and very well tranſlated into French, under the title of “Recherches Hiſtoriques et Critiques ſur les Principales Preuves d l'Accuſation intentée contre Marie Reine d'Ecoſſe.” The intereſt it excited among literary men may be judged of from the character of thoſe by whom it was reviewed on its publication, in the periodical works of the time. Dr Douglas, now biſhop of Saliſbury, Dr Samuel Johnſon, Dr John Campbell, and Dr Smollet—all wrote reviews of Mr Tytler's book, containing very particular accounts of its merits, and elaborate analyſes of the chain of its arguments. As an argument on evidence, no ſuffrage could perhaps be more deciſive of its merit than that of one of the greateſt lawyers, and indeed one of the ableſt men that ever ſat on the woolſack of England, the late Lord Chancellor Hardwicke, who declared Mr Tytler's Inquiry to be the beſt concatenation of circumſtantiate proofs brought to bear upon one point that he had ever peruſed. What effect that body of evidence, or the arguments deduced from it, ought to have upon the minds of thoſe to whom the ſubject may become matter of inveſtigation, we do not preſume to determine. The opinion of the late Dr Henry, author of the Hiſtory of Great Britain on a New Plan, may perhaps be thought neither partial nor confident. He ſays, in a letter to Mr Tytler, publiſhed in the firſt volume of Tranſactions of the Antiquarian Society of Scotland, That he would be a bold man who ſhould now publiſh an hiſtory of Queen Mary in the ſame ſtrain with the two hiſtorians (Mr Hume and Dr Robertſon), whoſe opinions on the ſubject the Inquiry had examined and controverted.

The moſt exceptionable part of Mary's conduct, which, though it may admit of an apology, cannot be

Tytler.

vindicated, is her marriage to Bothwell; and for that marriage Mr Tytler made an apology, founded on facts, which he would be a daring or very bigotted man who would attempt to controvert. See the article already referred to.

Beſides the *Hiſtorical Inquiry*, and the *Diſſertation on the Marriage of Queen Mary with the Earl of Bothwell*, our author publiſhed ſeveral other works on hiſtorical and literary ſubjects; of which the firſt was, the *Poetical remains of James I. King of Scotland*, conſiſting of *the King's Queir*, in ſix cantos, and *Chriſt's Kirk on the Green*; to which is prefixed a diſſertation on the Life and Writings of King James, in one volume 8vo, printed at Edinburgh in 1783. This diſſertation forms a valuable morſel of the literary hiſtory of Europe; for James ranked ſtill higher in the literary world as a *poet*, than in the political world as a *prince* (A). Great juſtice is done to his memory in both reſpects in this diſſertation: and the two morſels of poetry here reſcued from oblivion will be eſteemed by men of taſte as long as the language in which they are written can be underſtood.

2. “A Diſſertation on Scottiſh Muſic,” firſt ſubjoined to Arnot's hiſtory of Edinburgh. The ſimple melodies of Scotland have been long the delight of the natives, many of which, to them, convey an idea of pathos that can be equalled by none other; and are much admired by every ſtranger of muſical talents who has viſited this country. They have a powerful effect, indeed, when properly introduced, as a relief, into a muſical compoſition of complicated harmony. Theſe are of two kinds, pathetic and humorous. Thoſe who wiſh to receive information concerning this curious ſubject, will derive much ſatisfaction from the peruſal of this diſſertation. There is yet another kind of muſic peculiar to the Highlands of Scotland, of a more wild, irregular, and animating ſtrain, which is but ſlightly treated here, and requires to be ſtill more fully elucidated.

3. “Obſervations on the Viſion, a poem,” firſt publiſhed in Ramſay's Evergreen, now alſo printed in the Tranſactions of the Society of Antiquaries of Scotland. This may be conſidered as a part of the literary hiſtory of Scotland.

4. “On the Faſhionable Amuſements in Edinburgh during the laſt century,” *ibid*. It is unneceſſary to dwell on the light that ſuch diſſertations as theſe, when judiciouſly executed, throw upon the hiſtory of civil ſociety and the progreſs of manners. Mr Tytler was likewiſe the author of N° 16. of the Lounger, a weekly paper, publiſhed at Edinburgh in the year 1786. His ſubject is the Defects of Modern Female Education in teaching the Duties of a Wife; and he treats that ſubject like a maſter.

On all Mr Tytler's compoſitions the character of the *man* is ſtrongly impreſſed, which never, as in ſome other inſtances, is in the ſmalleſt degree contradicted by, or at variance with, the character of the *author*. He wrote what he felt, on ſubjects which he felt, on ſubjects relating to his native country, to the arts which he loved, to the times which he revered. His heart, indeed, was in every thing which he wrote, or ſaid, or did. He had, as his family and friends could warmly atteſt, all the kindneſs of benevolence: he had its anger too; for benevolence is often the parent of anger. There was nothing neutral or indifferent about Mr Tytler. In philoſophy and in hiſtory, he could not bear the coldneſs, or what ſome might call the temperance of ſcepticiſm; and what he firmly believed, it was his diſpoſition keenly to urge.

His mind was ſtrongly impreſſed by ſentiments of religion. His piety was fervent and habitual. He believed in the doctrine of a particular Providence, ſuperintending all the actions of individuals as well as the great operations of Nature: he had a conſtant impreſſion of the power, the wiſdom, and the benevolence of the Supreme Being; and he embraced, with thorough conviction, the truths of Chriſtianity.

His reading was various and extenſive. There was ſcarcely a ſubject of literature or taſte, and few even of ſcience, that had not at times engaged his attention. In hiſtory he was deeply verſed; and what he had read his ſtrong retentive memory enabled him eaſily to recal. Ancient as well as modern ſtory was familiar to him; and, in particular, the Britiſh hiſtory, which he had read with the moſt minute and critical attention. Of this, beſides what he has given to the public, a great number of notes, which he left in MS. touching many controverted points in Engliſh and Scottiſh hiſtory, afford the moſt ample proof.

In muſic as a ſcience he was uncommonly ſkilled. It was his favourite amuſement; and with that natural partiality which all entertain for their favourite objects, he was apt to aſſign to it a degree of moral importance which ſome might deem a little whimſical. He has often been heard to ſay, that he never knew a good taſte in muſic aſſociated with a malevolent heart: And being aſked, What preſcription he would recommend for attaining an old age as healthful and happy as his own? “My preſcription (ſaid he) is ſimple—ſhort but cheerful meals, muſic, and a good conſcience.”

In domeſtic life, Mr Tytler's character was particularly amiable and praiſe worthy. He was one of the kindeſt huſbands and moſt affectionate fathers. At the beginning of this account, we mentioned his having loſt, at an advanced period of life, an excellent wife, and a ſon and a daughter both grown to maturity, who merited and poſſeſſed his warmeſt affections. The temper of mind with which he bore theſe loſſes, he has himſelf expreſſed in a MS. note, written not long before his death; with which, as it conveys a ſentiment equally important in the conſideration of this life, and in the contemplation of that which is to come, we ſhall conclude the preſent memoir: “The lenient hand of time (ſays he, after mentioning the death of his wife and children), the lenient hand of time, the affectionate care of my remaining children, and the duty which calls on my exertions for them, have by degrees reſtored me to myſelf. The memory of thoſe dear objects gone before me, and the ſoothing hope that we ſhall ſoon meet again, is now the ſource of extreme pleaſure to me. In my retired walks in the country I am never alone; thoſe dear ſhades are my conſtant companions! Thus what I looked upon as a bitter calamity, is now become to me the chief pleaſure in life.”

(A) There is a beautiful hiſtorical picture of this prince playing on the harp, with his queen and a circle of his courtiers liſtening to the muſic, by Graham, in London; one of the moſt eminent artiſts of the age.

VACUUM Boyleanum, is the approach to a real vacuum, to which we can arrive by means of the air-pump.

Torricellian Vacuum, is the moſt complete vacuum which we can make by means of the torricellian tube. See Barometer, and Pneumatics, *Encycl.*

VADE mecum, the title given to ſuch books as men of particular profeſſions, having frequent occaſion to conſult, may eaſily carry about with them. Thus a ſmall volume, publiſhed in the beginning of the 18th century, giving an account of the ancient and preſent church of England, and of the duties, rights, privileges, and hardſhips of the clergy, is known by the title of *the Clergyman's Vade-mecum.*

VAKEEL, a miniſter, agent, or ambaſſador.

VALGUS, *Bow* or *Bandy Legged.* Some children are bow-legged from their birth; others become ſo from ſetting them on their feet too early. The tibia of ſome is crooked; the knees of others are diſtorted; from a fault in the ankle, the feet of ſome are turned inwards, theſe are called *vari;* and in others they turn outwards, theſe are called *valgi.* The beſt method of preventing theſe diſorders in weakly children, is to exerciſe them duly, but not violently; by dancing or toſſing them about in one's arms, and not ſetting them much on their feet, at leaſt not without properly ſupporting them: if the diſorder attends at the birth, or increaſes after it is begun, apply emollients, then apply boots of ſtrong leather, wood, &c. as required to diſpoſe the crooked legs gradually to a proper form: or other inſtruments may be uſed inſtead of boots, which, when not too coſtly, are uſually to be preferred. Slighter inſtances of theſe diſorders yield to careful nurſing without inſtruments.

VANDA', the Indian name of a plant of the genus Epidendrum; which ſee, *Encycl.* The *vandá* is thus deſcribed by Sir William Jones.

"Cal. *Spathes* minute, ſtraggling. Cor. *Petals* five, diverging, oval oblong, obtuſe, wavy; the two loweſt larger; the three higheſt equal, bent towards the nectary. *Nectary* central, rigid: *Mouth* gaping, oblique: *Upper lip* ſhorter, three parted, with a poliſhed honey-cup; *under lip* concave in the middle, keeled above, with two ſmaller cavities below, two proceſſes at the *baſe*, incurved, hollow, oval pointed, converging, honey-bearing. Stam. *Filaments* very ſhort. *Anthers* round, flattiſh, margined, covered with a lid, eaſily deciduous from the *upper lip* of the nectary. Pist. *Germ.* beneath long, ribbed, contorted with curves of oppoſite flexure. *Style* very ſhort, adhering to the *upper lip. Stigma* ſimple. Per. *Capſule* oblong-conic, wreathed, ſix-keeled, each with two ſmaller keels, three-celled, crowned with the dry corol. Seeds innumerable, like fine duſt affixed to the *receptacle* with extremely fine hairs, which become thick wool. *Scapes* incurved, ſolitary, from the cavity of the leaf, at moſt ſeven-flowered; pedicles alternate. *Petals* milk white externally, tranſparent; brown within, yellow-ſpotted. *Upper lip* of the nectary ſnow-white; *under lip* rich purple, or light crimſon, ſtriated at the baſe, with a bright yellow gland, as it ſeems, on each proceſs. The flowers gratefully fragrant, and exquiſitely beautiful, looking as if compoſed of ſhells, or made of enamel; criſp elaſtic, viſcid internally. *Leaves* ſheathing, oppoſite, equally curved, rather fleſhy, ſword-form, retuſe in two ways at the ſummit, with one acute point. *Roots* fibrous, ſmooth, flexible; ſhooting even from the top of the leaves."

This lovely plant attaches itſelf chiefly to the higheſt *Amras* and *Bilvas* (the *Mangifera* and *Cratæva* of Lin.); but it is an air-plant, and lives (ſays the Preſident) in a pot *without earth or water:* its leaves are excavated upwards, to catch and retain dew.

VANDALIA, a duchy of Farther Pomerania, ſubject to the king of Pruſſia. Stolpen is the capital.

Vandalia, a country in Germany, in the circle of Lower Saxony and duchy of Mecklenburg. It lies between the biſhopric and duchy of Schwerin, the lordſhips of Stocrock and Stargard, Pomerania, and the marquiſate of Brandenburg; and is 75 miles in length and 7 in breadth. It contains ſeveral ſmall lakes, and the principal town is Guſtrow.

VANDERMONDE, member of the National Inſtitute of Sciences and Arts, was born at Paris in the year 1735. He devoted his youth to ſelf-inſtruction; and even at the age of thirty was far enough from ſuſpecting that he was deſtined to inſtruct others in his turn. Chance brought him near to the celebrated Fontaine. That ſexagenary geometrician eaſily divined the progreſs which Vandermonde would one day make in the mathematics; in him he anticipated, as it were, a ſucceſſor to himſelf; he patroniſed and careſſed him, let him into the ſecret of his reſearches, calculations, inventions, of that lively enjoyment which profound ſpeculation gives to an elevated attentive mind; and which, blended with the ſweets of tranquillity, the charms of retreat, and the conſciouſneſs of ſucceſs, becomes often a ſort of paſſion, as felicitous as durable. All that time Fontaine, whoſe attention was again directed to the reſearches which he had added to thoſe of Jean Bernoulli, relative to the then famous queſtion *of the toutocrones*, had the glory to be vanquiſhed only by D'Alembert and La Grange. Vandermonde, a witneſs to this combat, neceſſarily illuſtrious, animated by the honour which he ſaw annexed to that glorious defeat, enchanted with the ſight of Fontaine, as happy, in ſpite of his age, from his love of geometry, as a youth of twenty could be with a ſentiment leſs tranquil, thought he ſhould inſure his happineſs for ever, by yielding to a paſſion which the ice of age could not extinguiſh; in a word, he devoted himſelf to geometry.

His labours, however, were for ſome time ſecret; and perhaps the public would never have enjoyed the benefit of any of his works, if another geometrician (whoſe name, ſays Lacepede, cannot be pronounced, in this place, without a mixture of intereſt and regret) had not inſpired him with a conſciouſneſs of his own ſtrength, and courage to diſplay it. Fontaine had already devoted him to geometry; Duſejour exhorted him to penetrate even into its ſanctuary. In brief, he preſented himſelf to the Academy of Sciences, into which he was admitted in 1771; and in that very year juſtified the ſuffrages of his aſſociates, by a paper which he publiſhed relative to the reſolution of equations.

From the 16th century the method of reſolving equations of the four firſt degrees has been known, and ſince that time the general theory of equations has received great improvements. In ſpite, however, of the recent labours of many great geometricians, the ſolutions of equations of the fifth degree had in vain been attempted. Vandermonde wiſhed to conſolidate his labours with thoſe of other illuſtrious analyſts; and he propoſed a new theory of equations, in which he ſeems to have made it particularly his buſineſs to ſimplify the methods of calculation, and to contract the length of the *formulæ*, which he conſidered as one of the greateſt difficulties of the ſubject.

This work was quickly followed by another on the problems called by geometricians *problems of ſituation*. It ſeems to have been the deſtiny of Vandermonde, as well as of Fontaine, who firſt initiated him into the myſteries of mathematical ſcience, to labour frequently upon ſubjects already handled by the greateſt maſter. In his firſt memoir he had ſtarted, ſo to ſpeak, in competition with La Grange and Euler; in his ſecond, with Euler and Leibnitz. This laſt was of opinion that the analyſis made uſe of in his time, by the geometricians, was not applicable to all queſtions in the phyſical ſciences; and that a new geometry ſhould be invented, to calculate the relations of poſitions of different bodies, in ſpace: this he called *geometry of ſituation**. Excepting, however, one application, made by Leibnitz himſelf, to the game of *ſolitaire*, and which, under the appearance of an object of curioſity, ſcarcely worthy the ſublimity and uſefulneſs of geometry, is an example for ſolving the moſt elevated and important queſtions, Euler was almoſt the only one who had practiſed this geometry of ſituation. He had reſorted to it for the ſolution of a problem called the *cavalier*, which alſo appeared very familiar at firſt ſight, and was alſo pregnant with uſeful and important applications. This problem, with the vulgar, conſiſted merely in running through all the caſes of the cheſs board, with the *knight* of the game of cheſs; to the profound geometrician, however, it was a precedent for tracing the route which every body muſt follow, whoſe courſe is ſubmitted to a known law, by conforming to certain required conditions, through all the points diſpoſed over a ſpace in a preſcribed order. Vandermonde was chiefly anxious to find in this ſpecies of analyſis a ſimple notation, likely to facilitate the making of calculations; and he gave an example of this, in a ſhort and eaſy ſolution of the ſame problem of the cavalier, which Euler had rendered famous.

His taſte for the high conceptions of the ſpeculative ſciences, as blended with that which the *amor patriæ* naturally inſpires for objects immediately uſeful to ſociety, had led him to turn his thoughts towards perfecting the arts converſant in weaving, by indicating a manner of noting the points through which are to paſs the threads intended to form the lines which terminate the ſurface of different regular bodies: accordingly a great part of the above memoir is taken up with this ſubject.

In the year following (1772) he printed a third memoir; in which he traced out a new path for geometers, diſcovering, by learned analytical reſearches, *irrational* quantities of a new ſpecies, ſhewing the ſequels of which theſe *irrationals* are the terms or the ſum, and pointing out a direct and general method of making in them all the poſſible reductions.

In the ſame year appeared his work on the Elimination of unknown Quantities in Algebra. This elimination is the art of bringing back thoſe equations which include many unknown quantities, to equations which only contain one. The perfection of reſearches in this art would conſiſt in obtaining a general and particular *formula* of elimination in a form the moſt conciſe and convenient, in which the number of equations and their degrees ſhould be deſigned by indeterminate letters. Vandermonde, while he conſidered the geometers as very diſtant from this point, had ſome glimpſe of a poſſibility of reaching it, and propoſed ſome new methods of approaching nearer it.

In 1778, he preſented, in one of the public ſittings of the Academy, a new ſyſtem of harmony, which he detailed more fully in another public ſitting of 1780. In this ſyſtem, Vandermonde reduces the modes of proceeding adopted until his time, to two principal rules, which thus become eſtabliſhed on effects admitted by all muſicians. Theſe two general rules, one on the ſucceſſion of according ſounds, the other on the arrangement of the parts, depend themſelves on a law more elevated, which, according to Vandermonde, ought to rule the whole ſcience of harmony.

By the publication of this work, he ſatisfactorily attained the end he had propoſed to himſelf, and obtained the ſuffrages of three great men, repreſentatives, ſo to ſpeak, of the three great ſchools of Germany, France, and Italy; Gluck, Philidor, and Piccini.

With theſe labours, intermingled with frequent reſearches on the mechanic arts, as well as on objects of political economy, the attention of Vandermonde was taken up; when, July 14. 1789, the voice of liberty reſounded over the whole ſurface of France, and ſuddenly all the thoughts, as well as all the affections, of Vandermonde, were engaged on the ſide of what he called liberty.

He became ſo furious a democrate, ſo outrageous an enemy to every thing eſtabliſhed, that he concurred in the abolition of the Royal Academy, of which he had been ſo ambitious of becoming a member, and aſſociated himſelf cloſely with Robeſpierre, Marat, and the reſt of that atrocious gang of villains, who covered France with ruins, with ſcaffolds, and with blood. This part of Vandermonde's hiſtory is ſuppreſſed by his eulogiſt Lacepede, becauſe, forſooth, diſcuſſions on *political opinions* ought not, in his opinion, to be admitted into the ſanctuary of the ſciences.

In that ſanctuary he did not long remain. Soon after his atrocities, he was attacked by a diſorder in his lungs, which almoſt taking away his breath, manifeſted itſelf by alarming ſymptoms, and conducted him by rapid ſteps to the tomb. He died in the end of the year 1795; a ſtriking inſtance of the wayward violence of the human mind, which even the love of ſcience could not keep at a diſtance from tumult and uproar.

VARENIUS (Bernard), a learned Dutch geographer and phyſician of the 17th century, who was author of the beſt mathematical treatiſe on geography, intitled, *Geographia Univerſalis, in qua affectiones generalis Tellu-*

* See Position, *Suppl.*

ris explicantur. This excellent work has been tranſlated into all languages, and was honoured by an edition, with improvements, by Sir Iſaac Newton, for the uſe of his academical ſtudents at Cambridge.

VARIABLE, in geometry and analytics, is a term applied by mathematicians to ſuch quantities as are conſidered in a variable or changeable ſtate, either increaſing or decreaſing. Thus the abſciſſes and ordinates of an ellipſis, or other curve line, are variable quantities; becauſe theſe vary or change their magnitude together, the one at the ſame time with the other. But ſome quantities may be variable by themſelves alone, or while thoſe connected with them are conſtant: as the abſciſſes of a parallelogram, whoſe ordinates may be conſidered as all equal, and therefore conſtant; alſo the diameter of a circle, and the parameter of a conic ſection, are *conſtant*, while their abſciſſes are *variable.* See Fluxions, *Encycl.*

VARIATION of Curvature, in geometry, is uſed for that inequality or change which takes place in the curvature of all curves except the circle, by which their curvature is more or leſs in different parts of them; and this variation conſtitutes the quality of the curvature of any line.

1 Variolæ vaccinæ long known in Glouceſterſhire,

VARIOLÆ Vaccinæ, or *Cow-pox*, is the name commonly, though, as ſome people think, improperly, given to a very ſingular diſeaſe, which, for two or three years paſt, has occupied a great ſhare of the attention of medical men. It has been many years prevalent in ſome of the great dairy counties in England, particularly Glouceſterſhire; and it has been long underſtood by the farmers and others in theſe counties, that it for ever exempts all perſons who have been infected with it from the contagion of ſmall pox.

It is very ſurpriſing that, though they knew this fact, and although no perſon had ever been known to die of the cow-pox, they never thought of having recourſe to a voluntary infection of this kind, in order to free themſelves and their families from the poſſibility of being infected with the variolous poiſon, which ſo often proves mortal. In one caſe, indeed, communicated to Dr Pearſon by Mr Downe of Bridport, the experiment was long ago tried by a farmer upon his own perſon, and with complete ſucceſs: But this only makes it the more wonderful that his example ſhould not have been followed.

2 And in the duchy of Holſtein.

In the town of Kiel, however, in the duchy of Holſtein, where the diſeaſe is ſaid to be well known, as frequently affecting cows, we are told that children are ſometimes inoculated with cow-pox *(Die Finnen)*, with a view to preſerve their beauty; but that the people in the country do not like this inoculation, becauſe they pretend that it leaves behind it ſeveral diſorders.

3 Vaccine inoculation introduced by Dr Jenner.

With theſe exceptions, Dr Jenner was the firſt perſon who introduced the vaccine inoculation; and to him the public are alſo indebted for the firſt careful and accurate inveſtigation of this intereſting ſubject. The following is his account of the origin and hiſtory of the diſeaſe, and of its characteriſtic ſymptoms.

4 Origin of the diſeaſe, according to him.

"There is a diſeaſe to which the horſe, from his ſtate of domeſtication, is frequently ſubject. The farriers have termed it *the greaſe.* It is an inflammation and ſwelling in the heel, from which iſſues matter poſſeſſing properties of a very peculiar kind, which ſeems capable of generating a diſeaſe in the human body (after it has undergone the modification which I ſhall preſently ſpeak of), which bears ſo ſtrong a reſemblance to the ſmall pox, that I think it highly probable that it may be the ſource of that diſeaſe.

"In this dairy county (Glouceſterſhire), a great number of cows are kept, and the office of milking is performed indiſcriminately by men and maid ſervants. One of the former having been appointed to apply dreſſings to the heels of a horſe affected with *the greaſe*, and not paying due attention to cleanlineſs, incautiouſly bears his part in milking the cows with ſome particles of the infectious matter adhering to his fingers. When this is the caſe, it commonly happens that a diſeaſe is communicated to the cows, and from the cows to the dairy maids, which ſpreads through the farm until moſt of the cattle and domeſtics feel its unpleaſant conſequences. This diſeaſe has obtained the name of the cow pox.

5 Its appearance on the cow and the perſon who milks her.

It appears on the nipples of the cows in the form of irregular puſtules. At their firſt appearance they are commonly of a paliſh blue, or rather of a colour ſomewhat approaching to livid, and are ſurrounded by an eryſipelatous inflammation. Theſe puſtules, unleſs a timely remedy be applied, frequently degenerate into phagedenic ulcers, which prove extremely troubleſome. The animals become indiſpoſed, and the ſecretion of milk is much leſſened. Inflamed ſpots now begin to appear on different parts of the hands of the domeſtics employed in milking, and ſometimes on the wriſts, which quickly run on to ſuppuration, firſt aſſuming the appearance of the ſmall veſications produced by a burn. Moſt commonly they appear about the joints of the fingers, and at their extremities; but whatever parts are affected, if the ſituation will admit, theſe ſuperficial ſuppurations put on a circular form, with their edges more elevated than their centre, and of a colour diſtantly approaching to blue. Abſorption takes place, and tumors appear in each axilla. The ſyſtem becomes affected, the pulſe is quickened, and ſhiverings, with general laſſitude, and pains about the loins and limbs, with vomiting, come on. The head is painful, and the patient is now and then even affected with delirium. Theſe ſymptoms, varying in their degrees of violence, generally continue from one day to three or four, leaving ulcerated ſores about the hands, which, from the ſenſibility of the parts, are very troubleſome, and commonly heal ſlowly, frequently becoming phagedenic, like thoſe from whence they ſprung. The lips, noſtrils, eyelids, and other parts of the body, are ſometimes affected with ſores; but theſe evidently ariſe from their being needleſsly rubbed or ſcratched with the patient's infected fingers. No eruptions of the ſkin have followed the decline of the feveriſh ſymptoms in any inſtance that has come under my inſpection, one only excepted; and in this caſe a very few appeared on the arms: they were very minute, of a vivid red colour, and ſoon died away without advancing to maturation: ſo that I cannot determine whether they had any connection with the preceding ſymptoms.

"Thus the diſeaſe makes its progreſs from the horſe to the nipple of the cow, and from the cow to the human ſubject.

6 Its ſingularity,

"Morbid matter of various kinds, when abſorbed into the ſyſtem, may produce effects in ſome degree ſimilar; but what renders the cow-pox virus ſo extremely ſingular is, that the perſon who has been thus affected

is

is for ever after ſecure from the infection of the ſmall-pox; neither expoſure to the variolous effluvia, nor the inſertion of the matter into the ſkin, producing this diſtemper.

"It is neceſſary to obſerve, that puſtulous ſores frequently appear ſpontaneouſly on the nipples of cows; and inſtances have occurred, though very rarely, of the hands of the ſervants employed in milking being affected with ſores in conſequence, and even of their feeling an indiſpoſition from abſorption. Theſe puſtules are of a much milder nature than thoſe which ariſe from that contagion which conſtitutes the true cow-pox. They are always free from the bluiſh or livid tint ſo conſpicuous in that diſeaſe. No eryſipelas attends them, nor do they ſhew any phagedenic diſpoſition, as in the other caſe, but quickly terminate in a ſcab, without creating any apparent diſorder in the cow. This complaint appears at various ſeaſons in the year, but moſt commonly in the ſpring, when the cows are firſt taken from their winter food and fed with graſs. It is very apt to appear alſo when they are ſuckling their young. But this diſeaſe is not to be conſidered as ſimilar in any reſpect to that of which I am treating, as it is incapable of producing any ſpecific effects on the human conſtitution. However, it is of the greateſt conſequence to point it out here, leſt the want of diſcrimination ſhould occaſion an idea of ſecurity from the infection of the ſmall-pox, which might prove deluſive."

Dr Jenner adds, that the active quality of the virus from the horſe's heels is greatly increaſed after it has acted on the nipples of the cow, as it rarely happens that the horſe affects his dreſſer with ſores, and as rarely that a milkmaid eſcapes the infection when ſhe milks infected cows. It is moſt active at the commencement of the diſeaſe, even before it has acquired a pus-like appearance. Indeed the Doctor is rather induced to think that the matter loſes this property entirely as ſoon as it is ſecreted in the form of pus, and that it is the thin darkiſh looking fluid only, oozing from the newly formed cracks in the heels, ſimilar to what ſometimes exudes from eryſipelatous bliſters, which gives the diſeaſe. He is led to this opinion, from having often inſerted pus taken from old ſores in the heels of horſes, into ſcratches made with a lancet, on the ſound nipples of cows, which has produced no other effect than ſimple inflammation.

He is uncertain if the nipples of the cow are at all times ſuſceptible of being acted upon by the virus from the horſe, but rather ſuſpects that they muſt be in a ſtate of prediſpoſition, in order to enſure the effect. But he thinks it is clear that when the cow pox virus is once generated, the cows, when milked with a hand really infected, cannot reſiſt the contagion, in whatever ſtate their nipples may chance to be. He is alſo doubtful whether the matter, either from the cow or the horſe, will affect the ſound ſkin of the human body; but thinks it probable that it will not, except on thoſe parts where the cuticle is very thin, as on the lips.

At what period the cow-pox was firſt noticed in Glouceſterſhire is not upon record. The oldeſt farmers were not unacquainted with it in their earlieſt days when it appeared upon their farms, without any deviation from the phenomena which it now exhibits. Its connection with the ſmall pox ſeems to have been unknown to them. Probably the general introduction of inoculation firſt occaſioned the diſcovery. Dr Jenner conjectures that its riſe in that neighbourhood may not have been of very remote date, as the practice of milking cows might formerly have been in the hands of women only; and conſequently the cows might not in former times have been expoſed to the contagious matter brought by the men ſervants from the heels of horſes. He adds, that a knowledge of the ſource of the infection is new in the minds of moſt of the farmers, but has at length produced good conſequences; and that it ſeems probable, from the precautions they are now diſpoſed to adopt, that the appearance of the cow-pox in that quarter may either be entirely extinguiſhed or become extremely rare.

"With reſpect to the opinion adduced (Dr Jenner obſerves), that the ſource of the infection is a peculiar morbid matter ariſing in the horſe; although I have not (ſays he) been able to prove it from actual experiments conducted immediately under my own eye, yet the evidence I have adduced appears to eſtabliſh it.

"They who are not in the habit of conducting experiments, may not be aware of the coincidence of circumſtances, neceſſary for their being managed ſo as to prove perfectly deciſive; nor how often men engaged in profeſſional purſuits are liable to interruptions, which diſappoint them almoſt at the inſtant of their being accompliſhed; however, I feel no room for heſitation reſpecting the common origin of the diſeaſe, being well convinced that it never appears among the cows, except it can be traced to a cow introduced among the general herd which has been previouſly infected, or to an infected ſervant, unleſs they have been milked by ſome one who, at the ſame time, has the care of a horſe affected with diſeaſed heels."

The following caſe, which we alſo quote from Dr Jenner, would ſeem to ſhew that not only the heels of the horſe, but other parts of the body of that animal, are capable of generating the virus which produces the cow pox.

"An extenſive inflammation of the eryſipelatous kind appeared, without any apparent cauſe, upon the upper part of the thigh of a ſucking colt, the property of Mr Millet, a farmer at Rockhampton, a village near Berkeley. The inflammation continued ſeveral weeks, and at length terminated in the formation of three or four ſmall abſceſſes. The inflamed parts were fomented, and dreſſings were applied by ſome of the ſame perſons who were employed in milking the cows. The number of cows milked was twenty-four, and the whole of them had the cow-pox. The milkers, conſiſting of the farmer's wife, a man, and a maid ſervant, were infected by the cows. The man-ſervant had previouſly gone through the ſmall pox, and felt but little of the cow-pox. The ſervant maid had ſome years before been infected with the cow-pox, and ſhe alſo felt it now in a ſlight degree: but the farmer's wife, who never had gone through either of theſe diſeaſes, felt its effects very ſeverely. That the diſeaſe produced upon the cows by the colt, and from them conveyed to thoſe who milked them, was the *true* and not the *ſpurious* cow-pox, there can be ſcarcely any room for ſuſpicion; yet it would have been more completely ſatisfactory had the effects of variolous matter been aſcertained on the farmer's wife; but there was a peculiarity in her ſituation which prevented my making the experiment."

8
Dr Jenner's opinion of the origin of the diſeaſe controverted.

Subſequent authors have not been all diſpoſed to adopt Dr Jenner's opinion that this diſeaſe derives its origin from the greaſe in horſes. We have ſeen the Doctor himſelf allow that he has not been able to prove it deciſively by actual experiments; and to eſtabliſh a fact ſo contrary to all analogy, perhaps no weaker evidence ought to be admitted. The only other beſtial diſorder with which we are acquainted, which is capable of being communicated by contagion to the human ſpecies, is hydrophobia: but here the diſorder is the ſame in man as in the animal from which he derives it; and the analogy holds good in the propagation of the vaccine diſeaſe from the cow to her milker. But that the diſcharge from a local diſeaſe in the heel of a horſe ſhould be capable of producing a general diſorder in the conſtitution of a cow, with ſymptoms totally different, and that this new diſeaſe once produced ſhould be capable of maintaining an uniform character in the cow and in man, ſeems a much greater departure from the ordinary proceeding of Nature. We are very far from ſaying that this is impoſſible; for little indeed do we know of what Nature can or cannot do. All we mean to ſay is, that a fact ſo very extraordinary ought not to be haſtily admitted.

In Holſtein, we are told that the farmers do not know of any relation exiſting between the greaſe and the cow pox, at leaſt a perſon who reſided three years in that country never heard of any. This, however, is certainly no proof. The ſame communication which contains this remark (a letter from Dr De Carro of Vienna to Dr G. Pearſon) adds, "that in great farms men do not milk cows, but that in the ſmaller ones that happens very often; that a diſeaſe of horſes, called *mauke* (true German name for *greaſe*), is known by all thoſe who take care of them; that old horſes particularly, attacked with the mauke, are always put in cow's ſtables, and there are attended by women; and that it is particularly in harveſt that men in ſmall farms milk cows." It muſt be allowed, then, that in this ſituation, ſuppoſing Doctor Jenner's opinion well founded, the cow-pox was naturally to be looked for, and here accordingly we find it. The queſtion is certainly of no real utility, and therefore it has very properly been leſs attended to than other points reſpecting this diſorder which lead to important practical concluſions

Of all the queſtions which have ariſen relative to the cow-pox, there is none ſo intereſting, and luckily there is none which has received ſo full a diſcuſſion, or ſo ſatisfactory an anſwer, as the one we are now about to conſider. Are thoſe perſons who have once had the cow-pox effectually and for ever ſecured againſt the variolous contagion?

9
A previous attack of this diſeaſe renders the body unſuſceptible of ſmall-pox.

Dr Jenner, in his firſt publication, was decidedly of opinion that a previous attack of this diſorder rendered the human body for ever unſuſceptible of the variolous virus; and beſides the univerſal popular belief in the countries where cow-pox is known, he brought forward a number of caſes in ſupport of his aſſertion. By ſome of theſe it appeared that perſons who had been affected with the cow pox above twenty or thirty years before, continued ſecure againſt infection, either by the effluvia from patients under ſmall pox, or by inoculation. But along with this opinion he entertained other two, which, to many people, appeared ſo ſurpriſing as to take away all credit from the former. The firſt was, that a previous attack of ſmall-pox did not prevent a ſubſequent attack of cow-pox; and the ſecond was perhaps ſtill more wonderful, that the cow-pox virus, although it rendered the conſtitution unſuſceptible of the ſmall-pox, ſhould nevertheleſs leave it unchanged with reſpect to its own action, for that the ſame perſon is ſuſceptible of repeated attacks of the cow-pox.

These opinions have been ſubmitted to the teſt of very extenſive experience by a variety of intelligent practitioners; and we think there can now be little doubt that the two laſt are erroneous, while the truth of the firſt has been eſtabliſhed by an immenſe body of incontrovertible evidence.

10
Difficulties explained.

The opinions that a perſon who has had the ſmall-pox may afterwards have the cow-pox, and that the ſame perſon may have the cow-pox more than once, probably aroſe from the diſtinction between the local effects of the vaccine virus, and the general diſorder of the conſtitution not having been ſufficiently attended to. It is generally admitted, that in the inoculated ſmall-pox the local affection may go ſo far as that a puſtule ſhall ariſe on the part, containing matter capable of communicating the true ſmall pox to others, and yet, if no general affection of the conſtitution takes place, the patient is not ſecure from the diſorder. In like manner, there are caſes upon record which prove that a perſon may, after having had the ſmall pox, have a local affection produced by inoculation, in which true variolous matter ſhall be formed capable of communicating both the local and conſtitutional ſymptoms of ſmall-pox to others; and nurſes, when much expoſed to variolous contagion, often have an eruption reſembling ſmall-pox upon ſuch parts of their ſkin as have been expoſed to the action of the virus, though they have formerly undergone the diſeaſe. Yet there is probably no perſon at this day who will go ſo far as to aſſert that the ſame perſon can have the ſpecific variolous fever more than once.

The caſe ſeems to be preciſely the ſame with reſpect to cow-pox. Doctor Pearſon and others have inoculated a number of perſons after they have had the ſmall pox with the vaccine virus, and have produced only the local affection; and by the ſame teſt it is aſcertained that the ſame perſon cannot more than once have the conſtitutional ſymptoms of the cow-pox. Dr Woodville indeed tells us that he has ſeen one caſe of genuine cow-pox puſtule and ſpecific fever in a conſtitution which had previouſly ſuffered the ſmall-pox. There can be no higher authority on this ſubject than that of Dr Woodville; and if he had actually ſeen his patient in the ſmall-pox as well as the cow pox, we ſhould have admitted this ſingle caſe as completely deciſive of the queſtion. But the only evidence of this perſon having had the ſmall pox, is the aſſertion of the patient that he had it *when a child*. This we can by no means ſuſtain as concluſive in oppoſition to the Doctor's own experience, as well as the experience of Dr Pearſon.

That the milkers are ſubject to repeated attacks of the local ſymptoms of cow pox, whether they have had the ſmall-pox or not, is certain. In the caſe of the farmer's ſervants at Rockhampton, which we have quoted above from Dr Jenner, one of whom had previouſly undergone the ſmall pox, and the other the cow-pox, and both of whom were afterwards infected

by

by the cow pox *in a ſlight degree*, it ſeems reaſonable to conclude that the local ſymptoms only were preſent in the laſt attack. We may at the ſame time obſerve, that in a caſe of this kind, where a very painful ulcer is produced in a very ſenſible part, this may probably be attended by an increaſed frequency of pulſe; yet if this has not the ſpecific marks of the cow-pox fever, we ſhould not ſay that ſuch a perſon has the diſorder conſtitutionally.

11 ſs of ine ula- t.

With reſpect to the principal propoſition, that the ſpecific fever of cow-pox renders the conſtitution unſuſceptible of the variolous fever, we think no doubt now remains. Above 1000 perſons who have undergone the vaccine inoculation have been afterwards inoculated with variolous matter, which has produced no other than local effects. Beſides theſe, there have been a vaſt number inoculated by private practitioners in different parts of the kingdom, the reſult of which has not been reported. But we may ſafely ſuppoſe, that if any one of them had afforded a concluſion oppoſite to the one now generally admitted, it would have been communicated to the public.

We muſt not, however, conceal one ſeemingly well authenticated caſe which has lately occurred, and which, ſo far as it goes, certainly militates againſt this concluſion, and which, we doubt not, will be eagerly caught at by the opponents of the new practice. We quote it from the Medical and Chirurgical Review for September 1800.

12 ſeeming- well au- nticated ception.

"Mr Malim, ſurgeon of Carey Street, London, inoculated a child, two years and an half old, with vaccine matter procured from Dr Jenner. On the third day there were ſufficient marks of the action of the virus, and from this time to the end of the diſeaſe the local affection proceeded regularly and without interruption. On the eighth day the child complained of headache and ſickneſs; had a quick pulſe, white tongue, and increaſed heat, with an enlargement and tenderneſs in the axilla. Theſe ſymptoms ſubſided in the courſe of the next day, and the child remained well till the twelfth, when it had a very ſevere attack of fever, ſucceeded, the following day, by an eruption; the appearance, progreſs, and termination of which, left no doubt in the minds of ſeveral eminent practitioners of its being the ſmall-pox. That it was really ſo, has been ſince clearly proved by inoculation. There was a child ill of ſmall-pox in the houſe at the time the above inoculation for cow-pox was performed."

The Reviewers juſtly remark, that the hiſtory is defective, in not deſcribing more minutely the appearances of the inoculated parts at the different ſtages, as well as in not mentioning the length of time that the matter had been taken previous to being uſed. Both theſe points are the more important, as a ſuſpicion naturally ariſes, that the local affection which ſucceeded the vaccine inoculation was not the genuine cow-pox puſtule, but one of the ſpurious kind, which had not the power of deſtroying variolous ſuſceptibility. The matter having been furniſhed by Dr Jenner, no doubt, renders this ſuppoſition the leſs probable; but if it was either long or improperly kept after it came out of his hands, it may have undergone a material change, by putrefaction or otherwiſe. Dr Jenner mentions an inſtance of a practitioner, who had been accuſtomed to preſerve variolous matter in a warm pocket; a ſituation favourable for producing putrefaction in it. This matter, when inſerted, was found to produce inflammation, ſwellings of the axillary glands, fever, and ſometimes eruptions; but not of the true variolous kind, as patients thus inoculated were found ſtill ſuſceptible of the ſmall-pox contagion. It is ſurely a poſſible ſuppoſition, tho' merely a conjecture, that the vaccine matter in Mr Malim's caſe had undergone ſome ſuch change.

The caſe however, is in ſeveral reſpects an intereſting one. As it has been ſuppoſed that variolous contagion, communicated in the form of exhalation, does not affect the conſtitution in leſs than fourteen or fifteen days, and as the vaccine matter, communicated by inoculation, produces its ſpecific effects ſome days earlier, it has been ſuggeſted, that wherever a perſon has been accidentally expoſed to variolous effluvia, we ſhould endeavour to anticipate the ſmall-pox by immediately inoculating with the vaccine virus. But if there be nothing falacious in the above caſe, it appears that this meaſure would not ſtop the progreſs of the ſmall-pox, but that our patient would incur the additional danger of having two diſeaſes inſtead of one.

13 Probably accounted for.

At all events, it muſt be allowed that this child had been infected by the ſmall-pox before the vaccine matter had begun to produce its ſpecific effects, and probably even before the inoculation. Thus the ſmall-pox may be conſidered as having begun before the cow-pox; and though we ſhould be forced to allow that, matters being thus ſituated, the latter diſorder could not prevent the farther progreſs of the former, it by no means follows, that when the cow pox has fairly run its courſe, the conſtitution is ſtill ſuſceptible of ſmall pox. The two diſeaſes muſt have exiſted in this patient at the ſame time, though the one was in a latent ſtate during the active ſtage of the other.

This ſolitary caſe, then, is by no means concluſive, and certainly is not ſufficient to outweigh the immenſe mals of concurring evidence which is oppoſed to it.

14 Advantages of the new practice.

We proceed now to another highly important branch of our ſubject—the compariſon of the advantages and diſadvantages of the two diſeaſes, with a view to the practice of inoculation.

Notwithſtanding the immenſe number of caſes in which the inoculation of the cow-pox has been tried, we are not yet fully qualified to appreciate the value of the new practice; becauſe the diſeaſe has varied very much in ſeverity, and even in its moſt remarkable ſymptoms, and that without any cauſe which has yet been diſcovered.

Dr Jenner's account of the diſeaſe gave us reaſon to think that the local affection in cow-pox was more ſevere than in the inoculated ſmall-pox: That the fever in this diſeaſe was never attended with dangerous ſymptoms: that thoſe ſymptoms which affect the patient with ſeverity are entirely ſecondary, excited by the irritating proceſſes of inflammation and ulceration: that the diſeaſe was not attended with any eruption reſembling ſmall-pox: and that the ſore produced by the inoculation was apt to degenerate into a very diſtreſſing phagedenic ulcer, which required to be treated with applications of a cauſtic nature, of which he found the unguentum hydrargyri nitrati the moſt uſeful.

Soon after Dr Jenner's publication, the attention of medical men was forcibly drawn to the ſubject; and ſeveral eminent practitioners in London, particularly Dr

George Pearſon, and Dr Woodville phyſician to the ſmall pox and inoculation hoſpitals, immediately began to practiſe the vaccine inoculation. The latter gentleman ſoon publiſhed an accurate and candid account of the effect of this virus upon 200 patients, with a table of the reſults of above 500 caſes in which the inoculation was performed.

15
Anomalies in the progreſs of the diſeaſe.

It is very remarkable, that in none of theſe caſes did the inoculated part ulcerate in the manner deſcribed by Dr Jenner, nor did the inflammation ever occaſion any inconvenience, excepting in one inſtance, in which it was ſoon ſubdued by the aqua lythargyri acetati. The general affection of the conſtitution, on the other hand, though in a great majority of caſes it was very ſlight, yet, in ſome inſtances, was ſevere. An eruption, exactly reſembling ſmall-pox, was, contrary to expectation, a very common occurrence, and in ſome the puſtules were not fewer than 1000; and although in theſe caſes the diſeaſe was ſtill unattended with ſecondary fever, yet the febrile ſymptoms which took place from the commencement were conſiderable, and even alarming, as ſometimes alſo happens with the inoculated ſmall pox.

Dr Woodville ſometimes inoculated with matter from the primary ſore in the arm, and ſometimes with matter taken from the puſtular eruption; and it appears from the table that a much larger proportion of thoſe who were inoculated in the latter way had puſtules, than of thoſe who were inoculated either with matter immediately from the cow, or from the primary ſore in the human body. There were 447 patients in all inoculated, either from the cow or from the primary ſore; and of theſe 241 had puſtules, and 206 had none. Sixty-two perſons, on the other hand, were inoculated with matter from the puſtules of ten different patients; and of theſe no fewer than 57 had puſtules, and only 5 eſcaped without. Nor can it be ſaid that this diſproportion aroſe from theſe 10 patients having the diſeaſe in a more virulent form than ordinary, for matter was alſo taken from the primary ſore in 4 of the 10, with which 48 were inoculated; of whom 27 had puſtules, and 21 had none: whereas, of 9 perſons who were inoculated with matter from the puſtules of theſe ſame 4, only 2 eſcaped without puſtules. This obſervation correſponds alſo with Dr Pearſon's experience.

Although theſe eruptions have been met with by other practitioners, yet they certainly appear very rarely in private practice. Dr Woodville, for this reaſon, conſiders them, in a more recent publication, as the effect of ſome adventitious cauſe, independent of the cow-pox: And this he ſuppoſes to be the variolated atmoſphere of the hoſpital, which thoſe patients were neceſſarily obliged to inſpire during the progreſs of the cow-pox infection. This opinion, however, does not ſeem to agree well with his former remark, which, as we have ſaid, is confirmed by Dr Pearſon, that eruptions rarely took place, if care was taken to avoid matter for inoculation from ſuch as had puſtules; a fact that cannot be explained on ſuch a ſuppoſition. Neither is this idea reconcileable with what he alſo tells us, that the proportion of caſes in the hoſpital attended with puſtules has been of late only three or four in a hundred.

This change in the appearances of the diſeaſe in the hands of different practitioners, and even of the ſame practitioner at different times, is one of the moſt unaccountable circumſtances reſpecting this ſingular diſorder. There is ſome curious information on this ſubject, contained in a letter from Mr Stromeyer of Hanover to Mr Hannehmaun.

"This year (ſays he) we have inoculated 40 perſons, as well with the vaccine matter received of Dr Pearſon as with that from Dr Jenner; all of whom underwent the diſeaſe properly.

"Betwixt the London and Glouceſter vaccine matter, it appears to me there ſubſiſts an eſſential difference. The London matter produces frequently an eruption of ſmall pimples; but they diſappear within a day or two at fartheſt. Dr Pearſon calls theſe eruptions *puſtules*.—The Glouceſter matter has never produced this effect here; but *frequently occaſioned ulcerations of the inoculated part, of a tedious and long duration; which the latter never did:* on account of which I now only make uſe of Dr Pearſon's vaccine matter. The nettle-fever-like eruptions I have obſerved ſeveral times, but never that ſort of eruption, repeatedly noticed in London, which ſo much reſembles the ſmall pox."

If theſe obſervations of Mr Stromeyer ſhould be confirmed by the experience of others, they would go far to explain the difference which the London practitioners have found in this diſeaſe from the account given of it by Dr Jenner, notwithſtanding the abſence of the eruption reſembling ſmall-pox at Hanover. We believe an interchange of vaccine matter has once or twice taken place between London and Glouceſterſhire. Is it ſince that period that the eruption has been leſs frequent at London? Dr Pearſon is inclined to ſuppoſe, that the comparative ſeverity of the diſeaſe at London, during the firſt winter, aroſe rather from the difference in the human conſtitution at the different ſeaſons of the year, than from any change in the ſtate of the vaccine matter.

16
Mortality for the old practice over-rated by the advocates for the new.

In comparing the degree of danger from the inoculation of cow-pox with that ariſing from the inoculated ſmall-pox, we are convinced that Dr Pearſon greatly over-rates the mortality in the latter diſorder. He ſuppoſes it to be no leſs than one in 200. Dr Moſeley, on the other hand, who is a violent opponent of the vaccine inoculation, aſſerts, that he has inoculated ſeveral thouſands with variolous matter, in Europe and the Weſt Indies, without ever loſing a patient, and that ſeveral other perſons, whom he knows, have done the ſame, with the ſame ſucceſs. We are afraid, however, that the experience of other inoculators does not afford ſo favourable a reſult. We believe that in this country the mortality is often occaſioned by improper treatment; and from comparing the accounts which we have received from practitioners of extenſive experience, and undoubted veracity, we believe that, where the treatment is proper from the beginning, the ſymptoms very rarely ariſe to an alarming height, and that the mortality is not ſo great as one in 600. And this eſtimate nearly correſponds with Dr Woodville's very great experience. It muſt be allowed, that patients in an hoſpital are ſubject to ſome diſadvantages, which may be avoided in private practice; yet, out of the laſt 5000 caſes of variolous inoculation at the inoculation hoſpital, prior to the publication of the Doctor's reports, the mortality did not exceed one in 600.

Notwithſtanding this ſtatement, however, we are happy to ſay, that the danger in the vaccine diſeaſe is ſtill much leſs. Dr Pearſon tells us, that in little more than ſix months after the new inoculation was introduced into London, which includes the period at which the cow-pox aſſumed the moſt unfavourable appearance, 2000 perſons at leaſt underwent the operation; of theſe, one only, an infant at the breaſt, under the care of Dr Woodville, died. In this ſolitary fatal caſe, the local tumor was but very inconſiderable; and the eruptive ſymptoms took place on the ſeventh day, when the child was attacked with fits of the ſpaſmodic kind, which recurred at ſhort intervals, with increaſed violence, and carried it off on the eleventh day after the cow-pox matter had been inſected into its arm, and after an eruption of about 80 puſtules had appeared.

17 Great ſucceſs of the new inoculation.

Since that time a much greater number, amounting certainly to ſeveral thouſands, have been inoculated with cow-pox in different parts of Great Britain and on the continent. Among theſe, not one fatal inſtance, that we have heard of, has occurred.

But even if the danger to the individual from the ſmall-pox and from the cow-pox were equal, there is an important advantage to the public attending the latter, which we think would alone be ſufficient to intitle it to a preference—It is not capable of being propagated by the effluvia ariſing from the bodies of perſons infected with it. There are many ſituations in which a prudent ſurgeon will be reſtrained from inoculating with ſmall pox, leſt the contagion ſhould ſpread to other people, who may be either prevented by prejudice from ſubmitting to the operation, or in whom it would be obviouſly improper, from the circumſtances of age, teething, or the preſence of ſome other diſeaſe. Here the cow pox virus may be ſubſtituted with great propriety. It is chiefly from this quality that the cow pox bids fair to extirpate the ſmall pox entirely.

This valuable property of the vaccine diſorder is not, however, to be admitted without ſome limitation. When it produces numerous puſtules on the body, Dr Woodville tells us, that the exhalations they ſend forth are capable of affecting others, in the ſame manner as the ſmall-pox. Two inſtances of caſual infection in this way have fallen under his obſervation. In one, the diſeaſe was ſevere, and the eruption confluent; in the other, the diſeaſe was mild, and the puſtules few. It has been remarked, that the inoculated cow pox is little, if at all, different from the diſeaſe when caſually caught. But, ſtrictly ſpeaking, the above are the only two caſes in which the diſeaſe has been communicated otherwiſe than by inoculation.

18 Whether the cow-pox and ſmall-pox ought to be conſidered as different diſeaſes.

The writers upon this ſubject are divided in opinion, whether the cow-pox and ſmall pox ought to be conſidered as different diſeaſes, or whether they are merely varieties of the ſame diſeaſe.

They certainly, notwithſtanding the ſtrong analogy which ſubſiſts between them, differ from each other in ſeveral ſtriking particulars. The cow pox comes to man from the cow, and is capable of being carried back from him to that animal. Similar attempts with variolous matter have failed: in this reſpect, then, theſe two morbid poiſons are altogether different.

The local tumor produced by the inoculation of the cow-pox is commonly of a different appearance from that which is the conſequence of inoculation with variolous matter: for if the inoculation of the cow pox be performed by a ſimple puncture, the conſequent tumor, in the proportion of three times out of four, according to Dr Woodville, aſſumes a form completely circular, and it continues circumſcribed, with its edges elevated and well defined, and its ſurface flat, through every ſtage of the diſeaſe; while that which is produced from the variolous matter, either preſerves a peculiar form, or ſpreads along the ſkin, and becomes angulated, or irregular, or disfigured by numerous veſiculæ. Another diſtinction ſtill more deciſive and general, is to be drawn from the contents of the cow-pox tumor; for the fluid here formed very rarely becomes puriform; and the ſcab which ſucceeds is of a harder texture, exhibits a ſmoother ſurface, and differs in its colour from that which is formed by the concretion of pus. The appearances, however, are ſometimes ſo changed, that they can in no reſpect be diſtinguiſhed from thoſe which ariſe from the inoculation of ſmall-pox. We may alſo mention that the tendency of the ſore in the inoculated part to degenerate into a phagedenic ulcer does not occur in ſmall pox.

On the other hand, the points in which theſe two diſeaſes reſemble each other are very remarkable. When introduced into the body by inoculation, they affect the conſtitution in nearly the ſame length of time, and ſeem to be governed by nearly the ſame laws. They mutually deſtroy the ſuſceptibility of the body for the action of each other.

Dr Pearſon, who thinks the diſeaſes ought to be conſidered as diſtinct ſpecies, nevertheleſs draws the following concluſions, as eſtabliſhed by experience.

"That in certain conſtitutions, or under the circumſtances of certain co-operating agents, *the vaccine poiſon produces a diſeaſe reſembling the ſmall pox*; and of courſe the puſtule in the inoculated part is *very different from that of the vaccine pox ordinarily occurring*, and the eruptions *reſemble very much, if not exactly, ſome varieties of the ſmall-pox*: That in ſome inſtances theſe eruptions have occurred, although the inoculated part exhibited the genuine vaccine puſtule: That the matter of ſuch eruptive caſes, whether taken from the inoculated part, or from other parts, produces univerſally (A), or at leaſt generally, ſimilar eruptive caſes; and has not (he believes) been ſeen to go back, by paſſing through different conſtitutions, to the ſtate in which it produces what is called the *genuine vaccine diſeaſe*: That eruptions, of a different appearance from variolous ones, ſometimes occur in the true cow pox."

19 They are probably only varieties of the ſame diſeaſe.

From theſe facts we are ſtrongly inclined to think that the vaccine diſeaſe and the ſmall pox ought merely to be conſidered as varieties of the ſame diſeaſe; and we have little doubt that they both derive their origin from the ſame ſource.

If Dr Jenner's opinion, that the vaccine diſeaſe is derived from *the greaſe*, were fully eſtabliſhed, we ſhould be diſpoſed to offer a conjecture, that the *ſmall-pox*, in coming from the horſe to man, may have paſſed thro'

(A) We have ſeen that Dr Woodville's table contains a few exceptions to this rule, though it ſtrongly confirms the general truth of the propoſition.

ſome animal different from the cow, and may thus have undergone a modification ſimilar to, but not exactly, the ſame with what takes place in the paſſage of the virus through the conſtitution of the cow.

But without having recourſe to this conjecture, which is perfectly gratuitous, we are of opinion that the variations which have taken place in the cow pox within the laſt three years are ſufficient to warrant a belief, that the ſmall-pox may have originally been exactly the ſame diſeaſe, even in the human conſtitution, as the cow-pox is now; but that in a ſucceſſion of ages, and from the operation of cauſes wholly unknown to us, it may have been changed to what we now ſee it.

We ſhall now conclude this article with a few practical remarks, which we hope may be of uſe to practitioners who mean to begin the vaccine inoculation.

20
Practical remarks.

It is of the utmoſt conſequence that the matter employed ſhould be the genuine vaccine virus. Dr Jenner points out the following particulars as ſources of a ſpurious cow-pox: 1. That ariſing from puſtules on the nipples or udder of the cow, which puſtules contain no ſpecific virus. 2. From matter, although originally poſſeſſing the ſpecific virus, which has ſuffered a decompoſition, either from putrefaction, or any other cauſe leſs obvious to the ſenſes. 3. From matter taken from an ulcer in an advanced ſtage, though the ulcer aroſe from a true cow-pox. 4. From matter produced on the human ſkin from the contact of ſome peculiar morbid matter generated by a horſe.

Many have remarked that inoculation with the vaccine matter is more apt to fail in communicating the infection than with variolous matter, eſpecially if it be ſuffered to dry upon the lancet before it is uſed. This does not ſeem to depend upon the virus of the former being more volatile, but upon its becoming more hard and indiſſoluble upon exſiccation. Care ſhould therefore be taken to moiſten it a conſiderable time before it is uſed.

We have already noticed the danger that may ariſe from miſtaking the local effects of the vaccine diſeaſe for its effects upon the conſtitution. To guard practitioners againſt this error, Dr Woodville makes the following remarks: "When a conſiderable tumor and an extenſive redneſs take place at the inoculated part, within two or three days after the infectious matter has been applied, the failure of inoculation may be conſidered as certain as where neither redneſs nor tumor is the conſequence. This rapid and premature advancement of the inflammation will always be ſufficient to prevent the inoculator from miſtaking ſuch caſes for thoſe of efficient inoculation. But there are other circumſtances under which I have found the inoculation to be equally ineffectual, and which, as being more likely to deceive the inoculator, require his utmoſt circumſpection and diſcrimination. I here allude to caſes in which it happens that though the local affection does not exhibit much more inflammation than is uſual, yet neither veſicle nor puſtule ſupervenes; and in which, about the ſixth or ſeventh day, it rapidly advances into an irregular ſuppuration, producing a feſtering or cruſtaceous ſore. Care, however, ſhould be taken to diſtinguiſh this caſe from that in which the inoculated part aſſumes a puſtular form, though it continues for one or two days only, when the ſame appearances follow as thoſe above deſcribed; for I have experienced the latter inoculation to be as effectual as where the tumor has proceeded in the moſt regular manner."

"The efflореſcence at the inoculated part, which ſeldom intervenes before the eighth, or later than the eleventh, day, is to be regarded as an indication that the whole ſyſtem is affected; and if the patient has not felt any indiſpoſition on or before its approach, he may be aſſured that there will not be any afterwards. When effloreſcence does not commence till the eleventh day, it is almoſt always attended with more indiſpoſition than when it occurs on the eighth or ninth day. The effloreſcence is more frequent in young infants than in children advanced to three or four years of age; and the former have the effloreſcence and the diſeaſe more favourably than the latter, inſomuch that by far the greater part of them have no perceptible illneſs, and require no medicines. On the other hand, in adults, the cow-pox frequently produces headache, pain of the limbs, and other febrile ſymptoms, for two or three days, which are greatly relieved by a briſk purgative."

We would, upon the whole, recommend the vaccine inoculation to our medical readers as being an effectual preventative againſt the ſmall-pox, and ſafer to the individual, while it is more advantageous to the public at large, in being leſs capable of propagation by contagion.

VECTOR, or RADIUS VECTOR, in aſtronomy, is a line ſuppoſed to be drawn from any planet, moving round a centre, or the focus of an ellipſe, to that centre or focus. It is ſo called, becauſe it is that line by which the planet ſeems to be carried round its centre; and with which it deſcribes areas proportional to the times.

VEGETABLES. } See *Vegetable SUBSTANCES* in
VEGETATION. } this *Suppl.*

VENTILATION OF SHIPS is a matter of ſo great importance, that we would rather hazard the ſtating of an idle project for this purpoſe, than omit any thing which may be uſeful. We hazard nothing, however, in ſtating the following plan by Mr Abernethy, who candidly acknowledges that it is built upon the principles which we, together with the learned editor of Chambers's Cyclopædia, have borrowed from Dr Hailes. This plan conſiſts merely in cauſing two tubes to deſcend from above the deck to the bottom of a veſſel, or as low as ventilation is required; and which ſhould communicate by ſmaller pipes (open at their extremities) with thoſe places deſigned to be ventilated. There ſhould be a contrivance for ſtopping theſe communicating pipes, ſo that ventilation may be occaſionally prevented from taking place, or confined to any particular part of the veſſel.

One of the principal air tubes ſhould deſcend as near to the ſtern of the veſſel as convenient, and the other as near to the ſtem.

Through that tube which is in the head, the foul air is to be extracted; and through that which is in the ſtern, the freſh air is to deſcend to the different decks and other apartments of the veſſel.

The extraction of the air is eaſily effected in the following manner: Let a tranſverſe tube be fitted to that which deſcends in the head of the veſſel; it may be ſunk within the level of the deck, ſo as to cauſe no inequality of ſurface. Let it be continued till it comes beneath

neath the fire-place, then aſcend in a perpendicular direction through the fire, and open a little above it; or it may be made to communicate with the chimney. It would be more convenient if the fire was near the place where the tube riſes through the deck; but the experiment muſt equally ſucceed, if the tube be made to deſcend again till it is beneath the common fire-place. The effect that will reſult from this contrivance is obvious; when the tube which paſſes through the fire is heated, the air will aſcend with a force proportionable to its levity, and the aſcending column can only be ſupplied from below, conſequently it muſt come from all thoſe parts of the ſhip with which the main tube communicates.

When the ports are open, the quantity of air thus exhauſted from the ſhip will be ſupplied from all quarters; but if they were all ſhut, and the hatchways and other openings completely cloſed, the renewal of freſh air is made certain by means of the tube which deſcends in the ſtern. The main air tube, where it riſes above the deck in the ſtern, ſhould have an horizontal one fitted to it, which might be made to traverſe, ſo that it could be turned to windward; it might alſo expand at its extremity like the mouth of a trumpet; and thus perfectly freſh air muſt enter, and the force of the gale would tend to impel it into the veſſel.

When that part of the tube which paſſes through the fire is red hot, the draught which would be thus occaſioned might perhaps be too great, and the open pipes which communicate with the decks might emit and imbibe the freſh air in ſo direct a ſtream, that it might be injurious to thoſe perſons within the current.

Mr Abernethy therefore thinks it would be better if thoſe ſmaller pipes which lead from the main tubes were made to run along the decks, and communicate with them by numerous orifices. Two pipes opening into the main exhauſting tube might be extended along the tops of the deck, in the angle formed between the ſides and the cieling: and thus the air would be extracted equally from all parts, and in a manner not likely to occaſion injurious currents. Some diviſion of the ſtream of air which enters from the ſtern might alſo be made, if it were thought neceſſary.

Thus a very complete, and in no way injurious, ventilation may be obtained: the air in the veſſel would be perfectly changed when the fire was ſtrong, without expence or trouble; and a gradual and ſalubrious alteration of it might at all times be made, by a very little additional quantity of fuel. The air tubes ſhould conſiſt of ſeparate joints, ſo that occaſionally they might be taken to pieces; and to prevent their being injured or put out of order by rough uſage, the copper pipes ſhould be made of conſiderable ſtrength, placed againſt the ſides of the veſſel, and even incaſed in wood.

In the Letters and Papers of the Bath Society, &c. we have the following deſcription of a ventilator for preſerving corn on ſhip board, by Thomas South, Eſq;

Plate XLVII. Fig. 1. is a cylindrical air-veſſel, or forcing pump, of lead, tin, or other cheap metal; its internal diameter being ten inches, and its length three feet; having a crutch-handled piſton to work with, and an iron noſle, *viz.* a hollow inverted cone, two feet long, to condenſe the air, and increaſe its power in its paſſage downwards. This cylinder ſhould be rivetted or ſcrewed, by means of an iron collar or ſtraps, to the deck it paſſes through, both above and below, as at *a a*; and ſhould be farther ſecured by ſome holdfaſt near *b*, to keep it ſteady in working.

Fig. 2. is a bottom of wood, four inches and a half thick, with a projecting rim at its baſe, for the metal cylinder to reſt on when cemented and ſcrewed to the wood. The centre of this bottom is excavated, for the reception of the crown of the noſle. In the ſame figure the noſle is repreſented with its crown like a bowl diſh, to condenſe the air gradually, without reſiſtance, in its advance to the more contracted baſe of the inverted cone, *i. e.* the top or entrance of the noſle. About two-thirds down this noſle may be fixed a male ſcrew, as *c c*, for the purpoſe hereafter mentioned.

N. B. The forcing-pump ſhould be caſed in wood, to protect it from outward bruiſes, which would prevent the working of the piſton, and ruin its effects. The leather round the embolus ſhould be greaſed when uſed.

Fig. 3. is a crutch-handle, faſtened to the embolus A by its iron legs B, B. A is a cylinder of wood, caſed with leather, ſo as to fit well, but glide ſmoothly, in the metal cylinder; having an opening as large as its ſtrength will permit, for the free acceſs of atmoſpheric air. C is a valve well leathered on its top, and yielding downwards to the preſſure of the air when the piſton is raiſed up. D is a croſs bar of iron, to confine the valve, ſo that it may cloſe inſtantly on the return of the piſton downwards.

Fig. 4. is a tin pipe or tube, of leſs than four inches diameter, and of ſuch length as, when fixed to the baſe of the cylinder, fig. 1. ſhall admit the noſle *d*, fig. 2. to within half an inch of the valve E, at the bottom of the wooden cylinder F, in fig. 4; which valve E will then yield to the preſſure of air condenſed in its paſſage through the noſle, and deliver it into the pipes below. This valve muſt be well leathered on its upper ſurface, and faſtened with an hinge of leather to the cylinder it is meant to cloſe: affixed to its bottom is the ſpindle G, paſſing through a ſpiral ſpring H, which, being compreſſed on the deſcent of the valve, will, by its elaſticity, cauſe it to riſe again, cloſe the aperture above, and retain the air delivered beneath it. On connecting this cylinder with the upper end of the noſle, at *e e*, fig. 2. we muſt carefully prevent any lapſe of air that way, by a bandage of oakum ſmeared with wax, on which to ſcrew the cylinder, like the joints of a flute, air-tight. I is a bar of iron, having a riſing in its centre, wide enough for the ſpindle to play through, but at the ſame time ſufficiently contracted to prevent the paſſage of the ſpiral ſpring

Fig. 5. is an aſſemblage of tin pipes, of any lengths, ſhaped ſuitably and conveniently to their ſituation in the ſhip, to the form of which, when ſhut into one another, they muſt be adapted; obſerving only, that the neck be ſtraight for a length ſufficient to admit the lower end of the cylinder, fig. 4. as high as the letter F, or higher.

Fig. 6. To the middle pipe, which runs along the bottom, ſhould be fixed a perpendicular one, fully perforated, to convey the air more readily into the centre of the heap; and this may have a conical top, as repreſented in the Plate, perforated with a ſmaller punch to prevent the air from eſcaping too haſtily. In large cargoes, two or three of theſe perpendiculars may be

neceſſary; and each ſhould be well ſecured by an iron bar *g*, ſcrewed down to prevent their being injured by the ſhifting of the cargo in ſtormy weather or a rolling ſea. The top of the conical cap of theſe pipes may reach two-thirds up the cargo.

Fig. 7. is a valve of the ſame conſtruction as that repreſented in fig. 4. but incloſed in a tube of braſs, having a female ſcrew at *ff*, adapted to the male ſcrew *cc*, on the noſle fig 2. and may then be inſerted into the head of the pipe fig. 5. This will add to the expence; but in a large apparatus is to be preferred, as a more certain ſecurity from lapſe of air, than the junction of the tube fig. 4. to the neck *ee* in fig. 2.

N. B *ee* is a neck of wood, making a part of the bottom fig. 2. whereon to ſecure the tube fig. 4. when applied to the noſle. The joints of the pipes, when put together for uſe, ſhould be made air-tight, by means of bees wax or ſome ſtronger cement, till they reach the bottom of the veſſel, when there is no farther need of this precaution. The horizontal pipes ſhould run by the ſide of the kelſon the whole length of the hold. The tin plates of which K is made, ſhould be punched in holes, like the roſe of a watering pot, in two or three lines only at moſt, and then formed into a tube, with the rough ſide outwards. L may have four or five lines of the like perforations. M, and the reſt, ſhould gradually increaſe in their number as they advance towards the middle of the hold, and continue fully perforated to the laſt pipe which ſhould be cloſed at its end to prevent the ingreſs of the corn. It is the centre of the cargo which moſt requires ventilating, yet air ſhould pervade the whole. Like the trade-winds, it will direct its courſe to the part moſt heated, and, having effected its ſalutary purpoſe there, will diſperſe itſelf to refreſh the maſs.

Where the hatches are cloſe-caulked, to prevent the influx of water, vent-holes may be bored in convenient parts of the deck, to be bunged up, and opened occaſionally, from whence the ſtate of the corn may be known by the effluvia which aſcend when the ventilator is working.

The power of the ventilator is determined by the ſquare of its diameter multiplied into the length of the ſtroke, and that again by the number of ſtrokes in any given time.

The air-veſſel or forcing pump, with the reſt of the apparatus here deſcribed, is adapted to a veſſel of 120 tons burden; but by lengthening the air veſſel, extending its diameter to 14 inches, and adding 10 inches more to the length of the ſtroke, a power may be obtained of ventilating a cargo of 400 tons within the hour. If this machine be properly wrought for one hour every day, or even every two days, beginning the operations immediately when the corn is put on board, the cargo may be preſerved from taint or injury of every kind during the longeſt voyage.

VERDEN, a duchy of Germany, in the circle of Lower Saxony. It is bounded on the eaſt and ſouth by that of Lunenburg; on the weſt, by the Weſer and the duchy of Bremen; and on the north, by the duchies of Bremen and Lunenburg; extending both in length and breadth about 28 miles. It conſiſts chiefly of heaths and high dry lands; but there are good marſhes on the rivers Weſer and Aller. In 1712, the Danes wreſted this duchy from Sweden, and, in 1715, ceded it to the king of Great Britain, as elector of Hanover; which ceſſion, in 1718, was confirmed by the Swedes. The inhabitants are Lutherans.

VERDIGRIS, or ACETITE OF COPPER. See that article, *Encycl* where an account is given of the proceſs by which verdigris was long manufactured. A different, and more economical proceſs, however, has for ſome years been practiſed in Montpellier, which is worthy of notice, becauſe it may be adopted in this country by ſubſtituting the huſks of gooſeberries or currants for thoſe of grapes.

In the manufacture of verdigris, the materials are copper and the huſks of grapes after the laſt preſſing. The copper is formed into round plates, half a line in thickneſs, and from twenty to twenty five inches in diameter. Each plate, at Montpellier, is divided into twenty-five laminæ, forming almoſt all oblong ſquares of from four to ſix inches in length, three in breadth, and weighing about four ounces. They are beat ſeparately with the hammer on an anvil to ſmooth their ſurfaces, and to give the copper the neceſſary conſiſtence. Without this precaution it would exfoliate, and it would be more difficult to ſcrape the ſurface in order to detach the oxydated cruſt. Beſides this, ſcales of pure metal would be taken off, which would haſten the conſumption of the copper.

The huſks, which ſhould not be too much preſſed, are firſt made to ferment by being put into cloſe vats, and the fermentation is generally completed in three or four days The time, however, muſt vary according to the temperature in which they are kept, and other circumſtances. Whilſt the huſks are fermenting, a preliminary preparation is given to the copper plates. This conſiſts in diſſolving verdigris in water in an earthen veſſel, and rubbing over each plate with a piece of coarſe linen dipped in this ſolution. The plates are then immediately placed cloſe to each other, and left in that manner to dry. Sometimes the plates are only laid on the top of the fermented huſks, or placed under thoſe which have been already uſed for cauſing the copper to oxydate. It has been obſerved, that when this operation has not been employed, the plates grow black at the firſt operation, inſtead of becoming green. It is not, however, neceſſary to thoſe which have been once uſed, and are to be uſed again.

When the plates are thus prepared, and the huſks have been brought to ferment, the workmen try whether the latter are proper for the proceſs, by placing under them a plate of copper, and leaving it buried there for twenty-four hours. If the plate, after this period, is found covered with a ſmooth green cruſt, in ſuch a manner that none of the metal appears, they are then thought fit for being diſpoſed in layers with the copper. On the other hand, if drops of water are obſerved on the ſurface of the plates, the plates are ſaid to *ſweat*, and it is concluded that the heat of the huſks has not ſufficiently ſubſided. They conſequently defer making another trial till the next day. When they are aſſured that the huſks are in a proper ſtate, they form them into layers in the following manner:

The plates are all put into a box, which, inſtead of having a bottom, is divided in the middle by a wooden grate. The plates diſpoſed on this grate are ſo ſtrongly heated by a chaffing diſh placed under them, that the woman employed in this labour is ſometimes obliged

rdigris,
erdun.

to take them up with a cloth, in order that ſhe may not burn her hands. As ſoon as they have acquired that heat, they are put into jars in layers with the huſks. Each jar is then cloſed with a covering of ſtraw, and left to oxydate. Thirty or forty pounds of copper, more or leſs according to the thickneſs of the plates, are put into each jar. At the end of ten, twelve, fifteen, or twenty days, the jar is opened; and if the huſks are white, it is time to take out the plates. The cryſtals are then ſeen detached, and of a ſilky appearance on their ſurface. The huſks are thrown back, and the plates are put in what is called *relai*. For that purpoſe they are immediately depoſited in a corner of the cellar on ſticks ranged on the floor. They are placed in an upright poſition, one leaning againſt the other; and at the end of two or three days they are moiſtened, by taking them up in handfuls and immerſing them in water in earthen pans. They are depoſited quite wet in their former poſition, and left there for ſeven or eight days; after which they are once or twice immerſed again. This immerſion and drying are renewed ſix or eight times every ſeven or eight days. As the plates were formerly put into wine, theſe immerſions were called *one wine*, *two wines*, *three wines*, according to the number of times. By this proceſs the plates ſwell up, the green is nouriſhed, and a coat of verdigris is formed on all their ſurfaces, which may be eaſily detached by ſcraping them with a knife.

This verdigris, which is called *freſh* verdigris, *moiſt* verdigris, is ſold by the manufacturers to people who dry it for foreign exportation. In this firſt ſtate it is only a paſte, which is carefully pounded in large wooden troughs, and then put into bags of white leather, a foot in height and ten inches in diameter. Theſe bags are expoſed to the air or the ſun, and are left in that ſtate till the verdigris has acquired the proper degree of dryneſs. By this operation it decreaſes about 50 *per cent.* more or leſs according to its primitive ſtate. It is ſaid to ſtand proof by the knife, when the point of that inſtrument puſhed againſt a cake of verdigris through the ſkin cannot penetrate it. White lead may be made by a ſimilar proceſs.

Cryſtallized VERDIGRIS is manufactured at Montpellier in the following manner: A vinegar, prepared by the diſtillation of ſour wine, is put into a kettle, and boiled on the common verdigris. After ſaturation the ſolution is left to clarify, and then poured into another kettle of copper, where it is evaporated till a pellicle forms on the ſurface. Sticks are then immerſed into it, and by means of ſome packthread are tied to ſome wooden bars that reſt on the edge of the kettle. Theſe ſticks are about a foot long, and are ſplit croſs-wiſe nearly two inches at the end, ſo that they open into four branches, kept at about the diſtance of an inch from each other by ſmall bags. The cryſtals adhere to theſe ſticks and cover them entirely, forming themſelves into groups or cluſters, of a dark blue colour, and a rhomboidal ſhape. Each cluſter weighs from five to ſix pounds. Three pounds of moiſt verdigris are required for one pound of the cryſtals; the undiſſolved reſiduum is thrown away.

VERDUN, an ancient, ſtrong, and conſiderable town of France, in the department of Meuſe, and late province of Lorrain, with a biſhop's ſee, and a ſtrong citadel. Its fortifications were conſtructed by the Chevalier de Ville and Marſhal de Vauban. The latter was a native of this place. In 1755, great part of the cathedral was deſtroyed by lightning. Verdun was taken by the Pruſſians in 1792, but retaken by the French ſoon after. The inhabitants are noted for the fine ſweetmeats they make. It is ſeated on the river Maeſe. which runs through the middle, 42 miles ſouth-weſt of Luxemburg, and 150 eaſt of Paris. E. Lon. 5° 28' N. lat. 43° 9'.

Vermifuge.

VERMIFUGE, a medicine which expels worms from the inteſtines. Of theſe medicines numbers are daily advertiſed in the newſpapers as infallible, though the ingredients of which they are compoſed are carefully kept ſecret. We think it our duty therefore to aſſure our readers, that the medicines vended by quacks are generally the very ſame that would be preſcribed by a regular phyſician for the diſeaſe in which they are pretended to be ſpecifics, with this only difference, that the unſeen and unprincipled quack generally preſcribes them in more powerful doſes than the regular phyſician deems ſafe for his patient. Thus Ching's famous worm medicine, which has been ſo ſtrenuouſly recommended, is nothing more than mercury given in the very ſame form in which it is given by every phyſician; but Ching gives it in doſes, which, though they have not injured the children of a biſhop and a judge, we have *known* to *ſalivate* other children to the great hazard of their lives. It is indeed wonderful that parents ſhould truſt the health and the lives of their children to men whom they never ſaw, and whom they know to be not oppreſſed with an over delicate ſenſe of honour, in preference to a man of ſcience who has a character to ſupport, and who is probably their friend, and almoſt always their acquaintance.

Of the different vermifuges, however, it muſt be confeſſed that the greater number are liable occaſionally to fail. One of the moſt powerful which we have mentioned in the article MEDICINE, *Encycl.* is compoſed of the ſpiculæ of the *cowhage* or *cow-itch*; and ſince that article was publiſhed, it has come more into uſe, chiefly through the recommendation of Mr Chamberlaine ſurgeon. He ſays that a tea-ſpoonful of the electuary (See MEDICINE, *Encycl.* p. 342.) may be ſafely given to a young child, and one or even two table ſpoonfuls to adults. The medicine is to be taken in the morning faſting; and the doſe to be repeated for two or three mornings, after which a gentle purge completes the cure. This medicine, however, Mr Chamberlaine prohibits in every caſe where there is a tendency to inflammation in any part of the inteſtinal canal, or where the mucus has been carried off or greatly diminiſhed by dyſentery or any other cauſe.

Dr Haemmerlin of Ulm has lately recommended as a very powerful and ſafe vermifuge the coraline of Corſica, and ſays that it has been ſo uſed in that iſland with complete ſucceſs from time immemorial. It is a fucus adhering to the rocks waſhed by the ſea, and ſometimes to the ſtones and ſhells thrown upon the ſhore. It is found in little tufts. It is generally of a yellow colour, with a reddiſh tincture. When dried, as it appears when offered for ſale, it contains a ſtrong ſmell of the ſea. It conſiſts of little cartilaginous ſtalks, with full threads, gradually cylindrical and tubulated. Its taſte is ſalt and unpleaſant. In the ſyſtem of plants of Linnæus, it belongs to the claſs *cryptogamia*. Its moſt com-

Vermont, Veſpa

mon names are, ſea rock moſs; the Grecian herb; lemithochorton; and the coraline of Corſica. It is the *conferva helminthortos* of Schwendimann, and the *fucus helminthocorton* of Latourette. There is reaſon to think that all thoſe ſpecies of fucus whoſe texture is ſoft and ſpungy, might be applied to the ſame medicinal uſes. There is a ſort of red coraline found in Sweden which, according to ſome writers, is a greater deſtroyer of worms than any other known ſubſtance; being not too ſtrong for the ſtomach either of infants or of adults. Schwendimann aſſerts that the *conferva dichotoma* of Linnæus, which is found in the ditches in England, bears a ſtrong analogy to the coraline of Corſica. Might not this conferva be tried as a vermifuge? The Corſican coraline is in great eſtimation in the pharmacopœias of the Continent, eſpecially in that of Geneva, in which is given a recipe for preparing a ſyrup of it.

VERMONT, one of the United States of North America, bounded on the north by Canada; on the eaſt, by the river Connecticut, which divides it from New Hampſhire; on the ſouth, by Maſſachuſſets; and on the weſt by New York. It is about 155 miles long, and 60 broad, and is divided into 7 counties. A chain of high mountains, running north and ſouth, divides this ſtate nearly in the centre, between the river Connecticut and lake Champlain. The height of land is generally from 20 to 30 miles from the river, and about the ſame diſtance from the New York line. The natural growth upon this mountain is hemlock, pine, ſpruce, and other evergreens: hence it has always a green appearance, and, on this account, has obtained the deſcriptive name of Vermont, from the French *Verd Mont*, Green Mountain. On ſome high parts of this mountain, ſnow lies till May, and ſometimes till July. The country is generally hilly, but not rocky. It is finely watered, the ſoil is very fertile, and there is not a better climate in the world. The inhabitants have very lately been eſtimated at 100,000. The bulk of them are emigrants from Connecticut and Maſſachuſets. The principal town is Bennington, but the aſſembly generally hold their ſeſſions at Windſor.

VESPA (See *Encycl.*). A new ſpecies of this genus of inſects has been lately deſcribed by *Cuvier*, in a note read before the Philomathic Society of Paris. It has ſome reſemblance to the *veſpa nidulans* of Fabricius, which, as is generally known, is a native of certain parts of America. The neſts of the veſpa nidulans are conſtructed of a very fine web, of a very ſolid and pretty white paſte. Their form is that of a bell cloſed upon all ſides, excepting a narrow hole at the bottom; and they are ſuſpended from the branches of trees.

The *veſpa* deſcribed by Cuvier, which is a native of Cayenne in America, has in general more volume than the preceding ſpecies, and its paſte is grey, coarſer, leſs homogeneous, and leſs ſolid. The bottom of its neſt alſo, in lieu of being ſhaped funnel-like, is flat, and the orifice appears at one of the ſides of the bottom part, and not in the middle. In the country where it is found, this ſpecies of waſp is called the *tatou fly* (*mouche tatou*). It differs greatly in form from that which Fabricius has deſcribed; it is all entirely of a ſhining black; the firſt articulation, or joint of its abdomen, is narrow, and in form of a pear; the ſecond, larger than the others, is in form of a bell: the wings are brown. The following is the character aſſigned to it by Cuvier:

Veſpatatua, Nigra, Nitida, Alis fuſcis, abdomine pedicellato.

Veſpertilio.

VESPERTILIO (ſee *Encycl.*) has been ſubjected to ſome cruel, but curious experiments, by the Abbé Spallanzani and M. de Jurine. The former of theſe philoſophers having let looſe ſeveral bats in a chamber perfectly dark, found that they flew about in it without any impediment, neither ruſhing againſt any thing in the apartment, nor touching the walls with their wings. This ſurpriſed him; but imagining that they were conducted by ſome glimpſe of light which he did not perceive, he blindfolded them with a ſmall and very cloſe hood. They then ceaſed to fly; but he obſerved, at the ſame time, that this did not proceed from any deprivation of light, but rather from the conſtraint thence occaſioned, eſpecially when a hood of a very light texture was attended with the ſame effect.

He then conceived the idea of paſting up the eyes of the bats with a few drops of ſize or gum; but they ſtill flew about in the ſame manner as if their eyes had been open. As this, however, was not ſufficient, he paſted up the eyes of theſe animals with round bits of leather; and this even did not impede them in their flight.

That he might at length be certain of his object, he blinded them entirely, either by burning the cornea with a red hot wire, or by pulling out the pupil with a pair of ſmall pincers, and ſcooping out the eye entirely. Not contented even with this precaution, he covered the wounds with pieces of leather, that the light might have no influence whatever on the remains of the organs which had been deſtroyed. The animals ſeemed to ſuffer very much by this cruel operation; but when they were compelled to uſe their wings, either by day or by night, and even in an apartment totally dark, they flew perfectly well, and with great caution, towards the walls, in order to ſuſpend themſelves when they wiſhed to reſt. They avoided every impediment, great or ſmall, and flew from one apartment to another, backwards and forwards, through the door by which they were connected, without touching the frame with their wings. In a word, they ſhewed themſelves as bold and lively in their flight as any other animals of the ſame ſpecies which enjoy the uſe of their eye-ſight.

Theſe experiments were repeated by M. Jurine, and with the ſame reſults. Spallanzani had ſuppoſed that the bat poſſeſſed ſome organ or ſenſe which is wanting in the human ſpecies, and which ſupplies to theſe animals the place of viſion; and Jurine determined to aſcertain the truth or falſehood of this hypotheſis by anatomical reſearches. During the courſe of theſe, he found the organ of hearing very great in proportion to that of other animals, and a conſiderable nervous apparatus aſſigned to that part. The upper jaw alſo is furniſhed with very large nerves, which are expanded in a tiſſue on the muzzle.

M. Jurine then extended his experiments to the organ of hearing and that of ſmell. Having put a ſmall hood on a long-eared bat, it immediately pulled it off, and flew. He ſtopped up its ears with cotton; but it freed itſelf in the like manner from that inconvenience. He then put into its ears a maſtic of turpentine and wax. During the operation the animal ſhewed a great deal of impatience, and flew afterwards very imperfectly.

A long-eared bat, the ears of which had been bound up, flew very badly: but this did not ariſe from any pain

ertilio
bration
gures.

pain occaſioned by the ligature; for when its ears were ſewed up, it flew exceedingly well. In all probability the animal would have preferred having its ears bound up to having them ſewed. Sometimes it flew towards the cieling, extending its muzzle before it ſettled.

M. Jurine poured liquid pomatum into the ears of a bat which enjoyed the uſe of its ſight. It appeared to be much affected by this operation; but when the ſubſtance was removed it took flight. Its ears were again filled, and its eyes were taken out; but it flew then only in an irregular manner, without any certain or fixed direction.

The ears of a horſe ſhoe bat, which had the uſe of its ſight, were filled with tinder mixed with water. It was uneaſy under the operation, and appeared afterwards reſtleſs and ſtunned; but it conducted itſelf tolerably well. On being blinded, it ruſhed with its head againſt the cieling, and made the air reſound with ſtrokes which it gave itſelf on the muzzle. This experiment was repeated on other bats with the like effect.

The tympanum of a large horſe-ſhoe bat was pierced with a pin (*trois quart*). The animal appeared to ſuffer much from the operation, and fell down in a perpendicular direction when thrown into the air. It died next morning. The ſame effect was produced on piercing the tympanum of a long-eared bat with a needle.

The author then made very accurate reſearches on the difference between the organiſation of the brain of theſe two kinds of bats; and, after a careful diſſection, found that the eye of the long eared bat is much larger than that of the horſe ſhoe bat, but that the optic nerve is proportioned to it. The outer part of the ear of the former is much larger than that of the latter, but the interior part is ſmaller.

The horſe ſhoe bat is indemnified for this difference by a greater extenſion of the organ of ſmell, as evidently appears when the external elevations and irregularities of its muzzle are examined. When it is about to take flight, it agitates its noſe much more than the long-eared bat.

From theſe experiments, the author concludes: *Firſt*, That the eyes of the bat are not indiſpenſably neceſſary to it for finding its way; *ſecondly*, That the organ of hearing appears to ſupply that of ſight in the diſcovery of bodies, and to furniſh theſe animals with different ſenſations to direct their flight, and enable them to avoid thoſe obſtacles which may preſent themſelves.

VIBRATION Figures, are certain figures, formed by ſand or very dry ſaw duſt, on a vibrating ſurface, which is connected with the ſenſation of ſound in our organs of hearing. If the ſurface, on which the figures are to be formed, be ſtrewed over with bodies eaſily put in motion, theſe, during the vibration, remain on the parts at reſt, and are thrown from the parts in motion. The form of the parts at reſt, which will be ſhewn by the ſand that remains unmoved, and which, in general, is ſymmetric, is called a *vibration figure*. To produce ſuch a figure, nothing is neceſſary but to know the method of bringing that part of the ſurface which you wiſh not to vibrate into a ſtate of reſt, and of putting in motion that which you wiſh to vibrate. On this depends the whole expertneſs of producing vibration figures

Vibration
Figures,
Vieta

Thus take a ſquare piece of glaſs, pretty thin, and very ſmooth, ſuch as that uſed for windows, about four or five inches over, or even more. Smooth it at the edges on a grinding-ſtone; ſtrew a little ſaw-duſt over its ſurface, and lay hold of it gently with the thumb and fore-finger of the left hand. Holding it thus by the middle, with the right hand rub a violin bow ſoftly againſt one of its edges, drawing the bow either up or down in a direction almoſt perpendicular to the ſurface of the glaſs, and you will ſee a tremulous movement, and the whole duſt leap about. If the bow be exactly in the middle of one of the ſides, the duſt will arrange itſelf almoſt in the direction of the two diagonals, dividing the ſquare into four iſoſceles triangles. If the bow be applied at a quarter only of the diſtance of the one corner from the other, the duſt will arrange itſelf in ſuch a manner as to be found in the two diameters of the ſquare, dividing it into four equal ſquares. At other times, when the bow deviates a little, the duſt forms a figure like a double C, when the two letters are joined back to back. If the ſquare be held by the two extremities of the diameter, oppoſite to that againſt which the bow is applied, the duſt will form a kind of oval, one of the axes of which will be the ſame diameter. If the glaſs be of a circular figure, and be held by the middle, the duſt will arrange itſelf in ſuch a manner as to form the ſix radii of a regular hexagon. Theſe diſcoveries were made by Dr Chladni, about the time that he invented the muſical inſtrument, to which he gave the name of Euphon (ſee that article, *Suppl.*); and as he found the vibration figures to vary in form with the various tones produced by the vibrating ſubſtances, a proſecution of his experiments may probably contribute to throw new light on the philoſophy of muſical ſounds. We ſhall therefore give, from the 3d volume of *Neues Journal der Phyſik*, by Profeſſor Gren, a few directions for making ſuch experiments.

Any ſort of glaſs may be employed, provided its ſurface be ſmooth; and when the plate has acquired the proper vibration, it ſhould be kept in that ſtate for ſome ſeconds, by continuing to rub it with the bow. The figures will thus be accurately formed.

Such plates ſhould be procured as are pretty equal in thickneſs. It may be ſaid, in general, that a plate the thinner it is will be ſo much the fitter for theſe experiments, though in this reſpect there is a certain minimum. In ſmall plates, ſuch as thoſe that are circular, and not above ſix inches in diameter, the obſervation is general; but in larger plates too great thinneſs is prejudicial. Beſides, it will be found that very thin glaſs is commonly very uneven, and muſt therefore be unfit for the experiments.

In practiſing the experiments, it will be proper to have plates of different ſizes; and the ſand employed ſhould not be too fine. In other words, it muſt be of ſuch a nature that when you incline the glaſs-plate it may readily roll off; becauſe, in that caſe, it will be eaſily thrown from the vibrating parts. It will be of advantage that it be mixed with fine duſt, which ſhews peculiar phenomena during the experiments, as it collects itſelf at one place of the vibrating part.

The plate muſt be equally beſtrewed with ſand, and not too thick, as the lines will then be exceedingly fine, and the figures will acquire a better defined appearance.

VIETA (Francis), a very celebrated French mathematician, was born in 1540 at Fontenai, or Fontenai le-Comté, in Lower Poitou, a province of France. He

Hutton's Mathematical Dictionary.

He was Maſter of requeſts at Paris, where he died in 1603, being the 63d year of his age. Among other branches of learning in which he excelled, he was one of the moſt reſpectable mathematicians of the 16th century, or indeed of any age. His writings abound with marks of great originality, and the fineſt genius, as well as intenſe application. His application was ſuch, that he has ſometimes remained in his ſtudy for three days together without eating or ſleeping. His inventions and improvements in all parts of the mathematics were very conſiderable. He was in a manner the inventor and introducer of Specious Algebra, in which letters are uſed inſtead of numbers, as well as of many beautiful theorems in that ſcience. He made alſo conſiderable improvements in geometry and trigonometry. His angular ſections are a very ingenious and maſterly performance: by theſe he was enabled to reſolve the probem of Adrian Romanus, propoſed to all mathematicians, amounting to an equation of the 45th degree. Romanus was ſo ſtruck with his ſagacity, that he immediately quitted his reſidence of Wirtzbourg in Franconia, and came to France to viſit him, and ſolicit his friendſhip. His Apollonius Gallus, being a reſtoration of Apollonius's tract on Tangencies, and many other geometrical pieces to be found in his works, ſhew the fineſt taſte and genius for true geometrical ſpeculations.—He gave ſome maſterly tracts on Trigonometry, both plane and ſpherical, which may be found in the collection of his works, publiſhed at Leyden in 1646, by Schooten, beſides another large and ſeparate volume in folio, publiſhed in the author's life-time, at Paris, in 1579, containing extenſive trigonometrical tables, with the conſtruction and uſe of the ſame, which are particularly deſcribed in the introduction to Dr Hutton's Logarithms, p. 4. &c. To this complete treatiſe on trigonometry, plane and ſpherical, are ſubjoined ſeveral miſcellaneous problems and obſervations; ſuch as, the quadrature of the circle, the duplication of the cube, &c. Computations are here given of the ratio of the diameter of a circle to the circumference, and of the length of the ſine of 1 minute, both to a great many places of figures; by which he found that the ſine of 1 minute is

between 2908881959
and 2908882056;

alſo the diameter of a circle being 1000, &c. that the perimeter of the inſcribed and circumſcribed polygon of 393216 ſides will be as follows, viz. the

perim. of the inſcribed polygon - 31415926535
perim. of the circumſcribed polygon 31415926537

and that therefore the circumference of the circle lies between thoſe two numbers.

Vieta having obſerved that there were many faults in the Gregorian Kalendar, as it then exiſted, compoſed a new form of it, to which he added perpetual canons, and an explication of it, with remarks and objections againſt Clavius, whom he accuſed of having deformed the true Lelian reformation, by not rightly underſtanding it.

Beſides theſe, it ſeems a work, greatly eſteemed, and the loſs of which cannot be ſufficiently deplored, was his *Harmonicon Cœleſte*, which, being communicated to father Merſenne, was, by ſome perfidious acquaintance of that honeſt minded perſon, ſurreptitiouſly taken from him and irrecoverably loſt, or ſuppreſſed, to the great detriment of the learned world. There were alſo, it is ſaid, other works of an aſtronomical kind, that have been buried in the ruins of time.

Vieta was alſo a profound decipherer, an accompliſhment that proved very uſeful to his country. As the different parts of the Spaniſh monarchy lay very diſtant from one another, when they had occaſion to communicate any ſecret deſigns, they wrote them in ciphers and unknown characters during the diſorders of the league. The cipher was compoſed of more than 500 different characters, which yielded their hidden contents to the penetrating genius of Vieta alone. His ſkill ſo diſconcerted the Spaniſh councils for two years, that they publiſhed it at Rome, and other parts of Europe, that the French king had only diſcovered their ciphers by means of magic.

VINTAIN, a town, ſituated about two miles up a creek on the ſouthern ſide of the river Gambia. It is much reſorted to by Europeans, on account of the great quantities of bees-wax which are brought hither for ſale. The wax is collected in the woods by the Feloops, a wild and unſociable race of people. Their country, which is of conſiderable extent, abounds in rice; and the natives ſupply the traders, both on the Gambia and Caſſamanſa rivers, with that article, and alſo with goats and poultry, on very reaſonable terms. The honey which they collect is chiefly uſed by themſelves in making a ſtrong intoxicating liquor, much the ſame as the mead which is produced from honey in Great Britain.

In their traffic with Europeans, the Feloops generally employ a factor, or agent, of the Mandingo nation, who ſpeaks a little Engliſh, and is acquainted with the trade of the river. This broker makes the bargain; and, with the connivance of the European, receives a certain part only of the payment; which he gives to his employer as the whole; the remainder (which is very truly called the *cheating money*) he receives when the Feloop is gone, and appropriates to himſelf as a reward for his trouble. Vintain, according to Mr Park, from whoſe valuable travels this account of the Feloops is taken, is ſituated in 13° 9′ North Lat. and 15° 56′ Long. Weſt from Greenwich.

VIRGINITY, the teſt or criterion of a virgin; or that which intitles her to the denomination. See HYMEN, *Encycl.*

VISION. In the article OPTICS, n° 154. (*Encycl.*), it is ſaid, that as we have a power of contracting or relaxing the *ligamenta ciliaria*, and thereby altering the form of the cryſtalline humour of the eye, we hence ſee objects diſtinctly at different diſtances. It appears, however, from ſome experiments made by Mr Everard Home and Mr Ramſden, in the year 1794, that this power of contracting and relaxing the ligamenta ciliaria is not alone ſufficient to account for the phenomenon. Converſing with Mr Home on the different uſes of the chryſtalline humour, Mr Ramſden ſaid, that as that humour "conſiſts of a ſubſtance of different denſities, the central parts being the moſt compact, and from thence diminiſhing in denſity gradually in every direction, approaching the vitreous humour on one ſide, and the aqueous humour on the other, its refractive power becomes nearly the ſame with that of the two contiguous ſubſtances That ſome philoſophers have ſtated the uſe of the cryſtalline humour to be, for accommodating

commodating the eye to ſee objects at different diſtances; but the firmneſs of the central part, and the very ſmall difference between its refractive power near the circumference and that of the vitreous or the aqueous humour, ſeemed to render it unfit for that purpoſe; its principal uſe rather appearing to be for correcting the aberration ariſing from the ſpherical figure of the cornea, where the principal part of the refraction takes place, producing the ſame effect that, in an achromatic object-glaſs, we obtain in a leſs perfect manner by proportioning the radii of curvature of the different lenſes. In the eye the correction ſeems perfect, which in the object-glaſs can only be an approximation; the contrary aberrations of the lenſes not having the ſame ratio: ſo that, if this aberration be perfectly corrected, at any given diſtance from the centre, in every other it muſt be in ſome degree imperfect.

"Purſuing the ſame compariſon: In the achromatic object glaſs we may conceive how much an object muſt appear fainter from the great quantity of light loſt by reflection at the ſurfaces of the different lenſes, there being as many primary reflections as there are ſurfaces; and it would be fortunate if this reflected light was totally loſt. Part of it is again reflected towards the eye by the interior ſurfaces of the lenſes: which, by diluting the image formed in the focus of the object-glaſs, makes that image appear far leſs bright than it would otherwiſe have done, producing that milky appearance ſo often complained of in viewing lucid objects through this ſort of teleſcope.

"In the eye, the ſame properties that obviate this defect, ſerve alſo to correct the errors from the ſpherical figure, by a regular diminution of denſity, from the centre of the cryſtalline outward. Every appearance ſhews the cryſtalline to conſiſt of laminæ of different denſities; and if we examine the junction of different media, having a very ſmall difference of refraction, we ſhall find that we may have a ſenſible refraction without reflection. Now, if the difference between the contiguous media in the eye, or the laminæ in the cryſtalline, be very ſmall, we ſhall have refraction without having reflection: and this appears to be the ſtate of the eye; for although we have two ſurfaces of the aqueous, two of the cryſtalline, and two of the vitreous humour, yet we have only one reflected image; and that being from the anterior ſurface of the cornea, there can be no ſurface to reflect it back, and dilute an image on the retina.

"This hypotheſis may be put to the teſt whenever accident ſhall furniſh us with a ſubject having the cryſtalline extracted from one eye, the other remaining perfect in its natural ſtate; at the ſame time we may aſcertain whether or no the cryſtalline is that part of the organ which ſerves for viewing objects at different diſtances diſtinctly. Seeing no reflection at the ſurface of the cryſtalline, might lead ſome perſons to infer that its refractive power is very inconſiderable; but many circumſtances ſhew the contrary: yet what it really is may be readily aſcertained by having the focal length and diſtance of a lens from the operated eye, that enables it to ſee objects the moſt diſtinctly; alſo the focal length of a lens, and its diſtance from the perfect eye, that enables it to ſee objects at the ſame diſtance as the imperfect eye: theſe data will be ſufficient whereby to calculate the refractive power of the cryſtalline with conſiderable preciſion.

"Again, having the ſpherical aberration of the different humours of the eye, and having aſcertained the refractive power of the cryſtalline, we have data from whence to determine the proportional increaſe of its denſity as it approaches the central part, on a ſuppoſition that this property corrects the aberration.

"An opportunity preſented itſelf for bringing the obſervations of Mr Ramſden, reſpecting the uſe of the cryſtalline lens, to the proof. A young man came into St George's Hoſpital with a cataract in the right eye. The cryſtalline lens was readily extracted, and the union of the wound in the cornea took place unattended by inflammation; ſo that the eye ſuffered the ſmalleſt degree of injury that can attend ſo ſevere an operation. The man himſelf was in health, 21 years of age, intelligent, and his left eye perfect: the other had been an uncommonly ſhort time in a diſeaſed ſtate, and 27 days after the operation appeared to be free from every other defect but the loſs of the cryſtalline lens.

"A number of experiments were made on the imperfect eye, aſſiſted by a lens, and compared with the perfect eye. The aim of theſe trials, which were judiciouſly varied, was to aſcertain whether the eye which had been deprived of the cryſtalline lens was capable of adjuſting itſelf to diſtinct viſion at different diſtances. Among other reſults, the perfect eye, with a glaſs of $6\frac{1}{2}$ inches focus, had diſtinct viſion at 3 inches; the near limit was $1\frac{7}{8}$ inch, the diſtant limit leſs than 7 inches. The imperfect eye, with a glaſs $2\frac{2}{10}$ inches focus, with an aperture $\frac{3}{15}$ths of an inch, had diſtinct viſion at $2\frac{7}{8}$ inches, the near limit $1\frac{7}{8}$ inch, and the diſtant limit 7 inches. The accuracy with which the eye was brought to the ſame point, on repeating the experiment, proved it to be uncommonly correct; and as he did not himſelf ſee the ſcale uſed for admeaſurement, there could be no ſource of fallacy. From the reſult of this experiment, it appears that the range of adjuſtment of the imperfect eye, when the two eyes were made to ſee at nearly the ſame focal diſtance, exceeded that of the perfect eye. Mr Ramſden ſuggeſted a reaſon why the point of diſtinct viſion of the imperfect eye might appear to the man himſelf nearer than it was in reality; namely, that from the imperfection of this organ he might find it eaſier to read the letters when they ſubtended a greater angle than at his real point of diſtinct viſion. The experiments, however, appear to ſhew that the internal power of the eye, by which it is adjuſted to ſee at different diſtances, does not reſide in the cryſtalline lens, at leaſt not altogether; and that if any agency in this reſpect can be proved to reſide in the cryſtalline, the other powers, whatever they may be, are capable of exertion beyond their uſual limits, ſo as to perform its office in this reſpect.

"From theſe conſiderations, and in conſequence of other reflections tending to ſhew that an elongation of the optical axis is not probably the means of adjuſtment, theſe philoſophers directed their enquiries to aſcertain how far the curvature of the cornea might be ſubject to change. They found by trial that this part of the organ poſſeſſes a degree of elaſticity which is very conſiderable, both for its perfection and its range; and by anatomical diſſection it was found that the four ſtraight muſcles of the eye do in effect terminate in the cornea at their tendinous extremities: that the whole external lamina of the cornea could by gentle force be ſeparated, by means of theſe muſcles, from the eye; ſo that the tendons ſeem loſt in the cornea, and this laſt has the appearance of a central tendon. It was alſo ſeen that the central part of the cornea is the thickeſt and the moſt elaſtic.

"Theſe were conſiderable advances towards eſtabliſhing the hypotheſis of adjuſtment by the external curve of the eye. It remained to be ſhewn, by experiments on the living ſubject, that this curve does really vary in the due direction, when the mind perceives the diſtinct viſible ſenſation of objects at different diſtances. For this purpoſe Mr Ramſden provided an apparatus, conſiſting of a thick board ſteadily fixed, in which was a ſquare hole large enough to admit a perſon's face; the forehead and chin reſting againſt the upper and lower bars, and the cheek againſt either of the ſides; ſo that when the face was protruded, the head was ſteadily fixed by reſting on three ſides; and in this poſition the left eye projected beyond the outer ſurface of the board. A microſcope, properly mounted, ſo as with eaſe to be ſet in every requiſite poſition, was applied to view the cornea with a magnifying power of thirty times. In this ſituation, the perſon whoſe eye was the object of experiment was deſired to look at the corner of a chimney, at the diſtance of 235 yards, through a ſmall hole in a braſs plate, fixed for that purpoſe, and afterwards to look at the edge of the hole itſelf, which was only ſix inches diſtant. After ſome management and caution, which the delicate nature of theſe experiments requires, the motion of the cornea, which was immediately perceptible, became very diſtinct and certain. The circular ſection of its ſurface remained in a line with the wire in the field of the microſcope, when the eye was adjuſted to the diſtant object, but projected conſiderably beyond it when adapted to the near one. When the diſtant object was only 90 feet from the obſerver, and the near object ſix inches, the difference in the prominence of the cornea was eſtimated at 1 800th of an inch. Theſe experiments were repeated and varied at different times and on different ſubjects. The obſerver at the microſcope found no difficulty in determining, from the appearance of the cornea, whether the eye was fixed on the remote or the near object.

"From theſe different experiments Mr Home conſiders the following facts to have been aſcertained:

"1 That the eye has a power of adjuſting itſelf to different diſtances when deprived of the cryſtalline lens; and therefore the fibrous and laminated ſtructure of that lens is not intended to alter its form, but to prevent reflections in the paſſage of the rays through the ſurfaces of media of different denſities, and to correct ſpherical aberration.

"2 That the cornea is made up of laminæ; that it is elaſtic, and when ſtretched is capable of being elongated 1 11th part of its diameter, contracting to its former length immediately upon being left to itſelf

"3. That the tendons of the four ſtraight muſcles of the eye are continued on to the edge of the cornea, and terminate, or are inſerted, in its external laminæ: their action will therefore extend to the edge of the cornea.

"4. That in changing the focus of the eye from ſeeing with parallel rays to a near diſtance, there is a viſible alteration produced in the figure of the cornea, rendering it more convex; and when the eye is again adapted to parallel rays, the alteration by which the cornea is brought back to its former ſtate is equally viſible."

Mr Home made many other experiments with a view to throw light upon this curious ſubject; and the reſult of the whole appears to be, that the adjuſtment of the eye is produced by three different changes in that organ; an increaſe of curvature in the cornea, an elongation of the axis of viſion, and a motion of the cryſtalline lens. Theſe changes, in a great meaſure, depend upon the contraction of the four ſtraight muſcles of the eye. Mr Ramſden, from computations grounded on the principles of optics and general ſtate of the facts, eſtimates that the increaſe of curvature of the cornea may be capable of producing one-third of the effect, and that the change of place of the lens, and elongation of the axis of viſion, ſufficiently account for the other two thirds of the quantity of adjuſtment neceſſary to make up the whole.

VITALITY, the power of ſubſiſting in life, which the faſhionable philoſophers of the French and German ſchools attribute to *chemiſtry*. For a confutation of their abſurd and impious jargon on this ſubject, we refer our readers, with ſome degree of confidence, to the articles PHYSIOLOGY (*Encycl.*), and *Animal* SUBSTANCES (*Suppl.*)

VIVERRA (ſee *Encycl.*) A new ſpecies of this genus of animals was diſcovered by Vaillant during his laſt travels in Africa; at leaſt he ranks under the generic name *Viverra*, the animal of which he gives the following deſcription Its body was of the ſize of that of a kitten ſix months old: it had a very large noſe, the upper jaw exceeding the lower near two-thirds of an inch in length, and forming a ſort of moveable ſnout reſembling that of the *coati* of Guiana. The fore feet were armed with four large claws, very ſharp and curved; the hind ones have each five, but they are ſhort and blunt. All the fur on the upper part of the body is marked with croſs bands of a deep brown colour, on a ground of light brown with which many white hairs are intermixed. The lower part of the body and inſides of the legs are of a reddiſh white. The tail, which is very fleſhy, and more than two thirds longer than the body, is black at the tip, and the reſt brown, intermixed with white hairs

This animal employs its fore paws to dig very deep holes in the earth, in which it remains concealed during the day, not going out till ſun-ſet in queſt of food.

The Hottentots who accompanied our traveller called it *muys-hond* (a mouſe dog); a general name among the inhabitants of the Cape for all the ſmaller carnivorous quadrupeds

VIVES (Ludovicus), the contemporary and friend of Eraſmus, was a native of Valentia in Spain. Though well trained in all the ſubtleties of the ſcholaſtic philoſophy at Paris, he had the good ſenſe to diſcover its futility, and diligently applied himſelf to more uſeful ſtudies. At Louvain he undertook the office of a preceptor, and exerted himſelf with great ability and ſucceſs in correcting barbariſm, chaſtiſing the corrupters of learning, and reviving a taſte for true ſcience and elegant letters. Eraſmus, with whom he lived upon the footing

Vives, Ultramarine.

footing of intimate friendſhip, ſpeaking of Vives when he was only 26 years of age, ſays, that there was no part of philoſophy in which he did not excel; and that he had made ſuch proficiency in learning, and in the arts of ſpeaking and writing, that he ſcarcely knew his equal. He wrote a commentary upon Auguſtine's treatiſe *De Civitate Dei*, which diſcovers an extenſive acquaintance with ancient philoſophy. Henry VIII. of England, to whom he dedicated this work, was ſo pleaſed with it, that he invited the author to his court, and made him preceptor to his daughter Mary. Though he diſcharged his office with great fidelity, yet in conſequence of his oppoſition to the king's divorce, he fell under his diſpleaſure; and it was not without difficulty that he eſcaped to Bruges, where he devoted the remainder of his days to ſtudy. He died in the year 1537, or, according to Thuanus, in 1541. With Eraſmus and Buddæus he formed a triumvirate of literature which did honour to the age. He wrote *De Prima Philoſophia*, "On the Firſt Philoſophy;" *De Explanatione Eſſentiarum*, "On the Explanation of Eſſences;" *De Cenſura Veri*, "On the Teſt of Truth;" *De Initiis, Sectis, et Laudibus Philoſophiæ*, "On the Origin, Sects, and Praiſes of Philoſophy;" and *De Corruptis Artibus et Tradendis Diſciplinis*, "On the Corruption of Science, and on Education." Theſe writings, of which the two laſt are the moſt valuable, diſcover great ſtrength of judgment, an extenſive knowledge of philoſophy, much enlargement of conception, uncommon ſagacity in detecting the errors of ancient and modern philoſophers, particularly of Ariſtotle and his followers, and, in fine, a mind capable of attempting things beyond the ſtandard of the age in which he lived. To all this he added great perſpicuity and elegance of ſtyle, not unworthy of the friend of Eraſmus.

ULTRAMARINE is a very fine blue powder, almoſt of the colour of the corn-flower or blue-bottle, which has this uncommon property, that, when expoſed to the air or a moderate heat, it neither fades nor becomes tarniſhed. On this account it is uſed in painting; but it was employed formerly for that purpoſe much more than at preſent, as ſmalt, a far cheaper article, was not then known. (See COBALT, in this *Suppl.*) Ultramarine is made of the blue parts of the lapis lazuli, by ſeparating them as much as poſſible from the other coloured particles with which they are mixed, and reducing them to a fine powder. The real lapis lazuli is found in the mountains of that part of Tartary called Bucharia, which extends eaſtwards from the Caſpian ſea, and particularly at Kalab and Budukſchu. It is ſent thence to the Eaſt Indies, and from the Eaſt Indies to Europe. Good ultramarine muſt be of a beautiful dark colour, and free from ſand as well as every other mixture. It muſt unite readily with oil; it muſt not become tarniſhed on a red-hot tile or plate of iron, and it ought to diſſolve in ſtrong acids, almoſt like the zeolite, without cauſing an efferveſcence. In the year 1763, an ounce of it at Paris coſt four pounds ſterling, and an ounce of *cendre d'outremer*, which is the refuſe, two pounds. The baſis of this colour was long ſuſpected to be copper, but the experiments of Margraff ſhewed that it was iron, in ſome unknown ſtate of combination. New light has been thrown on this ſubject by Morveau, who has diſcovered that ſelenite loaded with iron, when decompoſed by carbonaceous matter, yields a blue ſulphuret of iron of equal permanency with the true ultramarine.

Vortices.

At preſent, ſmalt of a good colour is often purchaſed at a dear rate and ſubſtituted for ultramarine; and it is found that the colour of this preparation of cobalt is more durable in the fire than even that of the lapis lazuli. For the analyſis of lapis lazuli, ſee MINERALOGY, n° 69. *Suppl.*

VORTICES of Des Cartes are now juſtly exploded; but being the fiction of a very ſuperior mind, they are ſtill an object of curioſity, as being the foundation of a great philoſophical romance. According to the author of that romance, the whole of infinite ſpace was full of matter; for with him matter and extenſion were the ſame, and conſequently there could be no void. This immenſity of matter he ſuppoſed to be divided into an infinite number of very ſmall cubes; all of which, being whirled about upon their own centres, neceſſarily gave occaſion to the production of two different elements. The firſt conſiſted of thoſe angular parts which, having been neceſſarily rubbed off, and grinded yet ſmaller by their mutual friction, conſtituted the moſt ſubtle and moveable part of matter. The ſecond conſiſted of thoſe little globules that were formed by the rubbing off of the firſt. The interſtices betwixt theſe globules of the ſecond element were filled up by the particles of the firſt. But in the infinite colliſions, which muſt occur in an infinite ſpace filled with matter, and all in motion, it muſt neceſſarily happen that many of the globules of the ſecond element ſhould be broken and grinded down into the firſt. The quantity of the firſt element having thus been increaſed beyond what was ſufficient to fill up the interſtices of the ſecond, it muſt, in many places, have been heaped up together, without any mixture of the ſecond along with it. Such, according to Des Cartes, was the original diviſion of matter. Upon this infinitude of matter thus divided, a certain quantity of motion was originally impreſſed by the Creator of all things, and the laws of motion were ſo adjuſted as always to preſerve the ſame quantity in it, without increaſe, and without diminution. Whatever motion was loſt by one part of matter, was communicated to ſome other; and whatever was acquired by one part of matter, was derived from ſome other: and thus, through an eternal revolution from reſt to motion, and from motion to reſt, in every part of the univerſe, the quantity of motion in the whole was always the ſame.

But as there was no void, no one part of matter could be moved without thruſting ſome other out of its place, nor that without thruſting ſome other, and ſo on. To avoid, therefore, an infinite progreſs, he ſuppoſed that the matter which any body puſhed before it rolled immediately backwards to ſupply the place of that matter which flowed in behind it; as we may obſerve in the ſwimming of a fiſh, that the water which it puſhes before it immediately rolls backwards to ſupply the place of what flows in behind it, and thus forms a ſmall circle or vortex round the body of the fiſh. It was in the ſame manner that the motion originally impreſſed by the Creator upon the infinitude of matter neceſſarily produced in it an infinity of greater and ſmaller vortices, or circular ſtreams: and the law of motion being ſo adjuſted as always to preſerve the ſame quantity of motion in the univerſe, thoſe vortices either continued for ever, or by their diſſolution gave birth to others of the ſame kind. There was thus at all times an infinite number of greater and ſmaller vortices, or circular ſtreams, revolving in the univerſe.

But whatever moves in a circle is conſtantly endeavouring to fly off from the centre of its revolution. For the natural motion of all bodies is in a ſtraight line. All the particles of matter therefore, in each of thoſe greater vortices, were continually preſſing from the centre to the circumference, with more or leſs force, according to the different degrees of their bulk and ſolidity. The larger and more ſolid globules of the ſecond element forced themſelves upwards to the circumference, while the ſmaller, more yielding, and more active particles of the firſt, which could flow even through the interſtices of the ſecond, were forced downwards to the centre. They were forced downwards to the centre notwithſtanding their natural tendency was upwards to the circumference; for the ſame reaſon that a piece of wood, when plunged in water, is forced upwards to the ſurface, notwithſtanding its natural tendency is downwards to the bottom; becauſe its tendency downwards is leſs ſtrong than that of the particles of water, which, therefore, if one may ſay ſo, preſs in before it, and thus force it upwards. But there being a greater quantity of the firſt element than what was neceſſary to fill up the interſtices of the ſecond, it was neceſſarily accumulated in the centre of each of theſe great circular ſtreams, and formed there the fiery and active ſubſtance of the ſun. For, according to that philoſopher, the ſolar ſyſtems were infinite in number, each fixed ſtar being the centre of one; and he is among the firſt of the moderns who thus took away the boundaries of the univerſe: even Copernicus and Kepler, themſelves, have confined it within what they ſuppoſed the vault of the firmament.

The centre of each vortex being thus occupied by the moſt active and moveable parts of matter, there was neceſſarily among them a more violent agitation than in any other part of the vortex, and this violent agitation of the centre cheriſhed and ſupported the movement of the whole. But among the particles of the firſt element, which fill up the interſtices of the ſecond, there are many, which, from the preſſure of the globules on all ſides of them, neceſſarily receive an angular form, and thus conſtitute a third element of particles leſs fit for motion than thoſe of the other two. As the particles, however, of this third element were formed in the interſtices of the ſecond, they are neceſſarily ſmaller than thoſe of the ſecond, and are therefore, along with thoſe of the firſt, urged down towards the centre, where, when a number of them happen to take hold of one another, they form ſuch ſpots upon the ſurface of the accumulated particles of the firſt element, as are often diſcovered by teleſcopes upon the face of that ſun which enlightens and animates our particular ſyſtem. Thoſe ſpots are often broken and diſpelled by the violent agitation of the particles of the firſt element, as has hitherto happily been the caſe with thoſe which have ſucceſſively been formed upon the face of our ſun. Sometimes, however, they encruſt the whole ſurface of that fire which is accumulated in the centre; and the communication betwixt the moſt active and the moſt inert parts of the vortex being thus interrupted, the rapidity of its motion immediately begins to languiſh, and can no longer defend it from being ſwallowed up and carried away by the ſuperior violence of ſome other like circular ſtream; and, in this manner, what was once a ſun becomes a planet. Thus the time was, according to the ſyſtem, when the Moon was a body of the ſame kind with the ſun, the fiery centre of a circular ſtream of ether, which flowed continually round her; but her face having been cruſted over by a congeries of angular particles, the motion of this circular ſtream began to languiſh, and could no longer defend itſelf from being abſorbed by the more violent vortex of the earth, which was then, too, a ſun, and which chanced to be placed in its neighbourhood. The moon therefore became a planet, and revolved round the earth. In proceſs of time, the ſame fortune, which had thus befallen the moon, befel alſo the earth; its face was encruſted by a groſs and inactive ſubſtance; the motion of its vortex began to languiſh, and it was abſorbed by the greater vortex of the ſun: but though the vortex of the earth had thus become languid, it ſtill had force enough to occaſion both the diurnal revolution of the earth, and the monthly motion of the moon. For a ſmall circular ſtream may eaſily be conceived as flowing round the body of the earth, at the ſame time that it is carried along by that great ocean of ether which is continually revolving round the ſun; in the ſame manner, as in a great whirlpool of water, one may often ſee ſeveral ſmall whirlpools, which revolve round centres of their own, and at the ſame time are carried round the centre of the great one. Such was the cauſe of the original formation and conſequent motions of the planetary ſyſtem. When a ſolid body is turned round its centre, thoſe parts of it which are neareſt, and thoſe which are remoteſt from the centre, complete their revolutions in one and the ſame time. But it is otherwiſe with the revolutions of a fluid: the parts of it which are neareſt the centre complete their revolutions in a ſhorter time than thoſe which are remoter. The planets, therefore, all floating in that immenſe tide of æther which is continually ſetting in from weſt to eaſt round the body of the ſun, complete their revolutions in a longer or a ſhorter time, according to their nearneſs or diſtance from him.

This bold ſyſtem was eminently fitted to captivate the imagination; and though fraught with contradictions and impoſſibilities, attempts have been made to revive it, even in this country, under different names. All thoſe ſyſtems which repreſent the motions of the heavenly bodies as being the effect of the phyſical agency of æthers, of air, of fire, and of light, of which the univerſe is conceived to be full, labour under the ſame difficulties with the Carteſian hypotheſis; and very few of them, if any, are ſo neatly put together. It is ſurely ſufficient, however, to demoliſh this goodly fabric, barely to aſk how an abſolute infinity of matter can be divided into cubes, or any thing elſe? how there can poſſibly be interſtices in a perfect plenum? or how in ſuch a plenum any portion of matter can be thruſt from its place?

URALIAN Coſſacs, a people that inhabit the Ruſſian province of Orenburg in Aſia, on the ſouth ſide of the river Ural. Theſe Coſſacs are deſcended from thoſe of the Don: they are a very valiant race. They profeſs the Greek religion; but there is a kind of diſſenters from the eſtabliſhed religion, whom the Ruſſians called *Roſkolniki*, or Separatiſts, and who ſtyle themſelves *Staroverſki*, or Old Believers. They conſider the ſervice of the eſtabliſhed church as profane and ſacrilegious, and have their own prieſts and ceremonies. The Uralian Coſſacs are all enthuſiaſts for the ancient ritual, and prize their beards almoſt equal to their lives. A Ruſſian officer having ordered a number of Coſſac recruits to be publicly ſhaved in the town of Yaitſk, in 1771, this wanton inſult excited an inſurrection, which was ſuppreſſed for a time; but, in 1773, that daring impoſtor, Pugatchef, having aſſumed the name and perſon of Peter III. appeared among them, and taking advantage of this circumſtance, and of their religious prejudices, rouſed them once more into open rebellion. This being at laſt effectually ſuppreſſed by the defeat and execution of the impoſtor (See Suworow, *Suppl.*), in order to extinguiſh all remembrance of this rebellion, the river Yaik was called *Ural;* the Yaik Coſſacs were denominated *Uralian Coſſacs;* and the town of Yaitſk, *Uralſk.* The Uralian Coſſacs enjoy the right of fiſhing on the coaſt of the Caſpian Sea, for 47 miles on each ſide of the river Ural. Their principal fiſhery is for ſturgeons and beluga, whoſe roe ſupplies large quantities of caviare; and the fiſh, which are chiefly ſalted and dried, afford a conſiderable article of conſumption in the Ruſſian empire. In conſequence of theſe fiſheries, theſe Coſſacs are very rich.

URBINO, a town of Italy, in the territory of the Pope, and capital of the duchy of Urbino, with an old citadel, an archbiſhop's ſee, and a handſome palace, where the dukes formerly reſided. The houſes are well built, and great quantities of fine earthen ware are made here. It is ſeated on a mountain, between the rivers Metro and Foglia, 18 miles ſouth of Rimini, 58 eaſt of Florence, and 120 north-eaſt of Rome. E. Lon. 12. 40. N. lat. 43. 46.

Urbino, a duchy of Italy, in the territory of the church, bounded on the north by the gulph of Venice; on the ſouth, by Perugino and Umbria; on the eaſt, by the marquiſate of Ancona; and on the weſt, by Tuſcany and Romagna. It is about 55 miles in length, and 45 in breadth. Here is great plenty of game and fiſh; but the air is not very wholeſome, nor is the ſoil fertile. Urbino is the capital.

URCEOLA, a lately diſcovered genus of the *pentandria* claſs, and *monogynia* order of plants, ranking immediately after Tabernæ montana (ſee *Encycl.*), and conſequently belonging to the 30th natural order or claſs called *Contortæ* by Linnæus in his natural method of arrangement. One of the qualities of the plants of this order is their yielding, on being cut, a juice which is generally milky, and for the moſt part deemed of a poiſonous nature. The genus is thus characteriſed by Dr Roxburgh: *Calyx* beneath five-toothed; corol one petaled, pitcher ſhaped, with its contracted mouth five toothed: nectary entire, ſurrounding the germs; follicles two, round, drupacious; ſeeds numerous, immerſed in pulp. There is but one known ſpecies, which is thus deſcribed by the ſame eminent botaniſt;

Urceola elastica: Shrubby, twining, leaves oppoſite, oblong, panicles terminal, is a native of Sumatra, Prince of Wales's Iſland, &c. Malay countries. *Stem* woody, climbing over trees, &c. to a very great extent, young ſhoots twining, and a little hairy, bark of the old woody parts thick, dark coloured, conſiderably uneven, a little ſcabrous, on which are found ſeveral ſpecies of moſs, particularly large patches of lichen; the wood is white, light, and porous. *Leaves* oppoſite, ſhort-petioled, horizontal, ovate, oblong, pointed, entire, a little ſcabrous, with a few ſcattered white hairs on the under ſide. *Stipules* none. *Panicles* terminal, brachiate, very ramus. *Flowers* numerous, minute, of a dull greeniſh colour, and hairy on the outſide. *Bracts* lanceolate, one at each diviſion and ſubdiviſion of the panicle. *Calyx* perianth, one-leaved, five toothed, permanent. *Corol* one petaled, pitcher-ſhaped, hairy, mouth much contracted, five-toothed, diviſions erect, acute, nectary entire, cylindric, embracing the lower two-thirds of the germs. *Stamens*, filaments five, very ſhort from the baſe of the corol. Anthers arrow-ſhaped, converging, bearing their pollen in two grooves on the inſide, near the apex; between theſe grooves and the inſertions of the filaments they are covered with white ſoft hairs. *Piſtil*, germs two; above the nectary they are very hairy round the margins of their truncated tops. Style ſingle, ſhorter than the ſtamens. Stigma ovate, with a circular band, dividing it into two portions of different colours. *Per.* Follicles two, round, laterally compreſſed into the ſhape of a turnip, wrinkled, leathery, about three inches in their greateſt diameters—one celled, two valved. *Seeds* very numerous, reniform, immerſed in firm fleſhy pulp.

See Plate XLVII. where fig. 1. is a branchlet in flower of the natural ſize. 2. A flower magnified. 3. The ſame laid open, which expoſes to view the ſituation of the ſtamens inſerted into the bottom of the corol, the nectarium ſurrounding the lower half of the two germs, their upper half with hairy margins, the ſtyle and ovate party coloured; ſtigma appearing above the nectary. 4. Outſide of one of the ſtamens; and, 5. Inſide of the ſame, both much magnified. 6. The nectarium laid open, expoſing to view the whole of the piſtil 7. The two ſeed veſſels (called by Linnæus *follicles*), natural ſize; half of one of them is removed, to ſhew the ſeed immerſed in pulp. A portion thereof is alſo cut away, which more clearly ſhews the ſituation and ſhape of the ſeed.

From wounds made in the bark of this plant there oozes a milky fluid, which on expoſure to the open air ſeparates into an elaſtic coagulum, and watery liquid, apparently of no uſe, after the ſeparation takes place. This coagulum is not only like the American caoutchouc or Indian rubber, but poſſeſſes the ſame properties; for which, ſee Caoutchouc, both in the *Encycl.* and *Suppl.*

The chemical properties of this vegetable milk, while freſh, were found by Mr Howiſon, late ſurgeon on Prince of Wales's Iſland, ſurpriſingly to reſemble thoſe of animal milk. From its decompoſition, in conſequence of ſpontaneous fermentation, or by the addition of acids, a ſeparation takes place between its caſeous and ſerous parts, both of which are very ſimilar to thoſe produced by the ſame proceſſes from animal milk. An oily or butyrous matter is alſo one of its component parts, which appears upon the ſurface of the gum ſo ſoon as the latter has attained its ſolid form. He endeavoured to form an extract of this milk ſo as to approach to the conſiſtence of new butter, by which he hoped to retard its fermentative ſtage, without depriving it of its uſeful qualities; but as he had no apparatus for diſtilling, the ſurface of the milk, that was expoſed to the air, inſtantly formed into a ſolid coat, by which

which the evaporation was in a great degree prevented. He, however, learned, by collecting the thickened milk from the inſide of the coats, and depoſiting it in a jelly pot, that, if excluded from the air, it might be preſerved in this ſtate for a conſiderable length of time ; and even without any preparation he kept it in bottles, tolerably good, upwards of twelve months.

URINARY concretions. See *Animal Substances*, Suppl.

URTICA. See *Encycl.* where it is obſerved that the common nettle, though it has a place in the *materia medica*, is now very little uſed. It has lately been recommended, however, by *Zannetini*, a phyſician who attended the French army in Italy, as a good ſubſtitute in fevers for cinchona. The ſucceſs of ſome experiments, which he made with it in tertian and quartan malignant fevers, ſurpaſſed, he ſays, his moſt ſanguine expectation. The nettle often produces a ſpeedier effect than bark ; for it heats in a great degree, and when the doſe is pretty ſtrong, occaſions a lethargic ſleep. The doſe muſt never exceed a dram, and is given in wine two or three times in the courſe of 24 hours. Zannetini found this medicine of great ſervice to guard againſt that total exhauſtion which forms the principal character of malignant fevers ; and he recommends a ſlight infuſion of it in wine as an excellent preſervative for thoſe who reſide in marſhy and inſalubrious diſtricts. In employing the nettle in fever, Zannetini gives the ſame caution as ought to be obſerved in regard to cinchona, that is, that it muſt not be employed where there is an inclination to inflammation, or where a continued fever, ariſing from obſtructions, exiſts. This diſcovery is not unworthy the attention of phyſicians, and deſerves at leaſt to be farther inveſtigated, as a great deal would be ſaved if cinchona could be entirely diſpenſed with.

W.

WALES, New South, is a country which muſt be intereſting on account of the ſingular colony which was ſettled there in the year 1788. Under the title *New Holland* (*Encycl.*) ſome account has been given of that ſettlement, as well as of the climate and the ſoil about Port Jackſon ; but it will probably gratify the curioſity of our readers, if we give a ſhort hiſtory of thoſe European ſettlers, of whom it is to be hoped that they carried not with them, to that diſtant ſhore,

> “ Minds not to be changed by time or place.”

This hiſtory we ſhall take from the accurate *Account of the Engliſh Colony in New South Wales*, by David Collins, Eſq; who went out with Governor Phillip, and continued to execute the offices of Judge-advocate and Secretary till the cloſe of the year 1796 ; and we ſhall begin our narrative from the diſembarkation of the firſt coloniſts, when his Majeſty's commiſſion to the governor, and the letters patent eſtabliſhing courts of criminal and civil judicature in the territory were read.

The criminal court was conſtituted a court of record, and was to conſiſt of the judge-advocate and ſuch ſix officers of the ſea and land ſervice as the governor ſhall, by precept iſſued under his hand and ſeal, require to aſſemble for that purpoſe. This court has power to inquire of, hear, determine, and puniſh all treaſons, miſpriſions of treaſons, murders, felonies, forgeries, perjuries, treſpaſſes, and other crimes whatſoever that may be committed in the colony ; the puniſhment for ſuch offences to be inflicted according to the laws of England as nearly as may be, conſidering and allowing for the circumſtances and ſituation of the ſettlement and its inhabitants. The charge againſt any offender is to be reduced into writing, and exhibited by the judge-advocate : witneſſes are to be examined upon oath, as well for as againſt the priſoner ; and the court is to adjudge whether he is guilty or not guilty by the opinion of the major part of the court. If guilty, and the offence is capital, they are to pronounce judgment of death, in like manner as if the priſoner had been convicted by the verdict of a jury in England, or of ſuch corporal puniſhment as the court, or the major part of it, ſhall deem meet. And in caſes not capital, they are to adjudge ſuch corporal puniſhment as the majority of the court ſhall determine. But no offender is to ſuffer death unleſs five members of the court ſhall concur in adjudging him to be guilty, until the proceedings ſhall have been tranſmitted to England, and the king's pleaſure ſignified thereupon. The provoſt-marſhall is to cauſe the judgement of the court to be executed according to the governor's warrant under his hand and ſeal.

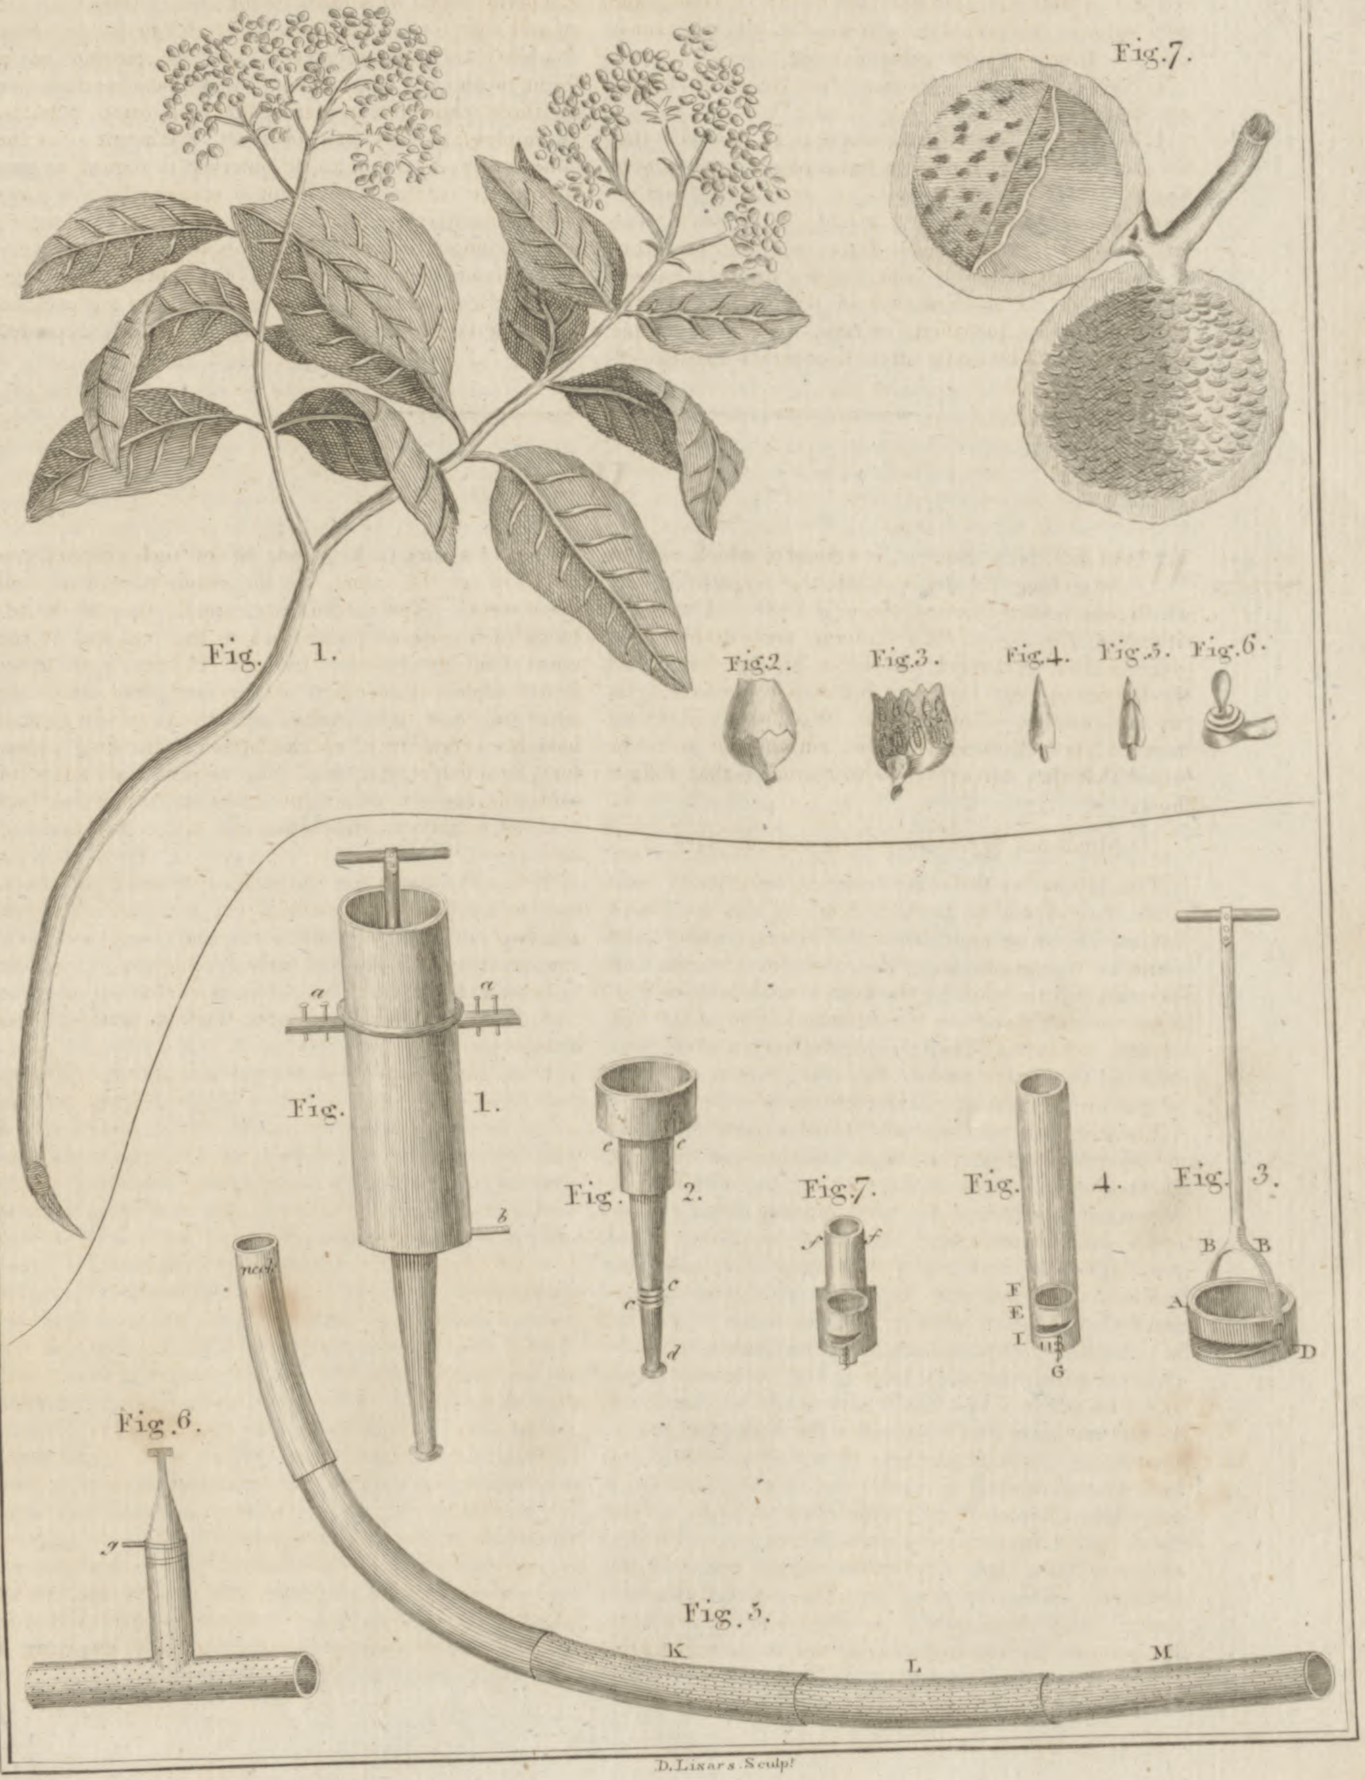
Beſide this court for the trial of criminal offenders, there is a civil court, conſiſting of the judge-advocate and two inhabitants of the ſettlement, who are to be appointed by the governor ; which court has full power to hear and determine in a ſummary way all pleas of lands, houſes, debts, contracts, and all perſonal pleas whatſoever.

From this court, on either party, plaintiff or defendant, finding himſelf or themſelves aggrieved by the judgment or decree, an appeal lies to the governor, and from him, where the debt or thing in demand ſhall exceed the value of L. 300, to the king in council.

A vice-admiralty court was alſo appointed, for the trial of offences on the high ſeas ; and the governor, lieutenant-governor, and judge-advocate, were by patent made juſtices of the peace, with a power in the governor to appoint other juſtices.

The ſituation which Governor Phillip had ſelected for his reſidence, and for the principal ſettlement, was the eaſt ſide of a cove in Port Jackſon, which he called *Sydney Cove*. Its latitude was found to be 33° 52′ 30″ ſouth, and its longitude 152° 19′ 30″ eaſt. This ſituation was choſen without due examination ; for it ſoon appeared that the head or upper part of the cove wore a much more favourable appearance than the ground immediately about the ſettlement. From the natives, the new ſettlers met no oppoſition : during the firſt ſix weeks they received only one viſit from them, two men ſtrolling one evening into the camp, and remaining in

URCEOLA ELASTICA. PLATE XLVII.



D. Lizars Sculp^t

it for about half an hour. They appeared to admire whatever they ſaw; and after receiving a hatchet (of the uſe of which the eldeſt inſtantly and curiouſly ſhewed his knowledge, by turning up his foot and ſharpening a piece of wood on the ſole with the hatchet) took their leave, apparently well pleaſed with their reception. The fiſhing boats alſo frequently reported their having been viſited by many of theſe people when hauling the ſeine; at which labour they often aſſiſted with cheerfulneſs, and in return were generally rewarded with a part of the fiſh taken.

The firſt labour in which the convicts were employed was that of building huts; and for this purpoſe it was found neceſſary to divide them into gangs, and to appoint an overſeer to each, who ſhould ſee that the proper quantity of work was performed. The proviſions were diſtributed by a weekly ration, and to each man were allowed 7 lb. of biſcuit, 1 lb. of flour, 7 lb. of beef or 4 lb. of pork, 3 pints of peaſe, and 6 ounces of butter. To the female convicts two thirds of this ration were allowed. This was the full ration, which, in many inſtances, it became neceſſary to reduce; and once, in conſequence of the delay of tranſports with a ſupply, the convicts were put on an allowance of which fleſh meat conſtituted no part.

The temporary huts in which the coloniſts lived, for ſome time after their arrival, were formed principally of the cabbage tree. With this the ſides and ends were filled; the poſts and plates being made of the pine; and the whole was plaſtered with clay. The roofs were generally thatched with the graſs of the gumruſh; though ſome were covered with clay, but ſeveral of theſe failed; the weight of the clay and rain ſoon deſtroying them. In a ſhort time they applied themſelves to the burning of bricks; by which their habitations ſoon became much more laſting and comfortable. The progreſs of the colony, however, towards that degree of convenience which was within its reach, was greatly impeded by the incorrigible vices of thoſe who principally compoſed it. Drunkenneſs, theft, robbery, and unconquerable lazineſs, continued to mark the character of the great body of the convicts. Though to fly from the colony, and venture into the interior of the country, was inevitable death in the form of famine or of murder, yet ſuch was the invincible antipathy to labour manifeſted by ſome of thoſe people, that they often fled to the woods, from which they ſeldom returned; ſome dying of hunger, and ſome being ſacrificed by the natives. Diſinclination to labour produced here, as elſewhere, its natural effect—robbery.

In the month of May 1788, a lad of 17 years of age was tried, convicted, and executed, for breaking open a tent belonging to one of the tranſport ſhips; ſeveral others were taken into cuſtody in that month for various thefts and burglaries, and two were afterward tried and executed. One of theſe had abſconded, and lived in the woods for 19 days, ſubſiſting by what he was able to procure by nocturnal depredations among the huts and ſtock of individuals. His viſits for this purpoſe were ſo frequent and daring, that it became abſolutely neceſſary to proclaim him an outlaw. By the negligence of one of thoſe fellows who had been entruſted with the care of the cattle, the bull and four cows were loſt: he left them in the fields, and returned to his hut to dine; and in the mean time they either ſtrayed away or were driven off by the natives. Five years elapſed before theſe cattle were diſcovered wild, at a conſiderable diſtance up the country, and greatly multiplied.

The perpetration of crimes, chiefly theft and robbery, had become ſo prevalent before twenty months had paſſed ſince the colony was eſtabliſhed, that it was neceſſary to think of a ſyſtem of police. A plan was preſented to the governor by a *convict*, which with ſome improvements was adopted on the 8th of Auguſt 1789. The following are the heads of the arrangement.

The ſettlement was divided into four diſtricts, over each of which was placed a watch conſiſting of three perſons, one principal and two ſubordinate watchmen. Theſe being ſelected from among thoſe convicts whoſe conduct and character had been unexceptionable ſince their landing, were veſted with authority to patrole at all hours in the night, to viſit ſuch places as might be deemed requiſite for the diſcovery of any felony, treſpaſs, or miſdemeanor, and to ſecure for examination all perſons that might appear to be concerned therein; for which purpoſe they were directed to enter any ſuſpected hut or dwelling, or to uſe any other means that might appear expedient. They were required to detain and give information to the neareſt guardhouſe of any ſoldier or ſeaman who ſhould be found ſtraggling after the tattoo had been beat. They were to uſe their utmoſt endeavours to trace out offenders on receiving accounts of any depredation; and in addition to their night-duty, they were directed to take cognizance of ſuch convicts as gamed, or ſold or bartered their ſlops or proviſions, and report them for puniſhment. A return of all occurrences during the night was to be made to the judge-advocate; and the military were required to furniſh the watch with any aſſiſtance they might be in need of, beyond what the civil power could give them. They were provided each with a ſhort ſtaff, to diſtinguiſh them during the night, and to denote their office in the colony; and were inſtructed not to receive any ſtipulated encouragement or reward from any individual for the conviction of offenders, but to expect that negligence or miſconduct in the execution of their truſt would be puniſhed with the utmoſt rigour. It was to have been wiſhed, ſays Mr Collins, that a watch eſtabliſhed for the preſervation of public and private property had been formed of free people, and that neceſſity had not compelled us, in ſelecting the firſt members of our little police, to appoint them from a body of men, in whoſe eyes, it could not be denied, the property of individuals had never before been ſacred. But there was not any choice: The military had their line of duty marked out for them, and between them and the convict there was no deſcription of people from whom overſeers or watchmen could be provided. It might, however, be ſuppoſed, that among the convicts there muſt be many who would feel a pride in being diſtinguiſhed from their fellows, and a pride that might give birth to a returning principle of honeſty. It was hoped that the convicts whom we had choſen were of this deſcription; ſome effort had become neceſſary to detect the various offenders who were prowling about with ſecurity under cover of the night; and the convicts who had any property were themſelves intereſted in defeating ſuch practices. They promiſed fidelity and diligence, from which the ſcorn of their fellow-priſoners ſhould not induce them to ſwerve, and began with a confidence of ſucceſs the duty which they had themſelves offered to undertake.

A ſpecies of diſturber now infeſted the colony, againſt which the vigilance of a police could not guard. Rats, in immenſe numbers, had attacked the proviſion-ſtores, and could be counteracted only by removing the proviſions from one ſtore to another. When their ravages were firſt diſcovered, it was found that eight caſks of flour were already deſtroyed by theſe vermin. Such of theſe animals as eſcaped the dogs, which were ſet upon them, flew to the gardens of individuals, where they rioted on the Indian corn that was growing, and did conſiderable miſchief.

Our author gives the moſt melancholy account of the extreme ſufferings of the early coloniſts from want of proviſions, and of the diſeaſes imported into the country by newcomers, who had either caught them on the voyage or brought them from England. The ſettlers on *Norfolk-Iſland* (ſee *Encycl.*), to which New South Wales was a mother country, muſt have been much more liable than that colony to ſuffer from famine, had they not ſometimes obtained a temporary ſupply from a ſource which was unknown at Sydney Cove. On a mountain in the iſland, to which had been given the name of *Mount Pitt*, they were fortunate enough to obtain, in an abundance almoſt incredible, a ſpecies of aquatic birds, anſwering the deſcription of that known by the name of the *puffin*. Theſe birds came in from the ſea every evening, in clouds literally darkening the air, and deſcending on Mount Pitt, depoſited their eggs in deep holes made by themſelves in the ground, generally quitting them in the morning, and returning to ſeek their ſubſiſtence in the ſea. From two to three thouſand of theſe birds were often taken in a night. Their ſeeking their food in the ocean left no doubt of their own fleſh partaking of the quality of that upon which they fed; but to people circumſtanced as were the inhabitants on Norfolk Iſland, this leſſened not their importance; and while any Mount Pitt birds (ſuch being the name given them) were to be had, they were eagerly ſought.

The firſt ſettler in New South Wales, who declared himſelf able to live on the produce of his farm, without any aſſiſtance from the ſtores, was James Ruſe; who in April 1792 relinquiſhed his claim to any farther ſhare of the public proviſion. As a reward, the governor immediately put him in poſſeſſion of an allotment of 30 acres.

In the July of the ſame year, the convicts whoſe terms of tranſportation had expired were now collected, and by the authority of the governor informed, that ſuch of them as wiſhed to become ſettlers in this country ſhould receive every encouragement; that thoſe who did not, were to labour for their proviſions, ſtipulating to work for 12 or 18 months certain; and that in the way of ſuch as preferred returning to England no obſtacles would be thrown, provided they could procure paſſages from the maſters of ſuch ſhips as might arrive; but that they were not to expect any aſſiſtance on the part of government to that end. The wiſh to return to their friends appeared to be the prevailing idea, a few only giving in their names as ſettlers, and none engaging to work for a certain time.

That the wiſh to return home was ſtrong indeed, and paramount to all other feelings, was evinced in a very melancholy inſtance ſome time before. A convict, an elderly man, was found dead in the woods, near the ſettlement; who, on being opened, it appeared, had died from want of nouriſhment; and it was found that he was accuſtomed to deny himſelf even what was abſolutely neceſſary to his exiſtence, abſtaining from his proviſions, and ſelling them for money, which he was reſerving, and had ſomewhere concealed, in order to purchaſe his paſſage to England when his time ſhould terminate!

Of ſome convicts whoſe terms of tranſportation had expired, the governor eſtabliſhed a new ſettlement in Auguſt 1791, at a place which he called *Proſpect Hill*, about twenty miles diſtant from Sydney Cove; and another reſidence was formed at the Ponds within three or four miles of the former. This made the fourth ſettlement in the colony, excluſively of that at Norfolk Iſland.

About this time the governor received from England a public ſeal for the colony: on the obverſe of which were the king's arms and royal titles; and on the reverſe, emblematic figures ſuited to the ſituation of the people for whoſe uſe it was deſigned. The motto was "*Sic fortis Etruria crevit*;" and in the margin were the words "*Sigillum Nov. Camb. Auſt.*" A commiſſion alſo arrived, empowering him to remit abſolutely, or conditionally, the whole or any part of the term for which the felons ſent to the colony might be tranſported. By this power he was enabled to beſtow on ſuperior honeſty and induſtry the moſt valuable reward which, in ſuch circumſtances, they could receive.

In addition to the calamities under which the ſettlement had ſo often laboured from being reduced to very ſhort allowance of proviſions, and the frequency of the ordinary diſeaſes which were to be expected among a people ſo ſituated, a new malady of a very alarming nature was perceived about April 1792. Several convicts were ſeized with inſanity; and as the major part of thoſe who were viſited by this calamity were females, who, on account of their ſex, were not haraſſed with hard labour, and who in general ſhared largely of ſuch little comforts as were to be procured in the ſettlement, it was difficult to aſſign a cauſe for this diſorder. It ſeems, however, to have been of ſhort duration; for we hear not of it again during the period that Mr Collins's narrative comprehends.

About this time (1792) the colony had aſſumed ſomething of an eſtabliſhed form. Brick huts were in hand for the convicts in room of the miſerable hovels occupied by many, which had been put up at their firſt landing, and in room of others which, from having been erected on ſuch ground as was then cleared, were now found to interfere with the direction of the ſtreets which the governor was laying out. People were alſo employed in cutting paling for fencing in their gardens. At a place called Paramatta, about 16 miles from Sydney Cove, ſituated on a ſmall river which runs into Port Jackſon, the people were employed, during the greateſt part of the month of May, in getting in the maize and ſowing wheat. A foundation for an hoſpital was laid, a houſe built for the maſter carpenter, and roofs prepared for the different huts either building or to be built in future.

In December 1792, when Captain Phillip reſigned the government, nearly five years from the foundation of of the colony, there were in cultivation at the different ſettlements 1429 acres, of which 417 belonged to ſettlers; that is, 67 ſettlers, for there were no more, cultivated nearly half as much ground as was cultivated by the public labour of all the convicts; a ſtriking proof of the ſuperior zeal and diligence with which men exert themſelves when they have an intereſt in their labour. Of free ſettlers, whoſe exertions promiſed ſo fairly to promote the intereſts of the colony, ſeveral arrived from England in January 1793, and fixed themſelves in a ſituation which they called *Liberty Plains*. To one of theſe, Thomas Roſe, a farmer from Dorſetſhire, and his family of a wife and four children, 120 acres were allotted. The conditions under which theſe people agreed to ſettle were, "to have their paſſage provided by government (A); an aſſortment of tools and implements to be given to them out of the ſtores; that they ſhould be ſupplied with two years proviſions; that their lands ſhould be granted free of expence; the ſervice of convicts alſo to be aſſigned to them free of expence; and that thoſe convicts ſhould be ſupplied with two years rations and one year's clothing."

Among the great difficulties with which this infant eſtabliſhment had to ſtruggle, not the leaſt was that of procuring cattle. Of thoſe which were embarked in England and other places for the colony, a very ſmall proportion only arrived; for of 15 bulls and 119 cows, which had been embarked for Botany Bay, only 3 bulls and 28 cows were landed at the ſettlement. It was not until the arrival of the Endeavour, Captain Bampton, in 1795, that the mode of conveying cattle to the colony without material loſs was diſcovered. In that veſſel, out of 130 head which he embarked at Bombay, one cow only died on the paſſage, and that too on the day before his arrival.

The ſcarcity of cattle naturally raiſed their price. Even after this laſt importation, an Engliſh cow in calf ſold for L. 80.

Notwithſtanding the various obſtacles which induſtry had met in the cultivation of this ſettlement, it yet made conſiderable advances; for in October 1793, the value of land had ſo riſen, that one ſettler ſold his allotment of 30 acres for as many pounds; and one farm, with the houſe, &c. ſold for L. 100. The value of ground, indeed, was conſiderably enhanced by government agreeing to purchaſe the redundance of the produce of the ſettlers at fixed prices. Wheat properly dried and cleanſed was received from the ſettlers at Sydney, by the commiſſary, at 10s. per buſhel. Some cultivators, however, had deviſed another mode of diſpoſing of their corn. One of them, whoſe ſituation was near Parramatta, having obtained a ſmall ſtill from England, found it more advantageous to draw an ardent diabolical ſpirit from his wheat, than to ſend it to the ſtores. From one buſhel of wheat he obtained nearly five quarts of ſpirit, which he ſold or paid in exchange for labour, at the rate of five or ſix ſhillings per quart. A better uſe was made of grain by another ſettler; who, having a mill, ground it, and procured 44lb. of good flour, from a buſhel of wheat taken at 59lb. This flour he ſold at 4d. per lb.

By a return of the number of perſons in New South Wales and Norfolk Iſland in April 1794, it appeared that there were in all 4414, including women and children; the annual expence of whom, to the mother-country, Mr Collins eſtimates at L. 161,101. Rapid ſtrides, however, were at that time making towards independence, if not towards an ability of repaying to England a part of what the ſettlement had coſt her. Already the colony lived on grain of its own growth, and an increaſe of live ſtock was become almoſt certain. There were now 4665 acres of ground cleared for cultivation; more than half of which had been effected by thoſe who had become ſettlers in the courſe of fifteen months.

To this ſpirit of improvement ſuch a check was given in September 1794, that not more than a third of government ground, and a fifth of ground belonging to individuals, was in cultivation 1795. As this event has been miſrepreſented, we ſuſpect purpoſely, by ſome of our journaliſts, we ſhall give the true account of it in the words of Mr Collins himſelf.

"The Francis ſchooner (ſays he) returned from Norfolk, having been abſent about eight weeks and three days. From Mr King, who commanded in that iſland, we learned that his harveſt had been prodigiouſly productive. He had purchaſed from the firſt crops, which the ſettlers had brought to market, upwards of 11,000 buſhels of maize: and bills for the amount were drawn by him in favour of the reſpective ſettlers; but requiring the ſanction of the Lieutenant governor, they were now ſent to Port Jackſon. Mr King had been partly induced to make this proviſional kind of purchaſe, under an idea, that the corn would be acceptable at Port-Jackſon, and alſo in compliance with the conditions on which the ſettlers had received their reſpective allotments under the regulations of Governor Phillip; that is to ſay, that their overplus grain ſhould be purchaſed at a fair market-price. Being, however, well ſtocked with that article already, the Lieutenant governor did not think himſelf juſtifiable in putting the crown to ſo great an expence (nearly L. 3000 Sterling), and declined accepting the bills." This naturally excited ſome diſcontents in Norfolk Iſland, and one or two ſettlers gave up their farms; but immediately on the arrival of Governor Hunter, he paid for the corn, and tranquillity was reſtored to the iſland.

Though ſeveral quarrels had occurred between the natives and individuals among the coloniſts, yet it was ſuppoſed that our people were in general the aggreſſors. The governor had taken much pains to inſpire the natives with confidence, and had in a great meaſure ſucceeded. To theft they were naturally and irreſiſtibly inclined: but, like other ſavages, they ſeemed unconſcious of the crime, and were ſeldom deterred by detection from mixing with the coloniſts. At a ſettlement which had early been formed at a river called the *Hawkeſbury* (and at which, cultivation having gone on well, there was, in courſe, much grain to ſtimulate to depredation), the natives aſſumed a more formidable appearance.

"At that ſettlement (ſays Mr Collins) an open war

(A) Government paid for the paſſage of each perſon above ten years of age L. 8, 8 s. and one ſhilling per day for victualling them.

ſeemed about this time to have commenced between the natives and the ſettlers; and word was received overland, that two people were killed by them; one a ſettler of the name of Wilſon, and the other a freeman, one William Thorp, who had hired himſelf to this Wilſon as a labourer. The natives appeared in large bodies, men, women, and children, provided with blankets and nets to carry off the corn, of which they appeared as fond as the natives who lived among us, and ſeemed determined to take it whenever and wherever they could meet with opportunities. In their attacks they conducted themſelves with much art; but where that failed they had recourſe to force; and on the leaſt appearance of reſiſtance made uſe of their ſpears or clubs. To check at once, if poſſible, theſe dangerous depredators, Captain Paterſon directed a party of the corps to be ſent from Paramatta, with inſtructions to deſtroy as many as they could meet with of the wood tribe (Bè-diagal); and, in the hope of ſtriking terror, to erect gibbets in different places, whereon the bodies of all they might kill were to be hung. It was reported that ſeveral of theſe people were killed in conſequence of this order; but none of their bodies being found (perhaps if any were killed they were carried off by their companions), the number could not be aſcertained. Some priſoners, however, were taken, and ſent to Sydney; one man (apparently a cripple), five women, and ſome children. One of the women, with a child at her breaſt, had been ſhot through the ſhoulder, and the ſame ſhot had wounded the babe. They were immediately placed in a hut near our hoſpital, and every care taken of them that humanity ſuggeſted. The man was ſaid, inſtead of being a cripple, to have been very active about the farms, and inſtrumental in ſome of the murders which had been committed. In a ſhort time he found means to eſcape, and by ſwimming reached the north ſhore in ſafety; whence, no doubt, he got back to his friends. Captain Paterſon hoped, by detaining the priſoners and treating them well, that ſome good effect might reſult; but finding, after ſome time, that coercion, not attention, was more likely to anſwer his ends, he ſent the women back. While they were with us, the wounded child died, and one of the women was delivered of a boy, which died immediately. On our withdrawing the party, the natives attacked a farm nearly oppoſite Richmond Hill, belonging to one William Rowe, and put him and a very fine child to death; the wife, after receiving ſeveral wounds, crawled down the bank, and concealed herſelf among ſome reeds half immerſed in the river, where ſhe remained a conſiderable time without aſſiſtance: being at length found, this poor creature, after having ſeen her huſband and her child ſlaughtered before her eyes, was brought into the hoſpital at Paramatta, where ſhe recovered, though ſlowly, of her wounds."

By the vigorous meaſures which were adopted, the colony, towards the cloſe of 1796, had acquired a degree of ſtrength which ſeemed to enſure its future proſperity. Not only the neceſſary edifices were raiſed for the habitations of its people, but ſome for the purpoſes of religion, amuſement, &c. A playhouſe had been erected at the expence of ſome perſons who performed in it for their own emolument, and who admitted auditors at one ſhilling each. A convenient church had been built, a printing-preſs had been ſet up, the civil court was open for the recovery of debts by action and for proving wills, licences had been iſſued to regulate the ſale of ſpirits, and paſſage-boats were eſtabliſhed for the convenience of communication between the different ſettlements. In the houſes of individuals were to be found moſt of the comforts, and not a few of the luxuries, of life; and, in a word, the former years of famine, toil, and difficulty, were now exchanged for thoſe of plenty, eaſe, and pleaſure.

The quantity of ground at this time in cultivation was 5419 acres; of which 2547 were occupied by ſettlers. The number of perſons in New South Wales and its dependencies amounted to 4848. The price of labour, however, compared with the prices of proviſions (as given in Mr Collins's Tables), does not appear ſo high as to enable the workman to live very comfortably. He who receives but three ſhillings for his day's work, and gives two ſhillings for a pound of mutton, fifteen pence for a pound of pork, and half of that ſum for a pound of flour, will ſcarcely derive from his mere labour the ſupport neceſſary for a family.

That many things are yet wanted to give full effect to the advantages which the colony now enjoys, Mr Collins declares in the following paragraph, with which he concludes his account:

"The want at this time of ſeveral public buildings in the ſettlement has already been mentioned. To this want muſt be added, as abſolutely neceſſary to the well-being and comfort of the ſettlers, and the proſperity of the colony in general, that of a public ſtore, to be opened on a plan, though not exactly the ſame, yet as liberal as that of the Iſland of St Helena, where the Eaſt India Company iſſue to their own ſervants European and Indian goods at 10 *per cent.* advance on the prime coſt. Conſidering our immenſe diſtance from England, a greater advance would be neceſſary; and the ſettlers and others would be well ſatisfied, and think it equally liberal, to pay 50 *per cent.* on the prime coſt of all goods brought from England; for at preſent they pay never leſs than 100, and frequently 1000, *per cent.* on what they have occaſion to purchaſe. It may be ſuppoſed that government would not chooſe to open an account, and be concerned in the retail of goods; but any individual would find it to his intereſt to do this, particularly if aſſiſted by government in the freight; and the inhabitants would gladly prefer the manufactures of their own country to the ſweepings of the Indian bazars.

"The great want of men in the colony muſt be ſupplied as ſoon as a peace ſhall take place; but the want of reſpectable ſettlers may, perhaps, be longer felt; by theſe are meant men of property, with whom the gentlemen of the colony could aſſociate, and who ſhould be thoroughly experienced in the buſineſs of agriculture. Should ſuch men ever arrive, the adminiſtration of juſtice might aſſume a leſs military appearance, and the trial by jury, ever dear and moſt congenial to Engliſhmen, be ſeen in New South Wales."

There is, however, one ſerious difficulty which the colony has not yet overcome, and which, until it be overcome, will certainly prevent ſuch men from ſettling in New South Wales. Till ſome ſtaple commodity can be raiſed for exportation, induſtrious free ſettlers will never be tempted to emigrate from Europe to a country where their induſtry cannot procure the comforts as

Wales, Walpole.

well as the neceſſaries of life. The American colonies, in their infancy, did not labour under this diſadvantage. Tobacco ſoon became, and ſtill continues to be, an article of ſuch importance, that its cultivation afforded the trans-atlantic farmer a ready exchange for European commodities; whilſt in New South Wales there ſeems to be no vegetable production of much value, except New Zealand hemp, which is produced indeed in great abundance in Norfolk Iſland, and which Captain Cook long ago pointed out as an article of great importance to the Britiſh navy. This is indeed a valuable plant, and grows in all the cliffs of the iſland, where nothing elſe will grow, in ſufficient abundance to give conſtant employment to 500 people; yet when Mr Collins left the ſettlement, there was no more than one loom on the iſland, and the ſlay or reed was deſigned for coarſe canvas; nor did they poſſeſs a ſingle tool required by flax-dreſſers or weavers beyond the poor ſubſtitutes which they were obliged to fabricate for themſelves. In this defect of neceſſaries for the manufacture, only 18 people could be employed in it; and of theſe the united labour in a week produced 16 yards of canvas, of the ſize called N° 7.

Beſides a uſeful manufactory of this plant, which certainly might be eſtabliſhed, the colony appears to poſſeſs ſeveral important advantages. From Mr Collins's narrative, it appears probable that a ſeal and perhaps a whale fiſhery might be eſtabliſhed with a fair proſpect of ſucceſs; good rich earth is found near Sydney Cove; there are immenſe ſtrata of coal in the ſouthern part of New Holland; Norfolk Iſland abounds with lime; and vaſt quantities of ſhells, which anſwer the ſame purpoſe, have been found on the main-land. Though the wood in general be not of a durable kind, it appears that there is ſome good timber near the Hawkeſbury river; and at Norfolk Iſland and New Zealand it is remarkably fine.

WALPOLE (Horace, Earl of Orford), was the youngeſt ſon of the celebrated Sir Robert Walpole, afterwards Earl of Orford, by his firſt wife, Catharine, daughter of Robert Shorter, Eſq; of Bybrook in Kent. He was born 1716; and was educated, firſt at Eton ſchool, and afterwards at Cambridge. At Eton he formed an intimate acquaintance with the celebrated poet Gray; and they went together on the tour of Europe, in the years 1739, 1740, and 1741. Unhappily they had a diſpute in the courſe of their travels, which produced a ſeparation.

Mr Walpole was able to make a ſplendid figure during the remainder of his deſtined courſe; but poor Gray, after the ſeparation, was obliged to obſerve a very ſevere economy. "This difference aroſe from the difference of their tempers: the latter being, from his earlieſt years, curious, penſive, and philoſophical; the former, gay, lively, and inconſiderate. This, therefore, occaſioned their ſeparation at Reggio. Mr Gray went before him to Venice; and ſtaying there till he could find means of returning to England, he made the beſt of his way home, repaſſing the Alps, and following almoſt the ſame rout, through France, which he had before gone to Italy. In juſtice to the memory of ſo reſpectable a friend, Mr Walpole (ſays Mr Maſon, Life of Gray, 4to, p. 41.) enjoins me to charge him with the chief blame in their quarrel, confeſſing that more attention, complaiſance, and deference, to a warm friendſhip, and ſuperior judgment and prudence, might have prevented a rupture that gave much uneaſineſs to them both, and a laſting concern to the ſurvivor; though in the year 1744 a reconciliation was effected between them, by a lady who wiſhed well to both parties."—This event took place after their return to England; but the *wound* in their friendſhip left a *ſcar* that never was totally effaced.

Walpole.

We do not, indeed, think that Horace Walpole and Mr Gray were formed, either by nature or by habits, to continue long in a ſtate of intimate friendſhip. Gray appears to have been a man of the pureſt moral principles, a friend to religion, penſive, and at leaſt ſufficiently conſcious of his intellectual powers and intellectual attainments. Walpole's morality was certainly of a looſer kind; he ſeems to have had no religion; he was often unſeaſonably gay; and to an equal ſhare of intellectual pride, though without equal reaſon, he added the pride of birth. It can therefore excite no ſurpriſe that a man of Gray's independent ſpirit could not bear the ſupercilious freaks of ſuch a character.

Mr Walpole was nominated to repreſent the city of Norwich, when his father viſited it July 3d, 1733, having acquired conſequence, not only as the ſon of the miniſter, but as having attended the Prince of Orange to England in that year. He was choſen member for Collington, in Cornwall, in the parliament which met June 25th, 1741; was a ſecond time in parliament as repreſentative for Caſtle-Riſing, in Norfolk, in 1747; and for King's Lynn in 1754 and 1761; and, at the expiration of that parliament, he finally retired from the ſtage of politics, and confined himſelf wholly to literary purſuits. He held to his death the office of uſher of his Majeſty's exchequer, comptroller of the pipe, and clerk of the eſtreats. Upon the death of his nephew, George, third Earl of Orford, 1791, he ſucceeded to the title and eſtates; but that event made ſo little alteration in his mode of living, that we know not whether he ever took his ſeat in the houſe of peers. During almoſt the whole courſe of his life he was the victim of the gout, which at laſt reduced him to a cripple: but it never impaired his faculties; and, to the very moment of death, his underſtanding ſeemed to bid defiance to the ſhock of Nature. He died at his houſe in Berkeſley Square, in 1796, having juſt entered his 80th year; and was interred in the family vault at Houghton, in a private manner, agreeably to his particular directions.

Horace, Lord Orford, was never married, and, by one of his biographers, his chief miſtreſs through life is ſaid to have been the muſe. It is certain that he devoted the greater part of his life to belles lettres and virtú, though he ridiculouſly affected, in his letters to his friends, to deſpiſe learning and learned men, for which he was very properly reprimanded both by Gray and Hume. It was an affectation peculiarly abſurd in him, who was conſtantly publiſhing ſomething, and who wrote with uncommon acrimony againſt all who preſumed to call in queſtion the fidelity of the picture which he had drawn of Richard III. or indeed to controvert any of his opinions. Hence his antipathy to Johnſon, becauſe he was a tory, a Chriſtian, and a rigid moraliſt; whilſt he himſelf was a whig, an infidel, and ſuch a moraliſt as could retail, without bluſhing, all the ſcandalous anecdotes, whether true or falſe, of that auguſt family, from whom he acknowledged his whole fortune to be derived He had, indeed, another reaſon for diſliking Johnſon. Lord Orford ſhone in converſation, and ſurpaſſed all his contemporaries in that kind of talk, which, without dazzling by its wit, always delighted; while Johnſon, when rouſed, knocked down, as by a flaſh of lightning, his Lordſhip, and every one elſe who had the confidence before him to talk profanely. Johnſon's wit was original: Lord Orford's conſiſted of ludicrous ſtories and of literary and political anecdotes. His works, of which by far the moſt valuable part has long been in the hands of the public, were collected in 1798, and publiſhed in five volumes, 4to. They reſemble his converſation, being rather amuſing than profound or inſtructive.

WARING (Edward, M. D.), Lucaſian Profeſſor of Mathematics in the univerſity of Cambridge, was the ſon of a wealthy farmer, of the Old Heath, near Shrewſbury. The early part of his education he received at the free ſchool in Shrewſbury; whence he removed to Cambridge, and was admitted on the 24th of March 1753 a member of Magdalen college. Here his talents for abſtruſe calculation ſoon developed themſelves, and, at the time of taking his degree, he was conſidered as a prodigy in thoſe ſciences which make the ſubject of the bachelor's examination. The name of Senior Wrangler, or the firſt of the year, was thought ſcarcely a ſufficient honour to diſtinguiſh one who ſo far outſhone his contemporaries; and the merits of John Jebb were ſufficiently acknowledged, by being the ſecond in the liſt. Waring took his firſt, or bachelor's degree, in 1757, and the Lucaſian Profeſſorſhip became vacant before he was of ſufficient ſtanding for the next, or maſter's degree, which is a neceſſary qualification for that office. This defect was ſupplied by a royal mandate, through which he became maſter of arts in 1760; and ſhortly after his admiſſion to this degree, the Lucaſian Profeſſor.

The royal mandate is too frequently a ſcreen for indolence; and it is now become almoſt a cuſtom, that heads of colleges, who ought to ſet the example in diſcipline to others, are the chief violaters of it, by making their office a pretext for taking their doctor's degree in divinity, without performing thoſe exerciſes which were deſigned as proofs of their qualifications. Such indolence cannot be imputed to Waring; yet ſeveral circumſtances, previous to his election into the profeſſorial chair, diſcovered that there was, at leaſt, one perſon in the univerſity who diſapproved of the anticipation of degrees by external influence.—Waring, before his election, gave a ſmall ſpecimen of his abilities, as proof of his qualification for the office which he was then ſoliciting; and a controverſy on his merits enſued: Dr Powell, the maſter of St John's college, attacking, in two pamphlets, the Profeſſor; and his friend, afterwards Judge Wilſon, defending. The attack was ſcarcely warranted by the errors in the ſpecimen; and the abundant proofs of talents in the exerciſe of the profeſſorial office are the beſt anſwers to the ſarcaſms which the learned divine amuſed himſelf in caſting on riſing merit. An office held by a Barrow, a Newton, a Whiſton, a Cotes, and a Sanderſon, muſt excite an ingenuous mind to the greateſt exertions; and the new Profeſſor, whatever may have been his ſucceſs, did not fall behind any of his predeceſſors, in either zeal for the ſcience, or application of the powers of his mind, to extend its boundaries. In 1762. he publiſhed his Miſcellanea Analytica; one of the moſt abſtruſe books written on the abſtruſeſt parts of algebra. This work extended his fame over all Europe. He was elected, without ſolicitation on his part, member of the ſocieties of Bononia and Gottingen; and received flattering marks of eſteem from the moſt eminent mathematicians at home and abroad. The difficulty of this work may be preſumed from the writer's own words, "I cannot ſay that I know any one who thought it worth while to read through the whole, and perhaps not the half of it."

Mathematics did not, however, engroſs the whole of his attention. He could dedicate ſome time to the ſtudy of his future profeſſion; and in 1767, he was admitted to the degree of doctor of phyſic; but, whether from the incapacity of uniting together the employments of active life with abſtruſe ſpeculation, or from the natural diffidence of his temper, for which he was moſt peculiarly remarkable; the degree which gave him the right of exerciſing his talents in medicine was to him merely a barren title. Indeed he was ſo embarraſſed in his manners before ſtrangers, that he could not have made his way in a profeſſion in which ſo much is done by addreſs; and it was fortunate that the caſe of his circumſtances permitted him to devote the whole of his time to his favourite purſuit. His life paſſed on, marked out by diſcoveries, chiefly in abſtract ſcience; and by the publication of them in the Philoſophical Tranſactions, or in ſeparate volumes, under his own inſpection. He lived ſome years after taking his doctor's degree, at St Ives, in Huntingdonſhire. While at Cambridge he married—quitted Cambridge with a view of living at Shrewſbury; but the air or ſmoke of the town being injurious to Mrs Waring's health, he removed to his own eſtate at Plaiſley, about 8 miles from Shrewſbury, where he died in 1797, univerſally eſteemed for inflexible integrity, modeſty, plainneſs, and ſimplicity of manners. They who knew the greatneſs of his mind from his writings looked up to him with reverence everywhere; but he enjoyed himſelf in domeſtic circles with thoſe chiefly among whom his purſuits could not be the object either of admiration or envy. The outward pomp which is affected frequently in the higher departments in academic life, was no gratification to one whoſe habits were of a very oppoſite nature; and he was too much occupied in ſcience to attend to the intrigues of the univerſity. There, in all queſtions of ſcience, his word was the law; and at the annual examination of the candidates for the prize inſtituted by Dr Smith, he appeared to the greateſt advantage. The candidates were generally three or four of the beſt proficients in the mathematics at the previous annual examination for the bachelor's degree, who were employed from nine o'clock in the morning to ten at night, with the exception of two hours for dinner, and twenty minutes for tea, in anſwering, *viva voce*, or writing down anſwers to the profeſſor's queſtions, from the firſt rudiments of philoſophy to the deepeſt parts of his own and Sir Iſaac Newton's works. Perhaps no part of Europe affords an inſtance of ſo ſevere a proceſs; and there was never any ground for ſuſpecting the Profeſſor of partiality,

lity. The zeal and judgment with which he performed this part of his office cannot be obliterated from the memory of thoſe who paſſed through his fiery ordeal.

Wiſhing to do ample juſtice to the talents and virtue of the Profeſſor, we feel ourſelves ſomewhat at a loſs in ſpeaking of the writings by which alone he will be known to poſterity. He is the diſcoverer, according to his own account, of nearly 400 propoſitions in the analytics. This may appear a vain glorious boaſt, eſpecially as the greater part of thoſe diſcoveries are likely to ſink into oblivion; but he was, in a manner, compelled to make it by the inſolence of Lalande, who, in his life of Condorcet, aſſerts that, in 1764, there was no firſt-rate analyſt in England. In reply to this aſſertion, the Profeſſor, in a letter to Dr Maſkelyne, firſt mentions, with proper reſpect, the inventions and writings of Harriot, Briggs, Napier, Wallis, Halley, Bruncker, Wren, Pell, Barrow, Mercator, Newton, De Moivre, Maclaurin, Cotes, Stirling, Taylor, Simpſon, Emerſon, Landen, and others; of whom Emerſon and Landen were living in 1764. He then gives a fair and full detail of his own inventions, of which many were publiſhed anterior to 1764; and concludes his letter in theſe words.

" I know that Mr Lalande is a firſt-rate aſtronomer, and writer of aſtronomy; but I never heard that he was much converſant in the deeper parts of mathematics; for which reaſon I take the liberty to aſk him the following queſtions:

" Has he ever read or underſtood the writings of the Engliſh mathematicians: and, as the queſtion comes from me, I ſubjoin, particularly of mine? If the anſwer be in the negative, as it is my opinion, if his anſwer be the truth, that it will, then there is an end of all further controverſy;—but if he aſſerts that he has, which is more than Condorcet did by his own acknowledgment, then he may know, from the enumeration of inventions made in the prefaces, with ſome ſubſequent ones added, that they are ſaid to amount to more than 400 of one kind or other. Let him try to reduce thoſe to as low a number as he can, with the leaſt appearance of candour and truth; and then let him compare the number with the number of inventions of any French mathematician or mathematicians, either in the preſent or paſt times, and there will reſult a compariſon (if I miſtake not) not much to his liking; and, further, let him compare ſome of the firſt inventions of the French mathematicians with ſome of the firſt contained in my works, both as to utility, generality, novelty, difficulty, and elegance, but wiſely as to utility, there is little contained in the deep parts of any ſcience; he will find their difficulty and novelty from his difficulty of underſtanding them, and his never having read any thing ſimilar before; their generality, by the application of them; principles of elegance will differ in different perſons.—I muſt ſay, that he will probably not find the difference expected. After or before this inquiry is inſtituted for mine, let him perform the ſame for the other Engliſh mathematicians; and when he has completed ſuch inquiries, and not before, he will become a judge of the juſtice of his aſſertion; but I am afraid that he is not a ſufficient adept in theſe ſtudies to inſtitute ſuch inquiries; and if he was, ſuch inquiries are invidious, troubleſome, and of ſmall utility."

By mathematical readers this account, which was not publiſhed by the Profeſſor himſelf, is allowed to be very little, if at all, exaggerated. Yet if, according to his own confeſſion, " few thought it worth their while to read even half of his works," there muſt be ſome grounds for this neglect, either from the difficulty of the ſubject, the unimportance of the diſcoveries, or a defect in the communication of them to the public. The ſubjects are certainly of a difficult nature, the calculations are abſtruſe; yet Europe contained many perſons not to be deterred by the moſt intricate theorems. Shall we ſay then, that the diſcoveries were unimportant? If this were really the caſe, the want of utility would be a very ſmall diſparagement among thoſe who cultivate ſcience with a view chiefly to entertainment and the exerciſe of their rational powers. We are compelled, then, to attribute much of this neglect to a perplexity in ſtyle, manner, and language; the reader is ſtopped at every inſtant, firſt to make out the writer's meaning, then to fill up the chaſm in the demonſtration. He muſt invent anew every invention; for, after the enunciation of the theorem or problem, and the mention of a few ſteps, little aſſiſtance is derived from the Profeſſor's powers of explanation. Indeed, an anonymous writer, certainly of very conſiderable abilities, has aptly compared the works of Waring to the heavy appendages of a Gothic building, which add little of either beauty or ſtability to the ſtructure.

A great part of the diſcoveries relate to an aſſumption in algebra, that equations may be generated by multiplying together others of inferior dimenſions. The roots of theſe latter equations are frequently terms called *negative* or *impoſſible*; and the relation of theſe terms to the coefficients of the principal equation is a great object of inquiry. In this art the profeſſor was very ſucceſsful, though little aſſiſtance is to be derived from his writings in looking for the real roots. We ſhall not, perhaps, be deemed to depreciate his merits, if we place the ſeries for the ſum of the powers of the roots of any equation among the moſt ingenious of his diſcoveries; yet we cannot add, that it has very uſefully enlarged the bounds of ſcience, or that the algebraiſt will ever find occaſion to introduce it into practice. We may ſay the ſame on many ingenious transformations of equations, on the diſcovery of impoſſible roots, and ſimilar exertions of undoubtedly great talents. They have carried the aſſumption to its utmoſt limits; and the difficulty attending the ſpeculation has rendered perſons more anxious to aſcertain its real utility; yet they who reject it may occaſionally receive uſeful hints from the Miſcellanea Analytica.

The firſt time of Waring's appearing in public as an author was, we believe, in the latter end of the year 1759, when he publiſhed the firſt chapter of the Miſcellanea Analytica, as a ſpecimen of his qualifications for the profeſſorſhip; and this chapter he defended, in a reply to a pamphlet, intitled, " Obſervations on the Firſt Chapter of a book called Miſcellanea Analytica." Here the Profeſſor was ſtrangely puzzled with the common paradox, that nothing divided by nothing may be equal to various finite quantities, and has recourſe to unqueſtionable authorities in proof of this poſition. The names of Maclaurin, Sanderſon, De Moivre, Bernoulli, Monmort, are ranged in favour of his opinion: But Dr Powell was not ſo eaſily convinced, and returns to the charge in defence of the Obſervations; to which the

Profeſſor replied in a letter to the Rev. Dr Powell, Fellow of St John's college, Cambridge, in anſwer to his Obſervations, &c. In this controverſy, it is certain that the Profeſſor gave evident proofs of his abilities; though it is equally certain that he followed too implicitly the deciſions of his predeceſſors. No apparent advantage, no authority whatever, ſhould induce mathematicians to ſwerve from the principles of right reaſoning, on which their ſcience is ſuppoſed to be peculiarly founded. According to Maclaurin, Dr Waring, and others, If $P = \frac{a - x}{a^2 - x^2}$, then, when $x = a$, P is equal to $\frac{1}{2a}$; for, ſay they, $\frac{a - x}{a^2 - x^2}$ is equal to $\frac{a - x}{a - x} \times \frac{1}{a + x}$; that is, when x is equal to a, $P = \frac{1}{a + x}$, or $\frac{1}{2a}$. But when x is equal to a, the numerator and denominator of the fraction $\frac{a - x}{a^2 - x^2}$ are both, in their language, equal to nothing. Therefore, nothing divided by nothing is equal to $\frac{1}{2a}$. In the ſame manner, $\frac{a - x}{a^3 - x^3} = \frac{1}{a^2 + ax + x^2} \times \frac{a - x}{a - x}$, which, when x is equal to a, becomes $\frac{1}{3a^2}$. Therefore, nothing divided by nothing is equal to $\frac{1}{3a^2}$, or $\frac{1}{3a^2} = \frac{1}{2a}$; that is, $\frac{1}{3a} = \frac{1}{2}$; which is abſurd. But we need only trace back our ſteps to ſee the fallacy in this mode of reaſoning. For P is equal to ſome number multiplied into $\frac{a - x}{a - x}$; that is, when x is equal to a, P is equal to ſome number multiplied into nothing, and divided by nothing; that is, P is, in that caſe, no number at all. For $a - a$ cannot be divided by $a - x$ when x is equal to a, ſince, in that caſe, $a - x$ is no number at all.

If, in the beginning of his career, the Profeſſor could admit ſuch paralogiſms into his ſpeculations, and the writings of the mathematicians, for nearly a century before him, may plead in his excuſe, we are not to be ſurpriſed that his diſcoveries ſhould be built rather on the aſſumptions of others than on any new principles of his own. Acquieſcing in the ſtrange notion, that nothing could be divided by nothing, and produce a variety of numbers, he as eaſily adopted the poſition, that an equation has as many roots as it has dimenſions.—Thus 2 and — 4 are ſaid to be roots of the equation $x^2 - 2x = 8$, though 4 can be the root only of the equation; $x^2 - 2x = 8$, which differs ſo materially from the preceding, that in one caſe $2x$ is added, in the other caſe it is ſubtracted from x^2.

Allowances being made for this error in the principles, the deductions are, in general, legitimately made; and any one, who can give himſelf the trouble of demonſtrating the propoſitions, may find ſufficient employment in the Profeſſor's analytics. Perhaps it will be ſufficient for a ſtudent to devote his time to the ſimpleſt caſe $x^n \pm 1 = 0$; and when he has found a few thouſand roots of + 1 and — 1, the publication of them may afford to poſterity a ſtrong proof of the ingenuity of their predeceſſors, and the application of the powers of their mind to uſeful and important truths. In this exerciſe may be conſulted the method given by the Profeſſor, of finding a quantity, which, multiplied into a given irrational quantity, will produce a rational product, or conſequently exterminate irrational quantities out of a given equation; but if an irrational quantity cannot come into an equation, the utility of this invention will not be admitted without heſitation.

The "Proprietates Algebraicarum Curvarum," publiſhed in 1772, neceſſarily labour under the ſame defects with the Miſcellanea Analytica, the Meditationes Algebraicæ, publiſhed in 1770, and the Meditationes Analyticæ, which were in the preſs during the years 1773, 1774, 1775, 1776. Theſe were the chief and the moſt laborious works edited by the Profeſſor; and in the Philoſophical Tranſactions is to be found a variety of papers, which alone would be ſufficient to place him in the firſt rank in the mathematical world. The nature of them may be ſeen from the following catalogue.

Vol. LIII. p. 294, Mathematical Problems.—LIV. 193. New Properties in Conics.—LV. 143. Two Theorems in Mathematics.—LXIX. Problems concerning Interpolations.—86. A General Reſolution of Algebraical Equations.—LXXVI. 81. On Infinite Series. LXXVII. 71. On Finding the Values of Algebraical Quantities by Converging Serieſes, and Demonſtrating and Extending Propoſitions given by Pappus and others.—LXXVIII. 67. On Centripetal Forces.—*Ib.* 588. On ſome Properties of the Sum of the Diviſion of Numbers.—LXXIX. 166. On the Method of Correſpondent Values, &c.—*Ib.* 185. On the Reſolution of Attractive Powers.—LXXXI. 146. On Infinite Serieſes.—LXXXIV. 385—415. On the Summation of thoſe Series whoſe general term is a determinate function of z, the diſtance of the term of the Series.

For theſe papers, the Profeſſor was, in 1784, deſervedly honoured by the Royal Society with Sir Godfrey Copley's medal; and moſt of them afford very ſtrong proofs of the powers of his mind, both in abſtract ſcience, and the application of it to philoſophy; though they labour, in common with his other works, under the diſadvantage of being clothed in a very unattractive form. The mathematician, who has reſolution to go through them, will not only add much to his own knowledge, but be uſefully employed in dilating on thoſe articles for the benefit of the more general reader. We might add in this place, a work written on morals and metaphyſics in the Engliſh language; but as a few copies only were preſented to his friends, and it was the Profeſſor's wiſh that they ſhould not have a more extenſive circulation, we ſhall not here enlarge upon its contents.

In the mathematical world, the life of Waring may be conſidered as a diſtinguiſhed æra. The ſtrictneſs of demonſtration required by the ancients had gradually fallen into diſuſe, and a more commodious, though almoſt mechanical mode by algebra and fluxions took its place, and was carried to the utmoſt limit by the Profeſſor. Hence many new demonſtrations may be attributed to him, but 100 diſcoveries can ſcarcely fall to the lot of a human being. If we examine thoroughly thoſe which our Profeſſor would diſtinguiſh by ſuch names, we ſhall find many to be mere deductions, others, there, as in the ſolution of biquadratics, anticipated by former writers. But if we cannot allow to him the merit of ſo inventive a genius, we muſt applaud his aſſiduity; and, diſtinguiſhed as he was in the ſcientific world, the purity of his life, the ſimplicity of his manners, and the zeal which he always manifeſted for the truths of the Goſpel, will intitle him to the reſpect of all who do not eſteem the good qualities of the heart inferior to thoſe of the head.

WARTON (Joſeph, D. D.) was born either towards the end of the year 1721, or in the beginning of the year 1722. He was the eldeſt ſon of Thomas Warton, B. D. who had been fellow of Magdalen College, Oxford; poetry profeſſor from the year 1718 to 1728, and vicar of Baſingſtoke in Hampſhire, and of Cobham in Surrey. Where the ſubject of this memoir was born we have not learned, though, were we to hazard a conjecture, we would ſay that it was in Oxford, as his father probably reſided in that city during his profeſſorſhip.

Our knowledge of the private hiſtory of Dr Warton is indeed extremely limited. We do not even know at what ſchool, or in what college, he was educated; tho' it was probably at Wincheſter ſchool, and certainly in ſome of the colleges in the univerſity of Oxford. For many years, he was ſucceſſively under and upper maſter of Wincheſter college; but reſigned the laſt of theſe offices when he found the infirmities of age coming upon him; and was ſucceeded by Dr Goddard the preſent excellent maſter. He was likewiſe prebendary of the cathedral church of Wincheſter, and rector of Wickham in Hampſhire, where he died, aged 78.

His publications are few, but valuable. A ſmall collection of poems, without a name, was the firſt of them, and contained the Ode to Fancy, which has been ſo much and ſo deſervedly admired. They were all of them afterwards printed in Dodſley's collection. He was alſo a conſiderable contributor to the Adventurer, publiſhed by Dr Hawkeſworth; and all the papers which contain criticiſms on Shakeſpeare were written by him and his brother Thomas Warton, the ſubject of the next article.

The firſt volume of his Eſſay on the Life and Writings of Pope was publiſhed, had paſſed through ſeveral editions, and an interval of between 20 and 30 years had elapſed, before he gave a ſecond volume of that elegant and inſtructive work to the world. He had not only meditated, but had collected materials for a literary hiſtory of the age of Leo X.; and propoſals were actually in circulation for a work of that kind; but it is probable that the duties of his ſtation did not leave him the neceſſary leiſure for an undertaking which required years of ſecluſion and independence. His laſt and late work, which he undertook for the bookſellers at a very advanced age, was an edition of Pope's Works, that has not altogether ſatisfied the public expectation. He retained, with great propriety indeed, many of the notes of Warburton; but is ſeverely reprehended by the author of the Purſuits of Literature for ſuppreſſing the name of that prelate on his title-page, or including it only, as ſubordinate to his own, in the general expreſſion *others*.

Dr Warton was cheerful in his temper, convivial in his diſpoſition, of an elegant taſte and lively imagination, with a large portion of ſcholarſhip, and a very general knowledge of the Belles Lettres of Europe; it may be preſumed that Dr Warton poſſeſſed, beyond moſt men, the power of enlivening Claſſical Society. He was the intimate friend of Dr Johnſon; was ſeen at the parties of Mrs Montague, as well as at the table of Sir Joſhua Reynolds, and was an original member of the Literary Club. He poſſeſſed a liberal mind, a generous diſpoſition, and a benevolent heart. He was not only admired for his talents and his knowledge, but was beloved for thoſe qualities which are the beſt gifts of this imperfect ſtate.

WARTON (Thomas), the brother of the preceding, was born in the year 1728. He received, as we have reaſon to believe, the firſt part of his education at Wincheſter; and at the age of 16 was entered a commoner of Trinity College, Oxford, under the tuition of Mr Geering.

Biog. Dict.

He began his poetical career at an early age. In 1745, he publiſhed five paſtoral eclogues, in which are beautifully deſcribed the miſeries of war to which the ſhepherds of Germany were expoſed. Not long after, in the year 1748, he had full ſcope afforded for the exertion of his genius. It is well known that Jacobite principles were ſuſpected to prevail in the univerſity of Oxford about the time of the rebellion in the year 1745. Soon after its ſuppreſſion, the drunkenneſs and folly of ſome young men gave offence to the court, in conſequence of which a proſecution was inſtituted in the court of King's Bench, and a ſtigma was fixed on the vice chancellor and ſome other heads of colleges in Oxford. Whilſt this affair was the general ſubject of converſation, Mr Maſon publiſhed his "Iſis," an elegy, in which he adverts to the above mentioned circumſtances. In anſwer to this poem, Mr Warton, encouraged by Dr Huddesford, the preſident of his college, publiſhed, in 1749, "The Triumph of Iſis," which excelled more in manly expoſtulation and dignity than the poem that produced it did in neatneſs and elegance. With great poetical warmth, and a judicious ſelection of circumſtances, he characteriſes the eminent men who had been educated in Oxford, and draws a ſtriking and animated portrait of Dr King, the celebrated public orator of that time. The whole poem ſhews the early maturity of his genius, and is finiſhed with happy diligence.

In the year 1751, he ſucceeded to a fellowſhip of his college, and was thus placed in a ſituation eaſy and independent, and particularly congenial with his habits of retirement and ſtudy. In 1753, appeared his obſervations on "The Faery Queen of Spencer," in 8vo, a work which he corrected, enlarged, and republiſhed, in two volumes crown octavo, in the year 1762. He ſent a copy of the firſt edition to Dr Johnſon, who, in a letter to him upon the ſubject, expreſſed this handſome compliment: "I now pay you a very honeſt acknowledgement for the advancement of the literature of our native country: you have ſhewn to all, who ſhall hereafter attempt the ſtudy of ancient authors, the way to ſucceſs, by directing them to the peruſal of the books which theſe authors had read."

In 1754, Dr Johnſon viſited Oxford for the firſt time after he had quitted reſidence there. Much of his time was ſpent with Mr Warton; and there appeared to have been a conſiderable degree of confidential intercourſe between them upon literary ſubjects, and particularly on their own works. A pleaſing account of this viſit was communicated by Mr Warton to Mr Boſwell, who has inſerted it in his life of Johnſon.

In 1755, Mr Warton exerted himſelf to procure for his friend the degree of maſter of arts by diploma from the univerſity of Oxford; an honour which Johnſon eſteemed of great importance to grace the title page of his dictionary which he was about to publiſh. In 1756, Mr Warton was elected profeſſor of poetry, which office he held for the uſual term of ten years. His lectures were remarkable for elegance of diction and juſtneſs of obſervation. One of them, on the ſubject of paſtoral poetry, was afterwards prefixed to his edition of Theocritus. In 1758, he contributed to aſſiſt Dr Johnſon in the ſubſcription to his edition of Shakeſpeare, and furniſhed him with ſome valuable notes. The Doctor remarks, in a letter to him, when ſoliciting his farther aid, "It will be reputable to my work, and ſuitable to your profeſſorſhip, to have ſomething of yours in my notes."

From the Clarendon preſs, in the year 1766, he publiſhed "Anthologiæ Græcæ, a Conſtantino Cephalâ conditæ, Libri tres," in 2 vols, 12mo. He concludes the learned and claſſical preface to this work, which is replete with accurate remarks on the Greek epigram, in the following words, which mark this publication for his own: "Vereor ut hactenus in plexendis florum corollis otium nimis longum pertraxerim. Proximè ſequetur, cui nunc omnes operas et vires intendo, Theocritus. Interea quaſi promulſidem convivii Lectoribus meis elegantias haſce vetuſtatis eruditæ propino."

In the year 1770, he conferred a ſimilar honour upon the academical preſs by his edition of Theocritus, in 2 vols, 8vo. He undertook this work by the advice of Judge Blackſtone, then fellow of All-Souls College, and an ardent promoter of every publication that was likely to do credit to the Clarendon preſs. This elaborate publication reflects no ſmall credit on the learning, diligence, and taſte of the editor.

In 1771, he was elected a fellow of the Antiquarian Society, and was preſented by the Earl of Lichfield to the ſmall living of Kiddington in Oxfordſhire, which he held till his death. He likewiſe in this year publiſhed an improved account of "The Life of Sir Thomas Pope, founder of Trinity College, Oxford. In compoſing theſe memoirs, he beſtowed much labour and reſearch, and ſhewed great judgment in the arrangement of his materials. But poſſibly, in his ardour to pay a debt of gratitude, he has not ſufficiently conſidered what was due to his own fame. The ſame ſtrength of deſcription and vigour of remark would have better ſuited the life of ſome eminently diſtinguiſhed character, and extended the reputation of the author as a biographer beyond the circle of thoſe academical readers who are influenced by the ſame feelings of veneration, reſpect, and gratitude which prompted Mr Warton to compoſe this work. The preface contains ſome excellent remarks on biographical writing.

The plan for a hiſtory of Engliſh poetry was laid by Pope, enlarged by Gray: but to bring an original plan nearly to a completion was reſerved for the perſeverance of Warton. In 1774 appeared his firſt volume; in 1778, the ſecond and third; which brings the narrative down to the commencement of the reign of Elizabeth in 1581. This work diſplays the moſt ſingular combination of extraordinary talents and attainments. It unites the deep and minute reſearches of the antiquary with the elegance of the claſſical ſcholar and the ſkill of the practiſed writer. The ſtyle is vigorous and manly; the obſervations acute and juſt; and the views of the ſubject are extenſive and accurate.

In 1777, he collected his poems into an octavo volume, containing miſcellaneous pieces, odes, and ſonnets. This publication may be conſidered in ſome meaſure original; there being only ſeven pieces that had before appeared, and near three times that number which were then printed for the firſt time.

In vindication of the opinion he had given in his ſecond volume of "The Hiſtory of Poetry," relative to the ingenious attempt of Chatterton to impoſe upon the public, he produced, in 1782, "An Inquiry into the Authenticity of the Poems attributed to Rowley." In this excellent pamphlet the principles of true criticiſm are laid down, an appeal is properly made to the internal evidence of the poems; and upon theſe grounds it is proved, in the moſt ſatisfactory manner, that they could not have been written by a monk of the fourteenth century.

The year 1785 brought him thoſe diſtinctions which were no leſs honourable to thoſe who conferred than to him who received them. He was appointed poet laureat on the death of Whitehead, and elected Camden profeſſor of ancient hiſtory on the reſignation of Dr Scott. His inauguration lecture was delivered in a clear and impreſſive manner from the profeſſorial chair. It contained excellent obſervations on the Latin hiſtorians, and was written in a ſtrong, perſpicuous, and claſſical ſtyle. In his odes, the vigour and brilliancy of his fancy were not proſtituted to an inſipid train of courtly compliments: each preſents an elegant ſpecimen of deſcriptive poetry, and as all of them have only a ſlight relation to the particular occaſion on which they were written, and have always a view to ſome particular and intereſting ſubject, they will be peruſed with pleaſure as long as this ſpecies of compoſition is admired.

He made occaſional journeys to London to attend the literary club, of which he was ſome years a member; and to viſit his friends, particularly Sir Joſhua Reynolds. At his houſe he was ſure to meet perſons remarkable for faſhion, elegance, and taſte.

His laſt publication, except his official odes, conſiſted of Milton's ſmaller poems. A quarto edition appeared in 1790, with corrections and additions. The great object of theſe notes is to explain the alluſions of Milton, to trace his imitations, and to illuſtrate his beauties.

Until he reached his ſixty ſecond year, he continued to enjoy vigorous and uninterrupted health. On being ſeized with the gout, he went to Bath, and flattered himſelf, on his return to college, that he was in a fair way of recovery. But the change that had taken place in his conſtitution was viſible to his friends On Thurſday, May 20, 1790, he paſſed the evening in the common room, and was for ſome time more cheerful than uſual. Between ten and eleven o'clock he was ſtruck with the palſy, and continued inſenſible till his death, which happened the next day at two o'clock. On the 27th, his remains were interred in the college chapel with the moſt diſtinguiſhed academical honours.

The inſcription upon the flat ſtone which is placed over his grave contains only an enumeration of his preferments.

Such was the general conduct and behaviour of Mr Warton as to render him truly amiable and reſpectable. By his friends he was beloved for his open and eaſy manners; and by the members of the univerſity at large he was reſpected for his conſtant reſidence, ſtrong attachment to Alma Mater, his ſtudious purſuits, and high literary character In all parties where the company accorded with his inclination, his converſation was eaſy and gay, enlivened with humour, enriched with anecdote, and pointed with wit. Among his peculiarities it may be mentioned that he was fond of all military ſights. He was averſe to ſtrangers, particularly to thoſe of a literary turn; and yet he took a great pleaſure in encouraging the efforts of riſing genius, and aſſiſting the ſtudious with his advice; as many of the young men of his college, who ſhared his affability and honoured his talents, could teſtify. He was bred in the ſchool of punſters; and made as many good ones as Barton and Leigh, the celebrated word-hunters of his day. Under the maſk of indolence, no man was more buſy; his mind was ever on the wing in ſearch of ſome literary prey. Although, at the accuſtomed hours of Oxford ſtudy, he was often ſeen ſauntering about, and converſing with any friend he chanced to meet; yet, when others were waſting their mornings in ſleep, he was indulging his meditations in his favourite walks, and courting the Muſes. His ſituation in Oxford was perfectly congenial with his diſpoſition, whether he indulged his ſallies of pleaſantry in the common room, retired to his own ſtudy, or to the Bodleian library; ſauntered on the banks of his favourite Cherwell, or ſurveyed, with the enthuſiaſtic eye of taſte, the ancient gateway of Magdalen College, and other ſpecimens of Gothic architecture.

The following is a liſt of Mr Warton's works: 1. "Five Paſtoral Eclogues," 4to, 1745. Reprinted in Pearch's Collection of Poems. 2. "The Pleaſures of Melancholy," written in 1745; firſt printed in Dodſley's Collection, and afterwards in the Collection of Mr Warton's Poems. 3. "Progreſs of Diſcontent," written in 1746. Firſt printed in the "Student," a periodical paper. 4. "The Triumph of Iſis, a Poem," 4to, 1750. 5. "Newmarket, a Satire," folio, 1751. 6. "Ode for Muſic," performed at the theatre in Oxford 1751. 7. "Obſervations on the Faerie Queen of Spenſer," 8vo, 1754. 8. "Inſcriptionum Metricarum Delectus," 4to, 1758. 9. "A Deſcription of the City, College, and Cathedral, of Wincheſter," 8vo, no date. 10. "The Life of Sir Thomas Pope," in the 5th volume of the Biographia Britannica," republiſhed in 1772. 11. "The Life and literary Remains of Ralph Bathurſt, M. D. Dean of Wells, and Preſident of Trinity College in Oxford," 1761. 12. "A Companion to the Guide, and a Guide to the Companion," 12mo, 1762. 13. "The Oxford Sauſage," in which are ſeveral Poems by Warton. 14. "Anthologiæ Græcæ a Conſtantino Cephalâ conditæ Libri tres," 2 tom. 1766. 15. "Theocritis Syracuſii quæ ſuperſunt, cum Scholiis Græcis," &c. 2 tom. 4to, 1770. 16. "Hiſtory of Engliſh Poetry, from the Cloſe of the 11th to the Commencement of the 18th Century," 4to, Vol. I. 1774. Vol. II. 1778. Vol. III. 1781 17. "Poems," 8vo, 1777 18. "Specimen of a Hiſtory of Oxfordſhire," 1783. 19. "An Enquiry into the Authenticity of the Poems attributed to Thomas Rowley," 8vo, 1782. 20. Verſes on Sir J. Reynolds's painted Window in New College Chapel, 4to." 1782. 21. "Poems on ſeveral Occaſions, by John Milton, with Notes critical and explanatory," 8vo, 1785.

WASHINGTON (George), whoſe name is likely to live as long as that of any modern, was born on the 11th of February 1732, in the pariſh of Waſhington, Virginia. He was deſcended from an ancient family in Cheſhire, of which a branch had been eſtabliſhed in Virginia about the middle of the 17th century. We are not acquainted with any remarkable circumſtances of his education or his early youth; and we ſhould not indeed expect any marks of that diſorderly prematureneſs of talent, which is ſo often fallacious, in a character whoſe diſtinguiſhing praiſe was to be regular and natural. His claſſical inſtruction was probably ſmall, ſuch as the private tutor of a Virginian country gentleman could at that period have imparted; and if his opportunities of information had been more favourable, the time was too ſhort to profit by them (A). Before he was twenty he was appointed a major in the colonial militia, and he had very early occaſion to diſplay thoſe political and military talents, of which the exertions on a greater theatre have ſince made his name ſo famous throughout the world.

The plenipotentiaries who framed the treaty of Aix la Chapelle, by leaving the boundaries of the Britiſh and French territories in North America unfixed, had ſown the ſeeds of a new war, at the moment when they concluded a peace. – The limits of Canada and Louiſiana, negligently deſcribed in vague language by the treaties of Utrecht and Aix la Chapelle, becauſe the greater part of theſe vaſt countries was then an impenetrable wilderneſs, furniſhed a motive, or a pretext, for one of the moſt ſucceſsful, but one of the moſt bloody and waſteful wars in which Great Britain had ever been engaged. See BRITAIN, *Encycl.*

In the diſputes which aroſe between the French and Engliſh officers on this ſubject, Major Waſhington was employed by the governor of Virginia, in a negociation with the French governor of Fort du Queſne (now Pitſburgh); who threatened the Engliſh frontiers with a body of French and their Indian allies He ſucceeded in averting the invaſion; but hoſtilities becoming inevitable, he was in the next year appointed lieutenant colonel of a regiment raiſed by the colony for its own defence; to the command of which he ſoon after ſucceeded. The expedition of Braddock followed in the

---

(A) Several accounts of the life of Waſhington have ſtated that he ſerved as a midſhipman on board a Britiſh frigate. This is a miſtake. His elder brother, who died young, ſerved in that capacity in Vernon's expedition againſt Carthagena; whence the family ſeat was called Mount Vernon. Waſhington himſelf never left the United States, except in one ſhort voyage to a Weſt India iſland, when he was very young.

year 1755; of which the fatal iſſue is too well known to require being deſcribed by us. Colonel Waſhington ſerved in that expedition only as a volunteer; but ſuch was the general confidence in his talents, that he may be ſaid to have conducted the retreat. Several Britiſh officers are ſtill alive who remember the calmneſs and intrepidity which he ſhewed in that difficult ſituation, and the voluntary obedience which was ſo cheerfully paid by the whole army to his ſuperior mind. After having acted a diſtinguiſhed part in a ſubſequent and more ſucceſsful expedition to the Ohio, he was obliged by ill health, in the year 1758, to reſign his military ſituation. The ſixteen years which followed of the life of Waſhington ſupply few materials for the biographer. Having married Mrs Cuſtis, a Virginian lady of amiable character and reſpectable connections, he ſettled at his beautiful ſeat of Mount Vernon, of which we have had ſo many deſcriptions; where, with the exception of ſuch attendance as was required by his duties as a magiſtrate and a member of the aſſembly, his time was occupied by his domeſtic enjoyments, and the cultivation of his eſtate, in a manner well ſuited to the tranquillity of his pure and unambitious mind. At the end of this period he was called by the voice of his country from this ſtate of calm and ſecure though unoſtentatious happineſs.

For almoſt half a century ſymptoms of diſaffection to the mother-country had been ſo viſible in the New England provinces, that ſo early as 1734 the celebrated Biſhop Berkeley had predicted a total ſeparation of North America from Great Britain. That prelate, when a private clergyman, had lived three years in Rhode Iſland, and was an attentive and ſagacious obſerver of the manners and principles of the people, among whom he perceived the old leaven of their forefathers fermenting even then with great violence. The middle and ſouthern provinces, however, were more loyal, and their influence, together with perpetual dread of the French before the peace of 1763, put off the ſeparation to a more diſtant day than that at which, we have reaſon to believe, the Biſhop expected it to take place. Virginia, the moſt loyal of all the colonies, had long been in the habit of calling itſelf, with a kind of proud pre-eminence, *his Majeſty's ancient dominion;* and it was with ſome difficulty that the demagogues of New England could gain over that province when the time arrived for effecting their long meditated revolt. At laſt, however, they ſucceeded; and we find Mr Waſhington as a delegate from Virginia in the Congreſs which met at Philadelphia on the 26th of October 1774. (See AMERICA, nº 174. *Encycl.*) As no American united in ſo high a degree as he did, military experience with reſpectability of character, he was appointed to the command of the army which had aſſembled in the New England provinces, to hold in check the Britiſh army which was then encamped under General Gage at Boſton.

At this period there is ſome reaſon to believe that neither Mr Waſhington nor his conſtituents entered heartily into the views of the New Englanders; but afraid leſt the army of thoſe rebellious fanatics, after ſhaking off the yoke of Great Britain, might give law to the continent, he took upon himſelf the command of that army in the month of July 1775 (B). To detail his conduct in the years which followed, would be to relate the hiſtory of the American war, which we have already related in the article AMERICA (*Encycl.*). Within a very ſhort period after the declaration of independence, the affairs of America were in a condition ſo deſperate, that perhaps nothing but the *peculiar* character of Waſhington's genius could have retrieved them. Activity was the policy of invaders. In the field of battle the ſuperiority of a diſciplined army is diſplayed. But delay was the wiſdom of a country defended by undiſciplined ſoldiers againſt an enemy who muſt be more exhauſted by time than he could be weakened by defeat. It required the conſummate prudence, the calm wiſdom, the inflexible firmneſs, the moderate and well-balanced temper of Waſhington to embrace ſuch a plan of policy, and to perſevere in it: to reſiſt the temptations of enterprize; to fix the confidence of his ſoldiers without the attraction of victory; to ſupport the ſpirit of the army and the people amidſt thoſe ſlow and cautious plans of defenſive warfare which are more diſpiriting than defeat itſelf; to contain his own ambition and the impetuoſity of his troops; to endure temporary obſcurity for the ſalvation of his country, and for the attainment of ſolid and immortal glory; and to ſuffer even temporary reproach and obloquy, ſupported by the approbation of his own conſcience and the applauſe of that ſmall number of wiſe men, whoſe praiſe is an earneſt of the admiration and gratitude of poſterity. Victorious generals eaſily acquire the confidence of their army. Theirs, however, is a confidence in the *fortune* of their general. That of Waſhington's army was a confidence in his *wiſdom.* Victory gives ſpirit to cowards, and even the agitations of defeat ſometimes impart a courage of deſpair. Courage is inſpired by ſucceſs, and it may be ſtimulated to deſperate exertion even by calamity; but it is generally palſied by inactivity.—A ſyſtem of cautious defence is the ſevereſt trial of human fortitude; and by this teſt the firmneſs of Waſhington was tried. It muſt not, however, be concealed, that ſome of the Britiſh commanders gave him advantages, which he ſurely did not expect; for more than once, as it appears to us, they had it in their power to annihilate his army, merely by following up their victories. The iſſue of the conteſt is known.

Much has been ſaid by the Britiſh and American democrates of the magnanimity of Waſhington during the ravages of a civil war, in which he acted ſo conſpicuous a part; and we feel not ourſelves inclined to refuſe him the praiſe which he may have merited on this or on any other account. But granting that duty required him to execute as a ſpy the accompliſhed *André,* true magnanimity would have prevented him from inſultingly erecting, in the view of that unfortunate officer, the gallows on which he was to be hung, ſeveral days

---

(B) That ſuch were the motives of his conduct on this occaſion, is rendered in the higheſt degree probable in the preface to *A View of the Cauſes and Conſequences of the American Revolution, in thirteen Diſcourſes, Preached in North America, between the years* 1763 and 1775; by Jonathan Boucher, A. M. and F. A. S. Vicar of Epſom in the County of Surrey.

days before his execution! When Earl Cornwallis was overpowered by numbers, and obliged at York town to ſurrender to the united armies of America and France, a magnanimous conqueror would not have maliciouſly claimed, contrary to the uſage of civilized war, the ſword from the hands of that gallant nobleman. On theſe two occaſions, and on ſome others, the conduct of Waſhington agreed ſo ill with his general character, that we are inclined to believe that he muſt have been influenced by the leaders of the French army Rochembeau and Fayette. One thing is certain, that he was ſo little pleaſed either with his own conduct on particular occaſions, or with the general principle of the American revolution, that he never could be forced to talk on the ſubject. An Italian nobleman, who viſited him after the peace, had often attempted, in vain, to turn the converſation to the events of the war. At length he thought he had found a favourable opportunity of effecting his purpoſe; they were riding together over the ſcene of an action where Waſhington's conduct had been the ſubject of no ſmall animadverſion. Count —— ſaid to him, "Your conduct, Sir, in this action has been criticiſed." Waſhington made no anſwer, but clapped ſpurs to his horſe; after they had paſſed the field, he turned to the Italian and ſaid, "Count ——, I obſerve that you wiſh me to ſpeak of the war; it is a converſation which I always avoid. I rejoice at the eſtabliſhment of the liberties of America. But the time of the ſtruggle was a horrible period, in which the beſt men were compelled to do many things repugnant to their nature." This, we think, is the language of a good man not altogether ſatisfied with the part which he had been compelled to act, and who though he rejoiced at the eſtabliſhment of the *liberties* of America, probably foreſaw that ſhe would reap no benefit from her favourite *independence*.

The concluſion of the American war permitted Waſhington to return to thoſe domeſtic ſcenes, from which no views of ambition ſeem to have had the power to draw him. But he was not allowed long to enjoy this privacy. The ſupreme government of the United States, haſtily thrown up, in a moment of turbulence and danger, as a temporary fortification againſt anarchy, proved utterly inadequate to the preſervation of general tranquillity and permanent ſecurity. The confuſions of civil war had given a taint to the morality of the people, which rendered the reſtraints of a juſt and vigorous government more indiſpenſably neceſſary. Confiſcation and paper money, the two greateſt ſchools of rapacity and diſhoneſty in the world, had widely ſpread their poiſon among the Americans. One of their own writers tells us, that the whole ſyſtem of paper money was a ſyſtem of public and private frauds. In this ſtate of things, which threatened the diſſolution of morality and government, good men ſaw the neceſſity of concentrating and invigorating the ſupreme authority. Under the influence of this conviction, a convention of delegates was aſſembled at Philadelphia, which ſtrengthened the bands of the Federal Union, and beſtowed on Congreſs thoſe powers which were neceſſary for the purpoſes of good government. Waſhington was the preſident of this convention, as he, in three years after, was elected preſident of the United States of America, under what was called "The New Conſtitution," tho' it ought to have been called a *reform* of the republican government, as that republican government itſelf was only a *reform* of the ancient colonial conſtitution under the Britiſh crown. None of theſe changes extended ſo far as an attempt to new-model the whole ſocial and political ſyſtem.

Events occurred during his chief magiſtracy which convulſed the whole political world, and which tried moſt ſeverely his moderation and prudence. The French revolution took place; Waſhington, who had experienced the evils of one revolution, augured, from the beginning, no good from the daring ſpeculations of inexperienced viſionaries; and the progreſs of the revolution was not calculated to cure his diſtruſt. When, in the year 1793, France, then groaning under the moſt intolerable and hideous tyranny, became engaged in war with almoſt all the governments of the civilized world, it is ſaid to have been a matter of deliberation with the Preſident of the United States, whether the republican envoy, or the agent of the French princes ſhould be received in America as the diplomatic repreſentative of France. But whatever might be his private feelings of repugnance and horror, his public conduct was influenced only by his public duties. As a virtuous man he muſt have abhorred the ſyſtem of crimes which was eſtabliſhed in France. But as the firſt magiſtrate of the American commonwealth, he was bound only to conſider how far the intereſt and ſafety of the people whom he governed were affected by the conduct of France. He ſaw that it was wiſe and neceſſary for America to preſerve a good underſtanding and a beneficial inrercourſe with that great country, in whatever manner ſhe was governed, as long as ſhe abſtained from committing injury againſt the United States. Guided by this juſt and ſimple principle, uninfluenced by the abhorrence of crimes which he felt, and which others affected, he received Mr Genet, the miniſter of the French Republic. The hiſtory of the outrages which that miniſter committed, or inſtigated, or countenanced, againſt the American government, muſt be freſh in the memory of all our readers. The conduct of Waſhington was a model of firm and dignified moderation. Inſults were offered to his authority in official papers, in anonymous libels, by incendiary declaimers, and by tumultuous meetings. The law of nations was trampled under foot. His confidential miniſters were ſeduced to betray him, and the deluded populace were ſo inflamed by the arts of their enemies, that they broke out into inſurrection. No vexation, however galling, could diſturb the tranquillity of his mind, or make him deviate from the policy which his ſituation preſcribed. With a more confirmed authority, and at the head of a longer eſtabliſhed government, he might perhaps have thought greater vigour juſtifiable. But in his circumſtances, he was ſenſible that the nerves of authority were not ſtrong enough to bear being ſtrained. Perſuaſion, always the moſt deſirable inſtrument of government, was in his caſe the ſafeſt. Yet he never overpaſſed the line which ſeparates conceſſion from meanneſs. He reached the utmoſt limits of moderation, without being betrayed into puſillanimity. He preſerved external and internal peace by a ſyſtem of mildneſs, without any of thoſe virtual confeſſions of weakneſs, which ſo much diſhonour and enfeeble ſupreme authority. During the whole of that arduous ſtruggle, his perſonal character gave that ſtrength to a *new magiſtracy* which in other countries ariſes from ancient habits of obedience and reſpect. The authority of his virtue was more efficacious for the preſervation of America than the legal powers of his office.

During this turbulent period, he was re-elected to the office of the Preſidency of the United States, which he held from April 1789 till September 1796. Probably no magiſtrate of any commonwealth, ancient or modern, ever occupied a place ſo painful and perilous. Certainly no man was ever called upon ſo often to ſacrifice his virtuous feelings (he had no other ſacrifices to make) to his public duty. Two circumſtances of this ſort deſerve to be particularly noticed. In the ſpring of 1794, he ſent an ambaſſador to Paris with credentials, addreſſed to his "Dear friends the citizens compoſing the Committee of Public Safety of the French Republic," whom he prays God "to take under his holy protection." Fortunately the American ambaſſador was ſpared the humiliation of preſenting his credentials to theſe bloody tyrants. Their power was ſubverted, and a few of them had ſuffered the puniſhment of their crimes, which no puniſhment could expiate, before his arrival at Paris. Readily as we admit the purity of the motives which induced him to ſend this embaſſy to Paris, we cannot poſſibly approve of his conduct in deviating ſo far from the uſual diplomatic ſtyle, as to call Robeſpierre his friend: but he was beſet by an abſurd, though formidable, faction at home.

He had another ſtruggle of feeling and duty to encounter, when he was compelled to ſuppreſs the inſurrection in the weſtern counties of Pennſylvania by force of arms. But here he had a conſolation. The exerciſe of mercy conſoled his mind for the neceſſity of having recourſe to arms. Never was there a revolt quelled with ſo little blood. Scarcely ever was the baſeſt daſtard ſo tender of his own life, as this virtuous man was of the lives of his fellow-citizens. The value of his clemency is enhanced by recollecting that he was neither without provocations to ſeverity, nor without pretexts for it. His character and his office had been reviled in a manner almoſt unexampled among civilized nations. His authority had been inſulted.—His ſafety had been threatened. Of his perſonal and political enemies ſome might, perhaps, have been ſuſpected of having inſtigated the inſurrection; a greater number were thought to wiſh well to it; and very few ſhewed much zeal to ſuppreſs it. *Is habitus animorum fuit, ut peſſimum faſcinus auderent pauci, plures vellent, omnes paterentur.* But neither reſentment, nor fear, nor even policy itſelf, could extinguiſh the humanity of Waſhington. This ſeems to have been the only ſacrifice which he was incapable of making to the intereſt of his country.

Throughout the whole courſe of his ſecond Preſidency, the danger of America was great and imminent almoſt beyond example. The ſpirit of change, indeed, at that period, ſhook all nations. But in other countries it had to encounter ancient and ſolidly eſtabliſhed power; it had to tear up by the roots long habits of attachment in ſome nations for their government; of awe in others; of acquieſcence and ſubmiſſion in all.—But in America the government was new and weak. The people had ſcarce time to recover from the ideas and feelings of a recent civil war. In other countries the volcanic force muſt be of power to blow up the mountains, and to convulſe the continents that held it down, before it could eſcape from the deep caverns in which it was impriſoned: in America it was covered only by the aſhes of a late convulſion, or at moſt by a little thin ſoil, the produce of a few years quiet.

The government of America had none of thoſe ſalutary prejudices to employ, which in every other country were uſed with ſucceſs to open the eyes of the people to the enormities of the French revolution. They had, on the contrary, to contend with the prejudices of their people in the moſt moderate precautions againſt internal confuſion, in the moſt meaſured and guarded reſiſtance to the unparalleled inſults and enormous encroachments of France. Without zealous ſupport from the people, the American government was impotent. It required a conſiderable time, and it coſt an arduous and dubious ſtruggle, to direct the popular ſpirit againſt a ſiſter republic, eſtabliſhed among a people to whoſe aid the Americans aſcribed the eſtabliſhment of their independence. It is probable, indeed, that no policy could have produced this effect, unleſs it had been powerfully aided by the crimes of the French government, which have proved the ſtrongeſt allies of all eſtabliſhed governments; which have produced ſuch a general diſpoſition to ſubmit to any *known* tyranny, rather than ruſh into all the unknown and undefinable evils of civil confuſion, with the horrible train of new and monſtrous *tyrannies* of which it is uſually the forerunner. But of theſe circumſtances Waſhington availed himſelf with uncommon addreſs. He employed the horror excited by the atrocities of the French revolution for the moſt honeſt and praiſe-worthy purpoſes; to preſerve the internal quiet of his country; to aſſert the dignity, and to maintain the rights, of the commonwealth which he governed, againſt foreign enemies. He avoided war without incurring the imputation of puſillanimity. He cheriſhed the deteſtation of Americans for anarchy, without weakening the ſpirit of liberty; and he maintained, and even conſolidated, the authority of government, without abridging the privileges of the people.

The reſignation of Waſhington in 1796 was certainly a meaſure of prudence, and we doubt not of patriotiſm; but the conduct of his ſucceſſor has been ſuch as to give the Americans reaſon to regret that the reins of government were thrown up by the only hand, perhaps, that was fit to guide them during ſo unſettled a ſtate of public affairs. When he retired, he publiſhed a valedictory addreſs to his countrymen, as he had before done when he quitted the command of the army in 1783. In theſe compoſitions, the whole heart and ſoul of Waſhington are laid open. Other ſtate papers have, doubtleſs, ſhewn more ſpirit and dignity, more eloquence, greater force of genius, and a more enlarged comprehenſion of mind; but none ever diſplayed more ſimplicity and ingenuouſneſs, more moderation and ſobriety, more good ſenſe, more prudence, more honeſty, more earneſt affection for his country and for mankind, more profound reverence for virtue and religion; more ardent wiſhes for the happineſs of his fellow-creatures, and more juſt and rational views of the means which alone can effectually promote that happineſs.

From his reſignation till the month of July 1798, he lived in retirement at Mount Vernon. At this latter period, it became neceſſary for the United States to arm. They had endured with a patience, of which there is no example in the hiſtory of ſtates, all the contumely and wrong which ſucceſſive adminiſtrations in France had heaped upon them. Their ſhips were everywhere captured, their miniſters were detained in a ſort of impriſonment at Paris; while incendiaries, clothed in the ſacred character of ambaſſadors, ſcattered over their peaceful provinces the fire-brands of ſedition and civil war. An offer was made to terminate this long courſe of injuſtice, for a bribe to the French miniſters. This offer was made by perſons who *appeared* to be in the confidence of M. Talleyrand, who *profeſſed* to act by his authority; who have been ſince, indeed, diſavowed by him; but who never will be believed not to have been his agents, till he convict them of impoſture by legal evidence, and procure them to be puniſhed for ſo abominable a fraud.

The United States reſolved to arm by land and ſea. The command of the army was beſtowed on General Waſhington; which he accepted, becauſe he was convinced that "every thing we hold dear and ſacred was ſeriouſly threatened*;" though he had flattered himſelf "that he had quitted for ever the boundleſs field of public action, inceſſant trouble and high reſponſibility, in which he had long acted ſo conſpicuous a part." In this office he continued during the ſhort period of his life which ſtill remained.—On Thurſday the 12th December 1799, he was ſeized with an inflammation in his throat, which became conſiderably worſe the next day; and of which, notwithſtanding the efforts of his phyſicians, he died on Saturday the 14th of December 1799, in the 68th year of his age, and in the 23d year of the independence of the United States, of which he may be conſidered as the founder. The ſame calmneſs, ſimplicity, and regularity, which had uniformly marked his demeanor, did not forſake him in his dying moments. He ſaw the approaches of death without fear:—he met them without parade.—Even the perfectly well ordered ſtate of the moſt minute particulars of his private buſineſs, bore the ſtamp of that conſtant authority of prudence and practical reaſon over his actions, which was a diſtinguiſhing feature of his character. He died with theſe ſentiments of piety which had given vigour and conſiſtency to his virtue, and adorned every part of his illuſtrious life.

WATCHWORK. Our intention in this article does not extend to the manual practice of this art, nor even to all the parts of the machine. We mean to conſider the moſt important and difficult part of the conſtruction, namely, the method of applying the maintaining power of the wheels to the regulator of the motion, ſo as not to hurt its power of regulation. Our obſervations would have come with more propriety under the title SCAPEMENT, that being the name given by our artiſts to this part of the conſtruction. Indeed they were intended for that article, which had been unaccountably omitted in the body of the Dictionary under the words CLOCK and WATCH. But the bad health and occupations of the perſon who had engaged to write the article, have obliged us to defer it to the laſt opportunity which the alphabetical arrangement affords us; and, even now, the ſame cauſes unfortunately prevent the author from treating the ſubject in the manner he intended, and which it well deſerves. But we truſt that, from the account which is here given, the reader, who is converſant in mathematical philoſophy, will perceive the juſtneſs of the concluſions, and that an intelligent artiſt will have no heſitation in acceding to the propriety of the maxims of conſtruction deduced from them.

The regulator of a clock or watch is a pendulum or a balance. Without this check to the motion of the wheels, impelled by a weight or a ſpring, the machine would run down with a motion rapidly accelerating, till friction and the reſiſtance of the air induced a ſort of uniformity, as they do in a kitchen jack. But if a pendulum be ſo put in the way of this motion, that only one tooth of a wheel can paſs it at each vibration, the revolution of the wheels will depend on the vibration of the pendulum. This has long been obſerved to have a certain conſtancy, inſomuch that the aſtronomers of the Eaſt employed pendulums in meaſuring the times of their obſervations, patiently counting their vibrations during the phaſes of an eclipſe or the tranſits of the ſtars, and renewing them by a little puſh with the finger when they became too ſmall. Gaſſendi, Riccioli, and others, in more recent times, followed this example. The celebrated phyſician Sanctorius is the firſt perſon who is mentioned as having applied them as regulators of clock movements. Machines, however, called *clocks*, with a train of toothed wheels leading round an index of hours, had been contrived long before. The earlieſt of which we have any account is that of Richard of Wallingford, Abbot of St Alban's, in 1326 (A). It appears to have been regulated by a fly like a kitchen jack*. Not long after this Giacomo Dondi made one at Padua, which had a *motus ſuccuſſorius*, a hobbling or trotting motion; from which expreſſion it ſeems probable that it was regulated by ſome alternate movement. We cannot think that this was a pendulum, becauſe, once it was introduced, it never could have been ſupplanted by a balance. The alternate motion of a pendulum, and its ſeeming uniformity, are among the moſt familiar obſervations of common life; and it is ſurpriſing that they were not more early thought of for regulating time meaſurers. The alternate motions of the old balance is one of the moſt far-fetched means that can be imagined, and might paſs for the invention of a very reflecting mind, while a pendulum only requires to be drawn aſide from the plumb-line, to make it vibrate with regularity. The balance muſt be put in motion by the clock, and that motion muſt be ſtopped, and the contrary motion induced; and we muſt know that the ſame force and the ſame checks will produce uniform oſcillations. All this muſt be previouſly known before we can think of it as a regulator; yet ſo it is that clocks, regulated by a balance, were long uſed, and very common through Europe, before Galileo propoſed the pendulum, about the year 1600. Pendulum clocks then came into general uſe, and were found to be greatly preferable to balance clocks as accurate meaſurers of time. Mathematicians ſaw that their vibrations had ſome regular

* See his *Letter of Acceptance*.

* *Conradi Geſneri Epitome*, p. 604.

(A) Profeſſor Beckmann, in the firſt volume of his *Hiſtory of Inventions*, expreſſes a belief that clocks of this kind were uſed in ſome monaſteries ſo early as the 11th century, and that they were derived to the monks from the Saracens. His authorities, however, are diſcordant, and ſeem not completely ſatisfactory even to himſelf.

gular dependance on uniform gravity, and in their writings we meet with many attempts to determine the time and demonſtrate the iſochroniſm of the vibrations. It is amuſing to read theſe attempts. We wonder at the awkwardneſs and inſufficiency of the explanation given of the motions of pendulums, even by men of acknowledged eminence. Merſennus carried on a moſt uſeful correſpondence with all the mathematicians of Europe, and was the means of making them acquainted with each other; nay, he was himſelf well converſant in the ſcience; yet one cannot but ſmile at his reaſonings on this ſubject. Standing on the ſhoulders of our predeceſſors, we look around us, in great ſatisfaction with our own powers of obſervation, not thinking how we are raiſed up, or that we are trading with the ſtock left us by the diligent and ſagacious philoſophers of the 17th century (B). Riccioli, Gaſſendus, and Galileo, made ſimilar attempts to explain the motion of pendulums; but without ſucceſs. This honour was reſerved for Mr Huyghens, the moſt elegant of modern geometers. He had ſucceeded in 1656 or 1657 in adapting the machinery of a clock to the maintaining of the vibrations of a pendulum. Charmed with the accuracy of its performance, he began to inveſtigate with ſcrupulous attention the theory of its motion. By the moſt ingenious and elegant application of geometry to mechanical problems, he demonſtrated that the wider vibrations of a pendulum employed more time than the narrower, and that the time of a ſemicircular vibration is to that of a very ſmall one nearly as 34 to 29; and, aided by a new department of geometrical ſcience invented by himſelf, namely, the evolution of curves, he ſhewed how to make a pendulum ſwing in a cycloid, and that its vibrations in this curve are all performed in equal times, whatever be their extent.

But before this time, Dr Hooke, the moſt ingenious and inventive mechanician of his age, had diſcovered the great accuracy of pendulum clocks, having found that the manner in which they had been employed had obſcured their real merit. They had been made to vibrate in very large arches, the only motion that could be given them by the contrivances then known; and in 1656 he invented another method, and made a clock which moved with aſtoniſhing regularity. Uſing a heavy pendulum, and making it ſwing in very ſmall arches, the clocks ſo conſtructed were found to excel Mr Huyghens's cycloidal pendulums; and thoſe who were unfriendly to Huyghens had a ſort of triumph on the occaſion. But this was the reſult of ignorance. Mr Huyghens had ſhewn, that the error of $\frac{1}{100}$ of an inch, in the formation of the parts which produced the cycloidal motion, cauſed a greater irregularity of vibration than a circular vibration could do, although it ſhould extend five or ſix degrees on each ſide of the perpendicular. It has been found that the unavoidable inaccuracies, even of the beſt artiſts, in the cycloidal conſtruction, make the performance much inferior to that of a common pendulum vibrating in arches which do not exceed three or four degrees from the perpendicular. Such clocks alone are now made, and they exceed all expectation.

We have ſaid that a pendulum needed only to be removed from the perpendicular, and then let go, in order to vibrate and meaſure time. Hence it might ſeem, that nothing is wanted but a machinery ſo connected with the pendulum as to keep a regiſter, as it were, of the vibration. It could not be difficult to contrive a method of doing this; but more is wanted. The air muſt be diſplaced by the pendulum This requires ſome force, and muſt therefore employ ſome part of the momentum of the pendulum. The pivot on which it ſwings occaſions friction— the thread, or thin piece of metal by which it is hung, in order to avoid this friction, occaſions ſome expenditure of force by its want of perfect flexibility or elaſticity. Theſe, and other cauſes, make the vibrations grow more and more narrow by degrees, till at laſt the pendulum is brought to reſt. We muſt therefore have a contrivance in the wheelwork which will reſtore to the pendulum the ſmall portion of force which it loſes in every vibration. The action of the wheels therefore may be called a *maintaining power*, becauſe it keeps up the vibrations

But we now ſee that this may affect the regularity of vibration. If it be ſuppoſed that the action of gravity renders all the vibrations iſochronous, we muſt grant that the additional impulſion by the wheels will deſtroy that iſochroniſm, unleſs it be ſo applied that the ſum total of this impulſion and the force of gravity may vary ſo with the ſituation of the pendulum, as ſtill to give a ſeries of forces, or a law of variation, perfectly ſimilar to that of gravity. This cannot be effected, unleſs we know both the law which regulates the action of gravity. producing iſochroniſm of vibration, and the intenſity of the force to be derived from the wheels in every ſituation of the pendulum.

The neceſſary requiſite for the iſochronous motion of the pendulum is, that the force which urges it toward the perpendicular, be proportional to its diſtance from it (ſee DYNAMICS, n° 103. Cor. 7. *Suppl.*); and therefore, ſince pendulums ſwinging in ſmall circular arches are ſenſibly iſochronous, we muſt infer that ſuch is the law by which the accelerating action of gravity on them is really accommodated to every ſituation in thoſe arches.

Plate XLVIII.

It will greatly conduce to the better underſtanding of the effect of the maintaining power, if the reader keep in continual view the chief circumſtances of a motion of this kind. Therefore let AC*a* (fig. 1.) repreſent the arch paſſed over by the pendulum, ſtretched out into a ſtraight line. Let C be its middle point, when the pendulum hangs perpendicular, and A and *a* be the extremities of the oſcillation. Let AD be drawn perpendicular to AC, to repreſent the accelerating action of gravity on the pendulum when it is at A. Draw the ſtraight line DC*d*, and *ad*, perpendicular to A*a*. About C, as a centre, deſcribe the ſemicircle AFH*a*. Through

---

(B) We are provoked to make this obſervation, by obſerving at this moment, in a literary journal, a pert and petulant upſtart ſpeaking of Newton's optical diſcoveries in terms of ridicule and abuſe, employing theſe very diſcoveries to diminiſh his authority. Is it not thus that Chriſtianity is now ſlighted by thoſe who enjoy the fruits of the pure morality which it introduced?

Through any points B, K, *k*, *b*, &c. of A *a*, draw the perpendiculars BFE, KLM, &c. cutting both the ſtraight line and the ſemicircle. Then,

1. The actions of gravity on the pendulum, when in the ſituations B, K, &c. by which it is urged toward C, are proportional to, and may be repreſented by, the ordinates BE, KL, *b e*, *k l*, &c. to the ſtraight line DC *d*.

2. The velocities acquired at B, K, &c. by the acceleration along AB, AK, &c. are proportional to the ordinates BF, KM, &c. to the ſemicircle AH *a*; and, therefore, the velocity with which the pendulum paſſes through the middle point C, is to its velocity in any other point B, as CH to BF.

3. The times of deſcribing the parts AB, BK, KC, &c. of the whole arch of oſcillation, are proportional to, and may be repreſented by, the arches AF, FM, MH, &c. of the ſemicircle.

4. If one pendulum deſcribe the arch repreſented by AC *a*, and another deſcribe the arch KC *k*, they will deſcribe them in equal times, and their maximum velocities (viz. their velocities in the middle point), are proportional to AC and KC; that is, the velocities in the middle point are proportional to the width of the oſcillations.

The ſame proportions are true with reſpect to the motions outwards from C. That is, when the pendulum deſcribes CA, with the initial velocity CH, its velocity at K is reduced to KM by the retarding action of gravity. It is reduced to BF at B, and to nothing at A; and the times of deſcribing CK, KB, BA, CA, are as HM, HF, HA. Another pendulum ſetting out from C, with the initial velocity CO, reaches only to K, CK being = CO. Alſo the times are equal.—If we conſider the whole oſcillation as performed in the direction A *a*, the forces AD, BE, KL accelerate the pendulum, and the ſimilar forces *a d*, *b e*, *k l*, on the other ſide, retard it. The contrary happens in the next oſcillation *a*CA.

5. The areas DABE, DAKL, &c. are proportional to the ſquares of the velocities acquired by moving along AB, AK, &c. or to the diminution of the ſquares of the velocities ſuſtained by moving outwards along BA or KA, &c.

The conſideration of this figure will enable the reader (even though not a mathematician) to form ſome notion of the effect of any propoſed application of a maintaining power by means of wheelwork: For, knowing the weight of the pendulum, we know the accelerating action of that weight in any particular ſituation A of the pendulum. We alſo know what addition or ſubtraction we produce on the pendulum in that ſituation by the wheel-work. Suppoſe it is an addition of preſſure equal to a certain number of grains. We can make AD to D δ as the firſt to the laſt; and then A δ will be the whole force urging the pendulum toward C. Doing the ſame for every point of AC, we obtain a line $\delta\,\varepsilon\,\lambda\,c$, which is a new ſcale of forces, and the ſpace DC δ, comprehended between the two ſcales CD and C δ, will expreſs the addition made to the ſquare of the velocity in paſſing along AC by the joint action of gravity and the maintaining power. Alſo, by drawing a line $\kappa\,\pi$ perpendicular to AC, making the ſpace C $\tau\,\kappa$ equal to CAD, the point π will be the limit of the oſcillation outward from C, where the initial velocity HC is extinguiſhed. If the line $\kappa\,\pi$ cut the ſame circle in θ, one-half the arch θ A will nearly expreſs the contraction made in the time of the outward oſcillation by the maintaining power. An accurate determination of this laſt circumſtance is operoſe, and even difficult; but this ſolution is not far from the truth, and will greatly aſſiſt our judgment of the effect of any propoſal, even though $\kappa\,\pi$ be drawn only by the judgement of the eye, making the area left out as nearly equal to the area taken in as we can eſtimate by inſpection. This is ſaid from experience.

Since the motion of a pendulum or balance is alternate, while the preſſure of the wheels is conſtantly in one direction, it is plain that ſome art muſt be uſed to accommodate the one to the other. When a tooth of the wheel has given the balance a motion in one direction, it muſt quit it, that it may get an impulſion in the oppoſite direction. The balance or pendulum thus eſcaping from the tooth of the wheel, or the tooth eſcaping from the balance, has given to the general contrivance the name of SCAPEMENT among our artiſts, from the French word *echappement*. We proceed, therefore, to conſider this ſubject more particularly, firſt conſidering the ſcapements which are peculiarly ſuited to the ſmall vibrations of pendulums, and then thoſe which muſt produce much wider vibrations in balances. This, with ſome other circumſtances, render the ſcapements for pendulums and balances very different.

I. *Of the Action of a Wheel and Pallet.*

THE ſcapement which has been in uſe for clocks and watches ever ſince their firſt appearance in Europe, is extremely ſimple, and its mode of operation is too obvious to need much explanation. In fig. 2. XY repreſents a horizontal axis, to which the pendulum P is attached by a ſlender rod, or otherwiſe. This axis has two leaves C and D attached to it, one near each end, and not in the ſame plane, but ſo that when the pendulum hangs perpendicularly, and at reſt, the piece C ſpreads a few degrees to the right hand, and D as much to the left. They commonly make an angle of 70, 80, or 90 degrees. Theſe two pieces are called PALLETS. AFB repreſents a wheel, turning round on a perpendicular axis EO, in the order of the letters AFEB. The teeth of this wheel are cut into the form of the teeth of a ſaw, leaning forward, in the direction of the motion of the rim. As they ſomewhat reſemble the points of an old-faſhioned royal diadem, this wheel has got the name of the CROWN WHEEL. In watches it is often called the *balance wheel*. The number of teeth is generally odd; ſo that when one of them B is preſſing on a pallet D, the oppoſite pallet C is in the ſpace between two teeth A and I. The figure repreſents the pendulum at the extremity of its excurſion to the right hand, the tooth A having juſt eſcaped from the pallet C, and the tooth B having juſt dropped on the pallet D. It is plain, that as the pendulum now moves over to the left, in the arch PG, the tooth B *continues* to preſs on the pallet D, and thus accelerates the pendulum, both during its deſcent along the arch PH, and its aſcent along the arch HG. It is no leſs evident, that when the pallet D, by turning round the axis XY, raiſes its point above the plane of the wheel, the tooth B eſcapes from it, and I drops on the pallet C, which is now nearly perpendicular. I preſſes C to the right, and

and accelerates the motion of the pendulum along the arch GP. Nothing can be more obvious than this action of the wheel in maintaining the vibrations of the pendulum. We can eaſily perceive, alſo, that when the pendulum is hanging perpendicularly in the line XH, the tooth B, by preſſing on the pallet D, will force the pendulum a little way to the left of the perpendicular, and will force it ſo much the farther as the pendulum is lighter; and, if it be ſufficiently light, it will be forced ſo far from the perpendicular that the tooth B will eſcape, and then I will catch on C, and force the pendulum back to P, where the whole operation will be repeated. The ſame effect will be produced in a more remarkable degree, if the rod of the pendulum be continued through the axis XY, and a ball Q put on the other end to balance P. And, indeed, this is the contrivance which was firſt applied to clocks all over Europe, before the application of the pendulum. They were balance clocks. The force of the wheel was of a certain magnitude, and therefore able, during its action on a pallet, to communicate a certain quantity of motion and velocity to the balls of the balance. When the tooth B eſcapes from the pallet D, the balls are then moving with a certain velocity and momentum. In this condition, the balance is checked by the tooth I catching on the pallet C. But it is not inſtantly ſtopped. It continues its motion a little to the left, and the pallet C forces the tooth I a little backward. But it *cannot* force it ſo far as to eſcape over the top of the tooth I; becauſe all the momentum of the balance was generated by the force of the tooth B; and the tooth I is equally powerful. Beſides, when I catches on C, and C continues its motion to the left, its lower point applies to the face of the tooth I, which now acts on the balance by a long and powerful lever, and ſoon ſtops its farther motion in that direction, and now, continuing to preſs on C, it urges the balance in the oppoſite direction.

Thus we ſee that in a ſcapement of this kind, the motion of the wheel muſt be very hobbling and unequal, making a great ſtep forward, and a ſhort ſtep backward, at every beat. This has occaſioned the contrivance to get the name of the RECOILING SCAPEMENT, the recoiling pallets. This hobbling motion is very obſervable in the wheel of an alarm.

Thus have we obtained two principles of regulation. The firſt and moſt obvious, as well as the moſt perfect, is the natural iſochronous vibration of a pendulum. The only uſe of the wheelwork here, beſides regiſtering the vibrations, is to give a gentle impulſion to the pendulum, by means of the pallet, in order to compenſate friction, &c. and thus maintain the vibrations in their primitive magnitude. But there is no ſuch native motion in a balance, to which the motion of the wheels muſt accommodate itſelf. The wheels, urged by a determined preſſure, and acting through a determined ſpace (the face of the pallet), muſt generate a certain determined velocity in the balance; and therefore the time of the oſcillation is alſo determined, both during the progreſſive and the retrograde motion of the wheel. The actions being ſimilar, and through equal ſpaces, in every oſcillation, they muſt employ the ſame time. Therefore a balance, moved in this manner, muſt be iſochronous, and a regulator for a time-keeper.

By thus employing a balance, the horizontal poſition of the axis XY is unneceſſary. Accordingly, the old clocks had this axis perpendicular, by which means the whole weight of the balance reſted on the point of the pivot Y or X, according as the balance PQ was placed above or below. By making the ſupporting pivot of hard ſteel, and very ſharp, friction was greatly diminiſhed. Nay, it was entirely removed from this part of the machine by ſuſpending the balance by a thread at the end X, inſtead of allowing it to reſt on the point of the pivot Y.

As the balance regulator of the motion admits of every poſition of the machine, thoſe clocks were made in an infinite variety of fanciful forms, eſpecially in Germany, a country famous for mechanical contrivances. They were made of all ſizes, from that of a great ſteeple clock, to that of an ornament for a lady's toilet. The ſubſtitution of a ſpring in place of a weight, as a firſt mover of the wheel-work, was a moſt ingenious thought. It was very gradual. We have ſeen, in the Emperor's muſeum at Bruſſels, an old (perhaps the firſt) ſpring clock, the ſpring of which was an old ſword blade, from the point of which a catgut was wound round the barrel of the firſt wheel. Some ingenious German ſubſtituted the ſpiral ſpring, which both took leſs room, and produced more revolutions of the firſt wheel.

When clocks had been reduced to ſuch ſmall ſizes, the wiſh to make them portable was very natural; and the means of accompliſhing this were obvious, namely, a farther reduction of their ſize. This was accompliſhed very early; and thus we obtained pocket watches, moved by a ſpiral ſpring, and regulated by a balance with the recoiling ſcapement, which is ſtill in uſe for common watches. The hobbling motion of the crown wheel is very eaſily ſeen in all of them.

It is very uncertain who firſt ſubſtituted a pendulum in place of the balance (CLOCK, *Encycl.*) Huyghens, as we have already obſerved, was the firſt who inveſtigated the motions of pendulums with ſucceſs, and his book *De Horologio Oſcillatorio* may be conſidered as the elements of refined mechanics, and the ſource of all the improvements that have been made in the conſtruction of ſcapements. But it is certain that Dr Hooke had employed a pendulum for the regulation of a clock many years before the publication of the abovementioned treatiſe, and he claims the merit of the invention of the *only proper* method of employing it. We imagine therefore that Dr Hooke's invention was nothing more than a ſcapement for a pendulum making ſmall vibrations, without making uſe of the oppoſite motions of the two ſides of the crown wheel. Dr Hooke had contrived ſome ſcapement more proper for pendulums than the recoiling pallets, becauſe certainly thoſe might be employed, and are actually employed as a ſcapement for pendulum clocks to this day, although they are indeed very ill adapted to the purpoſe. He had not only remarked the great ſuperiority of ſuch pendulum clocks as were made before Huyghens's publication of the cycloidal pendulum over the balance clocks, but had alſo ſeen their defects, ariſing from the light pendulums and wide arches of vibration, and invented a ſcapement of the nature of thoſe now employed. The pendulum clock which he made in 1658 for Dr Wilkins, afterwards Biſhop of Cheſter, is mentioned by the inventor as peculiarly ſuited to the moderate ſwing of a pendulum; and he oppoſes this circumſtance to a general practice of wide vibrations and trifling pendulums. The French are not in the practice of aſcribing to us any thing that they can claim as their own; yet Lepaute ſays that the *Echappement à l'Ancre* came from England about the year 1665. It is alſo admitted by him that clock-making flouriſhed in England at that time, and that the French artiſts went to London to improve in it. Putting theſe and other circumſtances together, we think it highly probable that we are indebted to Dr Hooke for the ſcapement now in uſe. The principle of this is altogether different from the ſimple pallets and direct impulſe already deſcribed; and is ſo far from being obvious, that the manner of action has been miſunderſtood, even by men of ſcience, and writers of ſyſtems of mechanics.

In this ſcapement we employ thoſe teeth of the wheel which are moving in one direction; whereas in the former ſcapement, oppoſite teeth were employed moving in contrary directions. Yet even here we muſt communicate an alternate motion to the axis of the pallets. The contrivance, in general, was as follows: On the axis A (See fig. 3) of the pendulum or balance is fixed a piece of metal BAC, called the CRUTCH by our artiſts, and the ANCHOR by the French. It terminates in two faces B b C c of tempered ſteel, or of ſome hard ſtone. Theſe are called the PALLETS, and it is on them that the teeth of the wheel act. The faces B b C c are ſet in ſuch poſitions that the teeth puſh them out of the way. Thus B puſhes the pallet to the left, and C puſhes its pallet to the right. Both puſh their pallets ſidewiſe outward from the centre of the wheel. The pallet B is uſually called the *leading*, and C the *driving* pallet by the artiſts, although it appears to us that theſe names ſhould be reverſed, becauſe B *drives* the pallet out of the way, and C *pulls* or leads it out of the way. They might be called the *firſt* and *ſecond* pallet, in the order in which they are acted on by the wheel. We ſhall uſe either denomination. The figure is accommodated to the inactive or reſting poſition of the pendulum. Suppoſe the pendulum drawn aſide to the right at Q, and then let go. It is plain that the tooth B, preſſing on the face of the pallet β B b all the way from β to b, thruſts it aſide outwards, and thus, by the connection of the crutch with the pendulum rod, aids the pendulum's motion along the arch QPR. When the pendulum reaches R, the point of the tooth B has reached the angle b of the pallet, and eſcapes from it. The wheel preſſing forward, another tooth C drops on the pallet face C c, and, by preſſing this pallet outward, evidently aids the pendulum in its motion from R to P. The tooth C eſcapes from this pallet at the angle c, and now a tooth B′ drops on the firſt pallet, and again aids the pendulum; and this operation is repeated continually.

The mechaniſm of this communication of motion is thus explained by ſeveral writers of elements. The tooth B (fig. 2.) is urged forward in the direction BD, perpendicular to the radius MB of the SWING WHEEL. It therefore preſſes on the pallet, which is moveable only in the direction BE, perpendicular to BA the radius of the pallet. Therefore the force BD muſt be reſolved into two, *viz.* BE, in the direction in which alone the pallet can move, and ED, or BF, perpendicular to that direction. The laſt of theſe only preſſes the pallet and crutch againſt the pivot hole A. BE is the only uſeful force, or the force communicated to the pallet, enabling it to maintain the pendulum's motion, by reſtoring the momentum loſt by friction and other cauſes.

But this is a very erroneous account of the *modus operandi*, as may be ſeen at once, by ſuppoſing the radius of the pallets to be a tangent to the wheel. This is a poſition moſt frequently given to them, and is the very poſition in fig. 3. In this caſe MB is perpendicular to BA, and therefore BD will coincide with BA, and there will be no ſuch force as BE to move the pendulum. It is a truth, deducible from what we know of the mechanical conſtitution of ſolid bodies, and confirmed by numberleſs obſervations, that when two ſolid bodies preſs on each other, either in impulſion or in dead preſſure, the direction in which the mutual preſſure is exerted is always perpendicular to the touching ſurfaces, whatever has been the direction of the impelling body (See IMPULSION, *Suppl.* n° 66. MACHINERY, *Suppl.* n° 35. and ſeveral other parts of this Work) Moreover this preſſure is mutual, equal, and oppoſite. Whatever be the ſhapes of the faces of the tooth and pallet, we can draw a plane BN, which is the common tangent to both ſurfaces, and a line HBI through the point of contact perpendicular to BN. It is farther demonſtrated in the article MACHINERY, *Suppl.* n° 35, &c. that the action of the wheel on the pendulum is the ſame as if the whole crutch were annihilated, and in its ſtead there were two rigid lines AH, MI, from the centres of the crutch and wheel, perpendicular to HI, and connected by a third rigid line or rod HI, touching the two in H and I.

For if a weight V be hung at v, the extremity of the horizontal radius M v of the wheel, it will act on the lever v MI, preſſing its point I upwards in the direction IH perpendicular to MI; the upper end of this rod IH will, in like manner, preſs the extremity H of the rod HA, and this will urge the pendulum from P toward R. To withſtand this, the pendulum rod AP may be withheld by a weight z, hanging by a thread on the extremity of the horizontal lever A z, equal to M v, and connected with the crutch and pendulum. The weights V and z may be ſo proportioned to each other that, by acting perpendicularly on the crooked levers v MI, and z AH, the preſſures at H and I ſhall be equal, and juſt balance each other by the intervention of the rod HI. When this is the caſe, we have put things into the ſame mechanical ſtate, in reſpect of mutual action, as is effected by the crutch, pallets, and wheel, which, in like manner, produce equal preſſures at B the point of contact, in the direction BH and BI. The weight V may be ſuch as produces the very ſame effect at B that is produced by the previous train of wheel-work. The weight z therefore muſt be juſt equal to the force produced by the wheel-work on the point z of the pendulum rod, becauſe by acting in the oppoſite direction it juſt balances it. Let us ſee therefore what force is communicated to the pendulum by the wheels.

Let x be the upward preſſure excited at I, and y the equal oppoſite preſſure excited at H. Then, by the property of the lever, we have $\mathrm{MI} : \mathrm{M}v = \mathrm{V} : x$, and $x \times \mathrm{MI} = \mathrm{V} \times \mathrm{M}v$. In like manner $y \times \mathrm{AH} = \mathrm{Z} \times \mathrm{A}z$. Therefore, becauſe $x = y$, and $\mathrm{A}z = \mathrm{M}v$, we have $\mathrm{V} : \mathrm{Z} = \mathrm{MI} : \mathrm{AH}$. That is, the force exerted by the tooth of the wheel in the direction of its motion is to the force impreſſed on the pendulum rod at a diſtance equal to the radius of the wheel as MI to AH. The force impreſſed on the ball of the pendulum is leſs than this in the proportion of AP to A z, or M v.

Cor. 1. If the perpendiculars MN. AV, be drawn on the tangent plane, the forces at B and z will be as BN to BO. For theſe lines are reſpectively equal to MI and AH.

Cor. 2. If HI meet the line of the centres AC in S, the forces will be as SM to SA ; that is, $V : Z = SM : SA$.

Cor. 3. If the face β B b of the pallet be the evolutrix of a circle deſcribed with the radius AH, and the face of the tooth be the evolutrix of a circle deſcribed with the radius MI, the force impreſſed on the pendulum by the wheels will be conſtant during the whole vibration (Machinery, nº 36) But theſe are not the only forms which produce this conſtancy. The forms of teeth deſcribed by different authors, ſuch as De la Hire, Camus, &c. for producing a conſtant force in trains of wheel-work, will have the ſame effect here. It is alſo eaſy to ſee that the force impreſſed on the pendulum may be varied according to any law, by making theſe faces of a proper form. Therefore the face, from B outwards, may be ſo formed that the force communicated to the pendulum by the wheels, during its deſcent from Q to P, may be in one conſtant proportion to the acceleration of gravity, and then the ſum of the forces will be ſuch as produce iſochronous vibrations. If the inner part B b of the face be formed on the ſame principle, the difference of the forces will have the ſame law of variation. If the face βb be the evolutrix of a circle, and the tooth B terminate in a point gently rounded, or quite angular, the force on the pendulum will continually increaſe as the tooth ſlides from β to b For the line AH continues of the ſame magnitude, and MI diminiſhes. The contrary will happen, if the pallet be a point, either ſharp or rounded, and if the face of the tooth be the evolutrix now mentioned ; for MI will remain the ſame, while AH diminiſhes. If the tooth be pointed, and βb be a ſtraight line, the force communicated to the pendulum will diminiſh, while the tooth ſlides from β to b. For in this caſe AH diminiſhes and MI increaſes.

Cor. 4. In general, the force on the pendulum is greater as the angle MB b increaſes, and as AB b diminiſhes.

Cor. 5. The angular velocity of the wheel is to that of the pendulum, in any part of its vibration, as AH to MI. This is evident, becauſe the rod IH moving (in the moment under conſideration) in its own direction, the points H and I move through equal ſpaces, and therefore the angles at A and M muſt be inverſely as the radii.

All that has now been ſaid of the firſt pallet AB may be applied to the ſecond pallet AC.

If the perpendiculars C s be drawn to the touching plane o C n, cutting AM in s, we ſhall have $V : z = sM : sA$, as in Cor. 2. And if the perpendiculars Mi, Ah, be drawn on Cs, we have $V : Z = Mi : Ah$, as in the general theorem. The only difference between the action on the two pallets is, that if the faces of both are plain, the force on the pendulum increaſes during the whole of the action on the pallet C, whereas it diminiſhes during the progreſs of the tooth along the other pallet.

The reader will doubtleſs remark that each tooth of the wheel acts on both pallets in ſucceſſion ; and that, during its action on either of them, the pendulum makes one vibration. Therefore the number of vibrations during one turn of the wheel is double the number of the teeth : conſequently, while the tooth ſlides along one of the pallets, it advances half the ſpace between two ſucceſſive teeth ; and when it eſcapes from the pallet, the other tooth *may* be juſt in contact with the other pallet. We ſay it *may* be ſo ; in which caſe there will be no dropping of the teeth from pallet to pallet. This, however, requires very nice workmanſhip, and that every tooth be at preciſely the ſame diſtance from its neighbour. Should the tooth which is juſt going to apply to a pallet chance to be a little too far advanced on the wheel, it would touch the pallet before the other had eſcaped. Thus, ſuppoſe that before B eſcapes from the point b of the pallet, the tooth C is in contact with the pallet CG, B cannot eſcape. Therefore when the pendulum returns from R towards Q, the pallet βb, returning along with it, will puſh back the tooth B of the wheel. It does this in oppoſition to the force of the wheel. Therefore, whatever motion the wheel had communicated to the pendulum, during its ſwing from P to Q, will now be taken from it again. The pendulum will not reach Q, becauſe it had been aided in its motion from Q, and had proceeded further than it would have done without this help. Its motion toward Q is further diminiſhed by the friction of the pallet. Therefore it will now return again from ſome nearer point q, and will not go ſo far as in the laſt vibration, but will return through a ſtill ſhorter arch : And this will be ſtill more contracted in the next vibration, &c. &c. Thus it appears that if a tooth chances to touch the pallet before the eſcape of the other, the wheel will advance no farther, and ſoon after the pendulum will be brought to reſt.

For ſuch reaſons it is neceſſary to allow one tooth to eſcape *a little before* the other reaches the pallet on which it is to act, and to allow a ſmall drop of the teeth from pallet to pallet. But it is accounted bad workmanſhip to let the drop be conſiderable, and *cloſe ſcapement* is accounted a mark of care and of good workmanſhip It is evidently an advantage, becauſe it gives a longer time of action on each pallet. This freeing the ſcapement cannot be accompliſhed by filing ſomething from the face of the tooth ; becauſe this being done to all, the diſtance between them is diminiſhed rather than augmented. The pallets muſt be firſt ſcaped as cloſe as poſſible. This obliges the workman to be careful in making the teeth equidiſtant. Then a ſmall matter is taken from the point of each pallet, by filing off the back $b\,r$ of the pallet. The tooth will now eſcape before it has moved through half a ſpace.

From all that has been ſaid on this particular, it appears that the interval between the pallets muſt comprehend a certain number of teeth, and half a ſpace more.

The firſt circumſtance to be conſidered in contriving a ſcapement is the angular motion that is intended to be given to the pendulum during the action of the wheel. This is uſually called the *angle of ſcapement*, or the *angle of action*. Having fixed on an angle a that we think proper, we muſt ſecure it by the poſition and form of the face of the pallets. Knowing the number of teeth in the ſwing-wheel, divide 180° by this number, and the quotient is the angle b of the wheel's motion during one vibration of the pendulum. In the line AM, joining the centres of the crutch and wheel, make SM to SA, and sM to sA, as the angle a to the angle b; and then, having determined how many teeth ſhall be comprehended between the pallets, call this number n. Multiply the angle b by $n + 1$. and take the half of the product. Set off this half in the circumference of the wheel (at the points of the teeth) on each ſide of the line joining the centres of the crutch and wheel, as at TB and TC. Through S and s draw SB and sC, and through B draw β B b perpendicular to SB, for the medium poſition of the face of the firſt pallet; that is, for its poſition when the pendulum hangs perpendicular. In like manner, drawing o C n perpendicular to sC, we have the medium poſition of the ſecond pallet. The demonſtration of this conſtruction is very evident from what has been ſaid.

We have hitherto ſuppoſed that the pendulum finiſhes its vibration at the inſtant that a tooth of the wheel eſcapes from a pallet, and another tooth drops on the other pallet. But this is never, or ſhould never be, the caſe. The pendulum is made to ſwing ſomewhat beyond the angle of ſcapement: for if it do not when the clock is clean and in good order, but ſtop preciſely at the drop of a tooth, then, when it grows foul, and the vibration diminiſhes, the teeth will not eſcape at all, and the clock will immediately ſtop. Therefore the force communicated by the wheels during the vibration within the limits of ſcapement, muſt be increaſed ſo as to make the pendulum *throw* (as the artiſts term it) farther out; and a clock is more valued when it throws out conſiderably beyond the angle of ſcapement. There are good reaſons for this The momentum of the pendulum, and its power to regulate the clock (which Mr Harriſon ſignificantly called its *dominion*), is proportional to the width of its vibrations very nearly.

This circumſtance of exceeding the angle of ſcapement has a very great influence on the performance of the clock, or greatly affects the dominion of the pendulum. It is eaſy to ſee that, when the face βb of the leading pallet is a plane, if the pendulum continue its motion to the right, from P toward Q, after the tooth B has dropped on it, the pallet will puſh the wheel back again, while the tooth ſlides outward on the pallet toward β. Such pallets therefore will make a *recoiling ſcapement*, reſembling, in this circumſtance, the old pallet employed with the crown wheel, and will have the properties attached to this circumſtance. One conſequence of this is, that it is much affected by any inequalities of the maintaining power. It is a matter of the moſt familiar obſervation, that a common watch goes ſlower when within a quarter of an hour of being down, when the action of the ſpring is very weak, in conſequence of its not pulling by a radius of the fuſee. We obſerve the ſame thing in the beating of an alarum clock. Alſo if we at any time preſs forward the wheelwork of a common watch with the key, we obſerve its beats accelerate immediately. The reaſon of this is pretty plain. The balance, in conſequence of the acceleration in the angle of ſcapement, would have gone much farther, employing a conſiderable time in the excurſion. This is checked abruptly, which both ſhortens the vibration and the time employed in it. In the return of the pendulum, the motion is accelerated the whole way, along an arch which is ſhorter than what correſponds to its velocity in the middle point; for it is again checked on the other ſide, and does not make its full excurſion. Moreover, all this irregularity of force, or the great deviation from a reſiſtance to the excurſion proportional to the diſtance from the middle point, is exerted on the pendulum when it is near the end of the excurſion, where the velocity being ſmall, this irregular force acts long upon it, at the very time that it has little force wherewith to reſiſt it. All temporary inequalities of force, therefore, will be more felt in this ſituation of the balance than if they had been exerted in the middle of its motion. And although the regulating power of a pendulum greatly exceeds that of the light balances uſed in pocket watches, ſomething of the ſame kind may be expected even in pendulum clocks. Accordingly this appears by a ſeries of experiments made by Mr Berthoud, a celebrated watchmaker of Paris. A clock, with a half ſecond pendulum weighing five drams, was furniſhed with a recoiling ſcapement, whoſe pallets were planes. The angle of ſcapement was $5\frac{1}{2}$ degrees. When actuated with a weight of two pounds, it ſwung 8°, and loſt 15″ per hour; with four pounds, it ſwung 10°, and loſt 6″. Thus it appears that by doubling the maintaining power, although the vibration was increaſed in conſequence of the greater impulſe, the time was leſſened 9″ per hour, viz about $\frac{1}{400}$. It is plain, from what was ſaid when we deſcribed the firſt ſcapement, that an increaſe of maintaining power muſt render the vibration more frequent. We ſaw, on that occaſion, that, even when the gravity of the pendulum is balanced by a weight on the other end of the rod, the force of the wheels will produce a vibratory motion, and that an augmentation of this force will increaſe it, or make the vibrations more rapid. The preciſe effect of any particular form of teeth can be learned only by computing the force on the pendulum in every poſition, and then conſtructing the curve $\delta \epsilon \lambda$ C of fig. 1. The rapid increaſe of the ordinates beyond thoſe of the triangle ADC, forms a conſiderable area DA πo, to compenſate the area πo C, and thus makes a conſiderable contraction A π of the vibration, and a ſenſible contraction $\frac{A\theta}{2}$ of the time.

Mr George Graham, the celebrated watchmaker in London, was alſo a good mathematician, and well qualified to conſider this ſubject ſcientifically. He contrived a ſcapement, which he hoped would leave the pendulum almoſt in its natural ſtate. The acting face of the pallet $a\,b\,c$ (fig. 4.) is a plane. The tooth drops on a, and eſcapes from c, and is on the middle point b when the pendulum is perpendicular. Beyond a, the face of the pallet is an arch $a\,d$, whoſe centre is A, the centre of the crutch. The maintaining power is made ſo great as to produce a much greater vibration than the angle of active ſcapement a A c. The conſequence of this is that, when the tooth drops on the angle a, the pendulum, continuing its motion, carries the crutch along with it, and the tooth paſſes on the arch $a\,d$, in a direction paſſing through the centre of the crutch. This preſſure can neither accelerate nor retard the motion

tion of the crutch and pendulum. As the pendulum was accelerated after it paſſed the perpendicular, by the other pallet, it will (if quite unobſtructed) throw out farther than what correſponds to the velocity which it had in the middle point of its vibration; perhaps till the tooth paſſes from *a* to *e* on the circular arch of the pallet. But although it ſuſtains no contrary action from the wheels during this excurſion beyond the angle of ſcapement, it will not proceed ſo far, but will ſtop when the tooth reaches *d*; becauſe there muſt be ſome reſiſtance ariſing from the friction of the tooth along the arch *a d*, and from the clammineſs of the oil employed to lubricate it: but this reſiſtance is exceedingly minute, not amounting to $\frac{1}{8}$th of the preſſure on the arch. Nay, we think that it appears from the experiments of Mr Coulomb that, in the caſe of ſuch minute preſſures on a ſurface covered with oil, there is no ſenſible retardation analogous to that produced by friction, and that what retardation we obſerve ariſes entirely from the clammineſs of the oil. We are ſo imperfectly acquainted with the manner in which friction and viſcidity obſtruct the motions of bodies, that we cannot pronounce deciſively what will be their effect in the preſent caſe. Friction does not increaſe much, if at all, by an increaſe of velocity, and appears like a fixed quantity when the preſſure is given. This makes all motions which are obſtructed by friction terminate abruptly. This will ſhorten both the length and the time of the outward excurſion of the pendulum. The viſcidity of the oil reſiſts differently, and more nearly in the proportion of the velocities. The diminution of motion will not be in this proportion, becauſe in the greater velocities it acts for a ſhorter time. Were this accurately the caſe, the reſiſtance of viſcidity would alſo be nearly conſtant, and it would operate as friction does. But it does not ſtop a motion abruptly, and the motions are extinguiſhed gradually. Therefore, although viſcidity muſt always diminiſh the extent of the excurſion, it may ſo vary as not to diminiſh the time. We apprehend, however, that it generally does. But whatever happens in the excurſion, the return will certainly be ſlower, and employ more time than if it had not been obſtructed, becauſe the velocity in every point is leſs than if perfectly free. The whole arch, conſiſting of a returning arch and an excurſion on the other ſide, may be either ſlower or quicker, according as the compenſation is complete or not, or is even overdone.

All theſe reflections occurred to Mr Graham; and he was perſuaded that the time of the tooth's remaining on the arch *a d*, both aſcending and deſcending, would differ very little from that of the deſcription of the ſame arch by a free pendulum. The great cauſes of irregularity ſeemed to be removed, viz. the inequalities in the action of the wheels in the vicinity of the extremity of the vibration, where the pendulum having little momentum is, long in the ſame little ſpace, expoſed to their action. The derangement produced by any force depends on the time of its action, and therefore muſt be greateſt when the motion is ſloweſt. The pendulum gets its impulſe in the very middle of its vibration, where its velocity is the greateſt; and therefore the inequalities of the maintaining power act on it only for a ſhort time, and make a very trifling alteration in the time of its deſcribing the arch of ſcapement. Beyond this, it is nearly in the ſtate of a free pendulum; nay, even though it be affected by an inequality of the maintaining power, and it be accelerated beyond its uſual rate in that arch, the chief effect of this will be to cauſe it to deſcribe a larger arch of excurſion. The ſhortening of the time of this deſcription by the friction will be the ſame as before, happening at the very end of the excurſion; but the return will be more retarded by the friction on a longer arch. And, by this, a compenſation may be made for the trifling contraction of the time of deſcribing the arch of ſcapement.

This circumſtance of giving the impulſe in the middle of the vibration, where its time of action is the ſmalleſt poſſible, and whereby the pendulum is ſo long left free from the action of the wheels, is of the very firſt importance in all ſcapements, and ſhould ever be in the mind of the mechanician. When this is adhered to, the form of the face *a b c* is ſcarcely of any moment. Much has been written ou this form, and many attempts have been made to make it ſuch that the action of the wheels ſhall be proportional to the action of gravity. To do this is abſolutely impoſſible. Mr Graham made them planes, not only becauſe of eaſieſt execution, but becauſe a plane really conſpires pretty well with the change of gravity. While the pendulum moves from Q to P (fig. 3.), the force of gravity, acting in the direction QP, is continually diminiſhing. So is the accelerating power of the pallet from *a* to *b*. When the pendulum riſes from P to R, a force in the oppoſite direction RP continually increaſes. This is analogous to the continual diminution of a force in the direction PR. Now we have ſuch a diminution of ſuch a force, in the action of the pallet from *b* to *c*, and ſuch an augmentation in the action of the other pallet.

For all theſe reaſons, this conſtruction of a ſcapement appeared very promiſing. Mr Graham put it in practice, and it anſwered his moſt ſanguine expectation, and is now univerſally adopted in all nice clocks. Mr Graham, however, did not think it prudent to cauſe a tooth to drop on the very angle *a* of the pallet. He made it drop on a point *f* of the arch of excurſion. This has alſo the advantage of diminiſhing the angle of action, which we have proved to be of ſervice. It requires, indeed, a greater maintaining power; but this can eaſily be procured, and is leſs affected by the changes to which it is liable by the effect of heat and cold on the oil. Our obſervations on the effects of friction and viſcidity in the arch *a d* ſeem to be confirmed by the obſervations of ſeveral artiſts, who agree in ſaying that a great increaſe of maintaining power increaſes the vibrations, but makes them perceptibly ſlower. When they wrote, much oil was applied to diminiſh the friction on the arch of repoſe; but, ſince that time, the rubbing parts were made ſuch as required no oil, and this retardation diſappeared. In the clock of the tranſit room of the Royal Obſervatory, the angle of action ſeldom exceeds one-third of the ſwing of the pendulum. The pallets are of oriental ruby, and the wheel is of ſteel tempered to the utmoſt degree of hardneſs. This clock never varies a whole ſecond from equable motion in the courſe of five days.

This contrivance is known by the name of the DEAD BEAT, the DEAD SCAPEMENT; becauſe the ſeconds index ſtands ſtill after each drop, whereas the index of a clock with a recoiling ſcapement is always in motion, hobbling backward and forward.

Theſe ſcapements, both recoiling and dead beat, have been made in a thouſand forms; but any perſon tolerably acquainted with mechanics, will ſee that they are all on the ſame principles, and differ only in ſhape or ſome equally unimportant circumſtance. Perhaps the moſt convenient of any is that repreſented in fig. 5. where the ſhaded part is the crutch, made of braſs or iron, and A and B are two pieces of agate, flint, or other hard ſtone, cut into the proper ſhape for a pallet of either kind, and firmly fixed in proper ſockets. They project half an inch, or thereabouts, in front of the crutch, ſo that the ſwing wheel is alſo before the crutch, diſtant about $\frac{1}{10}$th of an inch or ſo. Pallets of ruby, driven by a hard ſteel ſwing wheel, need no oil, but merely to be once rubbed clean with an oily cloth.

Sometimes the wheel has pins inſtead of teeth. They are ranged round the rim of the wheel, perpendicular to its plane, and both pallets are on one ſide of the wheel, ſtanding perpendicular to its plane. One of theſe pins drops from the firſt to the ſecond pallet at once. The pallets are placed on two arms, as in fig. 6. in which caſe the pins are alternately on different ſides of the wheel; or on one, as in fig. 7. By the motion of the pendulum to the right, the pin (in fig. 7.), after reſting on the concave arch *d a*, acts on the face *a c*, and drops from *c* on the other concave arch *i g*, which continues to move a little way to the right. It then returns, and the pin ſlides and acts on the pallet *i h*, and eſcapes at *h*; and the next pin is then on the arch of repoſe *d a*.

It being evident that the recoiling ſcapement accelerates the vibrations beyond the rate of a free pendulum, and it alſo appearing to many of the firſt artiſts that the dead ſcapement retards them, they have attempted to form a ſcapement which ſhall avoid both of theſe defects, by forming the arches *a d*, *i g*, ſo as to produce a very ſmall recoil. Mr Berthoud does this in a very ſimple manner, by placing the centre of *a d* at a ſmall diſtance from that of the crutch, ſo as to make the riſe of the pallet above the concentric arch about one-third of the arch itſelf. Applying ſuch a crutch to the light pendulum mentioned in a former paragraph, he found that doubling, and even trebling the maintaining power, produced no change in the time of vibration, though it increaſed the width from 8° to 12° and 14°. We have no doubt of the efficacy of this contrivance, and think it very proper for all clocks which require much oil, ſuch as turret clocks. &c. But we apprehend that no rule can be given for the angle that the recoiling arch ſhould make with the concentric one. We imagine that this depends entirely on the ſhare which friction and oil have in producing the retardation of the dead beat.

Other artiſts have endeavoured to avoid the inconveniences of friction and oil on the arch of repoſe in another way. Inſtead of allowing the tooth of the wheel to drop on the back of the pallet, which we called the *arch of excurſion*, and others call the *arch of repoſe*, it drops on a detent *o t a* (fig. 8.), of which the part *t a* is part of an arch whoſe centre is A, the centre of the crutch, and the part *t o* is in the direction of the radius. This piece does not adhere to the pallet, but is on the end of an arm *o* A, which turns round the axis A of the crutch on fine pivots: it is made to apply itſelf to the back of the pallet by means of a ſlender ſpring A*p*, attached to the pallet, and preſſing inward on a pin *p*, fixed in the arm of the detent. When ſo applied, its arch *t a* makes the repoſe, and its point *a* makes a ſmall portion of the face *a c* of the pallet.

The action of this apparatus is very eaſily underſtood. When a tooth eſcapes from the ſecond pallet, by the motion of the pendulum from the left to the right, another tooth drops on this pallet (which the figure ſhews to be the firſt or leading pallet) at the angle *t*, and reſts on the ſmall portion *t a* of an arch of repoſe. But the crutch, continuing its motion to the right, immediately quits the arm *o* A, carrying the pallet *a c r* along with it, and leaving the wheel locked on the detent *o t a*. By and bye the pendulum finiſhes its excurſion to the right, and returns. When it enters the arch of action, the pallet has applied itſelf to the detent *o t a*, and withdraws it from the tooth. The tooth immediately acts on the face *a c* of the pallet, and reſtores the motion loſt during the laſt vibration. The uſe of the ſpring is merely to keep the detent applied to the pallet without ſhaking. It is a little bent during their ſeparation, and adds ſomething of an oppoſing force to the aſcent of the pendulum on the other ſide of the wheel, and accelerates its return. A ſimilar detent on the back of the ſecond pallet performs a ſimilar office, ſupporting the wheel while the pendulum is beyond the arch of ſcapement, and quitting it when the pendulum enters that arch.

We do not know who firſt practiſed this very ingenious and promiſing invention. Mr Mudge certainly did ſo early as 1753 or 1754. Mr Berthoud ſpeaks obſcurely of contrivances of the ſame nature. So does Le Roy, and (we think) Le Paute. We ſay that it is very promiſing. Friction is almoſt annihilated by transferring it to the pivots at A; ſo that, in the excurſion beyond the angle of ſcapement, the pendulum ſeems almoſt free. Indeed ſome artiſts of our acquaintance have even avoided the friction of the pivots at A, by making the arm of the detent a ſpring of conſiderable thickneſs, except very near to A, where it is made very thin and broad. But we do not find that this conſtruction, though eaſily executed, and ſuſceptible of great preciſion and ſteadineſs of action, is much practiſed. We preſume that the performance has not anſwered expectations. It has not been ſuperior to the incomparably more ſimple dead ſcapement of Graham. Indeed we think that it cannot A part of the friction ſtill remains, which cannot be removed; namely, while the arch *t a* is drawn from between the tooth and pallet. Nay we apprehend that ſomething more than friction muſt be overcome here. The tooth is apt to force the detent outward, unleſs the part *t a* be a little elevated at its point *a* like a claw, above the concentric arch, and the face of the tooth be made to incline forward, ſo as to fit this ſhape of the detent. This will conſume ſome force, when the momentum of the pendulum is by no means at its maximum. Should the clock be foul, and the excurſions beyond ſcapement be very ſmall, this diſturbance muſt be exceedingly pernicious. But we have a much greater objection. During the whole excurſion beyond ſcapement, there is a new force of a ſpring acting on the pendulum, which deviates conſiderably from the proportions of the accelerating power of gravity. It does not commence its action till the detent ſeparates from the arm of the crutch. Then the ſpring of the detent acts as a retarding force againſt

againſt the excurſion of the pendulum, now on the other ſide, bringing it ſooner to reſt, and then accelerating it in its way back to the beginning of the arch of ſcapement. In ſhort, this conſtruction ſhould have the properties of a recoiling ſcapement. We got a clockmaker to make ſome experiments on one which he had made for an amateur, which fully confirmed our conjecture. When the detent ſpring was ſtrong, an increaſe of maintaining power made the vibrations both wider and more rapid. The artiſt reduced the ſtrength of the ſpring till this effect was rendered very ſmall. It might perhaps be quite removed by means of a ſtill weaker ſpring: But the ſpring was already ſo weak that a hard ſtep on the floor of the room did ſometimes diſengage the detent from the wheel. It appears, therefore, that nothing can be reaſonably expected from this conſtruction that is not as well performed by the dead ſcapement of Mr Graham, of much eaſier execution, and more certain performance.

Very ſimilar to this conſtruction (at leaſt in the excurſion beyond the angle of ſcapement) is the conſtruction of Mr Cumming, and it has the ſame defects. His pallets are carried, as in the one deſcribed, by the crutch. The detents preſs on them behind by their weight only: therefore, when the tooth is locked on the detent of one pallet, its weight is taken off from the pendulum on that ſide, and the weight of the detent on the other ſide oppoſes the aſcent, and accelerates the deſcent of the pendulum.

Mr Cumming executed another ſcapement, conſiſting, like thoſe, of a pallet and detent. But the manner of applying the maintaining power is extremely different in principle from any yet deſcribed. It is exceedingly ingenious, and ſeems to do all that is poſſible for removing every ſource of irregularity in the maintaining power, and every obſtruction to free motion ariſing from friction and oil in the ſcapement. For this reaſon we ſhall give ſuch an account of its eſſential circumſtances as may ſuffice to give a clear conception of its manner of acting, and its good properties and defects; but referring the inquiſitive reader to Mr Cumming's Elements of Clock and Watch Work, publiſhed in 1766, for a more full account.

In the ſcapements laſt deſcribed, the pallets were fixed to the crutch and pendulum, and the maintaining power, during its action, was applied to the pendulum by means of the pallets, in the ſame way as in ordinary ſcapements. The detents were unconnected with the pendulum, and it was free during the whole excurſion. In the preſent ſcapement both the pallets and detents are detached from the pendulum, except in the moment of unlocking the wheel; ſo that the pendulum may be ſaid to be free during its whole vibration, except during this ſhort moment.

ABC (fig. 9.) repreſents a portion of the ſwing wheel, of which O is the centre, and A one of the teeth; Z is the centre of the crutch, pallets, and pendulum. The crutch or detents is repreſented of a form reſembling the letter A, having in the circular croſs piece a ſlit *i k*, alſo circular, Z being the centre. This form is very different from Mr Cumming's, and inferior to his, but was adopted here in order to avoid a long deſcription. The arm ZF forms the firſt detent, and the tooth A is repreſented as locked on it at F. D is the firſt pallet on the end of the arm Z *d* moveable round the ſame centre with the detents, but moveable independently of them. The arm *d e*, to which the pallet D is attached, lies altogether behind the arm ZF of the detent, being fixed to a round piece of braſs *e f g*, which has pivots turning concentric with the verge or axis of the pendulum. To the ſame round piece of braſs is fixed the horizontal arm *e* H, carrying at its extremity the ball H, of ſuch ſize, that the action of the tooth A on the pallet D is juſt able (but without any riſk of failing) to raiſe it up to the poſition here drawn. ZP*p* repreſents the fork, or the pendulum rod, behind both detent and pallet. A pin *p* projects forward, coming through the ſlit *i k*, without touching the upper or under margin of it. There is alſo attached to the fork the arm *m n* (and a ſimilar one on the other ſide), of ſuch length that, when the pendulum rod is perpendicular, as is repreſented here, the angular diſtance of *n q* from the rod *e q* H is preciſely equal to the angular diſtance of the left ſide of the pin *p* from the left end *i* of the ſlit *i k*.

The mode of action on this apparatus is abundantly ſimple. The natural poſition of the pallet D is at δ, repreſented by the dotted lines, reſting on the back of the detent F. It is naturally brought into this poſition by its own weight, and ſtill more by the weight of the ball H. The pallet D, being ſet on the fore ſide of the arm at Z, comes into the ſame plane with the detent F and the ſwing-wheel. It is drawn, however, in the figure in another poſition. The tooth C of the wheel is ſuppoſed to have eſcaped from the ſecond pallet, on which the tooth A immediately engages with the pallet D, ſituated at δ, forces it out, and then reſts on the detent F, the pallet D leaning on the tip of the tooth. F is brought into this ſituation in a way that will appear preſently. After the eſcape of C, the pendulum, moving down the arch of ſemivibration, is repreſented as having attained the vertical poſition. Proceeding ſtill to the left, the pin *p* reaches the extremity *i* of the ſlit *i k*; and, at the ſame inſtant, the arm *n* touches the rod *e* H in *q*. The pendulum proceeding a hair's breadth further, withdraws the detent F from the tooth, which now even puſhes off the detent, by acting on the ſlant face of it. The wheel being now unlocked, the tooth following C on the other ſide acts on its pallet, puſhes it off, and reſts on its detent, which has been rapidly brought into a proper poſition by the action of A on the ſlant face of F. It was a ſimilar action of C on its detent, in the moment of eſcape, which brought F into a fit poſition for locking the wheel by the tooth A. The pendulum ſtill going on, the arm *m n* carries the weight of the ball H, and the pallet connected with it, and it comes to reſt before the pin *p* again reaches the end of the ſlit, which had been ſuddenly withdrawn from it by the action of A on the ſlant face of F. The pendulum now returns towards the right, loaded on the left with the ball H, which reſtores the motion which it had loſt during the laſt vibration. When, by its motion to the right, the pin *p* reaches the end *k* of the ſlit *i k*, it unlocks the wheel on the right ſide. At the ſame inſtant the weight H ceaſes to act on the pendulum, being now raiſed up from it by the action of a tooth like B on the pallet D.

Let us now conſider the mechaniſm of theſe motions. The prominent feature of the contrivance is the almoſt complete diſengagement of the regulator from the wheels.

The wheels, indeed, act on the pallets; but the pallets are then detached from the pendulum. The ſole uſe of the wheel is to raiſe the little weights while the pendulum is on the other ſide, in order to have them in readineſs at the arrival of the pendulum. They are then laid on the pendulum, and ſupply an accelerating force, which reſtores to the pendulum the momentum loſt during the preceding vibration. Therefore no inequalities in the action of the wheel on the pallets, whether ariſing from friction or oil, has any effect on the maintaining power. It remains always the ſame, namely, the rotative momentum of the two weights. The only circumſtance, in which the irregularity of the action of the wheels can affect the pendulum is at the moment of unlocking. Here indeed the regulator may be affected; but this moment is ſo ſhort, in compariſon with other ſcapements, that it muſt be conſidered as a real improvement.

It is very uncandid to refuſe the author a claim to the character of an ingenious artiſt on account of this contrivance, as has been done by a very ingenious univerſity Profeſſor, who taxes Mr Cumming with ignorance of the *firſt elements of mechanics*, and ſays that the beſt thing in his book is his advice to ſuſpend the pendulum from a great block of marble, firmly fixed in the wall *. This is certainly a good advice, and we doubt not but that the Profeſſor's clock would have performed ſtill better if he had condeſcended to follow it. It is ſtill leſs candid to queſtion the originality of the invention. We know for certain that it was invented at a time and place where the author *could* not know what had been done by others. It would have been more like the urbanity of a well educated man to have acknowledged the genius, which, without ſimilar advantages, had done ſo much.

But, while we thus pay the tribute of juſtice to Mr Cumming, we do not adopt all his opinions. The clock has the ſame defects of the former in reſpect of the laws of the force which accelerates the pendulum. The ſudden addition of the ſmall weight, and this almoſt at the extremity of the vibration, would derange it very much, if the addition were ſuſceptible of any ſenſible variation. The irregularity of the action of the wheels *may* ſenſibly affect the motion during the unlocking, when the clock is foul, and the pendulum *juſt* able to unlock; for any diſturbance at the extremity of the vibration greatly affects the time. We acknowledge that the parts which we here ſuppoſe to be foul may not be ſo in the courſe of twenty years, theſe parts being only the pivots of the ſcapement. The great defect of the ſcapement is its liableneſs to unlock by any jolt. It is more ſubject to this than the others already mentioned. This riſk is much increaſed by the ſlender make of the parts, in Mr Cumming's drawings, and in the only clock of the kind we have ſeen; but this is not neceſſary: and it ſhould be avoided for another reaſon; the interpoſing ſo many ſlender and crooked parts between the moving power and the pendulum weakens the communication of power, and requires a much more powerful wheelwork.

All theſe, however, are ſlight defects, and only the laſt can be called a fault. The clocks made on this principle have gone remarkably well, as may be ſeen by the regiſters of his majeſty's private obſervatory. But the greateſt objection is, that they do not perform better than a well-made dead ſcapement; and they are vaſtly more troubleſome to make and to manage. This is ſtrictly true, and is a ſerious objection. The fact is, that the dominion of a heavy pendulum is ſo great, that if *any one* of the ſcapements now deſcribed be well executed with pallets of agate, and a wheel of hard ſteel, and if the pendulum be ſuſpended agreeably to Mr Cumming's advice, there is hardly any difference to be obſerved in their performance. We ſhall content ourſelves with a ſingle proof of this from fact. The clock invented by the celebrated Harriſon is *at leaſt equal* in its performance to any other. Friction is almoſt annihilated, and no oil is required. It went fourteen years without being touched, and during that time did not vary one complete ſecond from one day to another, nor ever deviated half a minute by accumulation from equable motion: Yet the ſcapement, in ſo far as it reſpects the law of the accelerating force, deviates more from the proportion of the ſpaces than the moſt recoiling ſcapement that ever was put to a good clock. It is ſo different from all hitherto deſcribed, both in form and principle, that we muſt not omit ſome account of it, and with it we ſhall conclude our ſcapements for clocks.

Let GDO repreſent the ſwing wheel, of which M is the centre. A is the verge or axis of the pendulum. It has two very ſhort arms AB, AE. A ſlender rod BC turns on fine pivots in the joint B, and has at its extremity C a hook or claw, which takes hold of a tooth D of the ſwing-wheel when the pendulum moves from the right ſide to the left. This claw, when at liberty, ſtands at right angles, or, at leaſt, in a certain determinate angle, with regard to the arm AB; and when drawn a little from that poſition, it is brought back to it again by a very ſlender ſpring. The arm AE is furniſhed with a detent EF, which alſo, when at liberty, maintains its poſition on the arm by means of a very ſlender ſpring.

Let us now ſuppoſe that the tooth D is preſſing on the claw C, while the pendulum is moving to the right. The joint B yields, by its motion round A, to the preſſure of the tooth on the claw. By this yielding, the angle ABC opens a little. In the mean time, the ſame motion round A cauſes the point F of the detent on the other ſide to approach the circumference of the wheel in the arch of a circle, and the tooth G at the ſame time advances. They meet, and the point of G is lodged in the notch under the projecting heel *f*. When this takes place, it is evident that any farther motion of the point E round A muſt puſh the tooth G a little backward, by means of the detent EF. It cannot come any nearer to the wheel, becauſe the point of the tooth ſtops the heel *f*. The inſtant that F puſhes G back, the tooth D is withdrawn from the claw C, and C flies out, by the action of its ſpring, and reſumes its poſition at right angles to BA; and the wheel is now free from the claw, but is puſhing at the detent F (c). The pendulum, having

* See Ludlam's Eſſay.

(c) The reader may here remark the manner in which the preſſure of the tooth G on the detent is transferred to the joint E by the intervention of the ſhank FE, and from the joint E to the pendulum rod, by the intervention

Watch-work.

ving finiſhed its excurſion to the right (in which it cauſes the wheel to recoil by means of the detent F), returns toward the left. The wheel now advances again, and, by preſſing on F, aids the pendulum through the whole angle of ſcapement. By this motion the claw C deſcribes an arch of a circle round A, and approaches the wheel, till it take hold of another tooth, namely, the one following D, and pulls it back a little. This immediately frees the detent F from the preſſure of the tooth G, and it flies out a little from the wheel, reſuming its natural poſition by means of its ſpring. Soon after, the motion of the pendulum to the left ceaſes, and the pendulum returns; D pulling forward the hook C to aid the pendulum, and the former operation is repeated, &c. &c.

Such is the operation of the pallets of Harriſon and Hindley. Friction is almoſt totally avoided, and oil entirely (D). The motion is given to the pendulum by a fair pull or puſh, and the teeth of the wheel only apply themſelves to the detents without rubbing. There is no drop, and the ſcapement makes no noiſe, and is what the artiſts call *a ſilent ſcapement.* The mechanician will readily perceive, that by properly diſpoſing the arms AB, AE, and diſpoſing the pallets on the circumference of the wheel, the law, by which the action of the wheel on the pendulum is regulated, may be greatly varied, ſo as to harmonize, as far as the nature of ſcapement, alternately puſhing and pulling, will admit, with the action of gravity.

But this is evidently a recoiling ſcapement, and one of the worſt kind; for the recoil is made at the very confines of the vibration, where every diſturbance of the regular cycloidal vibration occaſions the greateſt diſturbance to the motion. Yet this clock kept time with moſt unexampled preciſion, far excelling all that had been made before, and equal to any that have been made ſince. This is entirely owing to the immenſe ſuperiority of the momentum of the pendulum over the maintaining power.

II. *Of Scapements for a Watch.*

The execution of a proper ſcapement for watches is a far more delicate and difficult problem than the foregoing, on account of the ſmall ſize, which requires much more accurate workmanſhip, becauſe the error of the hundredth part of an inch has as great a proportion to the dimenſions of the regulator as an inch in a common houſe clock. It is much more difficult on another account. We have no ſuch means of accumulating ſuch a dominion (to uſe Mr Harriſon's expreſſive term) over the wheel-work in the regulator of a watch as in that of a clock. The heavieſt balance that we can employ, without the certainty of ſnapping its pivots by every ſlight jolt, is a mere trifle, in compariſon with the pendulum of the moſt ordinary clock. A dozen or twenty grains is the utmoſt weight of the balance, even of a very large pocket watch. The only way that we can accumulate any notable quantity of regulating power in ſuch a ſmall pittance of matter is by giving it a very great velocity. This we do by accumulating all its weight in the rim, by giving it very wide vibrations, and by making them extremely frequent. The balance-rim of a middling good watch ſhould paſs through at leaſt ten inches in every ſecond. Now, when we reflect on the ſmall momentum of this regulator, the inevitable inequalities of the maintaining power, and the great arch of vibration on which theſe inequalities will operate, and the comparative magnitude even of an almoſt inſenſible friction or clammineſs, it appears almoſt chimerical to expect any thing near to equability in the vibrations, and incredible that a watch can be made which will not vary more than one beat in 86400. Yet ſuch have been made. They muſt be conſidered as the moſt maſterly exertions of human art. The performance of a reflecting teleſcope is a great wonder: the worſt that can find a market muſt have its mirrors executed without an error of the ten thouſandth part of an inch; but we now know that this accuracy is attained almoſt in ſpite of us, and that we ſcarcely *can* make them of a worſe figure. But the caſe is far otherwiſe in watch-work. Here all thoſe wonderful approaches to perfection are the reſults of rational diſcuſſion, by means of ſound principles of ſcience; and, unleſs the artiſt who puts theſe principles into practice be more than a mere copyiſt, unleſs the principles themſelves are perceived by him, and actually direct his hand, the watch may ſtill be good for nothing. Surely, then, this is a liberal art, and far above a manual knack. The ſtudy of the means by which ſuch wonders are ſteadily effected, is therefore the ſtudy of a gentleman.

In the account given above of the ſcapements for pendulums, we aſſumed as one leading principle that *the natural vibrations of a pendulum are performed in equal times, whether wide or narrow.* This is ſo nearly true, when the arches on each ſide of the perpendicular do not exceed four degrees, that the retardation of the wider arches within that limit will not become ſenſible, though accumulated for a long time. The common ſcapement with a plane face of the pallet, helps to correct even this ſmall inequality much better than the niceſt form of the cycloidal checks propoſed by Huyghens.

In watch-work we aſſume a ſimilar principle, namely, that *the oſcillations of a balance, urged by its ſpring, and undiſturbed*

---

tion of the arm EA. This communication of preſſure is preciſely the ſame that we made uſe of in explaining the common ſcapement. MG, FE, and EA, in this fig. 10. are performing the offices which we then gave to the lines MB, BH, and HA, in fig. 3. Harriſon's pallet realiſes the abſtract theory.

(D) Mr Harriſon was at firſt by profeſſion a carpenter in a country place. Being extremely ingenious and inventive, he had made a variety of curious wooden clocks. He made one, in particular, for a turret in a gentleman's houſe. Its expoſure made it waſte oil very faſt, and the maker was often obliged to walk two or three miles to renew it, and got nothing for his trouble. In trudging home, not in very good humour, he pondered with himſelf how to make a clock go without oil. He changed all his pinion leaves into rollers; which anſwered very well. But the pallets required it more than any other part. After various other projects, he contrived thoſe now repreſented, where there was no friction, and no oil is wanted. The turret clock continued to go without being touched till Mr Harriſon left the country.

undiſturbed by all foreign forces, are performed in equal times, whether they be wide or narrow. This principle was aſſumed by the celebrated mechanician Dr Robert Hooke, on the authority of many experiments which he had made on the bending and unbending of ſprings. He found that the force neceſſary for retaining a ſpring in any conſtrained poſition was proportional to its tenſion, or deflection from its natural form. He expreſſed this in an anagram, which he publiſhed about the year 1660, in order to eſtabliſh his claim to the diſcovery, and yet conceal it. till he had made ſome important application of it. When the anagram was explained ſome years afterwards, it was, "*Ut tenſio, ſic vis.*" Dr Hooke thought of applying this diſcovery to the regulation of watch movements. For, if a ſlender ſpring be *properly* applied to the axis of a watch balance, it will put that balance in a certain determinate poſition. If the balance be turned aſide from this poſition, it ſeems to follow that it will be urged back toward it by a force proportional to its diſtance from it. He immediately made the application to an old watch, which he afterward gave to Dr Wilkins, Biſhop of Cheſter. This was in 1658. Its motion was ſo amazingly improved, that Hooke was perſuaded of the perfection of his principle, and thought that nothing was now wanting for making a watch of this kind a perfect chronometer but the hand of a good workman. For his watch ſeemed almoſt perfect, though made in a ſmall country town, in a very coarſe manner. Mr Huyghens alſo claims this diſcovery. He publiſhed his claim about the year 1675, and propoſed to make watches for diſcovering the longitude of a ſhip at ſea. But there is the moſt unqueſtionable evidence of Dr Hooke's priority by fifteen years, and of his having made ſeveral watches of this kind. One of them was in the poſſeſſion of his majeſty king Charles II. Dr Hooke's firſt balance ſpring was ſtraight, and acted on the balance in a very imperfect manner. But he ſoon ſaw the imperfections, and made ſeveral ſucceſſive alterations; and, among others, he employed the cylindrical ſpiral now employed by Mr Arnold; but he gave it up for the flat ſpiral: and the king's watch had one of this kind before Mr Huyghens publiſhed his invention. His project of longitude watches had been carried on along with Lord Brouncker and Sir Robert Moray, and they had quarrelled ſome years before that publication. See WATCH, *Encycl.*

But both Dr Hooke and Mr Huyghens were too ſanguine in their expectations. We, by no means, have the evidence for the truth of this principle that we have for the accelerating action of gravity on a pendulum. It reſts on the nicety and the propriety of the experiments; and long experience has ſhewn that it is ſenſibly true only within certain limits. The demonſtrations by which Bernoulli ſupports the unqualified principle of Mr Huyghens, proceed on hypothetical doctrines concerning the nature of elaſticity. And even theſe ſhew that the law of elaſticity which he aſſumed was ſelected, not becauſe founded on ſimpler principles than any other, but becauſe it was conſiſtent with the experiments of Hooke and Huyghens. Beſides, although this ſhould be the true law of a ſpring, it does not follow that this ſpring, applied in *any way* to the axis of a balance, will urge that balance agreeably to the ſame law: and if it did, it ſtill does not follow that the oſcillations of the balance will be iſochronous; for the force has to move not only the balance but alſo the ſpring. Part of the reſtoring force of the ſpring is employed in reſtoring it rapidly to its quieſcent ſhape, and thus enabling it to *follow and ſtill impel* the yielding balance. It is therefore only the ſurplus which is employed in actually moving the balance, and it is uncertain whether this ſurplus varies according to the ſame law, being always the ſame proportion of the whole force of the ſpring. We find it an extremely difficult problem to determine the law of variation of this ſurplus, even in the ſimpleſt form of the ſpring; nay, it is by no means an eaſy problem to determine the law of oſcillation of a ſpring, unloaded with any balance; and we can eaſily ſhew that there are ſuch forms of a ſpring, that although the velocity with which the different parts approach to their quieſcent poſition be exactly as their excurſion from it, this is by no means the law of velocity which this ſpring will produce in a balance. The matter of fact is, that when the ſpring is a ſimple ſtraight ſteel wire, ſuſpending the balance in the direction of its axis, the motions of it, if not immoderate, are preciſely agreeable to Huyghens's and Hooke's rule; and that the motion of a balance urged by a ſpring wound up into a flat, or a cylindrical ſpiral, as in common watches, and thoſe of Arnold, deviates ſenſibly from it, unleſs a certain analogy be preſerved between the length and the elaſticity of the ſpring. If the ſpring be immoderately long, the wide vibrations are ſlower than the narrow ones; and the contrary is obſerved when the ſpring is immoderately ſhort. A certain taper, or gradual diminution of the ſpring, is alſo found to have an effect in equalizing the wide and narrow vibrations. There is alſo a great difference between the force with which a part of the ſpring unbends itſelf, and the action of that force in urging the balance round its axis; and the performance of many watches, good in other reſpects, is often faulty from the manner in which this unbending force is employed.

But, ſince theſe corrections are in our power in a conſiderable degree, we may ſuppoſe them applied, and the true motion (which we ſhall call the cycloidal) attained; and we may then adapt the conſtruction of the ſcapement to the preſerving this motion undiſturbed. And here we muſt ſee at once that the problem is incomparably more delicate than in the caſe of pendulums. The vibrations muſt be very wide, and the angular motion rapid, that it may be little affected by external motions. The ſmalleſt inequalities of maintaining power acting through ſo great a ſpace, muſt bear a conſiderable proportion to the very minute momentum of a watch balance. Oil is as clammy on the pallets of a watch as on thoſe of a clock; a viſcidity which would never be felt by a pendulum of 20 pounds weight will ſtop a balance of 20 grains altogether. For the ſame reaſon, it is evident that any impropriety in the form of the pallet muſt be incomparably more pernicious than in the caſe of a pendulum; the deviation which this may occaſion from a force proportional to the angular diſtance from the middle point, muſt bear a great proportion to the whole force.

The common recoiling ſcapement of the old clocks ſtill holds its place in the ordinary pocket watches, and anſwers all the common purpoſes of a watch very well. A well finiſhed watch, with a recoiling ſcapement, will keep time within a minute in the day. This is enough for the ordinary affairs of life. But ſuch watches are ſubject to great variation in their rate of going, by any change in the power of the wheels. This is evident; for if the watch be held back, or preſſed forward, by the key applied to the fuſee ſquare, we hear the beating greatly retarded or accelerated. The maintaining power, in the beſt of ſuch watches, is never leſs than one fifth of the regulating power of the ſpring. For, if we take off the balance ſpring, and allow the balance to vibrate by the impulſe of the wheels alone, we ſhall find the minute hand to go forward from 25 to 30 minutes per hour. Suppoſe it 30. Then, ſince the wheels act through equal ſpaces with or without a ſpring, the forces are as the ſquares of the acquired velocities. (Dynamics, *Suppl.* n° 95.) The velocity in this caſe is double; therefore the accelerating force is quadruple, and the force of the ſpring is three times that of the wheels. If the hand goes forward 25 minutes, the force of the wheels is about one-fifth of that of the ſpring. This great proportion is neceſſary, as already obſerved, that the watch may go as ſoon as unſtopped.

We have but little to ſay on this ſcapement; its principle and manner of action, and its good and bad qualities, being the ſame with thoſe of the ſimilar ſcapement for pendulums. It is evident that the maintaining power being applied in the moſt direct manner, and during the whole of the vibration, it will have the greateſt poſſible influence to move the balance. A given mainſpring and train will keep in motion a heavier balance by means of this ſcapement than by any other. But, on the other hand, and for the ſame reaſon, the balance has leſs dominion over the wheel-work, and its vibrations are more affected by any irregularities of the wheel-work. Moreover, the chief action of the wheel being at the very extremities of the vibrations, and being very abrupt, the variations in its force are moſt hurtful to the iſochroniſm of the vibrations.

Although this ſcapement is extremely ſimple, it is ſuſceptible of more degrees of goodneſs or imperfection than almoſt any other, by the variation of the few particulars of its conſtruction. We ſhall therefore briefly deſcribe that conſtruction which long experience has ſanctioned as approaching near to the beſt performance that can be obtained from the common ſcapement. Fig. 11. repreſents it in what are thought its beſt proportions, as it appears when looking ſtraight down on the end of the balance arbor. C is the centre of the balance and verge. CA and CB are the two pallets; CA being the upper pallet, or the one next to the balance, and CB being the lower one. F and D are two teeth of the crown wheel, moving from left to right; and E, G, are two teeth on the lower part of the circumference, moving from right to left. The tooth D is repreſented as juſt eſcaped from the point of CA, and the lower tooth E as juſt come in contact with the lower pallet. The ſcapement ſhould not, however, be quite ſo cloſe, becauſe an inequality on the teeth might prevent D from eſcaping at all. For if E touch the pallet CB before D has quitted CA, all will ſtand ſtill. This fault will be corrected by withdrawing the wheel a little from the verge, or by ſhortening the pallets.

The proportions are as follow The diſtance between the front of the teeth (that is, of G, F, E, D) and the axis C of the balance is one-fifth of FA, the diſtance between the points of the teeth. The length CA, CB of the pallets is three-fifths of the ſame diſtance. The pallets make an angle ACB of 95 degrees, and the front DH or FK of the teeth make an angle of 25° with the axis of the crown-wheel The ſloping ſide of the tooth muſt be of an epicycloidal form, ſuited to the relative motion of the tooth and pallet.

From theſe proportions it appears that the pallet A can *throw out*, by the action of the tooth D, till it reaches *a*, 120 degrees from CL, the line of the crown-wheel axis. For it can throw out till the pallet B ſtrike againſt the front of E, which is inclined 25° to CL. To this add BCA, = 95°, and we have LC*a* = 120. In like manner B will throw out as far on the other ſide. From 240°, the ſum of theſe angles, take the angle of the pallets 95°, and there remains 145° for the greateſt vibration which the balance can make without ſtriking the front of the teeth. This extent of vibration ſuppoſe the teeth to terminate in points, and the acting ſurfaces of the pallets to be planes directed to the very axis of the verge. But the points of the teeth muſt be rounded off a little for ſtrength, and to diminiſh friction on the face of the pallets. This diminiſhes the angle of ſcapement very conſiderably, by ſhortening the teeth. Moreover, we muſt by no means allow the point of the pallet to bank or ſtrike on the foreſide of a tooth. This would greatly derange the vibration by the violence and abruptneſs of the check which the wheel would give to the pallet. This circumſtance makes it improper to continue the vibrations much beyond the angle of ſcapement. One-third of a circle, or 120°, is therefore reckoned a very proper vibration for a ſcapement made in theſe proportions. The impulſe of the wheels, or the angle of ſcapement, may be increaſed by making the face of the pallets a little concave (preſerving the ſame angle at the centre). The vibration may alſo be widened by puſhing the wheel nearer to the verge. This would alſo diminiſh the recoil. Indeed this may be entirely removed by bringing the front of the wheel up to C, and making the face of the pallet not a radius, but parallel to a radius and behind it, *i. e.* by placing the pallet CA ſo that its acting face may be where its back is juſt now. In this caſe, the tooth D would drop on it at the centre, and lie there at reſt, while the balance completes its vibration But this would make the banking (as the ſtroke is called) on the teeth almoſt unavoidable. In ſhort, after varying every circumſtance in every poſſible manner, the beſt makers have ſettled on a ſcapement very nearly ſuch as we have deſcribed. Preciſe rules can ſcarcely be given; becauſe the law by which the force acting on the pallets varies in its intenſity, deviates ſo widely from the action of the balance ſpring, eſpecially near the limits of the excurſions.

The diſcoveries of Huyghens and Newton in rational mechanics engaged all the mathematical philoſophers of Europe in the ſolution of mechanical problems, about the end of the laſt century. The vibrations of elaſtic plates or wires, and their influence on watch balances, became familiar to every body. The great requiſites for producing iſochronous vibrations were well underſtood, and the artiſts were prompted by the ſpeculatiſts to attempt conſtructions of ſcapements proper for this purpoſe. It appeared clearly, that the moſt effectual means for

for this purpoſe was to leave the balance unconnected with the wheels, eſpecially near the extremities of the vibration, where the motion is languid, and where every inequality of maintaining power muſt act for a longer time, and therefore have a great effect on the whole duration of the vibrations The maxim of conſtruction that naturally ariſes from theſe reflections is to *confine*, if poſſible, *the action of the wheels to the middle of the vibration*, where the motion is rapid, and where the chief effect of an increaſe or diminution of the maintaining power will be to enlarge or contract the angular motions, but will make little change on their duration; becauſe the greateſt part of the motion will be effected by the balance ſpring alone. This maxim was inculcated in expreſs terms by John Bernoulli, in his *Recherches Mechaniques et Phyſiques*; but it had been ſuggeſted by common ſenſe to ſeveral unlettered artiſts before that time About the beginning of this century watches were made in London, where the verge had a portion *e d b* (fig. 12.) of a ſmall cylinder, having its centre *c* in the axis, and a radial pallet *b a* proceeding from it. Suppoſe a tooth juſt eſcaped from the point of the pallet, moving in the direction *b d e*, the cylindrical part was ſo ſituated that the next tooth dropped on it at a ſmall diſtance from its termination. While the verge continues turning in the direction *b d e*, the tooth continues reſting on the cylinder, and the balance ſuſtains no *action* from the wheels, and has only to overcome the minute frictions on the poliſhed ſurface of a hard ſteel cylinder. This motion may perhaps continue till the pallet acquires the poſition *f*, almoſt touching the tooth. It then ſtops, its motion being extinguiſhed by the increaſing force of the ſpring It now returns, moving in the direction *e d b*; and when the pallet has acquired the poſition *c i*, the tooth *g* quits the circumference of the cylinder, and drops in on the pallet at the very centre. The crooked form of the tooth allows the pallet to proceed ſtill farther, before there is any danger of banking on the tooth. This vibration being alſo ended, the balance reſumes its firſt direction, and the tooth now acts on the face of the pallet, and reſtores to the balance all the motion which it had loſt by friction, &c. during the two preceding vibrations.

It is evident that this conſtruction obviates all the objections to the former recoiling ſcapement, and that, by ſufficiently diminiſhing the diameter of the cylindrical part, the friction may be reduced to a very ſmall quantity, and the balance be made to move by the action of the ſpring during the whole of the excurſion, and of the returning vibration. Yet this conſtruction does not ſeem to have come much into uſe, owing, in all probability, to the great difficulty of making the drop ſo accurate in all the teeth. The ſmalleſt inequality in the length of a tooth would occaſion it to drop ſooner or later; and if the cylinder was made very ſmall, to diminiſh friction, the formation of the notch was almoſt a microſcopical operation, and the ſmalleſt ſhake in the axis of the verge or the balance-wheel would make the tooth ſlip paſt the cylinder, and the watch run down amain.

About the ſame time, a French artiſt in London (then the ſchool of this art) formed another ſcapement, with the ſame views. We have not any diſtinct account of it, but are only informed (in the 7th volume of the *Machines approuvées par l'Acad. des Sciences*) that the tooth reſted on the ſurface of a hollow cylinder, and then eſcaped by acting on the inclined edge of it. But we may preſume that it had merit, being there told that Sir Iſaac Newton wore a watch of this kind.

A much ſuperior ſcapement, on the ſame principle, was invented by Mr Geo. Graham, at the ſame time that he changed the recoiling ſcapement for pendulums into the dead beat. Indeed it is the ſame ſcapement, accommodated to the large vibrations of a balance In fig 13. DE repreſents part of the rim of the balance-wheel. A and C are two of its teeth, having their faces *b e* formed into planes, inclined to the circumference of the wheel, in an angle of about 15 degrees; ſo that the length *b e* of the face is nearly quadruple of its height *e m*. Suppoſe a circular arch ABC deſcribed round the centre of the wheel, and through the middle of the faces of the teeth. The axis of the balance paſſes thro' ſome point B of this arch, and we may ſay that the mean circumference of the teeth paſſes through the centre of the verge. On this axis is fixed a portion of a thin hollow cylinder *b c d*, made of hard tempered ſteel, or of ſome hard and tough ſtone, ſuch as ruby or ſapphire. Agates, though very hard, are brittle Chalcedony and cornelian are tough, but inferior in hardneſs. This cylinder is ſo placed on the verge, that when the balance is in its quieſcent poſition, the two edges *b* and *d* are in the circumference which paſſes through the points of the teeth. By this conſtruction the portion of the cylinder will occupy 210° of the circumference, or 30° more than a ſemicircle. The edge *b*, to which the tooth approaches from without, is rounded off on both angles. The other edge *d* is formed into a plane, inclined to the radius about 30°

Now, ſuppoſe the wheel preſſed forward in the direction AC The point *b* of the tooth, touching the rounded edge, will puſh it outwards, turning the balance round in the direction *b c d*. The heel *e* of the tooth will eſcape from this edge when it is in the poſition *h*, and *e* is in the poſition *f*. The point *b* of the tooth is now at *d*, but the edge of the cylinder has now got to *i*. The tooth, therefore, reſts on the inſide of the cylinder, while the balance continues its vibration a little way, in conſequence of the ſhove which it has received from the action of the inclined plane puſhing it out of the way, as the mould board of a plough ſhoves a ſtone aſide. When this vibration is ended, by the oppoſition of the balance-ſpring, the balance returns, the tooth (now in the poſition B) rubbing all the while on the inſide of the cylinder The balance comes back into its natural poſtion *b c d*, with an accelerated motion, by the action of its ſpring, and would, of itſelf, vibrate as far, at leaſt, on the other ſide. But it is aided again by the tooth, which, preſſing on the edge *d*, puſhes it aſide, till it come into the poſition *k*, when the tooth eſcapes from the cylinder altogether.. At this moment the other edge of the cylinder is in the poſition *l*, and therefore is in the way of the next tooth, now in the poſition A. The balance continues its vibration the tooth all the while reſting, and rubbing on the outſide of the cylinder. When this vibration, in the direction *d c b*, is finiſhed, the balance reſumes its firſt motion *b c d*, by the action of the ſpring, and the tooth begins to act on the firſt edge *b*, as ſoon as the balance gets into its natural poſition, ſhoves it aſide, eſcapes from it, and drops on the inſide of the cylinder. In this manner are the vibrations produced, gradually increaſed to their maximum, and maintained in that ſtate. Every ſucceeding tooth of the wheel acts firſt on the edge *b*, and then on the edge *d*; reſting firſt on the outſide, and then on the inſide of the cylinder. The balance is under the influence of the wheels while the edge *b* paſſes to *h*, and while *d* paſſes to *k*; and the reſt of the vibration is performed without any *action* on the part of the wheels, but is a little obſtructed by friction, and by the clammineſs of the oil. In the conſtruction now deſcribed, the arch of action or ſcapement is evidently 30°, being twice the angle which the face of a tooth makes with the circumference.

The reader will perceive, that when this ſcapement is executed in ſuch a manner that the ſucceeding tooth is in contact with the cylinder at the inſtant that the preceding one eſcapes from it, the face of the tooth muſt be equal to the inſide diameter of the cylinder, and that the diſtance between the heel of one tooth and the point of the following one muſt be equal to the outſide diameter. When the ſcapement is ſo cloſe there is no drop. A good artiſt approaches as near to this adjuſtment as poſſible; becauſe, while a tooth is dropping, but not yet in contact, it is not acting on the balance, and ſome force is loſt. The execution is accounted very good, if the diſtance between the centres of two teeth is twice the external diameter of the cylinder. This allows a drop equal to the thickneſs of the cylinder, which is about $\frac{1}{2}$ th of its diameter.

We muſt alſo explain how this cylinder is ſo connected with the verge as to make ſuch a great revolution round the tooth of the wheel. The triangular tooth *e b m* is placed on the top of a little pillar or pin fixed into the extremity of the piece of braſs *m* D formed on the rim of the wheel. Thus the wedge-tooth has its plane parallel to the plane of the wheel, but at a ſmall diſtance above it. Fig. B repreſents the verge, a long hollow cylinder of hard ſteel. A great portion of the metal is cut out. If it were ſpread out flat, it would have the ſhape of fig. C. Suppoſe this rolled up till the edges GH and G′H′ are joined, and we have the exact form. The part acted on by the point of the tooth is the dotted line *b d*. The part DIFE′ ſerves to connect the two ends. Thus it appears to be a very ſlender and delicate piece; but being of tempered ſteel, it is ſtrong enough to reſiſt moderate jolts. The ruby cylinders are much more delicate.

Such is the cylinder ſcapement of Mr Graham, called alſo the HORIZONTAL SCAPEMENT, becauſe the balance wheel is parallel to the others. Let us ſee how far it may be expected to anſwer the intended purpoſes. If the excurſions of the balance beyond the angle of impulſion were made altogether unconnected with the wheels, the *whole vibration* would be quicker than one of the ſame extent, made by the action of the balance-ſpring alone, becauſe the middle part of it is accelerated by the wheels. But the excurſions are obſtructed by friction and the clammineſs of oil. The effect of this in *obſtructing* the motion is very conſiderable. Mr Le Roy placed the balance ſo, that it reſted when the point of the tooth was on the middle of the cylindric ſurface. When the wheel was allowed to preſs on it, and it was drawn 80° from this poſition, it vibrated only during 4½ ſeconds. When the wheel was not allowed to touch the cylinder, it vibrated 90 ſeconds, or 20 times as long; ſo much did the friction on the cylinder exceed that of the pivots. We are not ſufficiently acquainted with the laws of either of theſe obſtructions to pronounce decidedly whether they will increaſe or diminiſh the *time* of the whole vibrations. We obſerve diſtinctly, in motions with conſiderable friction, that it does not increaſe nearly ſo faſt as the velocity of the motion; nay, it is often leſs when the velocity is very great. In all caſes it is obſerved to terminate motions abruptly. The friction requires a certain force to overcome it, and if the body has any leſs it will ſtop. Now this will not only contract the excurſion of the balance, but will ſhorten the time. But the return to the angle of impulſion will undoubtedly be of longer duration than the excurſion; for the arch of return, from the extremity of the excurſion to its beginning, where the angle of impulſion ends, is the ſame with the arch of excurſion. The velocity which the balance has in any point of the return is leſs than what it had in the ſame point of the excurſion; becauſe, in the excurſion, it had velocity enough to carry it to the extremity, and alſo to overcome the friction. In the return, it could, even without friction, only have the velocity which would have carried it to the extremity; and this ſmaller velocity is diminiſhed by friction during the return. The velocity being leſs through the whole return than during the excurſion, the time muſt be greater. It may therefore happen that this retardation of the return may compenſate the contraction of the excurſion and the diminution of its duration. In this caſe the vibration will occupy the ſame time as if the balance had been free from the wheels. But it may more than compenſate, and the vibrations will then be ſlower; or it may not fully compenſate, and they will be quicker. We cannot therefore ſay, *à priori*, which of the two will happen: but we may venture to ſay that an increaſe of the force of the wheels will make the watch go ſlower: for this will exert a greater preſſure, give a greater impulſion, produce a wider excurſion, and increaſe the friction during that greater excurſion, making the wide vibrations ſlower than the narrow ones; becauſe the angle of impulſion remaining the ſame, the preſſures exerted muſt be quadrupled, in order to double the excurſion (ſee DYNAMICS, n° 95. *Suppl.*), and therefore the friction will be increaſed in a greater proportion than the momentum which is to overcome it. But, with reſpect to the obſtruction ariſing from the viſcidity of the oil, we know that it follows a very different law. It bears a manifeſt relation to the velocity, and is nearly proportional to it. But ſtill it is difficult to ſay how this will affect the whole vibration. The duration of the excurſion will not be ſo much contracted as by an equal obſtruction from friction, becauſe it will not terminate the motion abruptly. There are therefore more chances of the increaſed duration of the return exceeding the diminution of it in the excurſion. All that we can ſay, therefore, is, that there will be a compenſation in both caſes. The time of excurſion will be contracted, and that of return augmented.

Now, as the friction may be greatly diminiſhed by fine poliſh, fine oil, and a ſmall diameter of the cylinder, we may reaſonably expect that the vibrations of ſuch a balance will not vary nearly ſo much from iſochroniſm as with a recoiling ſcapement, and will be little affected by changes in the force of the wheels.

Accord-

Watch-work.

Accordingly, Graham's cylindrical ſcapement ſupplanted all others as ſoon as it was generally known. We cannot compare the vibrations with thoſe of a free balance, becauſe we have no way of making a free balance vibrate for ſome hours. But we find that doubling or trebling the force of the wheels makes very little alteration in the rate of the watch, though it greatly enlarges the angular motion. Any one may perceive the immenſe ſuperiority of this ſcapement over the common recoiling ſcapement, by preſſing forward the movement of a horizontal watch with the key, or by keeping it back. No great change can be obſerved in the frequency of the beats, however hard we preſs. But a more careful examination ſhews that an increaſe of the power of the wheels generally cauſes the watch to go ſlower; and that this is more remarkable as the watch has been long going without being cleaned. This ſhews that the cauſe is to be aſcribed to the friction and oil operating on the wide arches of excurſion. But when this ſcapement is well executed, in the beſt proportions of the parts, the performance is extremely good. We know ſuch watches, which have continued for ſeveral weeks without ever varying more than 7′ in one day from equable motion. We have ſeen one whoſe cylinder was not concentric with the balance, but ſo placed on the verge that the axis of the verge was at o (fig. 13.), between the centre B of the cylinder and the entering edge b, and Be was equal to the thickneſs of the cylinder. The watch was made by Emery of London, and was ſaid to go with aſtoniſhing regularity, ſo as to equal any time piece while the temperature of the air did not vary; and when clean, was ſaid to be leſs affected by the temperature than a watch with a free ſcapement, but unprovided with a compenſation piece. It is evident that this watch muſt have a minute recoil. This was ſaid to be the aim of the artiſt, in order to compenſate for the obſtruction cauſed by friction during the return of the balance from its excurſions. It indeed promiſes to have this effect; but we ſhould fear that it ſubjects the excurſions to the influence of the wheels. We ſuſpect that the indifferent performance of cylinder watches may often ariſe from the cylinder being off the centre in ſome diſadvantageous manner.

The watch from which the proportions here ſtated were taken, is a very fine one made by Graham for Archibald Duke of Argyle, which has kept time with the regularity now mentioned. We believe that there are but few watches which have ſo large a portion of the cylinder: few indeed have more than one half, or 180° of the circumference. But this is too little. The tooth of the wheel does not begin to act on the reſting cylinder till its middle point A or B touch one of the edges. To obtain the ſame angle of ſcapement, the inclination of the face of the tooth muſt be increaſed (it muſt be doubled); and this requires the maintaining power to be increaſed in the ſame proportion. Beſides, in ſuch a ſcapement it may happen that the tooth will never reſt on the cylinder; becauſe the inſtant that it quits one edge it falls on the other, and puſhes it aſide, ſo that the balance acquires no wider vibration than the angle of ſcapement, and is continually under the influence of the wheels. The ſcapement is in its beſt ſtate when the portion of the cylinder exceeds 180° by twice the inclination of the teeth to the circumference of the wheel.

Watch-work.

It would employ volumes to deſcribe all the ſcapements which have been contrived by different artiſts, aiming at the ſame points which Graham had in view. We ſhall only take notice of ſuch as have ſome eſſential difference in principle.

Fig. 14. repreſents a ſcapement invented in France, and called the *Echappement à VIRGULE*, becauſe the pallet reſembles a comma. The teeth A, B, C, of the balance wheel are ſet very oblique to the radius, and there is formed on the point of each a pin, ſtanding up perpendicular to the plane of the wheel. This greatly reſembles the wheel of Graham's ſcapement, when the triangular wedge is cut off from the top of the pin on which it ſtands. The axis c of the verge is placed in the circumference paſſing through the pins. The pallet is a plate of hard ſteel $a e f d b$, having its plane parallel to the plane of the wheel. The inner edge of this plate is formed into a concave cylindrical ſurface between o and b, whoſe axis c coincides with the axis of the verge. Adjoining to this is the acting face $b d$ of the pallet. This is either a ſtraight line $b d$, making an angle of nearly 30° with a line $c b g$ drawn from the centre, or it is more generally curved, according to the noſtrum of the artiſt. The back of the pallet $a e f$ is alſo a cylindrical ſurface (convex) concentric with the other. This extends about 100° from a to f. The part between f and d may have any ſhape. The interval $a o$ is formed into a convex ſurface, in ſuch a manner as to be everywhere interſected by the radius in an angle of 30° nearly; *i. e.* it is a portion of an equiangular ſpiral. The whole of this is connected with the verge by a crank, which paſſes perpendicularly through it between f and e; and the plate is ſet at ſuch height on the crank or verge, that it can turn round clear of the wheel, but not clear of the pins. The teeth of the wheel are ſet ſo obliquely, and made ſo ſlender, that the verge may turn almoſt quite round without the crank's banking on the teeth. The part $f d b$, called the horn, is of ſuch a length, that when one pin B reſts on the outſide cylinder at a, the point d is juſt clear of the next pin A.

When the wheel is not acting, and the balance ſpring is in equilibrio, the poſition of the balance is ſuch that the point d of the horn is near i, about 30° from d. The figure repreſents it in the poſition which it has when the tooth A has juſt eſcaped from the point d of the horn. In this poſition the next tooth B is applied to the convex cylinder, a very little way (about 5°) from its extremity a. This deſcription will enable the reader to underſtand the operation of the virgule ſcapement.

Now ſuppoſe the pin A juſt eſcaped from the horn. The ſucceeding pin B is now in contact with the back of the cylinder; and the balance, having got an impulſe by the action of A along the concave pallet $b d$, continues its motion in the direction $d g h$, till its force is ſpent, the point of the horn arriving perhaps at h, more than 90° from d. All this while the following tooth B is reſting on the back $e f$ of the cylinder. The balance now returns, by the action of its ſpring; and when the horn is at i, the pin gets over the edge $a o$, and drops on the oppoſite ſide of the concave cylinder, where it reſts, while the horn moves from i to k, where it ſtops, the force of the balance being again ſpent. The balance then returns; and when the horn comes within

30° of *d*, the pin gets out of the hollow cylinder, ſhoves the horn out of its way, and eſcapes at *d*. Beſides the impulſe which the balance receives by the action of the wheel on the horn *b d*, there is another, though ſmaller, action in the contrary direction, while the point of B paſſes over the ſurface *a o*; for this ſurface being inclined to the radius, the preſſure on it urges the balance round in the direction *b d i*.

The chief difference of this ſcapement from the former is that the inclined plane is taken from the teeth of the wheel, and placed on the verge. This alone is a conſiderable improvement; for it is difficult to ſhape all the teeth alike; whereas the horn *b d* is invariable. Moreover, the reſting parts, although they be drawn large in this figure for the ſake of diſtinctneſs, may be made vaſtly ſmaller than Graham's cylinder, which muſt be big enough to hold a tooth within it. By this change, the friction, during the repoſe of the wheel, that is, during the excurſions of the balance, may be vaſtly diminiſhed. The inſide cylinder need be no bigger than to receive the pin. But although the performance of theſe ſcapements is excellent, they have not come into general uſe in this country. The cauſe ſeems to be the great nicety requiſite in making the pins of the wheel paſs exactly through the axis of the verge. The leaſt ſhake in the pivots of the balance and balance-wheel muſt greatly change the action. A very minute increaſe of diſtance between the pivots will cauſe the pin B to ſlide from the edge *a* to the horn, without reſting at all on the inſide cylinder; and when it does ſo, it will ſtop the balance at once, and, immediately after, the watch will run down. The ſame irregularities will happen if all the pins be not at preciſely the ſame diſtance from the axis of the wheel.

This ſcapement was greatly improved, and, in appearance, totally changed, by Mr Lepaute of Paris in 1753. By placing the pins alternately on the two ſides of the rim of the balance-wheel, he avoided the uſe of the outſide cylinder altogether. The ſcapement is of ſuch a ſingular form, that it is not eaſy to repreſent it by any drawing. We ſhall endeavour, however, to deſcribe it in ſuch a manner as that our readers, who are not artiſts, will underſtand its manner of acting. Artiſts by profeſſion will eaſily comprehend how the parts may be united which we repreſent as ſeparate.

Let ABC (fig. 15.) repreſent part of the rim of the balance-wheel, having the pins 1, 2, 3, 4, 5, &c. projecting from its faces; the pins 1, 3, 5, being on the ſide next the eye, but the pins 2 and 4 on the farther ſide. D is the centre of the balance and verge, and the ſmall circle round D repreſents its thickneſs. But the verge in this place is crooked, like a crank, that the rim of the wheel may not be interrupted by it. This will be more particularly deſcribed by and bye. There is attached to it a piece of hard tempered ſteel *a b c d*, of which the part *a b c* is a concave arch of a circle, having D for its centre. It wants about 30° of a ſemicircle. The reſt of it *c d* is alſo an arch of a circle, having the ſame radius with the balance-wheel. The natural poſition of the balance is ſuch, that a line drawn from D, through the middle of the face *c d*, is a tangent to the circumference of the wheel. But, ſuppoſe the balance turned round till the point *d* of the horn comes to *d*, and the point *c* comes to 2, in the circumference in which the pins are placed. Then the pin, preſſing on the beginning of the horn or pallet, puſhes it aſide, ſlides along it, and eſcapes at *d*, after having generated a certain velocity in the balance. So far this ſcapement is like the virgule ſcapement deſcribed already. But now let another pallet, ſimilar to the one now deſcribed, be placed on the other ſide of the wheel, but in a contrary poſition, with the acting face of the pallet turned away from the centre of the wheel. Let it be ſo placed at E, that the moment that the pin 1, on the upper ſide of the wheel, eſcapes from the pallet *c d*, the pin 4, on the under ſide of the wheel, falls on the end of the circular arch *e f g* of the other pallet. Let the two pallets be connected by means of equal pulleys G and F on the axis of each, and a thread round both, ſo that they ſhall turn one way. The balance on the axis D, having gotten an impulſe from the action of the pin 1, will continue its motion from A towards *i*, and will carry the other pallet with a ſimilar motion round the centre E from *b* towards *k*. The pin 4 will therefore reſt on the concave arch *g f e* as the pallet turns round. When the force of the balance is ſpent, the pallet *c d* returns towards its firſt poſition. The pallet *g b* turns along with it; and when the point of the firſt has arrived at *d*, the beginning *g* of the other arrives at the pin 4; and, proceeding a little farther, this pin eſcapes from the concave arch *e f g*, and ſlides along the pallet *g b*, puſhing it aſide, and therefore urging the pallet round the centre E, and conſequently (by means of the connection of the pulleys) urging the balance on the axis D round at the ſame time, and in the ſame direction. The pin 4 eſcapes from the pallet *g b*, when *b* arrives at 3; but in the time that the pin 4 was ſliding along the yielding pallet *g b*, the pin 3 is moving in the circumference BDA; and the inſtant that the pin 4 eſcapes from *b* at 3, the pin 3 arrives at 2, and finds the beginning *c* of the concave arch *c b a* ready to receive it. It therefore reſts on this arch, while the balance continues its motion. This perhaps continues till the point *b* of the arch comes to 2. The balance now ſtops, its force being ſpent, and then returns; and the pin 3 eſcapes from the circle at *c*, ſlides along the yielding pallet *c d*, and when it eſcapes at 1, another pin on the under ſide of the wheel arrives at 4, and finds the arch *g f e* ready to receive it. And in this manner will the vibration of the balance be continued.

This deſcription of the mode of action at the ſame time points out the dimenſions which muſt be given to the parts of the pallet. The length of the pallet *c d* or *g b* muſt be equal to the interval between two ſucceeding pins, and the diſtance of the centres D and E muſt be double of this. The radius D *e* or E *g* may be as ſmall as we pleaſe. The concave arches *c b a* and *g f e* muſt be continued far enough to keep a pin reſting on them during the whole excurſion of the balance. The angle of ſcapement, in which the balance is under the influence of the wheels, is had by drawing D *c* and D *d*. This angle *c* D *d* is about 30°, but may be made greater or leſs.

Fig. B will give ſome notion how the two pallets may be combined on one verge. KL repreſents the verge with a pivot at each end. It is bent into a crank MNO, to admit the balance wheel between its branches. BC repreſents this wheel, ſeen edgewiſe, with its pins, alternately on different ſides. The pallets are alſo repreſented

preſented edgewiſe by *b c d* and *h g f*, fixed to the inſide of the branches of the crank, fronting each other. The poſition of their acting faces may be ſeen in the preceding figure, on the verge D, where the pallet *g h* is repreſented by the dotted line 2 *i*, as being ſituated behind the pallet *c d*. The remote pallet 2 *i* is placed ſo, that when the point *d* of the near pallet is juſt quitted by a pin 1 on the upper ſide of the wheel, the angle formed by the face and the arch of reſt of the other pallet is juſt ready to receive the next pin 2, which lies on the under ſide of the rim. A little attention will make it plain, that the action will be preciſely the ſame as when the pallets were on ſeparate axes. The pin 1 eſcapes from *d*, and the pin 2 is received on the arch of reſt, and locks the wheel while the balance is continuing its motion. When it returns, 2 gets off the arch of reſt, puſhes aſide the pallet 2 *i*, eſcapes from it when *i* gets to 1, and then the pin 3 finds the point *c* ready to receive it, &c. The vibrations may be increaſed by giving a ſufficient impulſe through the angle of ſcapement. But they cannot be more than a certain quantity, otherwiſe the top N of the crank will ſtrike the rim of the wheel. By placing the pins at the very edge of the wheel, the vibrations may eaſily be increaſed to a ſemicircle. By placing them at the points of long teeth, the crank may get in between them, and the vibrations extended ſtill farther, perhaps to 240°.

This ſcapement is unqueſtionably a very good one; and when equally well executed, ſhould excel Graham's, both by having but two acting faces to form (and theſe of hard ſteel or of ſtone), and by allowing us to make the circle of reſt exceedingly ſmall without diminiſhing the acting face of the pallet. This will greatly diminiſh the friction and the influence of oil. But, on the other hand, we apprehend that it is of very difficult execution. The figure of the pallets, in a manner that ſhall be ſuſceptible of adjuſtment and removal for repair, and yet ſufficiently accurate and ſteady, ſeems to us a very delicate job.

Mr Cumming, in his Elements of Clock and Watch-work, deſcribes (ſlightly) pallets of the very ſame conſtruction, making what he conceives to be conſiderable improvements in the form of the acting faces and the curves of reſt. He has alſo made ſome watches with this ſcapement; but they were ſo difficult, that few workmen can be found fit for the taſk; and they are exceedingly delicate, and apt to be put out of order. The connection of the pallets with each other, and with the verge, makes the whole ſuch a contorted figure, that it is eaſily bent and twiſted by any jolt or unſkilful handling.

There remains another ſcapement of this kind, having the tooth of the balance-wheel reſting on a cylindrical ſurface on the axis of the verge during the excurſions of the balance beyond the angle of ſcapement, and which differs ſomewhat in the application of the maintaining power from all thoſe already deſcribed.

This is known by the name of *Dupleix's ſcapement*, and is as follows: Fig. 16. repreſents the eſſential parts greatly magnified. AD is a portion of the balance-wheel, having teeth *f*, *b*, *g*, at the circumference. Theſe teeth are entirely for producing the *reſt* of the wheel, while the balance is making excurſions beyond the ſcapement. This is effected by means of an agate cylinder *o p q*, on the verge. This cylinder has a notch *o*. When the cylinder turns round in the direction *o p q*, the notch eaſily paſſes the tooth B which is reſting on the cylindric ſurface; but when it returns in the direction *q p o*, the tooth B gets into the notch, and follows it, preſſing on one ſide of it till the notch comes into the poſition *o*. The tooth, being then in the poſition *b*, eſcapes from the notch, and another tooth drops on the convex ſurface of the cylinder at B.

The balance wheel is alſo furniſhed with a ſet of ſtout flat ſided pins, ſtanding upright on its rim, as repreſented by *a*, D. There is alſo fixed on the verge a larger cylinder GFC above the ſmaller one *o p q*, with its under ſurface clear of the wheel, and having a pallet C, of ruby or ſapphire, firmly indented into it, and projecting ſo far as juſt to keep clear of the pins on the wheel. The poſition of this cylinder, with reſpect to the ſmaller one below it, is ſuch that, when the tooth *b* is eſcaped from the notch, the pallet C has juſt paſſed the pin *a*, which was at A while B reſted on the ſmall cylinder; but it moved from A to *a*, while B moved to *b*. The wheel being now at liberty, the pin *a* exerts its preſſure on the pallet C in the moſt direct and advantageous manner, and gives it a ſtrong impulſion, following and accelerating it till another tooth ſtops on the little cylinder. The angle of ſcapement depends partly on the projection of the pallet, and partly on the diameter of the ſmall cylinder and the advance of the tooth B into the notch. Independent of the action on the ſmall cylinder, the angle of ſcapement would be the whole arch of the large cylinder between C and *x*. But *a* ſtops before it is clear of the pallet, and the arch of impulſion is ſhortened by all the ſpace that is deſcribed by the pin while a tooth moves from B to *b*. It ſtops at *a*.

We are informed by the beſt artiſts, that this ſcapement gives great ſatisfaction, and equals, if it do not excel, Graham's cylindrical ſcapement. It is eaſier made, and requires very little oil on the ſmall cylinder, and none at all on the pallet. They ſay that it is the beſt for pocket watches, and is coming every day more into repute. Theory ſeems to accord with this character. The reſting cylinder may be made very ſmall, and the direct impulſe on the pallet gives it a great ſuperiority over all thoſe already deſcribed, where the action on the pallet is oblique, and therefore much force is loſt by the influence of oil. But we fear that much force is loſt by the tooth B ſhifting its place, and thus ſhortening the arch of impulſion; for we cannot reckon much on the action of B on the ſide of the notch, becauſe the lever is ſo extremely ſhort. Accordingly, all the watches which we have ſeen of this kind have a very ſtrong main ſpring in proportion to the ſize and vibration of the balance. If we leſſen this diminution of the angle of impulſion, by leſſening the cylinder *o p q*, and by not allowing B to penetrate far into the notch, the ſmalleſt inequality of the teeth, or ſhake in the pivots of the balance or wheel, will cauſe irregularity, and even uncertainties in the locking and unlocking the wheel by this cylinder.

A ſcapement exceedingly like this was applied long ago by Detertre, a French artiſt, to a pendulum. The only difference is, that in the pendulum ſcapement the ſmall cylinder is cut through to the centre, half of it only being left; but the pendulum ſcapement gives a more effective employment of the maintaining power, becauſe the wheel acts on the pallet during the *whole* of the aſſiſted vibration. In a balance ſcapement, if we attempt to diminiſh the inefficient motion of the pin from A to *a*, by leſſening the diameter of the ſmall cylinder, the hold given to the tooth in the notch will be ſo trifling, that the tooth will be thrown out by the ſmalleſt play in the pivot holes, or inequality in the length of the teeth.

With this we conclude our account of ſcapements, where the action of the maintaining power on the balance is ſuſpended during the excurſion beyond the angle of impulſion, by making a tooth reſt on the ſurface of a ſmall concentric cylinder. In ſuch ſcapements, the balance, during its excurſions, is almoſt free from any connection with the wheels, and its iſochroniſm is diſturbed by nothing but the friction on this ſurface.—We come now to ſcapements of more artful conſtruction, in which the balance is really and completely free during the whole of its excurſion, being altogether diſengaged from the wheelwork These are called DETACHED SCAPEMENTS. They are of more recent date. We believe that Mr Le Roi was the firſt inventor of them, about the year 1748. In the Memoirs of the Academy of Paris for that year, and in the Collection of approved Machines and Inventions, we have deſcriptions of the contrivance. The balance-wheel reſts on a detent, while the balance is vibrating in perfect freedom. It has a pallet ſtanding out from the centre, which, in the courſe of vibration, paſſes cloſe by the point of a tooth of the wheel. At that inſtant a pin, connected with this pallet, withdraws the detent from the wheel, and the tooth juſt now mentioned follows the pallet with rapidity, and gives it a ſmart puſh forward. Immediately after, another tooth of the wheel meets the other claw of the detent, and the wheel is again locked. When the balance returns, the pin puſhes the detent back into its former place, where it again locks the wheel. Then the balance, reſuming its firſt direction, unlocks the wheel, and receives another impulſion from it. Thus the balance is unconnected with the wheels, except while it gets the impulſion, and at the moments of unlocking the wheels.

This contrivance has been reduced to the greateſt poſſible ſimplicity by the Britiſh artiſts, and ſeems ſcarcely capable of farther improvement. The following is one of the moſt approved conſtructions. In fig. 17. *a b c* repreſents the pallet, which is a cylinder of hard ſteel or ſtone, having a notch *a b*. A portion of the balance-wheel is repreſented by AB. It is placed ſo near to the cylinder that the cylinder is no more than clear of *two adjoining* teeth. DE is a long ſpring, ſo fixed to the watch plate at E, as to preſs very gently on the ſtop pin G. A ſmall ſtud F is fixed to that ſide of the ſpring that is next to the wheel. The tooth of the wheel reſts on this ſtud, in ſuch a manner that the tooth *a* is juſt about to touch the cylinder, and the tooth *f* is juſt clear of it. Another ſpring, extremely ſlender, is attached to the ſpring DE, on the ſide next the balance-wheel, and claps cloſe to it, but keeping clear of the ſtud F, and having its point *o* projecting about $\frac{1}{30}$th of an inch beyond its extremity. When the point *o* is preſſed towards the wheel, it yields moſt readily; but, when preſſed in the oppoſite direction, it carries the ſpring DE along with it. The cylinder being ſo placed on the verge that the edge *a* of the notch is cloſe by the tooth *a*, a hole is drilled at *i*, cloſe by the projecting point of the ſlender ſpring, and a ſmall pin is driven into this hole. This is the whole apparatus; and this ſituation of the parts correſponds to the quieſcent poſition of the balance.

Now, let the balance be turned out of this poſition 80 or 90 degrees, in the direction *a b c*. When it is let go, it returns to this poſition with an accelerated motion. The pin *i* ſtrikes on the projecting point of the ſlender ſpring, and, preſſing the ſtrong ſpring DE outward from the wheel, withdraws the ſtud F from the tooth; and thus unlocks the wheel. The tooth *a* engages in the notch, and urges round the balance. The pin *i* quits the ſlender ſpring before the tooth quits the notch; ſo that when it is clear of the pallet, the wheel is locked again on the ſtud F, and another tooth *g* is now in the place of *a*, ready to act in the ſame manner. When the force of the balance is ſpent, it ſtops, and then returns toward its quieſcent poſition with a motion continually accelerated. The pin *i* arrives at the point *o* of the ſlender ſpring, raiſes it from the ſtrong ſpring without diſturbing the latter, and almoſt without *being* diſturbed by this trifling obſtacle; and it goes on, turning in the direction *a b c*, till its force is again ſpent; it ſtops, returns, again unlocks the wheel, and gets a new impulſion. And in this manner the vibrations are continued. Thus we ſee a vibration, almoſt free, maintained in a manner even more ſimple than the common crutch ſcapement. The impulſe is given direct, without any decompoſition by oblique action, and it is continued through the *whole* motion of the wheel. No part of this motion is loſt, as in Dupleix's ſcapement, by the *gradual* approach of the tooth to its active poſition. Very little force is required for unlocking the wheel, becauſe the ſpring DFE is made ſlender at the remote end E, ſo that it turns round E almoſt like a lever turning on pivots. A ſudden twitch of the watch, in the direction *b a*, might chance to unlock the wheel. But this will only derange one vibration, and even that not conſiderably, becauſe the teeth are ſo cloſe to the cylinder that the wheel cannot advance till the notch comes round to the place of ſcapement. A tooth will continue preſſing on the cylinder, and by its friction will change a little the extent and duration of a ſingle vibration. The greateſt derangement will happen if the wheel ſhould thus unlock by a jolt, while the notch paſſes through the arch of ſcapement in the returning vibration. Even this will not greatly derange it, when the watch is clean and vibrating wide; becauſe, in this poſition, the balance has its greateſt momentum, and the direction of the only jolt that can unlock the wheel tends to increaſe this momentum relatively. In ſhort, conſidering it theoretically, it ſeems an almoſt perfect ſcapement; and the performance of many of theſe watches abundantly confirms that opinion. They are known to keep time for many days together, without varying one ſecond from day to day; and this even under conſiderable variations of the maintaining power. Other detached ſcapements may equal this, but we ſcarcely expect any to exceed it; and its ſimplicity is ſo much ſuperior to any that we have ſeen, that, on this account, we are diſpoſed to give it the preference. We do not mean to ſay that it is the beſt for a pocket watch. Perhaps the ſcapement of Dupleix or Graham may be preferable, as being ſuſceptible of greater ſtrength, and more able to withſtand jolts. Yet it is a fact that ſome of the watches made in this form by Arnold and others have kept time in the wonderful manner abovementioned while carried about in the pocket.

Mr Mudge of London invented, about the year 1763, another detached ſcapement, of a ſtill more ingenious conſtruction. It is a counterpart of Mr Cumming's ſcapement for pendulums. The contrivance is to this effect. In fig. 18. *a b c* repreſents the balance. Its axis is bent into a large crank EFGHIK, ſufficiently roomy to admit within it two other axes M and L, with the proper cocks for receiving their pivots. The three axes form one ſtraight line. About theſe ſmaller axes are coiled two auxiliary ſprings, in oppoſite directions, having their outer extremities fixed in the ſtuds A and B. The balance has its ſpring alſo, as uſual, and the three ſprings are ſo diſpoſed that each of them alone would keep the balance at reſt in the ſame poſition, which we may ſuppoſe to be that repreſented in the figure. The auxiliary ſprings A and B are connected with the balance only occaſionally, by means of the arms *m* and *n* projecting from their reſpective axes. Theſe arms are catched on oppoſite ſides by the pins *o*, *p*, in the branches of the crank; ſo that when the balance turns round, it carries one or other of thoſe arms round with it, and, during this motion, it is affected by the auxiliary ſpring connected with the arm ſo carried round by it.

Let us ſuppoſe that the balance vibrates 120° on each ſide of its quieſcent poſition *a b c*, ſo that the radius E *a* acquires, alternately, the poſitions E *b* and E *c*. The auxiliary ſprings are connected with the wheels by a common dead-beat pendulum ſcapement, ſo that each can be ſeparately wound up about 30°, and retained in that poſition. Let us alſo ſuppoſe that the ſpring A has been wound up 30° in the direction *a b*, by the wheel-work, and that the point *a* of the rim of the balance, having come from *c*, is paſſing through *a* with its greateſt velocity. When the radius E *a* has paſſed *a* 30° in its courſe toward *b*, the pin *o* finds the arm *m* in its way, and carries it along with it till *a* gets to *b*. But, by carrying away the arm *m*, it has unlocked the wheel-work, and the ſpring B is now wound up 30° in the other direction, but has no connection with the balance during this operation. Thus the balance finiſhes its ſemivibration *a b* of 120°, oppoſed by its own ſpring the whole way, and by the auxiliary ſpring A through an angle of 90°. It returns to the poſition E *a*, aided by A and by the balance ſpring, through an angle of 120°. In like manner, when E *a* has moved 30° toward the poſition E *c*, the pin *p* meets with the arm *n*, and carries it along with it through an angle of 90°, oppoſed by the ſpring B, and then returns to the poſition E *a*, aſſiſted by the ſame ſpring through an arch of 120°.

Thus it appears that the balance is oppoſed by each auxiliary ſpring through an angle of 90°, and aſſiſted through an angle of 120°. This difference of action maintains the vibrations, and the neceſſary winding up of the auxiliary ſprings is performed by the wheel-work, at a time when they are totally diſengaged from the balance. No irregularity of the wheel-work can have any influence on the force of the auxiliary ſprings, and therefore the balance is completely diſengaged from all theſe irregularities, except in the ſhort moment of unlocking the wheel that winds up the ſprings.

This is a moſt ingenious conſtruction, and the neareſt approach to a free vibration that has yet been thought of. It deſerves particular remark that, during the whole of the returning or accelerated ſemivibration, the united force of the ſprings is proportional to the diſtance from the quieſcent poſition. The ſame may be ſaid of the retarded excurſion beyond the angle of impulſe: therefore the only deviation of the forces from the law of cycloidal vibration is during the motion from the quieſcent poſition to the meeting with the auxiliary ſpring. Therefore, as the forces, on both ſides, beyond this angle, are in their due proportion, and the balance always makes ſuch excurſions, there ſeems nothing to diſturb the iſochroniſm, whether the vibrations are wide or narrow. Accordingly, the performance of this ſcapement, under the ſevereſt trials, equalled any that were compared with it, in as far as it depended on ſcapement alone. But it is evident that the execution of this ſcapement, though moſt ſimple in principle, muſt always be vaſtly more difficult than the one deſcribed before. There is ſo little room, that the parts muſt be exceedingly ſmall, requiring the moſt accurate workmanſhip. We think that it may be greatly ſimplified, preſerving all its advantages, and that the parts may be made of more than twice their preſent ſize, with even leſs load on the balance from the inertia of matter. This improvement is now carrying into effect by a friend.

Still, however, we do not ſee that this ſcapement is, theoretically, ſuperior to the laſt. The irregularities of maintaining power affect that ſcapement only in the arch of impulſion, where the velocity is great, and the time of action very ſmall. Moreover, the chief effect of the irregularities is only to enlarge the excurſions; and in theſe the wheels have no concern.

Mr Mudge has alſo given another detached ſcapement, which he recommends for pocket watches, and executed entirely to his ſatisfaction in one made for the Queen. A dead beat pendulum ſcapement is enterpoſed, as in the laſt, between the wheels and the balance. The crutch EDF (fig. 19.) has a third arm DG, ſtanding outwards from the meeting of the other two, and of twice their length. This arm terminates in a fork AGB. The verge V has a pallet C, which, when all is at reſt, would ſtand between the points A, B of the fork. But the wheel, by its action on the pallet E, forces the fork into the poſition B *g b*, the point A of the fork being now where B was before, juſt touching the cylindrical ſurface of the verge. The ſcapement of the crutch EDF is not accurately a dead beat ſcapement, but has a very ſmall recoil beyond the angle of impulſion. By this circumſtance the branch A (now at B) is made to preſs moſt gently on the cylinder, and keeps the wheel locked, while the balance is going round in the direction BHA. The point A gets moving from A to B by means of a notch in the cylinder, which turns round at the ſame time by the action of the branch AG on the pallet C; but A does not touch the cylinder during this motion, the notch leaving free room for its paſſage. When the balance returns from its excurſion, the pallet C ſtrikes on the branch A (ſtill at B), and unlocks the wheel. This now acting on the crutch pallet F, cauſes the branch *b* of the fork to follow the pallet C, and give it a ſtrong impulſe in the direction in which it is then moving, cauſing the balance to make a ſemivibration in the direction AHB. The fork is now in the ſituation A *g a*, ſimilar to B *g b*, and the wheel is again locked on the crutch pallet E.

The intelligent reader will admit this to be a very ſteady and effective ſcapement. The lockage of the wheel is procured in a very ingenious manner; and the friction on the cylinder, neceſſary for effecting this, may be made as ſmall as we pleaſe, notwithſtanding a very ſtrong action of the wheel: For the preſſure of the fork on the cylinder depends entirely on the degree of recoil that is formed on the pallets E and F. *Preſſure* on the cylinder is not *indiſpenſably* neceſſary, and the crutch ſcapement might be a real dead beat. But a ſmall recoil, by keeping the fork in contact with the cylinder, gives the moſt perfect ſteadineſs to the motion. The ingenious inventor, a man of approved integrity and judgment, declares that her Majeſty's watch was the beſt pocket watch he had ever ſeen. We are not diſpoſed to queſtion its excellency. We ſaw an experiment watch of this conſtruction, made by a country artiſt, having a balance ſo heavy as to vibrate only twice in a ſecond. Every vibration was ſenſibly beyond a turn and a half, or 540°. The artiſt aſſured us, that when its proper balance was in, vibrating ſomewhat more than five times in a ſecond, the vibrations even exceeded this. He had procured it this great mobility by ſubſtituting a roller with fine pivots in place of the ſimple pallet of Mudge. This great extent of detached vibration is an unqueſtionable excellence, and is peculiar to thoſe two ſcapements of this ingenious artiſt.

Very ingenious ſcapements have been made by Ernſhaw, Howel, Hayley, and other Britiſh artiſts; and many by the artiſts of Paris and Geneva. But we muſt conclude the article, having deſcribed all that have any difference in principle.

The ſcapement having been brought to this degree of perfection, we have an opportunity of making experiments on the law of action of ſprings, which has been too readily aſſumed. We think it eaſy to demonſtrate, that the figure of a ſpring, which muſt have a great extent of rapid motion, will have a conſiderable influence on the force which it impreſſes on a balance *in actual motion*. The accurate determination of this influence is not very difficult in ſome ſimple caſes It is the greateſt of all in the plane ſpiral, and the leaſt in the cylindrical; and, in this laſt form, it is ſo much leſs as the diameter is leſs, the length of the ſpring being the ſame. By employing many turns, in order to have the ſame ultimate force at the extremity of the excurſion, this influence is increaſed. A particular length of ſpring, therefore, will make it equal to a given quantity; and it may thus compenſate for a particular magnitude of friction, and other obſtructions. This accounts for the obſervation of Le Roy, who found that every ſpring, *when applied to a movement*, had a certain length, which made the wide and narrow vibrations iſochronous. His method of trial was ſo judicious, that there can be no doubt of the juſtneſs of his concluſion. His time-keeper had no fuzee; and when the laſt revolution of the main wheel was going on, the vibrations were but of half the extent of thoſe made during the firſt revolution. Without minding the real rate of going, he only compared the duration of the firſt and laſt revolution of the minute hand. An artiſt of our acquaintance repeated theſe experiments, and with the ſame reſult: But, unfortunately, could derive little benefit from them; becauſe in one ſtate of the oil, or with one balance, he found the lengths of the ſame ſpring, which produced iſochronous vibrations, were different from thoſe which had this effect in another ſtate of the oil, or with another balance. He alſo obſerved another difference in the rate, ariſing from a difference of poſition, according as XII, VI, III, or IX, was uppermoſt; which difference plainly ariſes from the ſwagging of the ſpring by its weight, and, in that ſtate, acting as a pendulum. This unluckily put a ſtop to his attempts to leſſen this hurtful influence by employing a cylindrical ſpiral of ſmall diameter and great length.

WATER-Blowing Machine, called in French *Soufflet d'eau* or *trompe*, is a machine which, by the action of falling water, ſupplies air to a blaſt furnace. It conſiſts of an upright pipe, through which a ſhower of water is made to fall; and this ſhower carries down with it a maſs of air, which is received beneath in a kind of tub, and conducted to the furnace by means of a pipe. The firſt idea of ſuch a machine was doubtleſs ſuggeſted by thoſe local winds, which are always produced by natural falls of water over precipices, and in the mountains (ſee page 278 of this Volume); but perhaps we are indebted for the firſt accurate theory of it to Profeſſor Venturi.

That philoſopher, in his experimental reſearches concerning the lateral communication of motion in fluids, proves that the water-blowing machine affords air to the furnace, by the accelerating force of gravity and the lateral communication of motion combined together. He begins with an idea, which, he candidly acknowledges, did not eſcape the penetration of Leonardo Da Vinci. Suppoſe a number of equal balls to move in contact with each other along the horizontal line AB (Plate XLVI. fig. 1.). Imagine them to paſs with an uniform motion, at the rate of four balls in a ſecond. Let us take BF, equal to 16 feet Engliſh. During each ſecond four balls will fall from B to F, and their reſpective diſtances in falling will be nearly BC = 1, CD, = 3, DE = 5, EF = 7. We have here a very evident repreſentation of the ſeparation, and ſucceſſive elongation, which the accelerating force of gravity produces between bodies which fall after each other.

The rain water flows out of gutters by a continued current; but during its fall it ſeparates into portions in the vertical direction, and ſtrikes the pavement with diſtinct blows. The water likewiſe divides, and is ſcattered in the horizontal direction. The ſtream which iſſues out of the gutter may be one inch in diameter, and ſtrike the pavement over the ſpace of one foot. The air which exiſts between the vertical and horizontal ſeparations of the water which falls, is impelled and carried downwards. Other air ſucceeds laterally; and in this manner a current of air or wind is produced round the place ſtruck by the water. Hence the following idea of a water-blowing maching:

Let BCDE (fig. 2.) repreſent a pipe, through which the water of a canal AB falls into the lower receiver MN. The ſides of the tube have openings all round, through which the air freely enters to ſupply what the water carries down in its fall. This mixture of water

Watch-work

and air proceeds to ſtrike a maſs of ſtone Q ; whence rebounding through the whole width of the receiver MN, the water ſeparates from the air, and falls to the bottom at XZ, whence it is diſcharged into the lower channel or drain, by one or more openings TV. The air being leſs heavy than the water, occupies the upper part of the receiver ; whence being urged through the upper pipe O, it is conveyed to the forge.

It has been ſuppoſed by ſome eminent chemiſts, that the air which paſſes through the pipe O is furniſhed by the decompoſition of water. To aſcertain whether this be the caſe or not, our author formed a water-blowing engine of a ſmall ſize. The pipe BD was two inches in diameter, and four feet in height. When the water accurately filled the ſection BC, and all the lateral openings of the pipe BDEC were cloſed, the pipe O no longer offered any wind. It is therefore evident, that in the open pipes the whole of the wind comes from the atmoſphere, and no portion is afforded by the decompoſition of water. It remains, therefore, to determine the circumſtances proper to drive into the receiver MN the greateſt quantity of air, and to meaſure that quantity.

1. To obtain the greateſt effect from the acceleration of gravity, it is neceſſary that the water ſhould begin to fall at BC, (fig. 2.) with the leaſt poſſible velocity ; and that the height of the water FB ſhould be no more than is neceſſary to fill the ſection BC. Our author ſuppoſes the vertical velocity of this ſection to be produced by an height or head equal to BC.

2. We do not yet know, by direct experiment, the diſtance to which the lateral communication of motion between water and air can extend itſelf; but we may admit with confidence, that it can take place in a ſection double that of the original ſection with which the water enters the pipe. Let us ſuppoſe the ſection of the pipe BDEC to be double the ſection of the water at BC ; and, in order that the ſtream of fluid may extend and divide itſelf through the whole double ſection of the pipe, ſome bars, or a grate, are placed in BC, to diſtribute and ſcatter the water through the whole internal part of the pipe.

3. Since the air is required to move in the pipe O with a certain velocity, it muſt be compreſſed in the receiver. This compreſſion will be proportioned to the ſum of the accelerations, which ſhall have been deſtroyed in the inferior part KD of the pipe. Taking KD = 1,5 feet, we ſhall have a preſſure ſufficient to give the requiſite velocity in the pipe O. The ſides of the portion KD, as well as thoſe of the receiver MN, muſt be exactly cloſed in every part.

4. The lateral openings in the remaining part of the pipe BK may be ſo diſpoſed and multiplied, particularly at the upper part, that the air may have free acceſs within the tube. We will ſuppoſe them to be ſuch that 0,1 foot height of water might be ſufficient to give the neceſſary velocity to the air at its introduction through the apertures.

All theſe conditions being attended to, and ſuppoſing the pipe BD to be cylindrical, it is required to determine the quantity of air which paſſes in a given time through the circular ſection KL. Let us take in feet KB = 1,5 ; BC = BF = a ; BD = b. By the common theory of falling bodies, the velocity in KL will be 7,76 $\surd\,(a + b - 1{,}4)$; the circular ſection KL = 0,785 a^2. Admitting the air in KL to have acquired the ſame velocity as the water, the quantity of the mixture of the water and air which paſſes in a ſecond through KL is = 6, 1 $a^2 \surd\,(a + b - 1{,}4)$. We muſt deduct from the quantity $(a + b - 1{,}4)$ that height which anſwers to the velocity the water muſt loſe by that portion of velocity which it communicates to the air laterally introduced ; but this quantity is ſo ſmall that it may be neglected in the calculation. The water which paſſes in the ſame time of one ſecond thro' BC is = 0.4 $a^2 \surd\,(a + 0{,}1)$. Conſequently, the quantity of air which paſſes in one ſecond through KL, will be = 6, 1 $a^2 \surd\,(a + b - 1{,}4) - 0{,}4\,a^2 \surd\,(a + 0{,}1)$, taking the air itſelf, even in its ordinary ſtate of compreſſion, under the weight of the atmoſphere. It will be proper, in practical applications, to deduct one-fourth from this quantity ; 1. On account of the ſhocks which the ſcattered water ſuſtains againſt the inferior part of the tube, which deprive it of part of its motion ; and, 2. Becauſe it muſt happen that the air in LK will not, in all its parts, have acquired the ſame velocity as the water.

Watch-work, Weaving.

If the pipe O do not diſcharge the whole quantity of air afforded by the fall, the water will deſcend at XZ ; the point K will riſe in the pipe, the afflux of air will diminiſh, and part of the wind will iſſue out of the lower lateral apertures of the pipe BK.

We ſhall not here examine the greater or leſs degree of perfection of the different forms of water-blowing machines which are uſed at various iron forges ; ſuch as thoſe of the Catalans, and elſewhere. Theſe points may be eaſily determined from the principles here laid down, compared with thoſe eſtabliſhed in the articles *Resistance of Fluids (Encycl.)*, and Dynamics (*Supplement.*).

WEAVING (ſee *Encycl.*) is an operation, which, by means of a well-known inſtrument called the *weaving-loom*, has hitherto been performed by bodily labour. That labour is pretty ſevere ; and Mr Robert Millar, an ingenious calico-printer in the county of Dumbarton, Scotland, wiſhing to leſſen it, invented, ſome years ago, a weaving-loom, which may be wrought by water, ſteam, horſes, or any other power. For his invention he received a patent, dated June 26th 1796 ; and though truth compels us to ſay, that we do not think it likely to emulate the ſpinning machine of Arkwright, it is ſufficiently ingenious to deſerve notice in a Work of this kind. The following is his own deſcription of his patent weaving-loom :

Fig. 1. (Plate L.) repreſents a ſide view of the loom, AA, BB, CC, DD, being the frame. *a* is an axis (which we ſhall call the ſpindle) acroſs the frame. On this axis is a ſheeve *b*, two inches thick, having a groove round it, two inches deep, and half an inch wide. The bottom of this groove is circular, except in one part *c*, where it is filled up to the top ; a lever *d* reſts on the bottom of this groove, and is lifted up by it when the elevation *c* comes round to the ſituation repreſented in the figure. By this motion, the lever *d* acts on the ratchet wheel *e* by the catch *f*, and draws it forward one tooth, each revolution of the ſheeve. This ratchet wheel is in an iron frame *g g*, which alſo properly carries the two catches *t* and *u*, which are connected with it at *v*. The catch *u* holds the ratchet-wheel in its poſition, while the lever *d*, and the catch *t*, are moved by the groove *c* in the ſheeve. On the arbor

of the ratchet is a ſmall pinion *h*, working in the wheel *f*; this wheel is fixed on the end of the roller *e* of fig. 3. On the ſide of the ſheeve *b* is fixed a wiper *k*, which lifts the treadle *l*. This treadle turns on its joints in the ſheeve E, which is fixed to the ſide of the frame A and D; it is kept preſſing on the bottom of the groove in the ſheeve by a ſpring *m*, fixed to the frame ſide A, and having a ſlender rod *n* from its extremity, joining it with the treadle at *l*. From the point of the treadle there goes a belt *o*, which paſſes over the pulley *p*, which is ſeen edgewiſe in this figure, and is joined to the top of the fly pin *q*, of fig. 2. At the end of the frame A is the ſhort poſt F; on this reſts the yarn beam *j*, having a ſheeve *r*, over which paſſes a cord, having a weight *s* ſuſpended to it. The other end of this cord is faſtened to the ſpring *v*: the weight cauſes the yarn-beam to ſtretch the web from the ratchet wheel *e*, with its catch *u*; and the ſpring *v* allows the rope to ſlide on the ſheeve as the ratchet is drawn round during the working.

Fig. 2. is a front view of the loom. *a a* is the ſpindle which carries the ſheeve *b*, and the wipers *d* and *d*, which move the treadles *w*. *w*. of fig. 1. Theſe uſe the treadles of the headles, with which they are connected by cords from the ſhafts of the headles *s*, *s*. From the upper ſhaft there go two leathern belts *f*, *f*, to the roller *y*, furniſhed each with a buckle, for tightening them at pleaſure. The two wipers *c*, *c*, on the ſhaft *a*, which ſerve for taking back the lay, have the two treadles *x*, *x*, in fig. 3. with a belt from each paſſing over the roller *h* 2 of fig. 1. and fixed to the ſword of the lay. From the ſwords of the lay forward is fixed a belt to each end of the roller *i*; from this roller there goes a cord to the ſpring *j*, which ſerves for taking forward the lay which is hinged on the rocking tree *t*. The ſtar-wheel *b* of fig. 3. and the ſheeve *b* of fig. 1. are fixed to the oppoſite ends of the ſpindle *a* without the frame; and both the wheel and ſheeve have a wiper *k* fixed to them for moving the treadles. In order to drive the ſhuttle, the belts *o*, *o*, go from the points of the treadles, over the pulleys *p*, *p*, to the top of the fly-pin *q*: This turns on a pin joint in a rail *r*, which goes acroſs the loom. From its lower end there go two ſmall cords to the ſhuttle drivers *g*. *g*, which ſlide on the iron rods *n*, *n*. A long iron rod *v* goes acroſs the lay, and is hung on two centres at the ends. In this rod *v* are fixed two ſmall crooked wires *w*, *w*, which are more diſtinctly marked in the little figure *w* above, which repreſents a ſection of the lay. The dot at the lower end of the wire *w*, in this figure, is the ſection of the rod *v*. The ſhuttle paſſes between theſe wires and the lay every ſhot, and lifts them up, cauſing the rod *v* to turn round a little. But if the ſhuttle ſhould not paſs theſe wires, nor lift them, it would be drawn home by the lay, and deſtroy the web. To prevent this, there is fixed on one end of the rod *v* a ſtout crooked wire *z*, having a broad or flat head, which naturally reſts on a plate of iron, marked and fixed to the back of the lay. This plate has a ſlit in its middle about an inch deep. In this ſlit reſts the rod *a* 2 of fig. 3. on which is a ſhort ſtud, which is caught by the wire *z* when the wire *w* is not lifted back by the paſſing ſhuttle. This will ſtop the lay from coming home, and will ſet off the loom.

Fig. 3. is another ſide-view of the loom oppoſite to fig. 1. On the ſpindle *a* is the ſtar wheel *b*, on the outſide of the loom frame, on the arms of which wheel is fixed the wiper *k*, as the ſimilar wiper is fixed to the ſheeves on the other end of the ſpindle. The wipers which drive the ſhuttles are fixed on oppoſite ſquares of the ſpindle, and work alternately. Below the ſtar-wheel is a pinion *c*, which is on a round ſpindle, turned by the water-wheel, by means of a wheel on this ſpindle. In a wheel on this ſpindle are two ſtuds, on which the pinion *c* ſlides off and on as the loom is ſet off and on by the lever *d*. At the farther end of this lever is the weight *s*, hanging by a cord which paſſes over a pulley *t*, fixed at the outer end of the ſpring-catch on which the lever *d* reſts; and thus the loom is drawn in at the upper end of the lever *d*. But when the ſhuttle does not lift the wire *z*, it catches on the ſtud on the rod *a* 2, which is connected with the ſpring-catch, and the lever *d* flies off with the weight *s*, and the loom ſtops working. On the head of the poſt F is the yarn-beam. The rollers *e* and *f* are cylinders, preſſed together by a ſcrew-lever, and take away the cloth between them at a proper rate. In the roller *f* is a groove for a band for driving the roller *g*, on which the cloth winds itſelf as it is wrought. Wherever ſprings are mentioned to be uſed in the above deſcription, weights may be uſed in their ſtead, and to the ſame effect, and more eſpecially upon the treadle of fig. 1. for driving the ſhuttle.

WEIGHTS AND MEASURES, in commerce, are ſo various, not only in different countries, but even in different provinces of the ſame country, and this variation is the ſource of ſo much inconveniency in trade, that writers on political and commercial economy have propoſed various methods for fixing an univerſal and immoveable ſtandard of weights and meaſures for all ages and nations. Sir James Stewart Denham's ſpeculations on this ſubject have been noticed in his life publiſhed in this *Supplement*; Mr Whitehurſt's ingenious contrivance for eſtabliſhing a ſtandard of weights and meaſures has been mentioned under the title MEASURE (*Encycl.*); and the new table of weights and meaſures, which the French republicans wiſh to impoſe upon all Europe, is given (*Encycl.*) under the title REVOLUTION, n° 183.

As theſe meaſures occur frequently, even in Engliſh tranſlations of French books of value, we ſhall here give ſuch an account of them as may enable the reader to reduce them with eaſe to the Engliſh ſtandards. They are of five kinds; *meaſures of length*, *of capacity*, *of weight*, *of ſuperficies for land*, *and of wood for fuel*. For every kind, there are many meaſures of different ſizes, one of which has been taken as the baſis of all the reſt, and its name aſſumed as the root of their names. Thus METRE is called the principal meaſure of length; LITRE, of capacity; GRAMME, of weight; ARE, of ſuperficies of land; and STERE, of wood for fuel. Theſe words being the radical terms of the names of other meaſures of length, capacity, &c. a relation is hereby preſerved between the names.

The meaſures of length above the *metre*, are ten times, a hundred times, a thouſand times, ten thouſand times, greater than the metre. The meaſures of length below the metre, are ten times, a hundred times, a thouſand times, leſs. To form the names of theſe meaſures, other words which indicate the relations of *ten times*, a

hundred

hundred times, greater; and of *ten times*, a *hundred times*, leſs, &c. are placed before the word *metre*. The ſame annexes have been uſed to form the names of meaſures, greater or leſs, than the *litre*, the *gramme*, &c. It is neceſſary, therefore, to ſtate in this place the Engliſh equivalents of only the *metre*, the *litre*, the *gramme*, the *are*, and the *ſtere*.

The METRE = 3.28084 feet Engliſh.

The LITRE = 61.0243 cubic inches, or $1\frac{103}{141}$ pint ale meaſure.

The GRAMME, or cubic *centi-metre* of water, at the freezing point, = $\frac{1}{443}$ lb. averd. or $\frac{1}{28}$ of an ounce, or $\frac{26}{45}$ of a dram nearly.

The ARE = $1076\frac{2}{5}$ ſquare feet, or $119\frac{3}{5}$ ſquare yards, or $\frac{1}{40}$ of an acre nearly.

The STERE, or cubic metre = 35.31467 cubic feet.

The better part of our countrymen, not chooſing to adopt the weights and meaſures preſcribed to them by the French Convention and the National Inſtitute, Sir George Shuckburgh Evelyn, Bart. turned his attention to this ſubject, and publiſhed, in the Philoſophical Tranſactions for 1798, an account of ſome endeavours to aſcertain a ſtandard of weights and meaſures. The principles upon which he proceeded are the ſame with Mr Whitehurſt's; but he has carried his experiments much farther than his predeceſſor, and ſeems to have conducted them with greater accuracy. His memoir is hardly ſuſceptible of abridgment; and our limits do not permit us to inſert it entire. This is indeed unneceſſary, if it be true, as another ingenious gentleman alleges *, that we are in the actual poſſeſſion, and the conſtant uſe, of a ſtandard both for weight and meaſure, as invariable as that now uſed in France. This ſtandard he finds in the foot meaſure, and in the avoirdupoiſe, or, as he thinks it ought to be called, the *decade* ounce weight.

The decade ounce weight of pure rain, or diſtilled water, at 60° of heat, is generally allowed to be equal in bulk to the one-thouſandth part of the cubic foot. Were 44.3511 parts out of 10000, or about $\frac{1}{225}$th part added to the preſent Wincheſter buſhel, that buſhel would then contain exactly 10 cubic feet or 10000 oz. of diſtilled water, at 60° of heat.

Our author then gives comparative tables between this ſyſtem and that which is now eſtabliſhed in France. Taking the metre at 3 French feet, and 11.296 lines †, and the French foot to be to the Engliſh as 1 : 1.065752004 ‡, one French foot will be equal to 10.65752004 Engliſh decades, or tenths of an Engliſh foot: hence he calculates the following

COMPARATIVE TABLES, Engliſh with French.

LONG MEASURE.

Long decade.	Metre.		Metre.		Long decades.
1 =	0.03047983	ferè	1 =		32.808583358, &c. or inches 39.3703.

SQUARE MEASURE.

Square decades.	Ares,		Ares.		Square decades.
1 =	0.0000092902	ferè	1 =		107640.3142, or ſqr. inch.155002.052448

CUBE MEASURE.

Cube decades.	Litres.		Litre.		Cube decades.
1 =	0.02831637	fere	1 =		35.3152622, &c. or cub.inch.61.0247727

WEIGHTS.

Avoird or decade oz.	Grammes.		Gramme.		Decade oz.
1 =	28.31637	ferè	1 =		0.03531526, &c. or grains, 15.45042625

$$\left.\begin{matrix}\text{Long,}\\ \text{Square,}\\ \text{or}\\ \text{Cube,}\end{matrix}\right\}\begin{matrix}\text{decades are}\\ \text{reduced to}\end{matrix}\left\{\begin{matrix}\text{Long,}\\ \text{Square,}\\ \text{or}\\ \text{Cube,}\end{matrix}\right\}\begin{matrix}\text{English}\\ \text{inches by}\\ \text{multiply-}\\ \text{ing by}\end{matrix}\left\{\begin{matrix}1.2\\ 1.44\\ 1.728\end{matrix}\right.$$

and decade ounces are reduced to grains,

$$\text{containing}\left\{\begin{matrix}7000,\\ \text{or}\\ 5760,\end{matrix}\right\}\text{to the lb.}\left\{\begin{matrix}\text{Avoird.}\\ \\ \text{Troy,}\end{matrix}\right\}\text{by}$$

multiplying the ounce by 437.5 = the number of grains in an avoirdupoiſe ounce.

Our author, who ſeems to have paid much attention to weights and meaſures, obſerves, that a ſtandard meaſure for the purpoſes of trade, in particular, as well as for others, that would uniformly give an accurate reſult, and could be eaſily made, examined, and aſcertained, by common mechanics, which neither our preſent liquid nor dry meaſures evidently can, would ſurely be an acquiſition of great value. Such an one, he preſumes, would be the following: A ſquare pyramid, whoſe perpendicular height is exactly thrice the length of the ſide of the baſe: for ſuch an one, and every ſection of it, made by a plane parallel to its baſe, would, in the firſt inſtance, poſſeſs, and, in every ſubdiviſion, retain theſe remarkable properties.

1ſt, Similar comparative dimenſions to thoſe above given, for the original pyramid, *i. e.* every ſmaller pyramid, formed by the above-mentioned parallel ſection, would have its perpendicular height thrice the length of the ſide of its baſe; and,

2dly, The length of the ſide of each baſe will always indicate, or equal the cube root of the ſolid content of the pyramid; *e. g.* If the length of the ſide of the baſe be 3, the ſolid content will be the cube of 3, *viz.* 3 × 3 × 3 = 27.

We do not perceive very clearly the great value of this ſtandard; but Mr Goodwyn ſays, that he has been many years in the habit of uſing a pyramid meaſure to examine corn; and is perfectly convinced that ſuch a one will indicate a far more accurate reſult than can ariſe from the manner in which corn is meaſured by the buſhel. This we are bound to believe; for it is abſurd to oppoſe theories to a fact aſcertained by experience.

WESTRINGIA, a new genus of plants deſcribed by J. E. Smith, M. D. preſident of the Linnæan Society of London. It was firſt diſcovered in New Holland by Dr Solander, who called it *Cunila Fruticoſa*, though it is totally different from the CUNILA (ſee that article, *Encycl.*), and more reſembles roſemary, from which, however, it is likewiſe different. Its peculiar character is: *Calyx ſemiquinquefidus, pentagonus; corolla reſupinata, limbo quadrifido, lobo longiore erecto, bipartito: Stamina diſtantia, duo breviora (inferiora) abortiva.* Dr Smith aſſigns it rather to the *didynamia-angioſpermia*, placing it immediately after the *Teucrium*, than to the *diandria* claſs of plants.

WHEAT (ſee TRITICUM, *Encycl.*) has for ſome years paſt been at ſo very high a price, that every hint for increaſing its quantity or improving its quality is intitled to notice. In the Leiceſter Journal for the 6th of December 1799, there is an ingenious paper on the ſubject of tranſplanting wheat, as a means of providing againſt

---

* H. Goodwyn Eſq; in *Nicholſon's Journal*, vol. ii. p. 163, &c.

† *Journal de Phyſ.* vol v. p. 460.

‡ *Phil. Tranſ.* 1798, p. 326. and *Connoiſſance des Temps*, 1795.

againſt the expected ſcarcity of that neceſſary of life. It is recommended "to ſow, in dry land, at the uſual ſeaſon, as much corn as may be deemed neceſſary to plant in the ſpring any number of acres which may be occupied with that article in the following year. When the ſoil is prepared, a furrow is to be made with a very ſmall plough and one horſe, in the centre of the ridge or land, returning back in the ſame track (this time only of every ridge); then turn towards the left hand, and plough another furrow, about eight or nine inches from the firſt furrow, turning always to the left hand, till the whole ridge is finiſhed; it will then be formed into trenches, in parallel lines of about eight or nine inches aſunder, and imitate what gardeners term drawing of drills. In theſe furrows the plants are to be laid." Mr John Ainſworth of Glen, the experienced author of this communication, ſays he has practiſed this method with the moſt complete ſucceſs.

It has been likewiſe practiſed, on a ſmall ſcale, with equal ſucceſs, but we know not in what county. About the end of Auguſt 1783, that gentleman threw a ſmall quantity of wheat, which near two years before had been ſteeped and limed (ſee WHEAT, *Encycl.*) into an unmanured corner of his garden. In the beginning of February following he had a piece of ground (alſo unmanured) dug in an open part of his orchard, and he tranſplanted it on beds of ſix rows wide, at nine inches aſunder every way. It tillered, and ſpread over the ground ſo completely, as to prevent even a weed growing among it. It produced admirable corn, and at the rate of near four quarters per acre.

From accurate calculations which he then made, he found that an acre, ſuppoſing the ſeed to be very good, and the plants ſet at the diſtance above mentioned, would require only *half a peck* of ſeed.

Beſides the ſaving of the ſeed, there are two other material advantages which attend ſuch a method; one is, that ſome ſuitable crop may be on the ground all the winter for uſe; and the other is, that ploughing the ground ſo late as February, will effectually bury and deſtroy thoſe weeds which were beginning to vegetate; and before others can ſpring up, the corn plants have taken to the ground, and ſo ſpread over it that the weeds cannot riſe, by which means there is a very clean crop, and all the cuſtomary expence for weeding is ſaved.

This author ſeems to think that wheat will thrive as well, and produce as full a crop, when ſown in the ſpring, as if it had been committed to the ground in the preceding autumn. In the ſouthern counties of England we doubt not but it may; but the caſe is otherwiſe in Scotland, where the ſpring is not ſo early, and where, from the narrowneſs of the iſland, the froſt is ſeldom ſo ſevere. We agree, however, with Dr Pike, in thinking it a pity that the way of ſetting wheat (as done in Norfolk and Suffolk) is not every where more general. The proceſs is indeed tedious and troubleſome; and we have often wondered that, among the numberleſs machines lately contrived to leſſen manual labour, none has been invented for dibbling wheat expeditiouſly and accurately. We are therefore pleaſed to learn, that Dr Pike himſelf has turned his attention to the ſubject, and hopes in the courſe of this year (1800) to preſent the public with a *method of ſetting wheat at* PERFECTLY EXACT *diſtances through a whole field, and as* EXPEDITIOUSLY *as the common broadcaſt ſowing, which can therefore be applied to farms of any magnitude;* and when a peck of ſeed is found to be ſufficient for an acre (and in ſome land much leſs), the ſaving on a large farm muſt be immenſe. We truſt to the liberality of his profeſſion, that he will not take out a patent for his invention.

Though we have elſewhere given the uſual recipes for preventing ſmut in wheat, it would be improper to conclude this article without mentioning the very ſimple one which Mr Wagſtaffe of Norwich has uniformly found attended with complete ſucceſs. This conſiſts in nothing more than immerſing the ſeed in pure water, and repeatedly ſcouring it therein, juſt before it is ſown or dibbled in the ſoil. Whether well, ſpring, or river water be uſed, is indifferent; but repeated ſtirring and change of water is eſſential to remove the particles of infection that may have imperceptibly adhered to the ſeeds thus purified. The ſubſequent crop will be perfect in itſelf, and its ſeeds, he ſays, ſucceſſively ſo likewiſe, if there are no adjacent fields from whence this contamination may be waſted. He recommends the ſame waſhing, and for the ſame reaſon, of barley and oats before they be ſown.

WILKIE (William, D. D.), the author of an heroic poem, intitled the *Epigoniad*, was born in the pariſh of Dalmeny, in the county of Weſt-Lothian, on the 5th of October 1721. He was deſcended of an ancient family in that county, though his father rented only a ſmall farm, and was poor and unfortunate through life. He was able, however, to give his ſon a liberal education; and that ſon, it is ſaid, diſcovered ſo early a propenſity to the ſtudy of poetry, that he began to write verſes in his tenth year.

As this wonderful prematurity of genius was never heard of during Wilkie's life, it will probably be conſidered as a ſtory fabricated to raiſe the Scottiſh poet to the ſame eminence with Pope, whoſe verſification he is allowed to have imitated with ſucceſs. We have no doubt but that Wilkie wrote in early life the deſcription of a ſtorm, which is publiſhed in the 9th volume of the Statiſtical Account of Scotland; but that he wrote it in his tenth year is not proved, and is highly improbable. The poem diſplays a notion—a confuſed notion indeed—of the laws of electricity, which a boy in his tenth year, and at a period when electricity was little underſtood, could not have acquired.

Having learned the rudiments of the Latin tongue at the pariſh-ſchool of Dalmeny, young Wilkie was, at the age of thirteen, ſent to the univerſity of Edinburgh, where he was ſoon diſtinguiſhed by his originality of thought, and by his rapid progreſs in erudition and ſcience. Among his fellow-ſtudents he was moſt cloſely aſſociated with Dr Robertſon the hiſtorian, Mr John Home the poet, Dr M'Ghie (A), who afterwards obtained

---

(A) According to Sir John Hawkins, this man bore arms on the ſide of government at the battle of Falkirk 1745. After which, taking a degree in phyſic, he went to London in hopes of employment through the intereſt tained the friendſhip of Johnſon, and became a member of the Ivy-lane Club; and a Mr Cleghorn, who promiſed be an ornament to the univerſity, in which he was afterwards a profeſſor, but died before he had time to realize the fond hopes of his friends. During the courſe of his education, Wilkie became acquainted with the celebrated David Hume and Dr Ferguſon, and at a later period with Dr Adam Smith, the far-famed author of "The Wealth of Nations." Of all thoſe men he regarded Dr Ferguſon with the greateſt affection, and Dr Smith with the greateſt admiration. This laſt writer he conſidered as equal to Robertſon and Hume in erudition, and vaſtly their ſuperior in originality and invention; and this opinion he cheriſhed to the day of his death.

Before he had completed his education, his father died, leaving him no other inheritance than the ſtock and unexpired leaſe of his farm, and the care of his three ſiſters. Wilkie, therefore, turned much of his attention to agriculture, in which he became eminent, not merely as a theoriſt, but as a practical farmer. He had too much ſcience to be the ſlave of ancient prejudice, and too much judgment to be hurried into hazardous experiments by the charms of untried ſpeculation. One of his ſiſters being married to a ſkilful, though unlettered farmer, he availed himſelf of his brother's experience; and upon the facts and maxims derived from him built a ſyſtem of practical farming, which fully anſwered his own expectation, and obtained the applauſe of all his neighbours.

He ſtill proſecuted his ſtudies in the univerſity, and without ceaſing to be a farmer became a preacher in the church of Scotland. For ſome years this made no alteration in the mode of his living. He preached occaſionally for the miniſters in his neighbourhood; cultivated his farm; read the claſſics; and, enamoured of the ſimple ſublimity of Homer, projected an epic poem on the Homeric model. The ſubject of his intended poem he drew from the fourth book of the *Iliad*, where Sthenelus gives Agamemnon a ſhort account of the ſacking of Thebes; and as that city was taken by the ſons of thoſe who had fallen before it, Wilkie gave to his poem the quaint title of *Epigoniad*, from the Greek word επιγονοι, which ſignifies *deſcendants*. It is not our buſineſs to write a criticiſm upon this poem. The ſubject was ill-choſen; for the learned reader has enough of the heroic ages in the immortal poems of Homer and Virgil, and in thoſe ages the unlearned reader can feel no intereſt. The Epigoniad, therefore, though compoſed in ſmooth and elegant verſe, with due attention to ancient manners, and conſtructed on the moſt regular plan, has fallen into neglect, from which no critic or biographer will ever reſcue it.

In the year 1753, Mr Wilkie was ordained miniſter of Ratho, in conſequence of a preſentation from the Earl of Lauderdale, who knew his worth and admired his genius. Without neglecting his favourite amuſements of huſbandry, or the ſtudy of the belles lettres, he diſcharged with fidelity the duties of a Chriſtian paſtor, was famed for his original and impreſſive mode of preaching, and ſoon came to be loved as well as eſteemed by his rural flock.

In the year 1757 the Epigoniad was publiſhed, the reſult of fourteen years ſtudy and application, which might ſurely have been more uſefully employed on ſome other work; and in 1759 a ſecond edition was called for, to which he added *A Dream in the manner of Spenſer*. He was, the ſame year, choſen profeſſor of natural philoſophy in the univerſity of St Andrew's; an office for which it is difficult to conceive how he could have been fitted by the ſtudy of epic poetry, and cloſe attention to the cultivation of his farm. He was, however, a man of a vigorous mind, and we never heard that he diſgraced his electors.

When he removed to St Andrew's, his whole fortune exceeded not L. 200 Sterling; a proof that his Epigoniad had not enriched him. With this ſum he purchaſed a few acres of land in the neighbourhood of the city, carried his two unmarried ſiſters with him, and continued to live in the univerſity exactly as he had lived at Ratho. In his profeſſorial career there was nothing remarkable. He patroniſed genius, eſpecially poetical genius, in the young men who attended his lectures, and by them was, of courſe, loved and eſteemed: (See Fergusson in this *Suppl*). In the year 1768 he publiſhed a volume of fables of no great value, previous to which the univerſity conferred upon him the degree of D. D.; and he died, after a lingering illneſs, on the 10th of October 1772.

The manners of Dr Wilkie were ſingular, and in ſome reſpects diſguſting. He has been ſeverely blamed for his penuriouſneſs, but, in our opinion, unjuſtly. His father had left him in debt, with nothing but the profits which he might make of a ſmall farm to diſcharge that debt, and to ſupport himſelf and three ſiſters. In him, therefore, rigid economy was, for many years, a virtue; and he knows little of human nature, who can blame a man for not breaking habits which it had been the duty, as well as the buſineſs, of a great part of his life to form. Amidſt his moſt rigid and offenſive economy, he was liberal in his donations to the poor.

He had been ſeized, while miniſter of Ratho, with an unformed ague, of which he never got entirely rid. For this complaint he thought an extraordinary perſpiration neceſſary, and generally ſlept, in winter, under twenty-four blankets. He had an utter averſion from clean linen, and has been known to bargain, when he ſtaid a night from home, not only for the proper quantity of blankets to his bed, but alſo for ſheets, which had been uſed by ſome other perſon, and rendered ſufficiently dirty to pleaſe his feeling. It will eaſily be conceived that ſuch a man was, to the laſt degree, ſlovenly in his dreſs.

Suſpicions have been thrown out by his lateſt, and we believe his only, biographer, that Dr Wilkie's belief of the Chriſtian religion was neither orthodox nor ſteady. Not having had the pleaſure of his acquaintance, we cannot poſitively ſay that theſe ſuſpicions are groundleſs; but the writer of this article has converſed much about the author of the Epigoniad with a clergyman

---

reſt of his countrymen, and perhaps in return for his loyalty. He was a learned, ingenious, and modeſt man; but ſo little ſucceſsful in his profeſſion, that he died of a broken heart, and was buried by a contribution of his friends.

man who knew him well, and who would have been glad to accuſe him of infidelity, if he could have preferred ſuch an accuſation with truth. He was a very abſent man, apt to forget what he was about even when diſcharging the moſt ſolemn parts of his clerical duty, and uſed to ſay of himſelf that he never could conduct a ſacrament. From this abſence of mind, and thoſe confeſſions of it, may have ariſen the ſuſpicion that he was not a firm believer; but no ſuch ſuſpicion was ever thrown out to this writer by the clergyman already referred to.

He had one very extraordinary defect in a poet: He could not read aloud the ſmootheſt verſes, ſo as to preſerve either the meaſure or the ſenſe of them. Of this Dr Anderſon has produced very complete proof in his life of Wilkie, prefixed to his poetical works in the Edinburgh edition of the Britiſh Poets. With all his defects, however, and all his foibles, he was unqueſtionably a genius, and, we are inclined to believe, a good man.

WINES (ſee that article, *Encycl.* and *Vegetable* SUBSTANCES, *Suppl.*) are ſo often adulterated with minerals prejudicial to the health, that various methods have been deviſed for detecting the adulteration. The property which liver of ſulphur (alkaline ſulphures) and hepatic air (ſulphurated hydrogen) poſſeſs of precipitating lead in a black form, has been long ago made public; and this property has been employed to determine the quality of wines by means of the *liquor probatorius Wirtembergenſis*, or Wirtemberg proving liquor. But in trying wines ſuppoſed to have been adulterated, this proof does more hurt than ſervice, becauſe it precipitates iron of the ſame colour as the pernicious lead. Many wine-merchants, therefore, of the greateſt reſpectability, rendered by theſe means ſuſpected, have been ruined.

The following is recommended by M. Hanhemann as a better teſt of ſound wines than the proving liquor of Wirtemberg. Mix equal parts of oyſter ſhells and crude ſulphur in a fine powder, and put the mixture into a crucible. Heat it in a wind furnace, and increaſe the fire ſuddenly, ſo as to bring the crucible to a white heat, for the ſpace of 15 minutes. Pulveriſe the maſs when it is cool, and preſerve it in a bottle cloſely ſtopped.

To prepare the liquor, put 120 grains of this powder, and 120 grains of cream of tartar (acidulous tartarite of potaſh), into a ſtrong bottle; fill the bottle with common water, which boil for an hour, and then let it cool; cloſe the bottle immediately, and ſhake it for ſome time: after it has remained at reſt to ſettle, decant the pure liquor, and pour it into ſmall phials capable of holding about an ounce each, firſt putting into each of them 20 drops of muriatic acid. They muſt be ſtopped very cloſely with a piece of wax, in which there is a ſmall mixture of turpentine.

One part of this liquor, mixed with three parts of ſuſpected wine, will diſcover, by a very ſenſible black precipitate, the leaſt traces of lead, copper, &c. but will produce no effect upon iron, if it contains any of that metal. When the precipitate has fallen down, it may ſtill be diſcovered whether the wine contains iron, by ſaturating the decanted liquor with a little ſalt of tartar (tartareous acidulum of potaſh), by which the liquor will immediately become black. Pure wines remain clear and bright after this liquor has been added to them.

WOOD CUTS are engravings on wood, commonly on box, which, in many caſes, are uſed with advantage inſtead of copper-plates. The art of cutting or engraving on wood is undoubtedly of high antiquity; for Chineſe printing is a ſpecimen of it. (See CHINA, n° 127. *Encycl.*) Even in Europe, if credit be due to Papillon, this art was practiſed at a period conſiderably remote; for he mentions eight engravings on wood, entitled, "A repreſentation of the warlike actions of the great and magnanimous Macedonian king, the bold and valiant Alexander; dedicated, preſented, and humbly offered, to the moſt holy father, Pope Honorius IV. by us Alexander Alberic Cunio Chevalier, and Iſabella Cunio, &c." This anecdote, if true, carries the art of cutting in wood back to 1284 or 1285; for Honorius occupied the papal throne only during theſe two years. Even this is not the remoteſt period to which ſome have carried the art in Europe; for the uſe of ſeals or ſignets being of very high antiquity, they imagine that the invention of wood-cuts muſt be coeval with them. The ſuppoſition is certainly plauſible, but it is not ſupported by proof. The earlieſt impreſſion of a wooden-cut, of which we have any certain account, is that of St Chriſtopher carrying an infant Jeſus through the ſea, in which a hermit is ſeen holding up a lantern to ſhew him the way; and a peaſant, with a ſack on his back, climbing a hill, is exhibited in the back ground. The date of this impreſſion is 1423.

In the year 1430 was printed at Haarlem, "The hiſtory of St John the evangeliſt and his revelation, repreſented in 48 figures in wood, by Lowrent Janſon Coſter;" and, in 1448, Jorg Schappf of Augſburg cut in wood the hiſtory of the Apocalypſe, and what was called *The poor man's bible.* (See ENGRAVING, *Encycl.* page 668.)

A folio chronicle, publiſhed 1493 by Schedal, was adorned with a vaſt number of wood-cuts by William Plydenwurff and Michael Wolgemut, whoſe engravings were greatly ſuperior to any thing of the kind which had appeared before them. Wolgemut was the preceptor of Albert Durer, whoſe admirable performances in this department of art are juſtly held in the higheſt eſteem even at the preſent day.

About this period it became the practice of almoſt all the German engravers on copper to engrave likewiſe on wood; and many of their wood cuts ſurpaſs in beauty the impreſſions of their copper-plates. Such are the wood-cuts of Albert Aldtorfer, Hiſbel Pen, Virgil Soles, Lucas van Cranach, and Lucas van Lyden, the friend and imitator of Albert Durer, with ſeveral others.

It appears that the Germans carried this art to a great degree of perfection. Hans or John Holbien, who flouriſhed in 1500, engraved the *Dance of Death*, in a ſeries of wooden-cuts, which, for the freedom and delicacy of execution, has hardly been equalled, and never ſurpaſſed.

Italy, France, and Holland, have produced many capital artiſts of this kind. Joan. Tornæſium printed a bible at Lyden, in 1554 (a copy of which we have ſeen), with wooden-cuts of excellent workmanſhip. Chriſtopher Jegher of Antwerp, from his eminence in the art, was employed by Rubens to work under his inſpection,

inſpection, and he executed ſeveral pieces which are held in much eſtimation; the character of theſe is boldneſs and ſpirit.

The next attempt at improvement in this art was by Hugo da Carpi, to whom is attributed the invention of the *chiaro ſcuro* Carpi was an Italian, and of the 16th century; but the Germans claim the invention alſo, and produce in evidence ſeveral engravings by Mair, a diſciple of Martin Schoen, of date 1499. His mode of performing this was very ſimple. He firſt engraved the ſubject upon copper, and finiſhed it as much as the artiſts of his time uſually did. He then prepared a block of wood, upon which he cut out the extreme lights, and then impreſſed it upon the print; by which means a faint tint was added to all the reſt of the piece, excepting only in thoſe parts where the lights were meant to predominate, which appear on the ſpecimens extant to be whitened with white paint. The drawings for this ſpecies of engraving were made on tinted paper with a pen, and the lights were drawn upon the paper with white paint.

There is, however, a material difference between the *chiaro ſcuros* of the old German maſters and thoſe of the Italians. Mair and Cranach engraved the outlines and deep ſhadows upon copper. The impreſſion taken in this ſtate was tinted over by means of a ſingle block of wood, with thoſe parts hollowed out which were deſigned to be left white upon the print. On the contrary, the mode of engraving by Hugo da Carpi was, to cut the outline on one block of wood, the dark ſhadows upon a ſecond, and the light ſhadows, or half tint, upon a third. The firſt being impreſſed upon the paper, the outlines only appeared: this block being taken away, the ſecond was put in its place, and being alſo impreſſed on the paper, the dark ſhadows were added to the outlines; and the third block being put in the ſame place upon the removal of the ſecond, and alſo impreſſed upon the paper, made the dim tints, when the print was compleated. In ſome inſtances, the number of blocks were increaſed, but the operation was ſtill the ſame, the print receiving an impreſſion from every block.

In 1698, John Baptiſt Michel Papillon practiſed engraving on wood with much ſucceſs, particularly in ornamental foliage and flowers, ſhells, &c. In the opinion, however, of ſome of the moſt eminent artiſts, his performances are ſtiff and cramped. From that period the art of engraving on wood gradually degenerated, and may be ſaid to have been wholly loſt, when it was lately re-invented by Mr Bewick of Newcaſtle.

This eminent artiſt was apprentice to Mr Bielby, an engraver on metal of the very loweſt order, who was ſeldom employed in any thing more difficult than the cutting of the face of a clock. Application having been made to this man for a wood-cut or two of the moſt trifling deſcription, the job was given to Thomas Bewick; by whom it was executed in ſuch a manner, that Mr Bielby, who was accuſtomed to employ his apprentices in ſuch work, adviſed him to proſecute engraving in that line. The advice was followed; and young Bewick inventing tools, even making them with his own hands, and ſawing the wood on which he was to work into the requiſite thickneſs, proceeded to improve upon his own diſcoveries, without aſſiſtance or inſtruction of any kind. When his apprenticeſhip expired, he went to London, where the obſcure wood-engravers of the time wiſhed to avail themſelves of his abilities, while they were determined to give him no inſight into their art. He remained ſome years in London; and during that time, if we miſtake not, received from the *Society for the Encouragement of Arts, &c.* a premium of conſiderable value for the beſt engraving in wood. Returning to Newcaſtle, he entered into copartnerſhip with his old maſter; and eſtabliſhed his reputation as an artiſt by the publication of his admirable Hiſtory of Quadrupeds. This was followed by his Hiſtory of Birds, of which only one volume has yet (1800) appeared.

John Bewick, brother to Thomas, learned the art of him, and practiſed it for ſeveral years in London with great applauſe. His abilities, however, though reſpectable, were not, by the beſt judges, deemed ſo brilliant as his brother's; and owing to bad health, and the nature of his connection with the bookſellers and others, he ſeems not to have advanced the art beyond the ſtage at which he received it. He died, three or four years ago, at Newcaſtle.

Mr Neſbit, who executed the admirable Hudibras publiſhed by Vernor and Hood (A), and Mr Anderſon, whoſe beautiful cuts adorn the poem entitled *Grove Hill*, were the next, and hitherto have been the laſt of Thomas Bewick's pupils, who have appeared before the public as artiſts. By theſe gentlemen we are authorized to ſay, that the method practiſed by the ancient engravers on wood, whoſe works are ſtill admired, muſt have been different from that of Bewick and his pupils. What that method was ſeems to be altogether unknown. Papillon, who writes the beſt hiſtory extant of the art, gueſſes indeed in what manner the old engravers proceeded ſo as to give to their works the ſpirit and freedom for which they are famed; but that his gueſſes are erroneous ſeems evident from the ſtiffneſs of his own works. The principal characteriſtic in the mechanical department of the productions of the ancient maſters is the croſſing of the black lines, which Papillon has attempted with the greateſt awkwardneſs, though it ſeems to have been accompliſhed by them with ſo much eaſe, that they introduced it at random, even where it could add nothing to the beauty of the piece. In Bewick's method of working, this croſs hatching is ſo difficult and unnatural, that it may be conſidered as impracticable (B).

The engravers of Bewick's ſchool work on the end of the wood which is cut acroſs the trunk of the tree,

---

(A) The deſigns were by Thornton; and the cuts from them have been compared to Holbein's far-famed Dance of Death.

(B) Mr Neſbit has indeed introduced ſomething of it into two or three of his pieces, merely to ſhew that he *could* do it; but ſo great was the labour, and ſo little the advantage of this improvement, if ſuch it can be called, that probably it will not be attempted again.

in pieces of the proper thickneſs. As wood-cuts are generally employed in the printer's preſs amidſt a form of types, this thickneſs muſt be regulated by the height of the types with which they are to be uſed. The tools employed are nearly the ſame with thoſe uſed in copperplate engraving, being only a little more deep, or lozenge, as engravers call it. They muſt have points of various degrees of fineneſs for the different purpoſes to which they are applied, ſome of them being ſo much rounded off at the bottom as to approach to the nature of a goodge, whilſt others are in fact little chiſſels of various ſizes. Theſe chiſſels and goodges, to which every artiſt gives the ſhape which he deems moſt convenient, are held in the hand in a manner ſomewhat different from the tool of the engraver on copper, it being neceſſary to have the power of lifting the chips upwards with eaſe. To attempt a deſcription of this in writing would be in vain; but it is eaſily acquired, we are told, by practice.

The pupils of the ſchool of Bewick conſider it as quite improper to ſpeak of his invention as a revival of the ancient art. Some old prints, it is true, have the appearance of being executed in the ſame way with his; but others have certainly been done by a method very different. It is therefore not fair to appreciate the preſent art by what has been done, but by what may be done; and that remains yet to be ſhewn. The art is in its infancy; and thoſe who are diſpoſed to compare it with the art of engraving on copper, ought to look back to the period when copperplate engraving was of as recent invention as Bewick's method of engraving on wood. Marc Antonio, who engraved under the direction of the great painter Raphael, thought it no mean proof of his proficiency in his art, that he was able to imitate on copper plates the wood-cuts of Albert Durer; and Papillon is highly indignant that there ſhould have been perſons ſo very blind as to miſtake the copies for the originals. If copper has its advantages over wood in point of delicacy and minuteneſs, wood has, in its turn, advantages not inferior in regard to ſtrength and richneſs. Thoſe prints which were executed under the auſpices of Titian and Rubens, will always remain a monument of the ſpirit and vigour natural to wood-engraving; and if there be not found in them all the attention to *chiaro ſcuro*, which the preſent age demands, it muſt not be attributed either to defect in the art, or to want of abilities in the artiſts, but to the taſte of the times when *chiaro ſcuro* was little underſtood. It remains for ſome enterpriſing artiſt to ſhew that the vigour of the ancient art may be attained by the preſent one, and at the ſame time to add to that vigour thoſe gradations of ſhade which are ſo much admired in good copperplates. As there ſeems to be a more perfect, or at leaſt a more pleaſant black produced by wood than by copperplate printing, and certainly a more perfect white (c), who will ſay that any intermediate ſhade whatever may not be produced by wood-cuts? To attempt this on a ſmall ſcale would indeed be vain, becauſe the ſlighteſt variation, produced by a little more or leſs ink, or a harder preſſure in printing, bears ſuch a proportion to a very ſhort line, as muſt neceſſarily render the attempt abortive. Wood-engraving, therefore, muſt always appear to diſadvantage while it is confined to ſmall ſubjects, and will never reach its ſtation *as a fine art*, till thoſe who are engaged in its cultivation improve upon the diſcoveries of one another, and apply to ſubjects to which it is properly adapted. As an *economical art* for illuſtrating mechanics and other ſubjects of ſcience, it is too little employed even in its preſent ſtate.

The works of Bewick and his pupils, which have hitherto been publiſhed, are not numerous. Beſides his quadrupeds and birds, the Hudibras by Neſbit, and the Grove Hill by Anderſon, which have been already noticed, we are acquainted with none but the following:—Goldſmith's *Traveller* and *Deſerted Village* with elegant plates, all by Thomas Bewick, except one or two which were executed by John; Somerville's *Chace* by the ſame artiſts, executed in a ſtyle of elegance which perhaps has never been ſurpaſſed; a View of St Nicholas's Church, Newcaſtle, 15 inches long, by Mr Neſbit, who received for it a ſilver medal from the Society for the Encouragement of Arts, and an honorary letter from the Society of Antiquaries.

WOOL-COMBING, a well known operation, which, when performed by the hand, is laborious, tedious, and expenſive. The expence of it through all England has been calculated at no leſs a ſum than L. 800,000; and to leſſen this expence, the Rev. Edmund Cartwright of Doncaſter in Yorkſhire bethought himſelf, ſome years ago, of carding wool by machinery. After repeated attempts and improvements, for which he took out three patents, he found that wool can be combed in perfection by machinery, of which he gives the following deſcription:

Plate L.

Fig. 1. Is the crank laſher. A is a tube through which the material, being formed into a ſliver, and ſlightly twiſted, is drawn forward by the delivering rollers. B, a wheel faſt upon the croſs-bar of the crank C, a wheel, on the oppoſite end of whoſe axis is a pinion working in a wheel upon the axis of one of the delivering rollers.

Note, When two or more ſlivers are required, the cans or baſkets, in which they are contained, are placed upon a table under the laſher (as repreſented at D), which, by having a ſlow motion, twiſts them together as they go up.

Fig. 2. Is the circular clearing comb, for giving work in the head, carried in a frame by two cranks. Fig. 3. The comb-table, having the teeth pointing towards the centre, moved by cogs upon the rim, and carried round upon trucks, like the head of a windmill *a*, *b*, the drawing rollers *c*, *d*, callender, or conducting rollers.

Note, Underneath the table is another pair of rollers, for drawing out the backings.

In the above ſpecification, we have omitted the frame in which the machine ſtands, the wheels, ſhafts, &c. Had theſe been introduced, the drawing would have been crowded and confuſed; beſides, as matters of information, they would have been unneceſſary, every mechanic, when he knows the principles of a machine, being competent to apply the movements to it.

The wool, if for particular nice work, goes through three operations, otherwiſe two are ſufficient: the firſt

---

(c) The parts of the print intended to be white are not even touched by the wood-block.

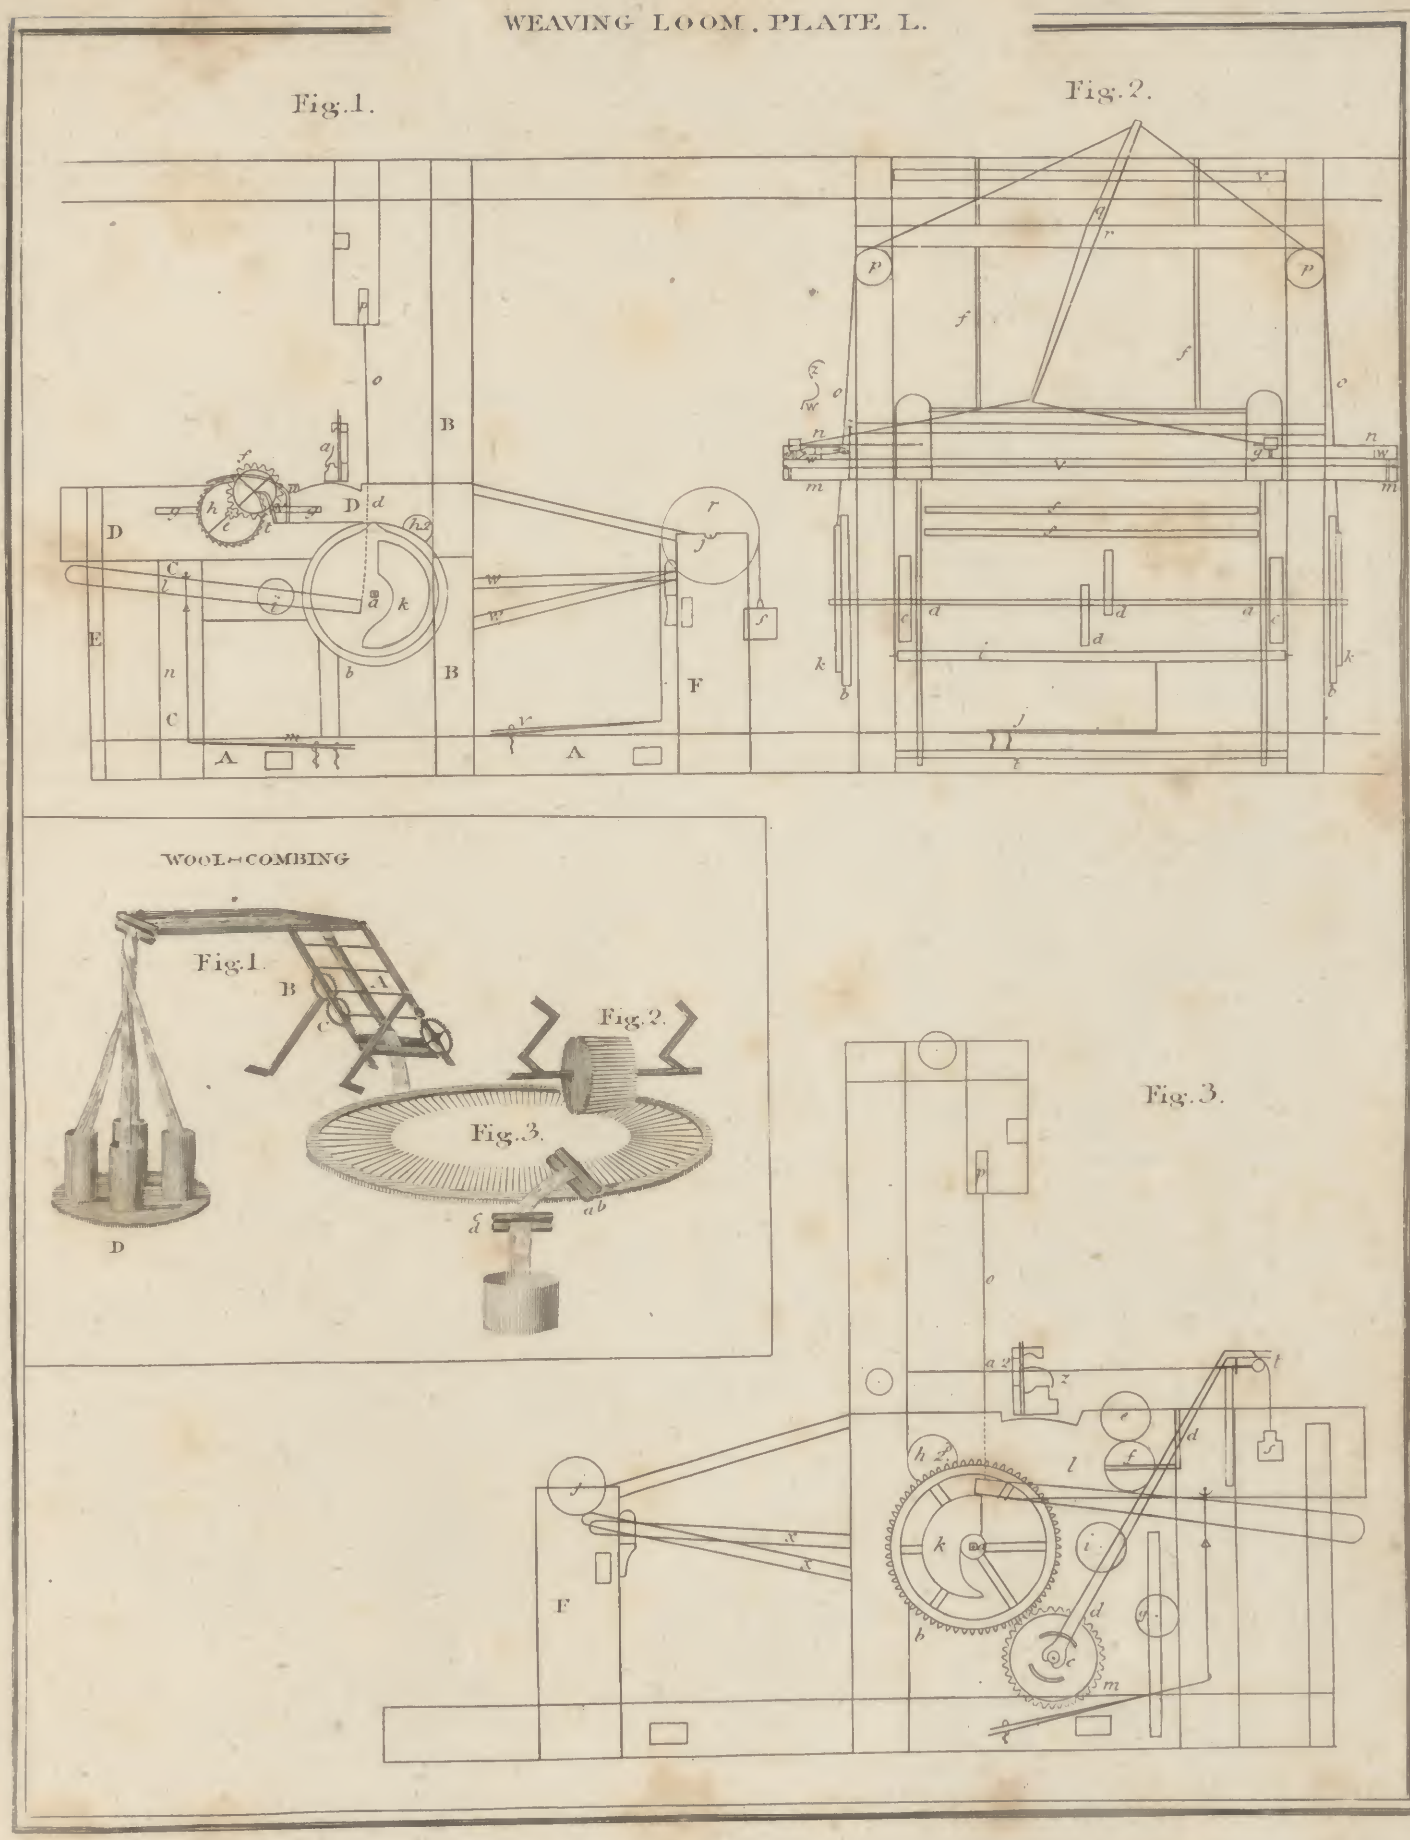
WEAVING LOOM. PLATE L.



Wool-combing.

operation opens the wool, and makes it conduct to gether into a rough fleece, but does not clear it. The cleaning is performed by the second, and, if necessary, a third operation. A set of machinery, consisting of three machines, will require the attendance of an overlooker and ten children; and will card a piece of [illegible] [illegible] [illegible] [illegible] machine performing the taking of [illegible] fire alone, will, in general, pay the wages of the overlooker and children; so that the actual saving to the manufacturer is the whole of what the combing costs, by the old imperfect mode of hand-combing. Machine-combed wool is better, especially for machine-spinning, [illegible] at least [illegible] per cent. being all equally mixed, and the fibres uniform, and of any required length.

Zemindary.

ZAMINDARY, or ZEMINDARY,

This is the [illegible] more [illegible] [illegible] [illegible] [illegible]

[illegible]

The [illegible] of [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] of [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] of office [illegible] [illegible] and [illegible] [illegible] the word [illegible] [illegible] is [illegible] in the Dewanny [illegible] for a [illegible].

[illegible] of the [illegible] the [illegible] the [illegible] [illegible] were [illegible] by the government. [illegible] [illegible] of the rights of [illegible] [illegible] a [illegible] on sovereignty, and [illegible] the [illegible] of the Emperor, [illegible] for the office of Zemindary were granted to the children of the deceased Zemindar; and as [illegible] [illegible] was accepted, [illegible] [illegible] never [illegible] for any [illegible] the [illegible] and [illegible] which they naturally [illegible] the [illegible] of the Zemindar, and would have been [illegible] [illegible] [illegible] been put over them. For this [illegible] the [illegible], considering it as a means of [illegible] the [illegible] of the people, graciously [illegible] and [illegible] the [illegible] of the deceased Zemindar in the [illegible] their fathers and grandfathers, by [illegible] [illegible] [illegible] the possession to them. [illegible] [illegible] [illegible] became their heritable property, which [illegible] [illegible] transferred by gift or sale from one [illegible] to another. They could likewise be [illegible] the [illegible] by the Zemindar [illegible] from his [illegible], or [illegible] to pay his tribute, or to discharge the duties of his station.

It is observable, however, that Sir Charles Rouse Boughton, that, when the provinces of Bengal, Bahar, and Orissa, were ceded to the English East India Company, the country was distributed among the Zemindars and Talookdars, [illegible] who paid a stipulated revenue, by twelve instalments, to the sovereign power or its delegates. They attended at the capital in the beginning of every Bengal year, commencing in April, in order to complete their [illegible] yet [illegible], and make up their annual accounts. [illegible]

Wool-combing

operation opens the wool, and makes it connect together into a rough ſliver, but does not clear it. The clearing is performed by the ſecond, and, if neceſſary, a third operation. A ſet of machinery, conſiſting of three machines, will require the attendance of an overlooker and ten children, and will comb a pack, or 240lb. in twelve hours. As neither fire nor oil is neceſſary for machine-combing, the ſaving of thoſe articles, even the fire alone, will, in general, pay the wages of the overlooker and children; ſo that the actual ſaving to the manufacturer is the *whole* of what the combing coſts, by the old imperfect mode of hand-combing. Machine-combed wool is better, eſpecially for machine-ſpinning, by at leaſt 12 *per cent.* being all equally mixed, and the ſlivers uniform, and of any required length.

Z.

Zaminy, Zemindars.

ZAMINY, in the language of Bengal, ſecurity.

ZEMINDARS, the great landholders of Bengal. This is the original ſenſe of the word; but it is now more ſtrictly applicable to thoſe who have their title conſtituted or confirmed by a patent or charter from government, by which they hold their lands or Zemindaries upon certain conditions. As far as can be aſcertained from the narrations of hiſtory, it appears that, in times prior to the irruptions of the Mahomedans, the rajahs who held their reſidence at Delhy, and poſſeſſed the ſovereignty of Hindoſtan, deputed officers to collect their revenues (Kherâje), who were called in the Indian language *Choudheries*. The word *Zemindar* is Perſian, and that language can have had no currency in the countries of India, until it was introduced by the people of Perſia. When the Emperor Shehâb ul Dien Ghory conquered the empire of Hindoſtan (A), he left Sultan Cutub ul Dien to be his viceroy at Delhy, and adminiſter the government of Hindoſtan. From that time the cuſtoms and practices of the Mahomedans began gradually to be eſtabliſhed in India: their armies were ſent into the countries of the reduced Rajahs, under the command of Omrahs, in order to preſerve the conqueſt; and lands were allotted to them to defray the expence. From hence aroſe the ſyſtem of Jaghiredarry in Hindoſtan. But when theſe Omrah Jaghiredars had eſtabliſhed their own ſtrength, ſeveral of them rebelled againſt the imperial authority, and aſpired at the crown. Thus circumſtanced, the emperors, in order to obviate theſe miſchiefs, thought it would be more politic to commit the management of the country to the native Hindoos, who had moſt diſtinguiſhed themſelves by the readineſs and conſtancy of their obedience to the ſovereign power.

In purſuance of this plan, diſtricts were allotted to numbers of them under a reaſonable revenue (Jummah Monâſib), which they were required to pay in money to the governors of the provinces, deputed from the Emperor. And in caſe any one of the Omrahs or provincial governors ſhould ſwerve from his allegiance, the Zemindars of that country were to exert themſelves in ſuch a manner as ſhould check rebellion, and reſtore good government. For this purpoſe, grants of Zemindary were ſeverally conferred upon ſuch of the Hindoos as were obedient; deſcribing their apportionment of the country; and every perſon who had received a grant under the authority of the crown was thereby fully inveſted with the functions of Zemindar.

The functions of a Zemindar are, 1ſt, The preſervation and defence of their reſpective boundaries from traitors and inſurgents; 2dly, The tranquillity of the ſubjects, the abundance of cultivators, and increaſe of his revenue. 3dly, The puniſhment of thieves and robbers, the prevention of crimes, and the deſtruction of highwaymen. The accompliſhment of theſe objects is conſidered in the royal grant as the diſcharge of office to the ſovereign; and on that account the word *office* (Khidmut) is employed in the Dewanny Sunnud for a Zemindary.

It was a rule in the times of the ancient emperors, that when any of the Zemindars died, their effects and property were ſequeſtrated by the government. After which, in conſideration of the rights of long ſervice, which is incumbent on ſovereigns, and elevates the dignity of the employer, Sunnuds for the office of Zemindary were granted to the children of the deceaſed Zemindar; and no other perſon was accepted, becauſe the inhabitants could never feel for any ſtranger the attachment and affection which they naturally entertain for the family of their Zemindar, and would have been afflicted if any other had been put over them. For this reaſon, the emperors, conſidering it as a means of conciliating the minds of the people, graciouſly fixed and confirmed the children of the deceaſed Zemindar in the office of their fathers and grandfathers, by iſſuing new ſunnuds to transfer the poſſeſſion to them. By degrees Zemindaries became truly heritable property, which, however, could be transferred by gift or ſale from one family to another. They could likewiſe be forfeited to the ſovereign, by the Zemindar's deviating from his allegiance, neglecting to pay his tribute, or to diſcharge the duties of his ſtation.

It is univerſally known, ſays Sir Charles Rouſe Boughton, that, when the three provinces of Bengal, Bahar, and Oriſſa, were ceded to the Britiſh Eaſt India Company, the country was diſtributed among the Zemindars and TALOOKDARS (ſee that article in this Vol.), who paid a ſtipulated revenue, by twelve inſtalments, to the ſovereign power or its delegates. They aſſembled at the capital in the beginning of every Bengal year (commencing in April), in order to complete their final payments, and make up their annual accounts; to

ſettle

(A) This event took place towards the cloſe of the 12th century. N. B. *Kherâje* ſignifies ſpecifically the tribute paid by a conquered country.

Zemindars. ſettle the diſcount to be charged upon their ſeveral remittances in various coins for the purpoſe of reducing them to one ſtandard, or adjuſt their concerns with their bankers; to petition for remiſſions on account of ſtorms, drought, inundation, diſturbances, and ſuch like; to make their repreſentations of the ſtate, and occurrences of their diſtricts: after all which they entered upon the collections of the new year; of which, however, they were not permitted to begin receiving the rents from their own farmers, till they had completely cloſed the accounts of the preceding year, ſo that they might not encroach upon the new rents, to make up the deficiency of the paſt. Our author proves, we think completely, the right of the Zemindars to transfer their poſſeſſions, either by inheritance to their children, or, with the conſent of the ſovereign, to other families; and he argues ſtrenuouſly and ſucceſsfully againſt the bad policy, as well as injuſtice, of interfering with thoſe rights, as long as the Zemindars diſcharge the duties of their ſeveral ſtations.
