Another striking symptom of the obturator dislocation, which is not much dwelt on, is the tense condition of the parts at the inner side of the thigh. This is not noticed by English authors, and has been only slightly alluded to by Fabbri, who describes it as "a tense cord parallel to the axis of the thigh, beginning at the spine of the pubes, widening as it descends, and disappearing in the middle third of the thigh." It is formed clearly enough by the adductor muscles (and chiefly the adductor longus), stretched and irritated by the displaced head.

Finally, I may mention the acute pain of which this patient complained. He could not describe it very accurately, but it was probably due to interference with the obturator nerve, and possibly the anterior crural also.

Having said so much about the symptoms, we now come to the method of reduction. Now I must repeat what I said before—that (under chloroform, at any rate) many different methods will succeed. The one before us is the only case of obturator dislocation in which I have had the opportunity of seeing the manipulation method tried, and those who were present saw how easily I succeeded in replacing the bone by my own unaided force. But I have seen the perfectly different method of Sir A. Cooper succeed without much difficulty more than once. Still, there can be no doubt that less violence is required, and therefore less risk of injury incurred, when the reduction is managed with reference to the real obstacles—*i.e.*, when the limb is placed in the position which will most relax the parts that are on the sketch before the surgeon commences his traction on the limb with a view to pull the head of the bone into the acetabulum.

No one who has produced, and afterwards dissected, artificial dislocations of the hip on the dead subject, can, I think, resist Bigelow's conclusion, that in the backward dislocations the main agent which fixes the thigh in its inverted position, and which swings it up as it were to the ilium, and limits the shortening of the limb, is the untorn portion of the capsule (that which he describes as the outer branch of the Y-ligament), the very thick part of the capsule attached to the trochanter major. And, similarly, the position of the limb in the obturator dislocation is maintained chiefly by the portion of the capsule attached around the lesser trochanter (the inner branch of Bigelow's Y-ligament); and it is to the relaxation of this same ligament that the surgeon's first efforts are to be directed. In other words, flexion of the limb is at the root of easy success in the reduction of all dislocations of the hip; and this practical fact seems to have been known to Hippocrates, and to have formed the basis of his practice in this injury.

Fabbri's explanation of the difficulties of reduction is not so clear as Bigelow's, but is possibly less artificial, less diagrammatic, if I may so express myself. For we must remember that the independence which Bigelow has given to the Y-ligament does not exist in nature. There is no definite ligament with two branches till the dissector has cut away the intervening part of the capsule. Fabbri, however, prescribes almost exactly the same method of reduction as Bigelow afterwards described and figured; and, as Fabbri's treatise is less known in this country than its merit entitles it to be, I will, in justice to an author who wrote long before the publication of Bigelow's work, transcribe what he says about the state of the capsule and the method of reduction:—

"The laceration of the capsular ligament," says Fabbri, "is variable. Sometimes the capsule is torn from all the inner half of the lip of the acetabulum; and in such cases the zone of Weber(a) embraces the neck of the bone, and the thigh is strongly flexed on the pelvis. In other instances the capsule is torn longitudinally between the inner margin of the triangular ligament (the ilio-femoral) and the zone. In such cases the latter has no longer anything to do with the dislocated limb, and the thigh is less bent. The aperture in the articular cavity is closed immediately by the portion of the capsule which has been left intact; and this is stretched from the outer to the inner side, and from above downwards, by the traction of the dislocated bone into which it is inserted."

You will observe that this description, though much less clear, is substantially identical with Bigelow's.

The coincidence between these authors is still more plainly marked when we come to the method of reduction, which Fabbri thus describes—

"First flex the thigh, then let it be held in this flexed position, and let the knee be carried from without inwards; this movement being arrested at the point where the limb, looked at from the front, is seen to be parallel to the median line.

"This manipulation has brought the head of the bone from the foramen ovale to a situation just inferior to the articular cavity; nothing now remains but to make it surmount the lower lip of the acetabulum.

"The button-hole in this ligament, and the psoas and iliacus muscles, are relaxed by the bent position of the thigh.

"Now let the surgeon slip his forearm under the popliteal space, and seize the thigh in the other hand at its back and upper part; then let him drag the knee towards him, and at the same time make a lever of the thigh by turning the knee downwards and raising the upper part of the thigh. In this manipulation the head will re-enter the cavity."

It is obvious that this manipulation differs only in non-essentials from Bigelow's method of reduction by flexion and internal rotation.

It is almost superfluous to add that in saying this I am as far as possible from attributing any plagiarism to Bigelow, who shows the most scrupulous care not to claim any originality not justly due to him, and to refer to the previous authors on the subject. Fabbri's pamphlet has never been translated, as far as I am aware, out of the *Transactions of the Medico-Chirurgical Society of Bologna*, where it first appeared, and had doubtless never fallen under Bigelow's notice. The coincidence between them gives a support to their doctrines, which indeed is now hardly needed, so amply has experience shown their truth.

Still, however successful the method by flexion and circumduction may be, it does not always succeed, in consequence probably of the projection of the lip of the acetabulum being too great for the head of the bone to pass over without more powerful assistance, or possibly in consequence of some torn portion of the capsule (such as Fabbri's zone of Weber) getting in between the bones. In such cases—in fact, in all forms of dislocation—the direct method of traction, which is used with such success in dislocation of the shoulder, will probably be successful; and it was in this manner that I reduced the dislocation in the case before us.

The patient may remain on his bed if the bedstead is perfectly strong and firm, but otherwise had better be laid on the floor. Flexion and internal circumduction having been sufficiently tried, will have considerably changed the position of the trochanter, and have placed the head of the bone, according to Fabbri's description, near the lower edge of the acetabulum. Then let the surgeon stand over his patient's body (which is of course held perfectly steady by the bystanders), and, placing his foot firmly on the horizontal ramus of the pubes, hooking one hand or arm under the flexed knee, and manipulating the thigh with the other, draw the head of the bone directly into the joint, giving it a little "wagging," or to-and-fro movement, so as to disengage it from any accidental obstructions, and lift it over any projecting ridges of bone or fascia.

If all this and other kinds of manipulation fail, the powerful force which Sir Astley Cooper's method sets in motion may be employed to drag the head of the bone directly into the cavity.

THE ELASTIC LIGATURE IN OVARIOTOMY.—Dr. Kleberg, "opérateur" in the Odessa Hospital, furnishes brief notes of three ovariotomies and three extirpations of the uterus in which he employed the elastic ligature instead of the clamp.—*St. Petersburg Med. Woch.*, October 6.

(a) The deeper part of the capsule, inserted like a ring round the neck of the femur.

ORIGINAL COMMUNICATIONS.

THE STRUCTURE AND FUNCTIONS OF THE NERVOUS SYSTEM.

By JAMES ROSS, M.D., M.R.C.P.,
Honorary Physician to the Manchester Southern Hospital for Diseases of Women and Children.

Before entering on the consideration of the nervous system, I may be permitted to make a few remarks by way of introduction on the fundamental properties of living matter. Every kind of living matter is found to be a complex combination of carbon, hydrogen, oxygen, and nitrogen, and some other secondary, but still essential, constituents. The peculiarities of the substance of living bodies, therefore, do not depend on the existence of a new kind of matter, but on new combinations or collocations of constituents with which we are familiar in their separate states, and in their simpler combinations.

But a great many persons cannot bring themselves to believe that the forces which produce the form and actions of living beings are the same as those which are operative in the organic world. Everyone must admit that certain kinds of living action, such as the motions of the limbs by muscular contraction, are subject to mechanical laws; but some think that the more recondite processes, such as the muscular contraction itself, are under the control of a higher principle. An attempt has been made in all ages to formulate this conception. Aristotle assumed the existence of a vegetative soul to account for living processes and actions. Van Helmont called the principle of life "Archæus," and Stahl called it "Anima"; while in modern times these ideas have been superseded by the conception of a "vital force," which is in no way related to the physical forces.

But science, especially in its objective aspect, cannot recognise the dualism which would ascribe some living actions to mechanical forces, and reserve others for the supervision of another force which is in no way related to the former. No living action or process has ever been, or can ever be, rescued from the unknown to the known except by the application to it of the laws of inorganic nature. Life does not introduce us to a new order of force, but to new combinations or collocations of the forces which have already been more or less made familiar to us in the study of the physical and chemical sciences. In one word, the great law of the conservation of energy is as applicable to the objective study of living beings as to any part of the universe within the reach of our observation.

The principle of conservation of energy asserts that force can neither be created nor annihilated, and that the quantity in the universe is as unalterable as the quantity of matter. The different forms of force may be transmuted into one another; but nothing is lost in the transfer. Mechanical force may pass into heat; but by suitable arrangements the heat might be reconverted into the original amount of mechanical momentum.

This is not the place to enter on an exposition of the doctrine of the conservation of energy, but I may be allowed to remind the reader that the various forms of force are on ultimate analysis reducible to two kinds—namely, attraction and repulsion. When two bodies which mutually attract each other are separated by a space, the system possesses energy, or a power of performing work. If they are prevented by an external force from obeying their attractions by moving towards one another, the energy of the system is potential; and when all hindrances to their movement towards one another are removed, the energy becomes actual, dynamic, or kinetic. In the case of bodies which have a mutual repulsion for each other, they must first be pressed towards one another by some external force before the system possess energy; and so long as this external force prevents the two repelling bodies from moving away from one another, the energy is potential; and when all hindrances to the free action of their mutual repulsions are removed, the energy becomes kinetic. The force which removes all the obstacles to the motion of attracting bodies towards each other, or of repelling bodies away from one another, and which thus converts the potential into kinetic energy, is called the liberating or discharging force. Two other terms are employed in describing the transformations of energy, which it is well to remember. When two bodies are so related to one another that a small liberating force renders kinetic their potential energy, then the system is said to be in a position of "unstable equilibrium"; and when the system either possesses no potential energy, or when a relatively large liberating force must be applied before its potential energy can be rendered kinetic, it is said to be in a position of "stable equilibrium." As a familiar instance of unstable equilibrium, I may take a thin book from my table, and place it on end on the floor. A slight touch at the free end of the book will cause its centre of gravity to project beyond its base, and the earth and book will then rush towards one another—the slight touch has converted the potential into kinetic energy. Now, however, when the book rests on its side, a relatively large amount of external force would require to be applied to it before it would give out any actual energy; the earth and book are in a position of stable equilibrium with relation to one another.

Let us now proceed to the consideration of the fundamental properties of living matter. The most casual observation must convince anyone that organisms are not an aggregate of materials heaped up in any fashion; but that, however diverse may be their forms, they are constructed in an orderly manner. Now, suppose that an intelligent inhabitant of Central Africa, on visiting this country, had been struck with the utility of brick buildings, and had wished to acquire a knowledge of their construction, what would be the best means of imparting the desired information? We should show him that the house is mainly composed of walls; that each wall, and each part of a wall, is made up of bricks. Having shown that the unit of composition, or, in other words, the structural unit of the house, is a single brick, we should then direct him to make a special study of the mode of formation and properties of the brick; and after he had mastered the details of brick-making, he could then be shown how brick is united to brick to form a wall, and so on, until he was taught how a house is built. In short, in order usefully to study such a simple construction as a brick house, there must first be either a real or ideal breaking down of the building into its constituents, and then either a real or ideal putting together of the constituents to form the building. Analysis and synthesis must go together, but the former ought to precede the latter.

If we subject organisms, in the first place, to ideal analysis, we shall find that each is composed of certain mechanisms or organs; and that each organ is composed of certain definite arrangements of tissues; and, finally, that each tissue is composed of structural units, which, for the sake of the illustration, we may call "organic bricks." To make a real analysis of a living organism is a much more difficult matter than to make a similar analysis of a brick building, since the living properties of the structural unit which we wish to study generally escape us in the act of making the analysis. But even in the higher organisms there are some units—such as the white blood-corpuscles—which can be kept alive for some time after detachment from the parent organism, and in which the fundamental properties of the structural unit can be usefully studied. We generally, however, avail ourselves of the analysis which nature has made ready to our hands. It is not possible to build a house with a single clay brick; but it is possible for a single organic brick to constitute a complete living individul. The lowest living organisms—if indeed they are entitled to be called organisms, since they do not possess real organisation—are mere specks of albuminoid matter, the protoplasm of biologists, and correspond to the structural units of the higher organisms. It is by the study of these lowly organisms that we must expect to ascertain the primordial properties of living matter.

Amongst these first organisms, probably the best adapted for the study of the fundamental properties of life are the amœbæ, both on account of their simplicity, and their similarity to the white corpuscles of vertebrate blood. There are several kinds of these, but all of them may be arranged under three leading orders:—

1. Organisms consisting of a simple speck of protoplasm, such as the *Protamœba primitiva* found by Hæckel in fresh water.

2. Organisms more or less similar to the former, but possessing a distinct nucleus.

3. Similar organisms, exhibiting, along with the granular protoplasmic interior or endosarc, a more solid external layer or ectosarc. The external layer, instead of being a membrane, is sometimes represented by a shell; but the former, owing to its similarity to the membrane surrounding the cells which form the tissue of the higher organisms, is of the most importance to us.

This classification shows that the protoplasm is the fundamental substance, without which no organism can exist, and that the other constituents found in the unit are mere specialisations of this fundamental substance. A knowledge of the primary properties of life will, therefore, be best gained by the study of the first order of unit.

1. If one of these lowly organisms be watched, it is seen to throw out processes of its substance, and then to retract them—changes which are accompanied by a flux and reflux of its granular substance,—and it is able by this means to perform a certain amount of locomotion. The amœba is "contractile."

Amœboid movements occur under two conditions. In the first place, contact with foreign bodies, and chemical and electrical agents, call forth these movements. These disturbing causes act as liberating forces in rendering kinetic the energy potential in the protoplasm; and, as usual in such cases, the energy set free is out of all proportion to the cause which determined the transformation. A disturbing force, which determines an explosion of energy in living matter, is called a "stimulus." In the amœba, the application of a stimulus leads to movement, but in some cases the energy set free by the explosion takes on the form, not of contraction, but of heat. We want, therefore, a generic term to express the fact that when living matter is acted on by a stimulus it suffers an explosion of energy, whatever be the form the energy may assume. The term employed for this purpose is "irritability," and a tissue which responds to a stimulus by an expenditure of energy is said to be "irritable." Irritability, therefore, is the genus, of which contractility is the most important species; the former is, but the latter is not, co-extensive with life.

But in the second place, the movements of the amœba cannot always be referred to the action of external stimuli; the energy is frequently set free in consequence of internal changes, and the movements are then called "spontaneous" or "automatic." It may therefore be said that protoplasm is irritable and automatic.

We have already seen that when there is an explosion of energy, matter has fallen from a relatively unstable to a relatively stable position, in which it possesses a comparatively small amount of energy or none. And if no counterbalancing actions were proceeding, the store of energy in the substance of the amœba would soon be exhausted; and, indeed, this store may be exhausted at one stroke by the application of a powerful stimulus. This action may be very readily watched with an organism closely allied to the amœba—the *Protococcus pluvialis*. While watching its movements under the microscope, if a drop of dilute alcohol or a weak solution of quinine or strychnine be placed at the edge of the cover-glass, when the chemical agent makes its way to the organism its ordinary movements give place to one or two violent contractions, which are followed by quiescence. In this condition no further stimulation will evoke movements; the protoplasm has lost its irritability. There was one violent explosion of energy, ending in complete expenditure of the stock. In this case the expenditure of the stock is followed by permanent loss of irritability, or death, probably because the chemical stimulus continues to act upon it; but when the action of the stimulus is temporary, as with an electric stimulus, the loss of irritability induced may be followed by gradual restoration. But whether the loss of irritability be temporary or permanent, when caused by the sudden application of a violent stimulus, the condition is called "shock." The loss of irritability may also be caused by the prolonged application of a moderate stimulus, if the conditions necessary to the acquirement of a new stock are prevented; and under these circumstances the state is called "exhaustion."

2. The allusion just made to the absorption by the protoplasm of the amœba of a new stock of energy leads us to the consideration of a second group of fundamental properties of living matter. Certain substances serving as food are received into its body, and there manufactured into new protoplasm. The latter process is called "assimilation." The protoplasm, however, is continually undergoing chemical change (metabolism); the old protoplasm is broken up, and the products of disintegration are cast out of the body as "excretions." Some of the products, however, are probably retained within the body for a time, and used in the solution and preliminary changes of the raw food, and these are termed "secretions."

3. But all the protoplasm formed by an amœba is not immediately disintegrated; some of it is added to its substance, constituting "growth."

4. And when the amœba attains a certain size, it generally resolves itself by fission, or by other means, into two or more parts, each of which is capable of living as a new individual, which passes through phases of life similar to the parent from which it is derived. This process, then, represents the first beginnings of two great living functions—reproduction and inheritance. So far we have spoken of the protoplasm as being the fundamental agent which exhibited all the properties of life, and there can be little doubt that this substance exhibits the great functions at present under consideration. When, however, the protoplasm becomes so far differentiated as to possess a nucleus, the latter constituent appears to preside in a peculiar manner over the functions of reproduction and inheritance. In the second order of amœbæ the nucleus is seen to divide into two or more parts prior to the fission of the protoplasm. When these units, instead of parting company and each leading a separate life of its own, aggregate together so as to form a compound organism or a compound tissue, this process of fission subserves the great function of growth, since the organism or tissue grows not so much by increase in the size, as by a multiplication in the number of units.

5. Two of the constituents of the unit have been passed in review. The nucleus being of denser consistence than the protoplasm, and presiding, as we have supposed it to do, over the great functions of reproduction and inheritance, will tend to make the offspring like the parents. The protoplasm, on the other hand, being of a semi-fluid consistence, and adapting itself, as it does, to different circumstances by changes of form, will tend to introduce variety, as well as to make the individual vary at different periods of its life, and to make the progeny unlike the parents. But this power of adaptation, although very varied in degree, is only of one kind—namely, contractious of the substance; and the fact that a stimulus produces a contraction at one time, does not enable the protoplasm to respond to a similar stimulus better a second time. So far there is no principle of improvement or progress. Under these circumstances we turn to the third constituent of the unit, namely, the cell membrane. The membrane in the first instance limits to a large extent the degrees of adaptation of the protoplasm. Being of denser consistence, it will offer greater passive resistance to external forces, and the flow of nourishment towards the interior will be retarded, so that the amount of irritable matter at the disposal of the organism will be diminished. The powers of the organism, then, are so far greatly limited by the membrane. But if the membrane diminishes the degrees it increases the kinds of adaptation. The increased density of the ectosarc enables it to offer a certain degree of passive resistance to external forces, and the endosarc is therefore more free to expend its energies in internal action. And although the membrane is not an active agent in producing adaptations, it tends to fix and perpetuate those adaptations which are frequently repeated, and in the compound organisms makes possible progressive improvement through successive modifications.

6. Besides the protoplasm and nucleus, other substances are found enclosed in the cell-membrane, technically called cell-contents. Sometimes the cell-contents are fluid, and then generally belong to the secretions or excretions already mentioned. Generally, however, they are solid, such as inorganic crystals, organic concretions like starch corpuscles, fat granules, chlorophyl, hæmoglobin, and various pigmentary granules. Some of these, like starch and fat, are stores of potential energy; chlorophyl and hæmoglobin appear to be subservient to the respiratory function, while the accumulation of pigment has obscure relations to other special functions.

The two most fundamental processes of life, then, are assimilation, or the process by which irritable matter is formed, and energy rendered potential; and disassimilation, or that by which the irritable matter is broken up and energy rendered kinetic. These processes underlie and render possible the other processes of life. When assimilation is in excess of disassimilation—or, in more general terms, when integration is in excess of disintegration—growth takes place; and when growth proceeds to a certain extent, a portion of the material is given away for the production of a new individual. On the other hand, the energy rendered active during the disintegration of the irritable matter is probably all applied in these lower organisms to the execution of movements, and, to some small extent, to the production of heat. All these functions, then, mutually aid each other in the preservation of the individual and of the race. Were that addition to the bulk of the organism which constitutes growth to cease, reproduction would soon become impossible, since, in the absence of the former, the process of fission, which is the essential factor of the latter, would soon diminish the size of the organism to a point incompatible with life; and that growth could not proceed far without reproduction is too manifest to require pointing out. These functions are in their turn dependent on the contractile power of the protoplasm, since without the latter property the circulation of materials which is necessary to life would cease.

But although the growth, reproduction, and motor functions of these simple organisms mutually aid each other, there are

fundamental antagonisms between them. Whenever multiplication occurs, it is clear that the parent individual must part with a certain amount of material, and that its bulk must be diminished by the bulk of the matter given away. The nutriment may be applied either to the growth of the parent or to the production of one or more new individuals; but it cannot at one and the same time be applied to both purposes. Every bit of material given away to form a new unit is a deduction from the size of the parent; and when the latter frequently parts with material for the production of progeny, its size will be diminished, or, in other words, rapid reproduction will be accompanied by small bulk of units. And again, an organism may use the nourishment it obtains in executing movements; and when movements are executed, nourishment must be transformed, just as coal must be transformed in order to put our locomotives in motion; and when it is transformed, it cannot at the same time be added to the bulk, nor devoted to the production of a new individual. A fresh supply of coal may be disposed of in several ways: it may be added to the previous stock, given away, or burnt; but it cannot at one and the same time be stocked, gifted, and burnt. And so it is with respect to the disposal of nourishment by protoplasm: it can be applied to increase the size of the organism, to its multiplication, or to the execution of movements; but so much of it as is applied in one direction cannot be applied in either of the other directions.

Once more. When the protoplasm is surrounded by a dense membrane, the flow of nourishment into it will be much retarded; and as an organism can neither expend, nor add to its bulk, nor give away what it does not receive, one surrounded by a dense membrane (or shell) can neither move actively, nor increase rapidly in size, nor multiply quickly. The membrane gives form, and fixity, and permanence, and resisting power to the protoplasm; but these properties are gained at the expense of the motor functions, growth, and production. There is, in short, a mutual antagonism between each and all of these functions, so that excess of activity in one direction means decrease of activity in the other directions.

In the construction of the higher animals, the units, instead of parting company, and each living an independent existence, aggregate together, and every new unit formed becomes incorporated with the general mass. But a simple aggregation of living units having similar properties would not confer any advantages on the organism; while the units themselves would greatly lose by the fact of their contact. One effect of the contact is that the surfaces exposed to the environment, and through which food can be absorbed, are greatly diminished, and their chances of obtaining prey when associated together are less than when each unit is free. When, therefore, we see an organism of considerable dimensions, we may be quite sure that the units, by the fact of their association, have gained advantages in certain directions, even if these are counterbalanced by losses in other directions.

In social organisms growth is rendered possible by the specialisation of function which is denominated "division of labour"; and the formation of a society of living units renders possible a similar specialisation of function which has been aptly named "a physiological division of labour." This "division of labour" does not introduce us to a new property of protoplasm, but merely to a new principle, whereby the properties with which we are already familiar may be combined in various ways. Certain groups of the constituent units become adapted for the manifestation of one or a few only of the fundamental properties of protoplasm, to the complete subordination of the other properties. This can be done with advantage to the organism only on condition that other groups of units become adapted for the manifestation of the properties which have become subordinate in the first group. In the higher organisms one group of units becomes pre-eminently contractile; a second pre-eminently irritable and automatic; other groups become respectively secretory, excretory, respiratory, and metabolic; while another group becomes specially adapted for reproduction; and a final group possesses only a passive or mechanical function.

"The physiological division of labour" has for its morphological correlative "differentiation of structure"; and the groups of units which assume special functions, correspond to the various tissues. In the formation of the tissues the cell-membrane assumes a great importance. It is evident that if the units of the tissues of a compound organism were entirely composed of the semi-fluid substance termed protoplasm, they would not have sufficient tenacity to stick together. In the formation of structure, therefore, the units must be surrounded by a membrane; and when the membranes of adjoining units become amalgamated, they are called intercellular substance. The disposition of the membrane or of the intercellular substance, and the relative amounts of the different constituents of the unit, must vary according to the function of the tissue. When the function of a tissue is of a passive nature—such as that of cartilage—a relatively large amount of intercellular substance is present; and if, in addition, the tissue requires rigidity, the intercellular substance is strengthened by the disposition of other materials, such as carbonate and phosphate of lime in bone. When, on the other hand, the tissue is actively growing, the proportion of intercellular substance to protoplasm is small, as in granulation tissue; and when the units multiply rapidly, the intercellular substance disappears, the nucleus becomes conspicuous, and the tissue breaks up into separate units, as in pus. We also meet with independent units, without membrane, in the white corpuscles of the blood, whose functions appear to be of a metabolic and therefore of an elementary character. When material is stored up in the tissue for future use, then the cell-contents come into prominence. The tissues which perform active functions, as muscle and nerve, must be composed of a due admixture of membrane and protoplasm. The transformation of the protoplasm supplies the motor force; and the disposition of the membrane gives fixity to the arrangements, and determines the direction in which the energy is expended. The burning of coal in our furnaces supplies the power which moves our factories; but the structural arrangements of engine and loom determine whether the factory shall be adapted for weaving or spinning, or for the manufacture of wool, cotton, or silk. And as the structural arrangements determine the functions of the factory, so it is with living tissues. The active tissues must therefore have a much more elaborate arrangement of the intercellular substance than the passive tissues, so that the energy given out by the transformation of their protoplasms may be directed to definite ends; and while the intercellular substance must be sufficiently dense to give fixity to the arrangements, it must not be so dense as greatly to retard the flow of nourishment from the blood to the protoplasm, otherwise the function of the tissue would be diminished as surely as a scanty supply of coal would diminish the work of the factory. It will be readily understood, from the antagonism between reproduction and active expenditure of energy, that a tissue which is performing an active function cannot have its units multiplying rapidly; and if from any cause these units begin to multiply, the capacity of the tissue for the display of function will become impaired.

In the formation of the higher organisms, the process of differentiation which ends in the formation of the tissues must be accompanied at every step by corresponding integration, whereby the tissues become united to form mechanisms or organs. Each organ is built up of a combination of tissues, and this is especially true of those organs which perform active functions. The fundamental tissue of each organ corresponds to its main function; but it is packed together to form an organ by means of a passive tissue.

Coincident with the integration of the tissues to form organs, there goes a corresponding integration of organs to form the individual. Some of these organs are devoted to the accumulation and elaboration of nourishment; others to its absorption and distribution; and others to the active expenditure of the nourishment, as in animal locomotion,—and this necessitates the formation of other arrangements for the removal of waste materials; and lastly, the integration is completed by the various tissues and organs being brought into close connexion under a central regulative organ, by means of which the various actions of the individual are duly co-ordinated.

(To be continued.)

NEURALGIA AND ITS TREATMENT.

By EVAN MARLETT BODDY, F.R.C.S., etc.

No. II.

In my last paper I drew the attention of the reader to the various so-called remedies which are advocated by many authorities in the treatment of neuralgia. I also mentioned the fact of the comparative obscurity in which the origin of this malady is enveloped, and the many different causes from which it is ascribed to originate. I endeavoured to give a plain definition, so that the diagnosis may be more easily determined, and, as a natural consequence, its successful treatment more thoroughly insured. I likewise showed the advisability of not only administering a sedative, but also

the advantages accruing from its combination with an antiperiodic, in order that the pain may be quickly relieved and its recurrence prevented. The reasons I advanced against the sole administration of a sedative were, that the pain was only momentarily arrested, and that in all probability it would return as soon as the soporific influence had passed off; and that, the pain recurring in paroxysms, soporifics would be of no permanent benefit. I also mentioned the fact that those forms of neuralgia which arise from some local lesion or derangement are not amenable to any therapeutic agent, and I designated them as spurious varieties; while I also showed that the definite form, or facial neuralgia, can be cured by the administration of a sedative combined with an antiperiodic.

Dr. Aitken says that in neuralgia "it is doubtful whether in any case medicine can be said to have cured it." He also affirms that "opiates are unquestionably serviceable in mitigating the sufferings of the patients, and perhaps in influencing the disease, but not to the extent generally supposed," and he accordingly mentions belladonna (both internally and as a plaster), stramonium, and chlorodyne; but he does not seem to have noticed that the combination of a sedative such as opium, and an antiperiodic such as arsenic, relieves the pain and prevents its recurrence, neither have any of the other authors whom I have previously mentioned—in fact, I think it has never been brought before the notice of the profession. It is clear that in those forms of spurious neuralgia no benefit would accrue from its administration, for reasons I have previously stated; and the cases I shall cite show that in what I call "definite" neuralgia it is a remedy which can be thoroughly relied on.

There is no doubt that in many females who are subject to neuralgia, some uterine derangement originates it. Therefore in these cases the subsequent treatment must be directed towards improving the general health, such as the administration of iron and quinine. It is in the male sex that we mostly meet with the definite form of neuralgia, which requires no other treatment than the administration of opium and arsenic. I have known quinine do good in some instances, but in my experience they are in the minimum compared to those cases which have been relieved by the method of treatment I am now advocating.

Mr. Erichsen, in his classical work on the "Science and Art of Surgery," affirms, after having mentioned the various modes of treatment, that "in many cases all these means are unfortunately unavailing, and the sufferer is doomed to an existence of almost constant pain, except at times when the disease appears to cease of itself, or has its intensity blunted by the administration of more powerful sedatives, such as morphia hypodermically, or veratria, aconite, or atropine externally." If these means fail, Mr. Erichsen advises division of the nerve, but at the same time says it may only afford temporary relief; but he does not mention the advantages derivable from soothing the pain and obviating its recurrence by combining opium with arsenic. The various modes of treatment which are advocated with such little benefit to the sufferer can be easily accounted for from the many conflicting opinions concerning the pathology of neuralgia, for all the authorities I have quoted do not agree either in their definitions or treatment of this malady.

Regarding the efficacy of opium and arsenic, I could cite many other cases besides those I now give, in which this remedy has invariably succeeded.

Case 1.—John S., aged fifty-five. Patient, a farmer, had been troubled with obstinate recurrent attacks of facial or definite neuralgia, and had tried various remedies, but had obtained no relief. He was in robust health, and there was nothing to be seen or felt on either the upper or lower jaw, and there were no decayed teeth. The attacks would come on violently and without any warning, and the pain was so excruciating that he said it made him "feel mad." After taking the opium and arsenic he fell into a profound sleep, and on awaking the pain had entirely left him. Now, in this case relief was almost immediately afforded, and no further treatment was necessary, for the attack no doubt depended upon "some obscure irritation of the fifth pair of nerves," and was not caused by the health being out of gear.

Case 2.—Henry H., aged forty, had been suffering, for some weeks previous to my seeing him, from the most excruciating attacks, and there were no carious teeth to account for them. As he was out of health, I treated it as a case of anæmic neuralgia. and so put him on a course of quinine and iron, which gave him no relief. At last he had such a severe attack that he was like one bereft; but the pain was immediately alleviated by the opium and arsenic, and left him, he said, "like a miracle." I now recommenced the tonic treatment and he very soon regained his ordinary health. In this case the neuralgia simply resulted from an "obscure irritation of the fifth pair of nerves," accompanied with debility.

Case 3.—Charlotte B., aged eighteen. Patient was what one would term in first-rate health, and, strange to say, had never had toothache. One evening, without any assignable cause she was attacked with the most "horrible pain" in the face—had never experienced it before. I administered the opium and arsenic, and the pain at once left her. The next day she had another attack, which immediately succumbed to the remedy.

Case 4.—Annie H., aged twenty-two. Patient had been irregular from puberty, and for the last six years had been subject to attacks of facial or definite neuralgia, and no remedy had afforded her the slightest relief. She was a well-formed girl, but was decidedly chlorotic and anæmic. The first dose relieved the pain slightly; the second entirely removed it, for she slept soundly, and there was no vestige of it on awaking. I now treated her general health by administering purgatives and tonics, such as iron and quinine. When I last saw her she had had no recurrence of the neuralgia, the catamenia were regular, and her general health had greatly improved.

These four cases, which I have selected from many others of which I have notes, are quite sufficient to show the efficacy of the combination of opium and arsenic in the treatment of this disease. Three of them are very good specimens of what I call definite neuralgia, and the last was of the same kind, though partly owing its origin to some uterine derangement. There is one very noticable fact—they all derived marked benefit from the remedy; it also quickly relieved them of an agonising pain, prevented its return, and no ill consequences resulted; and what is greatly in its favour, the opium promotes rest, which is so necessary, and the sufferer awakes up, feeling almost a new being, especially if the pain has been of long continuance.

The form of definite neuralgia which arises from hysteria is also amenable to opium and arsenic; but then it is desirable to give the patient a nervine sedative—such as the bromide of potassium or the tincture of valerian—after the neuralgic pain has subsided. The following is the mixture I always give:—R. Liq. arsen. ℥ ss., tinct. opii ℥ jss., aq. ad ℥iij.; one tablespoonful to be taken when required. The strength may be increased in very violent cases, but I have generally found the above sufficiently strong.

I am almost inclined to think that the neuralgic pain affecting other parts of the human system, such as the breasts, etc., would be benefited by the same method of treatment; but here I cannot speak so decidedly, as I have not yet had what would be considered a well-marked case under my care, for the most common, and one which is nearly an everyday occurrence, is the definite form or facial neuralgia, which of late years has so remarkably increased, and it has hitherto entirely baffled all the efforts of the profession to mitigate the agonising pain which is invariably experienced by the patient.

In conclusion, I must state that I hope this remedy will be as successful in the hands of others as it has been in mine, and that it may be given an impartial trial; for I have noticed there is not a medical man who does not find himself very frequently foiled in the treatment of definite or facial neuralgia, for the remedies which are in vogue at the present day are not in the least successful in allaying and alleviating the agony of this distressing malady.

Camberwell-road.

ON EARLY ANÆSTHETICS.

By J. DUDGEON, M.D., of Pekin.

In a late letter in the *Times* (May 25), calling attention to the proposed purchase by the British Museum of an ancient Chinese Encyclopædia, now on sale at Pekin, the writer falls into a series of curious blunders regarding the subject upon which he wishes to enlighten the public. He informs us that a copy of the work has long existed in Paris, and that it dates from 220 A.D. He takes occasion to extol the early discoveries of the Chinese; notes the early use of anæsthetics; and in true Oriental style, considering the idea to be quite fallacious that there is anything new under the sun, concludes thus:—"It is therefore probable that should England become possessed of the work in question, and should our Oriental philologists live long enough to translate it, we shall stumble prematurely

upon some of those results of a refined civilisation to which the ordinary progress would only bring us after the lapse of many centuries." We are naturally jealous of the honour of the discoveries of Harvey and Simpson, to both of which foreigners have laid claim for China. Let us review this latest claim to the knowledge and use of anæsthetics among the Chinese. The *Times'* correspondent, the author of "Flemish Interiors," has mistaken the age of the celebrated surgeon Hwato (whom he quotes), of the Wei dynasty, 220-230 A.D., for the age of the book. We say nothing of the error into which he has apparently fallen regarding the book itself, which cannot surely be esteemed either for its age or its bulk. The name of the book he quotes when translated into English is simply, "Collection of Ancient and Modern Medicines," and was published in the beginning of the sixteenth century. That the Chinese knew many of our later, but I hold separate and independent, discoveries, such as gunpowder, the mariner's compass, printing, etc., is well known, and in these pages we have already pointed out their early knowledge of laminaria in goitre, fish-oil in phthisis, and, we might add, arsenic in ague. It is incorrect to say that such things have been forgotten and discovered again in our day. The fact is that they were, generally speaking, never known to us at all, and certainly they have not been forgotten by the Chinese. What is remarkable, however, as we shall show, is that this same sort of knowledge seems to have been common property in both the East and the West. The writer refers to the existence of anæsthetics as in common use in surgery in the beginning of the third century, if not earlier. Such dangerous medicines, it need hardly be said, have never been in common use, and surgery can hardly be said to have ever existed in China, if we except, of course, acupuncture and the moxa. With the highest civilisation of all Asiatic countries, China stands lowest in medicine. The writer falls into a grievous error in stating *ma-yo* to be a specific name for Indian hemp. The term literally means anæsthetic medicine, and is applied in a generic sense to medicines of this class. There is no drug to be found either in the shops or books of China under this name, and the Russian physician Tatarinow has fallen into an error in calling it *Cannabis indica*. The late M. Stanislaus Julien, of Paris, called attention in 1849 to the employment of this class of medicines in China in ancient times. Other substances besides hemp entered into these benumbing recipes, such as the datura, a solanaceous plant probably identical with the *Atropa mandragora;* also aconite, hyoscyamus, etc. Some of these drugs form constituents of the formulæ said to be employed by kidnappers of children and robbers, and are therefore naturally forbidden in China to be sold or employed. The counterpart of this practice is found in early times in the West. The wine of mandragora was known in Greece, and is mentioned by Diascorides as administered for severe pains, insomnia, and in operations with the knife or cautery. Another preparation of the same, called morion, caused infatuation and took away the reason. Pliny refers much later to the same substance, and Lucius Apuleius (160 A.D.) tells us that under the administration of half an ounce of the wine a man may have a limb removed without pain or sense.

The Indian hemp, under the name *bhang*, is extensively used by the Mohammedans and others in Central Asia at the present day. One of the names for hemp in China is *hanma*, of Sanscrit origin, a word not unlike the German *Hauf;* and our hemp and the sounds *hannap* and *kannap* seem to run through nearly all languages. The most wonderful properties are ascribed to the hemp. Persons with ulcers, it is said, cannot look upon it without dying. Its antidote is linseed or huma. Taken in excess, the spirits and demons may be seen; it confers prophetic powers; it is sometimes taken by persons wishing to indulge in spiritualism; and it is used as an antidote to forgetfulness. It is supposed to prevent the hair turning white, and is consequently said to stop the advance of age. These foreign substances are usually so powerful, and their action so marvellous, that they are seldom, if ever, prescribed by the native faculty. I shall say nothing of the value of Chinese medical works, containing as they do so much that is shrewd and practical, with the most fanciful theories and puerile and ridiculous statements made in the most grandiose and sublime style. Although we are indebted for rhubarb, camphor, tea, etc., to China, I fear we need hardly look for any new discoveries, and certainly none that is to advance us in refined civilisation and material and scientific progress at such a rapid rate.

REPORTS OF HOSPITAL PRACTICE IN MEDICINE AND SURGERY.

CASES OF ABDOMINAL DISEASE.

MIDDLESEX HOSPITAL.

[REPORT abstracted from notes of Mr. F. W. Browne, House-Physician.]

Case 1.—*Pelvic Abscess situated between the Vagina and Rectum, causing Intestinal Obstruction—Abscess Evacuated from the Vagina—Cured with Exception of a very Small Sinus.*

(Under the care of Dr. CAYLEY and Mr. LAWSON.)

Elizabeth S., aged twenty-six, nursemaid, was admitted under Dr. Cayley's care on February 1, 1877. Her family history was good, and up to the present trouble her health had been good with the exception of slight occasional dyspepsia. On January 22, after breakfast, she vomited some green liquid, and had severe pain in both iliac fossæ. The pain was increased on pressure, and relieved for a time by poultices. Up to the 25th she vomited everything she took. Vomited material was green; nothing red or black was seen. From the 22nd till the present date (February 1) bowels have been moved twice very slightly—motions fluid and greenish; has not passed wind since attack. She took on the 23rd some antibilious pills, and since then some castor oil. The pains in the abdomen have continued without change, and there has also been a little pain in the left shoulder and side. Since the 28th she has felt a little relief from lying with her legs drawn up. Had an irregular period on the 24th and 25th. Says she has not passed enough water. Appetite poor.

Condition when admitted, February 1.—Patient very weak; has areolæ under eyebrows; lies with legs drawn up. Abdomen not much distended, very tender in parts below umbilicus. In both iliac fossæ there is dulness and resistance. She has no pain on deep inspiration. Tongue coated with dry yellowish fur; mouth very dry; skin fairly moist. Pulse 96; temperature 99°. Ordered simple enema, pulv. opii gr.ss., every three hours. Three leeches to be applied below the navel. The enema brought nothing away, but she passed water freely afterwards. In the evening she had vomited everything given to her.

February 2.—Pulse 120; temperature 100°; respirations 32. A little easier, but says the pain shoots from the navel. The breathing is entirely costal. She has hiccough, which she says gives her no pain. On left side, in hypogastric and iliac regions, there is some distinct hardness, with undefined margins. Right side percussion tympanitic. This evening an enema of three pints of tepid water was administered from a height of four feet. No passage of water through the bowel could be heard. She vomited after the enema, but said she felt slightly relieved. One grain of opium given. Some time after the enema the rest of the liquid came away; it was not tinged with blood. No fæces came away, but there was a fæcal smell. Before the injection there was a little blood noticed about the anus and genitals: the source of this was not discovered. Evening temperature 101°; pulse 120. In this case the symptoms clearly pointed to some obstruction situated low down in the large intestine. Dr. Cayley made an examination per anum, and found there was an elastic tumour bulging into the rectum in front, and requested Dr. Hall Davis to examine the case.

3rd.—Pulse 132; temperature 100°. Has vomited two quarts of brown, sour-smelling liquid. Everything brought up, including brandy. Pain very bad just about the navel. Tongue drier and browner in the centre. Has some tympanites. Has not passed any wind by the anus. Dr. Hall Davis made an examination per rectum and per vaginam. He found the os uteri and cervix natural. The sound passed into the uterus four inches. Beyond and behind the vaginal *cul-de-sac* a fluctuating soft tumour was felt. On rectal examination it was found that this tumour depressed the anterior rectal wall against the posterior wall, thus preventing escape of fæces. The examining finger brought away fæces. Mr. Lawson, who was called in consultation, found that the above tumour fluctuated, and it was determined to aspirate through the vagina. The patient was put under the influence of ether, and a duck-bill speculum

introduced into the vagina. Mr. Lawson plunged a medium-sized trocar and canula into the most prominent part of the tumour. After connecting the canula and the exhausting syringe, pus flowed freely; this, emptied into a porringer, was found very fetid. Under carbolic spray a free incision was made, and a copious discharge of brown fetid pus escaped, which at the end was intimately mixed with blood. This flowed away to the amount of at least a pint —ebbing and flowing with respiration. On exploring with the finger, Mr. Lawson found a large cavity occupying the whole recto-vaginal pouch. This was washed out with dilute Condy, and a drainage-tube passed in, which was connected with an indiarubber tube passing under the clothes into a basin of Condy. As much fluid passed away within half an hour after as had escaped during the operation. Patient complained of pain afterwards, and a hypodermic injection of morphia was administered. The abdomen became soft and yielding. In the evening, pulse 120, temperature 99·8°; the pain had gone, and she had been able to keep down some iced brandy-and-milk and blanc-mange. The abscess-cavity tended to contract and force out the tube. A piece of lint soaked in Condy was introduced into the vagina, encircling a short piece of perforated tube. This discharged below into a piece of oakum, which was secured outside the vagina by a T-bandage.

4th.—The amount of discharge into the oakum is not great. The tube is still kept in its place. Patient has had a fluid motion; the rectum is loaded with fæces. Tongue not so brown as it was; no pain; abdomen soft. 7 a.m.: Temperature 100°. 11 a.m.: Pulse 114; temperature 99°. Vagina, etc., syringed out with Condy; tube, oakum, and lint used as before. Enema of castor oil, very slightly retained, brought away only a small amount of liquid fæces.

5th.—Pulse 108; temperature 98°. Tongue brown but not dry. Has had a little hiccough and nausea, and has now slight tenderness in left iliac fossa. Discharge from vagina rather thick. Motions are found with the discharge in bed. The opium to be discontinued. Castor oil enema brought away a few lumps of fæces. Afterwards six ounces of olive oil were passed up into the bowel by a long flexible tube, and in one hour and a half afterwards a large enema of warm water was given. During the operation there was a continuous discharge of pale, thin, fetid fæces. Patient much relieved, but did not sleep well.

6th.—Puncture found now to be very small; some difficulty in passing tube into it; washed out with carbolic 1 in 100. Subsequently a catheter was introduced into the sinus, secured by a strip of plaster round the thigh, and surrounded by oakum.

9th.—An injection of half an ounce of tincture of iodine to one pint of water was ordered for the sinus. It was found on further examination that the direction of the rectum was towards the right.

10th.—Patient has acquired control over both micturition and defæcation.

17th.—Red lotion was to-day used as an injection instead of iodine, and the catheter was no longer kept permanently in.

19th.—Patient got up.

27th.—There is still a small sinus left, from which there is a scanty, inoffensive discharge; she has no pain, her appetite is good, and the bowels are opened naturally.

Arrangements were made for her to attend as an out-patient at the Gloucester Infirmary, which was near her home.

Case 2.—*Intestinal Obstruction—Enterotomy—Death.*

(Under the care of Dr. CAYLEY and Mr. LAWSON.)

Francis K., aged forty-seven, an engine-fitter, was admitted under Dr. Cayley on February 15, 1877. Patient was in his usual health on February 12. Bowels were opened once on that day; motions scanty, and of ordinary appearance. At 3 a.m. on February 13 he was seized with severe pain across the navel; vomiting came on at noon. Has only taken some milk since attack commenced. The pain has continued with very slight remission, and the vomiting has recurred repeatedly. He has passed some wind by the bowel this morning, but no blood and no stool. Has passed his water as usual.

On Admission.—Countenance anxious, and expressive of pain. Tongue coated, dry in centre. Has a purple line along gums. Breath offensive, but has decayed teeth. Pulse 78, soft, compressible; respirations 24; temperature 98·5°. He complains of severe pain about the navel, relieved by lying on the left side. Pain paroxysmal; paroxysms last sometimes five minutes, sometimes half an hour. Pain increased on pressure just below the umbilicus, but not elsewhere. Some gurgling is felt on pressure during the paroxysm. There is a distinct depression in each hypochondriac region, and the epigastric region is not at all full. Below the umbilicus there is a prominence, which passes from side to side of the abdomen. Over this prominence the resonance is less tympanitic than it is above. In the hypogastrium there is some dulness. In the afternoon six pints of tepid water were injected into the bowel from an elevation. Fluid returned with some scybala. After this there was a slight motion. Patient said he felt much relieved. He was ordered milk, ice, brandy, and pulv. opii gr. j. every three hours. He vomited half an ounce of bilious stuff, but retained some milk and brandy afterwards. Had some paroxysms of pain. At 9 p.m. he had hiccough. The prominence below the navel was considered a little less; otherwise the condition of the abdomen was unchanged. The injection as above was repeated; it gave the patient some distress. The injection came back discoloured, with a few flakes and fragments of fæces. Urine 1040, acid, no albumen; deposited urates.

February 16.—Pulse 60; temperature 99·2°. No vomiting since last injection; tongue large, thinly coated, not dry; not so thirsty; enjoys his milk; can now lie in any position; slight pain about navel; prominence continues, but is not tender; hypogastrium resonant; left flank not resonant. In the evening he woke with a paroxysm of pain. Enema of two ounces of castor oil with six pints of soap and water brought away scarcely any fæces; gave him pain afterwards; vomited also; but slept well.

17th.—Pulse 60; temperature 99·4°. Abdomen more tense, and tender on pressure in umbilical region; lies with his legs extended; passes water freely. Omit opium. Hypodermic injection of one-sixtieth of a grain of atropia to be given. At 11 p.m. a simple enema of tepid water from a height was administered. It gave the patient so much pain, and distended the abdomen so much, that not more than four pints could be given. During its passage gurgling was heard in the right and left flanks, and doubtfully in the epigastrium, but none in the umbilical region. Afterwards patient vomited half an ounce of green bilious matter. The injection returned stained with fæcal colour and with shreds of fæcal material floating in it. After this he was in a little pain, but took some milk, which he retained. Here the symptoms indicated an obstruction in the small intestine suddenly produced. Mr. Lawson was asked to see the patient, and he proposed to make an incision in the right loin, as if for colotomy, and to open the distended intestine which might present itself. He came to this determination from believing that if he were to open the abdominal cavity in front, and search for the seat of the obstruction, it would be quite impossible afterwards to replace the intestines owing to their distended condition. He also thought it improbable that the obstruction was due to a band which would admit of ready division.

18th.—Pulse 96; temperature 98·4°. Began to vomit at 5 a.m., and had great pain in the umbilical region. Vomited material sour smelling, contains thin pultaceous yellow material in suspension, and is acid in reaction. At 2.30 p.m., as the vomiting and distress were in no way abated, the patient was anæsthetised by equal parts of ether and chloroform, and Mr. Lawson made the usual incisions for right colotomy. The colon did not present, but coils of small intestine. One of these was apparently collapsed, one bulged; the latter was transfixed and attached to the edges of the abdominal wall, and then divided. The rest of the incision was sewn up. The division of the gut was followed by a discharge of yellow liquid. During the operation the patient vomited large quantities of sour yellow liquid. He was not much collapsed after the operation. A piece of carbolised lint was placed over the wound; over that a little oiled silk and a piece of flannel was lightly applied round the abdomen. The patient was taken back to bed, and one-sixth of a grain of morphia administered hypodermically. His pulse became feebler, and some milk and three drachms of brandy were given, which he retained. At 5.15 p.m. the wound was re-dressed. Half a pint of thin very fetid discharge had collected underneath. A single fold of warm flannel was placed over the wound, and above that some oakum. Patient afterwards slept. At 9 p.m., pulse 102; temperature 100·6°; respirations 25. Edges of wound rather puffy.

19th.—Began to vomit at 5 a.m., some thin sour yellow stuff; has altogether brought up about a pint of it. Temperature 102·4°. He does not complain of pain, but looks

very prostrate. Morphia ordered at frequent intervals. Died at 12.30 p.m.

Abstract of Post-mortem by Dr. Coupland.—Body was well nourished; a considerable amount of fat present in thoracic and abdominal wall. No undue distension of abdomen. In the right loin, immediately above the crest of the ilium, was an incision in the abdominal wall—the seat of a recent enterotomy. The edges of the wound were healthy-looking and blood-stained. On opening the abdominal cavity, the peritoneum generally appeared injected, and in the right iliac region it was covered with a scanty exudation of lymph. The omentum, well supplied with fat, was concealed in its lower half by two greatly distended coils of ileum, which passed across the cavity from right to left, each having a strongly marked flexure, the convexity of the bend being uppermost. Turning these coils aside, the omentum was exposed in its whole extent; and lying across the spine, in a perfectly collapsed and empty condition, was a large part of the ileum, arranged in the form of three well-marked loops. Tracing these coils in each direction, the gut was found to pass through a ring of fibro-fatty tissue, formed at the right lower angle of the omentum, where the intestine was firmly nipped, but not strangulated. The collapsed coils were of a bluish-black colour, but their mesentery (containing much fat) was unaltered, its vessels not being unduly engorged. The constricting band was three inches in circumference, and its free portion not thicker than stout whipcord. The included portion of bowel measured forty inches; the site of the distal strangulation being four inches from the ileo-cæcal valve. The ileum and jejunum about the constriction were much distended, forming the coils first noticed; and at a spot twenty-five inches above the constriction was a ragged opening, an inch and a half in length, which communicated with the wound in the right loin. The serous coat of the bowel was here covered by lymph. The small portion of ileum below the constriction, and also the cæcum and colon, were almost empty. The omentum was perfectly free from attachment to the parietal peritoneum, and no adhesion had taken place between the gut and the constricting band; in fact, it would not have been difficult to have gently drawn out the bowel through the ring at the lower part of the omentum. Two views were suggested as to the mode of formation of the constricting band. Either it was produced by a rent in the lower part of the omentum, just above its free border, or else some previous inflammatory condition had caused adhesion of the two portions of the omental margin, so as to form a loop through which the hernia took place. The absence of other peritoneal adhesions, and the presence of fatty tissue in the whole of the constricting band, pointed rather to the former alternative as opposed to the latter. The remaining viscera were perfectly natural, the lungs being, however, extremely engorged.

CLEVELAND-STREET ASYLUM.

Case 3.—*Syphilitic Disease of Rectum, for which Colotomy was performed.*

(Under the care of Dr. LEDIARD.)

Mary D., aged twenty-four, was admitted April 16, 1877.

History.—Patient states that she has suffered from syphilis in one way and another for seven years, and has had advice all along from various hospitals, both as an indoor and outdoor patient, having undergone a variety of operations of a minor character for extensive growth of warts, ulceration of the rectum, etc. During the last two years the rectum has given constant trouble, and now renders her existence unbearable, for she never has her bowels opened without enema or medicine, and when they act there is pain of acute character before and after for some time. There has been incessant discharge of matter and blood from the rectum, and ulceration both in and outside the rectum and vulva; she has never got rid of it even for a time. The throat has also been affected more or less from time to time.

Patient is a handsome girl, of very dark complexion, and a delicate and spotless skin. It seems that the disease which has rendered her life so miserable has altogether avoided the cutaneous system, and spent itself upon the orifices of the body more especially. She has a growth of fine black hair, and though she is pale and thin, yet no one would judge from her appearance only that she was the subject of visceral syphilis. She complains of great pain in the rectum on defæcation, and has a discharge of pus and blood. There are large condylomatous patches of ulceration outside the anus, and ulcerated surfaces within the vulva. Owing to the condition of parts, digital examination was not much employed, but the rectum was found ulcerated some distance up, and it was thought also to be contracted in calibre. The patient's temper was uncertain and irritable. The tongue was habitually foul, and the fauces always more or less red and irritable, but not much ulcerated at this time.

I commenced anti-syphilitic treatment, both internal and external, and continued it for three months with no success at all. She had a large quantity of the bichloride, but the gums were never touched. It seemed to me that so long as fæcal matter was passing over the ulcerated surface of the rectum there was little or no chance of healing going on. Externally, calomel dusting was used, and changed about with other things, but no permanent benefit obtained. The throat improved occasionally, but again relapsed. Under these circumstances I proposed colotomy, and she was very ready to accept relief in any form. Accordingly, on July 19, with the help of Mr. R. W. Lyell, I made an artificial anus in the left loin. The abdominal wall was very fat, and the incision made measured exactly nine inches. The colon took some time to find, since it was embedded in fat, and at one time the forceps seized the lower end of the kidney. (On the day after the operation there was slight hæmaturia.) The rectum was injected with water to afford assistance, and ultimately the bowel was secured to the skin without damage to the peritoneum. There was no bleeding to speak off, and the only difficulty experienced was caused by the presence of so much fat, which somewhat surprised me, seeing that the patient's appetite had been so indifferent, and little or no solid food taken. Subsequently she made very reasonable progress towards recovery, but there was a fair amount of suppuration about the deep part of the wound amongst the muscles; but under the circumstances, union by first intention could scarcely be looked for. The temperature and pulse naturally went up, but not to any alarming extent; the abdomen was tender on the left side for some time, but no peritonitis followed. The first passage of fæces from the loin took place on the fifth day, and by the eighth day all the stitches had been removed, and in a month's time consolidation of the parts had taken place. On August 20 she remarked, "I feel a different girl since the operation. I have no pain in the rectum, and less pain in the abdomen. I feel stronger." And here I may add that her spirits had undergone a very remarkable improvement, and the appetite returned. There is still discharge from the rectum, but much less; and to prove that the passage of fæces over the rectum was the cause of the great pain experienced; it may prove interesting to state that on August 24 she had a return of the old pain in the rectum. I ordered an injection, and a small lump of fæcal matter came away, after which she was easy. I then ordered, at the end of August, some mercury again, for there was a characteristic fringe of mucous tubercles all round the artificial anus, but in the course of three weeks this had disappeared. Still the ulceration of the skin round the anus, and also on the vulva, remained unhealed, though improved. At the present time her condition is one of general improvement, but the sores externally have defied treatment and cause great annoyance. The throat has not given trouble for some weeks, and she takes a fair amount of food, but exercise is impossible from the opposing sores outside the rectum; still, I am in hopes of sending her away perfectly well in the course of a few months.

Note by C. F. Maunder, Surgeon to the London Hospital.—I am often asked—How is the artificial anus controlled after the performance of lumbar colotomy? The answer is—As a general rule, a simple compress of soft rag retained by a bandage is all-sufficient. Occasionally, when the margin of the wound in the bowel becomes from any cause retracted, the tendency to cicatrisation and closure of the integumental wound is so great that another measure becomes necessary. The history of a case subsequent to colotomy which I here record will illustrate what is requisite. In November, 1876, I saw in consultation with Dr. Neale, of St. John's-wood, and Dr. Wilks, a male about fifty years of age, and performed lumbar colotomy on the right side. At the time of operation I prognosticated speedy closure of the skin-wound. About three months after, the opening would only admit a No. 6 catheter. To remedy this, and to delay, if not prevent, a similar occurrence in future, I cut away a circular piece of integument to the extent of one inch and a half around the aperture. In this way I expected, with or without some kind

of plug, to keep the opening patent. In a letter addressed to me on September 12 the patient says—"My health has gradually improved since the last operation. I am nearly as strong as I ever was; good appetite. I walk several miles a day without feeling fatigued, and forget for hours that I have anything the matter with me. I have also made flesh, and now weigh eleven stone (more than before my illness). The artificial anus is kept open by a vulcanite conical tube, and is washed morning and evening. The fæcal evacuations partly pass by it, but principally by the ordinary way. My bowels are in perfect order." I withhold the details, which would be lengthy, of this interesting case, and confine myself chiefly to the condition of a patient volunteered by himself ten months subsequent to operation. It should tend greatly to diminish the prejudice still unjustly cast upon an operation potent to afford instant relief to extreme suffering in most cases, and to prolong life indefinitely in a few.

SEASIDE SANITATION.

Mr. Brudenell Carter, in the excellent address delivered before the Sanitary Institute of Great Britain, noticed as one of the chief impediments which stand in the way of sanitary reform, "the existence of an apathy, which is the result of almost inconceivable ignorance, largely tempered by superstition." He evidently knows the struggle which will be necessary to awaken the sleepers from the dull dreams which are certain to end in death or in disease, for he acknowledges "that it is hopeless to talk to the average vestry or board of guardian mind about sewer-gas or polluted water as abstract agencies."

He advocates, as a first step, that education should be confined to argument, until the lazy, the selfish, and the ignorant can be persuaded to go to school, and learn what sanitary science means. Agreeing as we do with Mr. Carter, we wish to go a step further, and to point out that when the school is opened, and the unwilling pupils collected, "sanitary science" will receive a serious blow unless the "teachers" both know and do their work. We have lately watched with some interest the faint efforts of an apathetic and superstitious little community to struggle into life, and sense, and decency; and we fear that as they open their eyes they may look only on the results of bad sanitary measures in a neighbouring town, and so find an excuse for shutting them to dream over again that no precautions are required, and that "sanitation" means waste of money, increase of disease, unnecessary taxation, meddling interference and jobbery, invented by enthusiasts for the benefit of needy medical men. Moral lessons illustrated by vicious pictures are worthless.

> "Segnius irritant animos demissa per aurem,
> Quam quæ sunt oculis subjecta fidelibus."

The haters of improvement will not read sanitary lectures, but will prefer to look at a local board which has come to grief. Probably there is not a small place in all England which requires reformation more than the little townlet on the south-eastern shore of Devonshire, whose feeble struggles to emerge from the slough of ages of neglect we have lately been watching; for it is a place where disease may yet be prevented, and therefore dearer to the lovers of sanitation than a locality where disease has to be cured. Probably, the majority of the inhabitants regard the absence of disease as the best reason for ignoring medical advice; but we have long observed a growing feeling in the small community that "something" ought to be done. For a few years past the shopkeeper has shaken his head at the couduct and bad habits of the boatmen on the beach, and the toilers by the sea have grumbled at the impurities they have had to encounter in their little cottages, where the air is poisoned by the stench of the uncleansed slaughter-house and the neglected farmyard; but until very lately all were agreed that the "something" which ought to be done must be effected by the benevolence of some rich person who had plenty of money and nothing to do with it. The inhabitants got so far at last, that they ceased to object violently to sanitary measures, insisting only that they should not be made to pay anything for scientific experiments. The visitors to the place were the cause why matters were not allowed to rest without some real attempt at improvement. Strangers coming from better ordered towns and cities were outraged by the want of common cleanliness in the little seaside place they had selected for a health-resort. They noticed the streets dusty and uncared for, strewed with decaying sprats or pilchards or dog-fish, keeping company in death with the crushed rat or drowned kitten flung into the roadway by the careless householder. They observed the wells in the small gardens, into which drained the convenient cesspools; and they shuddered and held their breath as they passed the concealed slaughter-house and farmyard, hidden between the two streets of the little townlet. They grumbled at the want of all regulations upon the beach, and, when their month or six weeks devoted to recreation were at an end, the visitors expressed themselves pretty strongly, and made solemn vows to return no more, until the place, pretty as it was, should be improved by a local board. At last the eyes of some of the residents were fairly opened, and they acknowledged that the "something" which ought to be done should, in all fairness, be done by themselves. They saw that the visitors had reason to grumble, and they inferred that they probably would not return. They summed up the weaknesses of the little town for themselves, and recognised that the smells were bad, the sewers incomplete, the water not above suspicion, and the streets dirty; there was neither water-cart nor fire-engine in the place, there was no magistrate, no order, and no authority whatever. On the beach, things were worse. There were hardly any seats for visitors, the bathing was under no regulations, the watermen's boats were not licensed, and neither drags nor life-buoys were procurable in case of accident. An attempt was made a few months since to get a local board to remedy these wants, and of course a violent commotion ensued. Above the general chorus of personal abuse and incoherent

cursing of the followers of the heads of the rival factions arose the "assertion" that sanitation increased the diseases it pretended to cure. The board was won by votes, and lost by a legal technicality; and now, when the reformers are prepared to commence the struggle anew, they are met again with the assertion that sanitation means increased disease. "Look!" cry their opponents, "look at Sidmouth, only a few miles off, which has a local board. There see what sanitation does, and read the unsavoury report of Mr. Netten Radcliffe on the doings of a local board!" What can the sanitary reformers answer? They may say, of course, that sanitation is not bad because bad sanitation is no good; but what can they say when they are asked how they can insure better sanitation at their townlet than that which broke down at Sidmouth? It seems to us that, under the present system, local boards in small places, so far as sanitation is concerned, must always be breaking down. The health officer can scarcely afford to be independent in a small community, where, if he does his duty, he loses his practice, in addition to running the risk of not being listened to when he gives his advice. A remedy might probably most easily be found by *combining small districts*, and appointing a health officer whose salary would be sufficient to render him quite independent of the opinions of the ignorant and prejudiced, and leave him free to express his convictions in the strongest and plainest language. There would be no great difficulty now, and later on will be still less, in finding medical men fitted for the work, if their position were secured by an enactment which provided that both their local appointment and removal should be confirmed by the sanction of the Central Board. We are aware that when good advice is fearlessly given it need not be taken; but it will be taken by all classes when they learn that their interests suffer by their neglect; and "monthly reports" furnished to the central authorities of "recommendations made," and "whether attended to or not," would enable health-seekers on application to obtain a fair clue to the places where dirt, disorder, and disease were at a discount.

THE NEW ARMY HOSPITAL CORPS WARRANT AND THE ARMY MEDICAL DEPARTMENT.

Press of matter has, up to the present time, prevented our commenting upon the Royal Warrant for the Army Hospital Corps, dated August 14 last, which is destined to effect such an important change in the position of officers belonging to the Army Medical Department. The authorities have certainly done wisely in conceding, however reluctantly, the one great point which was necessary to make the unification of the Service palatable to the majority of its members—we mean disciplinary power over all persons connected with military hospitals. It had long been anything but an imaginary grievance that the Medical Officer was denied complete authority in his own special building, the hospital; and that in the great establishments of this character it was considered necessary to appoint a Commandant to superintend all military details. The new Warrant corrects all this, and gives to the Principal Medical Officer the powers which should never have been taken out of his hands.

The various clauses of the new Warrant direct that the Director-General of the Medical Department shall be invested with the administrative charge of the Army Hospital Corps. He is to be assisted by a staff officer, a member of the corps, who will be appointed on his recommendation. The officers of the Army Medical Department will, subject to the local military commanding officer, exercise command over the medical officers, all ranks of the Army Hospital Corps, all patients in hospital, and all such non-commissioned officers and men as may be attached thereto, without their own officers, for hospital duty. The Principal Medical Officer, subject to the general officer commanding the district, will have supreme authority in all matters of discipline affecting the Army Medical Department, including the Army Hospital Corps in his district. The medical officer in charge of each general, station, and field hospital will have disciplinary control over the medical officers, the Army Hospital Corps, and all soldiers in or attached to the hospital; but is to refer to the local military authority such cases as require to be dealt with by court-martial. The medical officer in charge will thus be vested with all the authority of an officer commanding a regiment, except in the matter of convening courts-martial. The officers and non-commissioned officers of the Army Hospital Corps will, under the medical officers, command not only the men of their own corps, but also the patients in hospital, and all non-commissioned officers and men attached without their own officers for hospital duty. On active service the "bearer companies" (the new institution which we recently explained and commented on) will be under the command of the senior medical officer present with each, who will be responsible to the principal medical officer of the force to which he may be attached; and the officer of orderlies under him will only take command of the company in the event of his absence. The officers of the Army Hospital Corps will act as quartermasters, and take over and be responsible for the equipment of bearer companies and field hospitals, under the superintendence and control of the medical officer. Further, the officers of the Army Hospital Corps will at all times perform such pay and clothing duties as are performed by captains in line regiments.

The new Warrant thus places the Army Hospital Corps directly under the command and control of medical officers; and this is exactly as it should be, considering that its duties are entirely connected with their province. It is also satisfactory inasmuch as that for the future the medical officer will cease to be an officer only in name, without any real control. Instructions are appended to the Warrant, which enjoin that the duties connected with the equipment and dieting of hospitals, and all duties formerly performed by the Purveyor's Department, shall in future be conducted by the officers of the Army Hospital Corps, under the supervision of the medical officers.

The foregoing is the substance of the new Warrant, which must certainly be regarded with feelings of satisfaction by the members of the Army Medical Service, since it accords to them complete authority in their own department, and releases them from the annoying pressure of administrative details. It is true that we cannot go so far as to say that it leaves nothin to be desired, but if those in high quarters have at length begun to perceive that the Medical Department of the Army has just grounds for dissatisfaction and complaint, it is not too much to hope that the present concession may in time be followed by others, and that in the end the Service may regain that position in the profession which of late years it has most certainly lost.

NORMAL OVARIOTOMY.

The title of this article is a term used to signify the extirpation of ovaries which are either not diseased at all, or not enough diseased to (of themselves) directly endanger life. The name comes from America, where the verbal critics have found much fault with it. We do not think it a happy one, but cannot here discuss its propriety. The thing it denotes being of greater moment than the name, we will go at once to that.

This operation has now been done often enough to enable us to form an opinion (liable, of course, to modification) as to whether, and when, it is a mode of treatment which ought to be carried out. Before stating that opinion, we will shortly put before our readers the evidence on which it is based.

Professor Hégar, of Freiburg, has in two cases removed both healthy ovaries, in order to bring on the climacteric, and so lead to the cessation of hæmorrhage from uterine fibromata.

In each case other means had been tried, and had failed. This operation was chosen as being easier and less dangerous than the taking out of the tumour. Both patients got quite well, one without a bad symptom, the other after some suppuration in the abdomen. In each case hæmorrhage stopped, and had not recurred nine months after the operation. The fibroids, Professor Hégar was certain, had got smaller. The patients both gained strength and got fat. Dr. Trenholme, of Montreal, has also removed the ovaries in a case of fibroid tumour. Enucleation had been unsuccessfully attempted; the cervix had been incised, and many milder measures tried, without relief. The patient recovered well from the operation. Periodical pains and hæmorrhage recurred afterwards, though not, it would seem, to the same extent as formerly. Four months after, Dr. Trenholme thought his patient well.

These cases form a class by themselves. In them all, hæmorrhage, the result of fibroids, was destroying health. The operator went on the sound principle that if he could lessen the blood-supply, the hæmorrhage would stop or diminish, and the tumour cease to grow. To do this, he removed the organs whose influence effected a monthly determination of blood. The result was as he had foreseen.

We next have some cases in which the ovaries were taken out to relieve distant symptoms, of which they were believed to be the cause. Hégar removed the uterus and both ovaries, to rid the patient of a most violent cough, which was thought to be due to anteflexion of the uterus, a conjecture supported by the fact, that her symptoms were absent when the uterus was kept straight by a stem: but this instrument caused so much pain and hæmorrhage that its use could not be endured. Therefore Professor Hégar removed the whole organs. The patient perfectly recovered, and three months after the cough had not returned. Peaslee, of New York, took out both ovaries by abdominal section, for epilepsy, but the patient died from peritonitis. Dr. Battey, of Georgia, U.S., removed both ovaries from a patient suffering from amenorrhœa, with vicarious hæmorrhages and epileptiform convulsions, which seemed to threaten life. After the operation, health greatly improved, the symptoms disappeared, and uterine hæmorrhage set in regularly (we are not told for how long).

The last set of cases to which we shall refer are those in which the disease was presumed to be local. In four of these only one ovary was taken away. Three of them were under the care of Dr. Battey, one under Dr. Trenholme. In each case it was done for so-called "ovarian dysmenorrhœa." In one the ovary was enlarged and cystic, and in one adherent. In these cases the organs were removed through the vagina by incision in its posterior *cul-de-sac*. Three patients recovered well, one slowly. In three cases there was temporary relief, but the symptoms returned, as was supposed, in the other ovary. In the other case there was no relief to any symptom, except some local tenderness caused by the ovary which had been displaced. In one of them the other ovary subsequently went the way of its fellow: it was found to be adherent, which was not so when the first was removed; the patient recovered perfectly from the operation, but no benefit followed.

The course of these cases seems to prove that, even if alterations in the ovary were the cause of the symptoms, these changes themselves depended on some deeper peculiarity, less easily removed; for, if not, why should it have returned in the other ovary? The clinical lesson of them is, that our diagnosis of ovarian dysmenorrhœa is not yet certain enough to warrant the hazard of so serious an operation.

Then we have five cases by Dr. Battey, in which both ovaries were taken out for what is described either as ovarian neuralgia or ovarian dysmenorrhœa. In two of these insanity is said to have been threatened; in one there was pelvic cellulitis and hæmatocele; in one there was retroversion of the uterus. In one case the method was by abdominal section, in the others by vaginal incision. Two of the latter died—one by peritonitis; in the other no autopsy was made. In one case there was prolonged suppuration, but ultimate recovery; and in one some pyrexia followed, but nothing more serious. The others recovered without a bad symptom. In one the menopause took place, the uterus underwent atrophy, and the symptoms ceased; the patient with retroversion also got quite well. The remaining one, in which there were pelvic adhesions and suppuration, was in no way benefited.

The result of these operations cannot be called satisfactory—two deaths and one failure to secure the object for which the operation was done. When we bear in mind that by extirpating both ovaries a great change is made in the uterus and in the whole organism, we see that ablation of the ovaries might be expected to extinguish other troubles than ovarian ones, and that therefore the one failure to give relief implies a greater error of diagnosis than the non-success by removal of one ovary only.

The evidence at present before us points to the following conclusions:—That removal of the ovaries, in cases of fibroid tumour in which hæmorrhage is so copious as to endanger life, and in which the conditions present make removal of the growth very unsafe, is a justifiable proceeding. It is not preferable to removal of the tumour, because, first, the ovaries are important organs, and the tumour a useless excrescence; and second, because the cure cannot be so certain or so complete. That in reflex symptoms threatening life, and dependent upon the generative organs, it seems (if the cases are correctly reported) an allowable expedient, other means having failed. Two conditions ought to be complied with before it is thought of: the patient's state should be really dangerous; and it ought to be absolutely certain (so far as is possible in a concrete science like ours) that the symptoms depend upon the reproductive organs. Lastly, that in the present state of our knowledge we are not able to be sure that pelvic pain depends solely and entirely upon the ovaries. Until we have this knowledge we cannot think it right to subject the patient to an operation of which the mortality at present is one in five, the cures two(a) in nine. This mortality might, doubtless, be lowered; but until we have more precise diagnosis, we do not think the results can justify even a much less risk.

Dr. Battey's paper (in the American *Gynæcological Transactions*) is one most commendable for the candour with which he narrates his cases. But the details given of their history are not exact or full enough to help forward the work of diagnosis; and in his reasoning upon them we do not think he has rightly seized the lessons they teach. Should this mode of treatment be further carried out, either here or elsewhere, we hope the fullest details will be given as to their history and symptoms; for in elucidating their pathology an operation of this kind is almost as valuable as an autopsy.

THE WEEK.

TOPICS OF THE DAY.

The Chaplain of Horsemonger-lane Gaol, the Rev. Mr. Jessopp, has pointed out a serious infringement of sanitary precautions practised in that and many other prisons. In a recent report to the Surrey magistrates he calls attention to the present rule of burying all persons executed for murder within the precincts of the gaol. This custom, he remarks, is a relic of a barbarous period, when to deprive a criminal of life was deemed an insufficient punishment unless some additional indignity was offered to his remains. In the present age the practice is indefensible, as burial within towns is prohibited by statute, and there is nothing to render a murderer's

(a) Or perhaps three, for Dr. Battey has been told by a third person that one of his unsuccessful cases has since got well.

corpse exceptionally exempt from submission to sanitary requirements. In Horsemonger-lane Gaol, Mr. Jessopp states, thirteen bodies lie buried side by side in a double row, within a few feet of the well which, until recently, supplied the whole establishment with drinking-water. A few feet further off, three other bodies have been recently deposited. This subject certainly demands consideration at the hands of the authorities, for, although we believe the bodies are covered with quicklime, it would certainly be better that they should be interred extramurally, whereby no ulterior danger would be incurred of the murderer revenging his own death by poisoning the air or water of his sometime gaolers, or, still better, that their bodies should be made to serve a beneficent purpose by being handed over to the medical schools.

The fortnightly returns from the London small-pox hospitals, which were presented to the managers of the Metropolitan Asylum District at their last meeting, show that 81 patients had been admitted, 21 had died, and 44 had been discharged since the previous report; and the number remaining in the hospitals on the 19th inst. was 162 as against 146 patients on the 6th inst., showing an increase of 16. A report was also brought up, showing that the number of patients received in the hospitals under the charge of the managers from October 21, 1876, to September 21, 1877, was 7333, of whom 1329 had died, showing an average mortality upon all cases of 18·1 per cent. On the motion of Dr. Cortis, it was agreed that this report should not be printed on the minutes until the returns for twelve months ending October 21 of the present year had been made up. Mr. Barringer, chairman of the Homerton Small-pox Hospital Committee, expressed his regret that the report of that Committee was not more favourable. The number of the patients now in hospital was double the number of its inmates a month since; this fact proved that the fever hospital had not been re-opened a day too soon, and in the first six days of its being re-opened ninety-five patients had been admitted.

An outbreak of scarlet fever is reported on board the Queensland emigrant ship *Gauntlet*, which left London on the 12th inst., with 302 emigrants for that colony. The ship, which put into Plymouth, was last week visited by the Board of Trade officials; and the medical officer, Dr. Eccles, ordered the two children affected, together with the families to which they belong, to be at once landed. The remainder of the passengers on board will be placed in a hulk while the *Gauntlet* is fumigated and disinfected. In the meantime, no communication is allowed between the ship and the shore.

The numerous cases of hydrophobia recorded from so many different localities have induced a gentleman at Birmingham to address an application to the Home Secretary on the subject. In his reply, Mr. Cross states that no representation has been made to the Home Office that local authorities have not sufficient power under the existing statute (Dogs Act, 1870) to deal with the matter, and he feels sure that they may be trusted to put in force the powers they possess. It is difficult to see how special legislation could obviate the occurrence of this terrible malady. In ordering all stray dogs to be destroyed, the local authorities do nearly all that can be done. Only the other day a lady lost her life from this disease through a bite from her own pet dog; so that the danger is not confined entirely to the streets, but exists more or less wherever these animals are found.

The Chairman of the Water Committee of the Liverpool Town Council has announced that that body has matured a scheme for the supply of water to the town, sufficient to provide for all requirements for many years to come. The supply is to be got from North Wall at a cost of a million and a quarter, and the interest upon this large amount would be paid without additional taxation of the ratepayers, and would be met by the saving of waste water in the borough, estimated at £50,000 per annum.

The Committee of the General Hospital, Birmingham, have published a denial of the statements made by Mr. Lawson Tait as to the unhealthiness of their hospital. Some years ago, they state, the sum of £20,000 was spent in practically reconstructing the building, the result being an almost absolute immunity from pyæmia and erysipelas; and, consequently, a great saving of life after severe accidents and operations has been effected. They are, therefore, astonished to find that in Mr. L. Tait's book, and subsequently in a paper read by him at the meeting of the British Association at Plymouth, the mortality following certain operations is stated to be twice as great in the Birmingham Hospital as in smaller hospitals in the neighbourhood, and nearly twice as great as in the new Infirmary at Leeds. On an examination of the statistics contained in Mr. Tait's book, it has been found that in one of his tables (table D) a death-rate, deduced by himself, when more correctly worked out from his own figures, gives a markedly lower result. And further he is reported to have compared the death-rate of the several hospitals, not only for different years, but for different numbers of years. In the table for Leeds he includes six years, for the smaller hospitals from four to six years, while for the Birmingham hospital he includes a period of sixteen years. The effect is that the death-rate of the latter hospital for a long period —a considerable portion of which was prior to the reconstruction alluded to—is compared with the mortality of a few recent years in entirely new hospitals. This mortality still continues to decrease, so that a comparison with the Leeds Infirmary for the year 1876 shows a marked difference in favour of the Birmingham hospital, and the records of the present year show a result still more favourable. The Committee of that institution express their belief that at the present time no hospital in England is more healthy, and that there is none where a patient suffering from severe accident or operation is more likely to recover. If Mr. Lawson Tait has really fallen into error in his statements on this subject, he will doubtless rectify them when his attention is called to the matter.

At the Portsmouth Hospital Saturday dinner, given by the Mayor of that town last week, it was announced that the gross amount received was £364, the expenditure requisite to realise this sum having been about 8 per cent.; last year the amount collected reached only £239, so that the present result may be looked upon as satisfactory. The result of the recent Hospital Sunday collection in Dover shows a total of £232 17s. for distribution amongst the local institutions for the relief of the sick.

A curious misunderstanding seems to have arisen between the Dorset bench of magistrates and Mr. Howard, the coroner for Portland, on the subject of the inquests held by the latter gentleman on the bodies of some of the unfortunate sufferers in the recent collision between the *Avalanche* and *Forest*. Mr. Howard's costs have been disallowed, and he has applied to the magistrates for advice on the subject. At the Dorset Quarter Sessions, held last week, Viscount Portman, the chairman, observed that it appeared to him that they had a very important question to decide, which he thought ought to be carefully considered. The standing order stated that no costs of inquests should be allowed on dead bodies cast on shore, manifestly drowned on the high seas. That standing order was founded upon a decision of the Court of Queen's Bench, the name and title of which was given in their standing order. It appeared quite impossible for them to justify payment of any sum for holding an inquest upon any body which had manifestly been drowned on the high seas, and therefore

he thought the Finance Committee had acted wisely in desiring Mr. Howard to show cause for his demand. It would be necessary that the case should come before the clerk of the peace, so that he might search the law books; and if Mr. Howard could produce any judgment subsequent to this, to alter the law, then he might show some cause for his demand. In case the law had not been altered since this standing order was made, he (the chairman) held that the Court could not be called upon to pay out of the county rate any sum for holding an inquest on a dead body cast on shore manifestly drowned on the high seas. In the interests of maritime parishes it is highly important that this point should be authoritatively settled, as it is certain that the decision of the Court of Queen's Bench on this subject, referred to by the Dorset magistrates, is not generally known.

Dr. Lawrence-Hamilton, who has warmly taken up the subject of "Art in Hospitals," has designed a picture-frame to meet the objections which have been advanced on the score of hanging prints and pictures collecting dirt. The frame is constructed of metal, and is intended to hold two pictures back to back, which are to be well glazed or varnished to do away with the necessity of a glass covering. It is proposed that each frame should be reversed at intervals, which would give a change of picture and insure a periodical cleansing, and they are stated to be extremely cheap and durable. It is to Dr. Lawrence-Hamilton that the suggestion is due of acquiring the site of the now defunct Cremorne Gardens for the formation of a hospital standing in its own site, instead of being closely surrounded by other buildings, as is the case with most of our metropolitan hospitals. The subject is worthy attention, but we fear its un-central position, to say nothing of the large outlay such a scheme would necessitate, preclude any possibility of converting Cremorne Gardens to so useful a purpose. Dr. Lawrence-Hamilton seems very active in meddling with other people's affairs.

The Statistical Society has announced that the Howard Medal will be awarded in November, 1878, to the author of the best essay on "The Effects of Health and Disease on Military and Naval Operations." The essays are to be sent in before June 30 next; and the Council have decided to grant the sum of £20 to the successful competitor in addition to the medal. Further particulars or explanations may be obtained at the office of the Society.

We are informed that Mr. Brudenell Carter has resigned the Surgeoncy to the Royal South London Ophthalmic Hospital.

THE INFLUENCE OF THE WAR ON THE HEALTH OF RUSSIA.

In an article on the "Dearth of Doctors," the *Globe* says it was a fact well known in Russia previous to the outbreak of hostilities that the supply of doctors fell far short of the actual needs of the empire. This deficiency is now aggravated by the departure of the *élite* of the medical profession for the seats of war, while the doctors at home have left their ordinary duties to wait upon the large numbers of sick and wounded soldiers at present located in various parts of the interior. The public are thus compelled in many places to prescribe for themselves, and their empirical treatment—by no means successful at the best of times—has been rendered all the more uncertain by the prodigious spread of epidemics. Official reports issued by the Municipal Council of St. Petersburg place the death-rate of the capital for the past quarter as high as 35 per 1000, at Moscow 38, and in the southern towns from 40 to 45—a mortality surpassing that of India during the most unhealthy seasons. Scarlet fever, small-pox, and cholera are the diseases most prevalent, and, if anything, they rage with greater intensity in the country than in the towns. This great mortality is largely due to the utter neglect of the most simple laws of sanitary science on the part of the Russian peasants, who thereby lay themselves open to the reception of every epidemic that passes over the land. These evils are of course largely increased by the removal of doctors from the provincial towns to the military hospitals, and still more so by the careless manner in which the invalids from Bulgaria are being transported through the country. Unless the reports in the Russian press are greatly exaggerated, train-loads of men suffering from typhus fever, small-pox, and other malignant diseases daily pass along the lines, and stay for hours in the stations, without any attempt being made by the authorities to prevent the spread of infection. According to the reports received from Bulgaria, the medical staff of the Russian troops there consists of 849 doctors, 3285 assistant-surgeons, and 146 chemists, besides the sanitary corps of the guards, the doctors of the Red Cross Society, and the sisters of charity. A telegram to the Russian paper the *Golos* further states that typhus fever and dysentery have broken out among the Montenegrin soldiers at Nicsics, and have already decimated the garrison there. In many other places in the principality epidemics have also made their appearance, and, as there is a dearth of doctors and of medical stores, fears are entertained that the country will be ravaged by disease. After making due allowance for exaggerated statements, it is evident that the present war is responsible for more evils than the loss of life by actual fighting, and its effects are likely to be felt, in the shape of transmitted disease, through many of the remoter portions of Russia.

THE HEALTH OF ST. GILES'S DISTRICT.

In his sanitary report on the St. Giles's District for the year ending March 25 last, Mr. Samuel R. Lovett, the Medical Officer of Health for the district, calls attention to the fact that scarlet fever was very prevalent among the children of persons residing over stables; and after careful inspection, he noted certain circumstances which may probably account for outbreaks of this disease in similar localities in other districts. Many of the houses he found to be defective in through ventilation; the mews in which they are situate being "no thoroughfares," the current of air was unable to pass freely as in streets open at both ends. The houses had windows and doors in front only, and no opening at the back, sides, or top. The water-supply was mostly from a tank, partly underground; the pails used by the grooms to obtain water were dipped into the tank, and the water for domestic purposes was obtained from the same tank by the same means, the water becoming thereby contaminated. In many cases where the tanks were not underground, they were too close to the water-closet. The pebble paving of the mews, also, held offensive matter between the stones, from which noxious gases were evaporated, so that robust health was impossible under such a state of things. Mr. Lovett records the case of a woman in his district who removed her child from the London Fever Hospital before the infectious period of scarlet fever had passed away or the clothes had been disinfected. The woman was eventually charged with this offence, and fined, but the case elicited an important statement from the medical officer of the London Fever Hospital, to the effect that whilst the authorities of that Hospital were powerless to detain their patients under such circumstances, the hospitals under the control of the Asylum Board had full power to prevent their removal without an order from the medical officer. The attention of the Home Secretary and the President of the Local Government Board was subsequently called to this important fact. Mr. Lovett further remarks that his district is in urgent need of a proper mortuary for the reception of the dead, and in such a central and populous parish it is somewhat singular that steps have not already been taken to supply so necessary a building, with all its proper appurtenances for holding post-mortem examinations and coroners' inquests.

THE BRISTOL SCHOOL OF MEDICINE.

The Students' Registration List at the Royal College of Surgeons gives eleven as the number of new students entered this year at the Bristol School of Medicine. This number, small as it seems, cannot be looked upon as bad, considering the very evil fortuue that has, it is said, of late befallen the students of that School at the examinations of the Royal College of Surgeons. We have heard that on a very late, if not on the latest, occasion when Bristol students were examined by that august body, 80 per cent. of them were rejected; and if that, or anything very near it, is true, there can be no doubt that it demanded some attention and consideration from the Council of the College. We are not surprised, therefore, to learn that the Council have had before them the question whether they should not exercise their power of visiting and inspecting the School. But the Faculty of the School have represented that the School has for some time been in a trausitional state, which is now at an end, as the School will henceforth be conducted as a department of the newly established Uuiversity College of Bristol; and this fact, together with a suggestion or suspicion that some other, also special and temporary, conditions may have exercised an unfortunate influence upon the success of the students, has induced the Council to resolve that they will not at present take any action with a view to an inspection of the School, but that at the end of the present winter session the Faculty of the School shall be required to report upon the steps which have been taken by them to carry out the amalgamation with University College, Bristol, and on the materials and arrangements which the School shall then have for the effective instruction of students; that such report shall be accompanied by returns showing the several courses of lectures which shall have been delivered at the School in this summer session, mentioning the date, duration, and subject-matter of each lecture, the number of students entered for each class, and the average attendances at each course; that such report shall also show what examinations have been held in each class, and by what average number of students the examinations of each class have beeu attended; what arrangements there are for superintendence, instruction, and examination in the dissecting-room; what subjects have been received for dissection during the session, aud how many students have taken part in dissecting them. The report, when received, is to be submitted to the Council, that they may then determine whether or not to take further steps in the matter, and as to the future recognition or non-recognition of the Bristol School of Medicine. Considering how many good men there are on the staffs of the Royal Infirmary and the General Hospital, from both of which institutions the teaching staff of the School is formed, we think the Council have decided wisely, both in granting a time of grace, and in hinting in the plainest terms what will be the result if they do not receive a satisfactory report. But we trust that a brighter and more prosperous future awaits the Bristol School of Medicine. The Royal Iufirmary and the General Hospital together contain more than 400 beds; each contains a library and a museum, aud offers valuable prizes and scholarships; aud there have beeu, and are, eminent and well-known men on the medical and surgical staffs of each institution. Bristol ought, therefore, to have no difficulty in supplying a really good and efficient medical school for the West of England.

THE CONJOINT EXAMINING BOARD FOR ENGLAND.

A meeting of the Conference of the Representatives of the Medical Authorities concerned in the formation of the English Conjoint Examining Board was held at the Royal College of Surgeons on Tuesday last, when it was resolved that the various medical authorities should be requested to elect respectively their representatives on the Committee of Reference. We suppose that this was virtually the last meetiug of the Conference, as, when the Committee of Reference has been elected, all the power of taking the next steps necessary for the formation of the new Examining Board will be in its hands, and the Conference of Delegates or Representatives will have ceased to exist. It will be remembered that the Committee of Reference is to consist of two representatives from each of the universities and medical corporations of Englaud; and it may be expected that in many instances the medical authorities will elect on the Committee the men who have represented them on the Confereuce; so that in some, and not improbably in a large, measure the latter body will be merged in the former. The Committee of Reference will possess very large and important powers: they have to nominate the men who may be appointed examiners on the new Board; they have, subject to the approval of the medical authorities, or of the majority of them, to arrange and superintend all matters relating to the examinations; and they have to consider such questions iu relation to the examinations as they may think fit, or as shall be referred to them by any of the co-operating medical authorities. Too much consideration aud care cannot, therefore, be given to the selection of the men who are to constitute such a body, and the authorities will, we should suppose, uaturally desire to elect on it the men who, having already represeuted them in various committees and conferences in connexion with the subject, are most intimately acquainted with the whole history of the Conjoint Scheme—with the causes of its failures, and of its fiual formation. But very possibly some of those men may shrink from the demands that the work of the Committee would make on their time, while some of them may aspire to be on the new Board of Examiners; and uo member of the Committee will be eligible for nomination as an examiner. The first duty of the Committee will be the *nomination* of double the number of persons required to be appointed as examiners, the *appointment* itself being vested in the three medical corporations—the Royal Colleges of Physicians aud of Surgeons, and the Society of Apothecaries; so that, in all probability, a considerable time will pass before the new Board actually comes into existence, and a long time must lapse before students can be required to present themselves for examination by it. It is to be remembered, also, that some legal difficulties regarding it—as respecting the admission of female medical students, for instance—have still to be settled.

THE HEALTH OF LONDON.

The Registrar-General's Return of deaths in London for the week ending October 20 shows an increase iu the rate of mortality. The annual death-rate from all causes, which in the four previous weeks had steadily increased from 17·4 to 19·5 per 1000, further rose last week to 20·7. To the seven principal diseases of the zymotic class 214 deaths were referred, against 153 and 195 in the two preceding weeks. Scarlet fever is spreading, 68 deaths having occurred from it, against 38 and 50 in the two preceding weeks; and the Metropolitau Asylum Hospitals and the Loudon Fever Hospital contaiued on Saturday last 139 scarlet fever patients, against 123 at the end of the previous week. The deaths referred to fever, also, which had been but 19 and 29 in the two preceding weeks, further rose to 47 last week, a number exceeding that returned in any week since October, 1873, and 10 above the corrected weekly average; 5 were fatal cases of typhus, 36 of enteric fever, and 6 of simple continued fever. The 5 deaths from typhus occurred in St. Mary's Hospital, admitted from Silvester-mews, Kensington; at 9, Albert-place, Hammersmith; at 10, Mead's-place, Hackney; at 48, Farringdon-buildings, Clerkenwell; and at 20, London-street, Southwark. The 36 deaths from enteric fever included 4 in Islington, 4 in Hackney, 2 in St. Giles's, 2 in Mile-end Old Town, 2 in Bow and Poplar, 3 in Lambeth, and 2 in Battersea. The fever

patients in the Metropolitan Asylum Hospitals and the London Fever Hospital rose last week from 92 to 114. The deaths from small-pox declined again from 14 to 8, all of which were recorded in the Metropolitan Asylum Hospitals; 4 of the fatal cases were certified as unvaccinated, and the other 4 (all adult cases) as vaccinated. The number of small-pox patients in the Metropolitan Asylum Hospitals, which had been 137 and 144 at the end of the two preceding weeks, rose to 153 last week; and the new cases admitted were 42, against 28 and 45 in the two preceding weeks. The deaths referred to diseases of the respiratory organs, which had steadily increased during the seven preceding weeks from 108 to 259, rose last week to 297, and exceeded the corrected weekly average by 45; 178 resulted from bronchitis, and 89 from pneumonia. The Registrar-General records, also, a death on the 13th inst., in Guy's Hospital, from hydrophobia; and remarks that "this is the thirteenth fatal case of hydrophobia which has been registered in London since the beginning of this year, whereas only six were recorded during the year 1876, and the corrected average annual number during the ten years 1866-75 was less than four."

KING AND QUEEN'S COLLEGE OF PHYSICIANS IN IRELAND.

The annual stated meeting of the College was held on the feast day of St. Luke the Evangelist, Thursday, October 18, 1877. The following officers for the ensuing year were appointed:—*President:* Samuel Gordon, M.D. Dub. (this being Dr. Gordon's third year of office). *Censors:* James Little, M.D. Edin. (*Vice-President*); Thomas Wrigley Grimshaw, A.M., M.D. Dub.; Wensley Bond Jennings, B.A. Dub.; George Frederick Duffey, M.D. Dub. *Registrar:* John Magee Finny, M.D. Dub. *Treasurer:* Aquilla Smith, M.D. Dub. *Examiners in Midwifery:* Edward B. Sinclair, M.D. Dub.; Fleetwood Churchill, jun. *Professor of Medical Jurisprudence:* Robert Travers, M.A., M.D. Dub. *Representative on the General Medical Council:* Aquilla Smith, M.D. Dub. *Agent to the Trust Estates:* Charles U. Townshend. *Law Agent:* Charles Woodward. *Librarian:* Hugh J. Fennell. The following Licentiates of the College were on the same occasion elected to the Fellowship:—Arthur Vernon Macan, M.B. and M.Ch. Dub., 1868, and M.A.O. Dub., 1877; Stephen Myles MacSwiney, M.D. St. And., 1847.

NEW SANATORIUM AT LUXOR.

We have received from Messrs. Cook notice of a very spirited venture which they are about to make in the shape of an hotel at Luxor. In so doing Messrs. Cook naturally seek the support of the medical profession. For certain cases of early phthisis and of bronchial catarrh, such a place, if well appointed and liberally managed, will be a great boon. We confess to considerable satisfaction that Messrs. Cook have secured the medical skill of Mr. J. E. Maclean. Mr. Maclean, besides having taken good degrees at the University of London, has, to our knowledge, held valuable resident posts at University Hospital, and appointments also at the Ophthalmic Hospitals at Moorfields and Westminster. The knowledge that a carefully educated and competent medical man is at the disposal of any invalids who may be sent to Luxor will greatly increase the confidence of doctors in the place. Mr. Maclean, we are informed, leaves England this week, and we heartily wish him success in treating a goodly number of patients at this new sanatorium.

MIDLAND MEDICAL SOCIETY.

At the annual meeting of this Society, held in Birmingham, October 19, the following officers were elected:—*President:* Dr. Sawyer. *New Members of Council:* Mr. Bartlect, Mr. Berry, Mr. Ross Jordan, Dr. Russell, and Mr. Watkin Williams. *Treasurer:* Mr. Harmar. *Secretaries:* Mr. Thomas and Dr. Savage.

ROYAL COLLEGE OF PHYSICIANS, LONDON.

The Lumleian Lectures, at the Royal College of Physicians, for the ensuing year, will be given by Dr. Bucknill; the Croonian, by Dr. Pavy; and the Gulstonian, by Dr. Ferrier; and Dr. Burdon-Sanderson has been appointed to deliver the Harveian Oration.

ELEPHANTIASIS IN CHINA.

The following interesting remarks and cases relating to elephantiasis in China are from the able pens of Drs. Jamieson of Shanghai, and Manson of Amoy, respectively. They were originally printed in a most heterogeneous publication called the *Customs Gazette*, circulating among the European inhabitants of the Chinese treaty ports. This little-known periodical often contains much valuable matter; and we propose from time to time to lay before our readers certain extracts of more than local importance. Dr. Jamieson writes:—

A-cho, a female, aged twenty, was admitted to the Gutzlaff Hospital on July 14. She was a native of a marshy district near Paoshan, but had never suffered from fever. Catamenia appeared at fifteen, and have continued regularly ever since. Eight years ago, elephantiasis attacked the right leg, invading first the foot and toes, and three years later the thigh. Her father states that the disease is very common in his neighbourhood, but that the leg only is attacked. His daughter's case is the only one he knows of where the entire lower extremity is affected.

On examination, the left side was found perfectly healthy. The right leg was enormously enlarged, the hypertrophy of the skin being clearly defined by the fold of the groin. There was a marked contraction above and below the knee; the leg in the region of the calf, and the foot, were elephantine, but the ankle and the base of the toes were contracted. The skin was of natural warmth (to the touch), but livid, hard, thick, and covered with scales formed by the drying of a serous fluid which exuded from the surface of the limb, mingled with cast epithelium. The skin could not be made to glide over the deeper structures. The entire limb constituted an enormous almost shapeless mass, in which it was impossible to discover the pulsation of any artery. The femoral could be faintly felt at the brim of the pelvis. At the level of the ankle, on the posterior surface, was situated an elliptical ulcer, four centimetres long by seven centimetres wide, from which there was a profuse discharge of a serous or lymphous fluid, mingled with pus cells, corpuscles, and epidermic scales. The discharge amounted on an average to a quarter of a litre in the twenty-four hours.

An attempt was made to carry out Hebra's treatment by warm baths, inunction of mercurial ointment, and an elevated position of the limb. The two former were done conscientiously, but it was impossible to get the patient to lie down with the leg raised, except during the period of the daily visit. The following were the measurements (in centimetres) taken on the day of entry and eighteen days later:—

Circumference round—	Left side.	Right side. July 21.	Right side. August 1.
Base of toes . . .	18	20	21·5
Ankle	20	31	31
Calf	28	55·5	56
Below knee . . .	26·5	40	41·5
Above „ . . .	31	52	52·5
Middle of thigh . .	57	85·5	86
Level of great trochanter	44·5	75	75

It will thus be seen that the limb was steadily enlarging in spite of the treatment. The girl was extremely anxious to have anything done short of amputation. The risk and uncertainty of the operation of tying the external iliac were explained to her, but she only stipulated that in the event of her dying her funeral expenses should be defrayed. Accordingly, at 3 p.m. on August 1, a purgative enema having previously been given, and the bladder emptied, I ligatured the right external iliac according to Liston's method. There was no difficulty encountered. Immediately upon knotting the ligature, the entire limb became of a marbly white colour. At the expiration of half an hour, the skin on the operated side was sensibly warmer than that on the left. The right leg was

enveloped in cotton, 2·5 centigrammes of morphia were injected into the arm, and the patient was laid on a fracture-bed. Next morning the patient said that she had slept well, but was made uncomfortable by the strips of adhesive plaster by which the wound was supported. The temperature in the mouth was 37·25° C. She had emptied her bladder twice. In the evening there was a rise of 1·4° C. The wound appeared about to unite by first intention. Morphia injection repeated.

On August 3, at 2 a.m. (thirty-four hours after the operation), the limb became painful, and the toes cold and livid. A similar dose of morphia was injected, and hot bottles laid round the leg. The temperature of the thigh had not fallen. By the afternoon the leg was warm again; there was no pain; the patient was calm, and satisfied with her condition. She had eaten a bowl of rice with mutton-broth. At 7.30 p.m. she suddenly became breathless and cyanosed, and died in less than five minutes.

It seems probable that the initial rise of temperature on the operated side, and the retention of at least a natural degree of heat for thirty-four hours after ligature of the artery, were due to molecular changes in the tissues of the leg—in fact, to the commencement of disintegration or decomposition. This, however, was not sufficient to maintain the skin heat for any longer time, and then the effect of interrupted blood-supply declared itself. The collateral circulation must have been established by the afternoon, when the limb was again warm; and one of its earliest effects was to wash a clot out of one of the veins and carry it on to the right heart. There was no post-mortem, but the history points clearly to this as the immediate cause of death.

In this case death must undoubtedly be attributed to the operation. The patient might have lived miserably for some years, but at all events she would probably have lived. On the other hand, she knew the risk and was willing to take it. However, this case once more raises the question whether ligature of the main vessel in elephantiasis is justifiable in itself. Carnochan, of New York, first suggested it in 1851, and announced a cure. It has since been practised with varying success by Butcher (of Dublin), Richard (of the Hôpital Cochin), Fayrer, Bryant, Bochard, Baum, Simon, and others. Up to 1872, twenty-eight cases were recorded, in the majority of which the result was negative, while in a few there was marked diminution of the hypertrophy, and in one or two cases there would seem to have been actual cure (Vanzetti, *Gaz. des Hôp.*, December, 1867, page 572). A summary of the history of the operation up to date will be found in the *Révue Médico-Photographique des Hôpitaux de Paris*, 6me année (1874), page 121. More recently Wernher (*Deutsche Zeitschr. f. Chir.*, 1875) cites thirty-two cases in which ligature gave variable results. Fayrer, Simon, and Demarquay pronounce decisively against it—the last, I think, on theoretical grounds; the two former in consequence of their failures. As the statistics stand, and without taking any account of the pathology of the disease, there seems no reason why each surgeon should not exercise his individual judgment. Obviously this is not the place for a discussion of the pathology of elephantiasis Arabum, which can be found in many books. The latest investigations are summarised in the *Archives Générales de Médecine*, 1876, vol. ii., page 100. But after carefully perusing this summary, in expectation of light to be thrown on the treatment, my impression is that the propriety of ligature is still an open question, only to be decided by its results.

Dr. Manson says, in reference to deaths occurring after operation for elephantiasis scroti :—

We regret to have to record two deaths after this operation. They are the first which have occurred in a long series of cases, now sixty-one in number.

The first death was attributable to pyæmia. The patient, from whom a tumour of some ten or fifteen pounds weight had been removed, did well for more than a week after operation, and a considerable portion of the wound had healed by adhesion, when sloughing of the tissues about the inguinal canals along the track of the spermatic cords, and symptoms of pyæmia, set in. The weather was very warm, and the hospital crowded at the time. In the same ward a man was dying from pyæmia following putrid suppuration in a chronic abscess, and we believe a careless dresser had carried contamination from this patient.

Pyæmia, erysipelas, and allied diseases, are fortunately very rare, notwithstanding the overcrowding, the great number of open suppurating wounds, and the imperfect sanitary condition in the native hospital. Another instance occurred this year. It followed on a very simple operation—tapping for hydrocele. The patient had a big spleen, and on that account should not have been operated on. Strangely enough, he occupied the same place in the ward as the fatal chronic abscess case. The bed, however, had been sunk in salt water for some days, and thoroughly cleansed.

The second fatal elephantiasis case had been operated on before. His first operation is recorded in the *Customs Medical Reports*, No. 3, page 32; case 8. At that time a tumour weighing 51 lbs., with very extensive attachments, was removed. Unfortunately the disease returned in the skin around the cicatrix, and when we saw him this autumn it had developed into two enormous masses extending from near the umbilicus far back on the gluteal region. Between the lobes was the healthy cicatrix of the previous operation, with the glans penis about its centre. The man was very thin, and had an intermittent pulse and other signs of heart disease. We were very averse to operating, but he was so urgent and anxious for something to be done to relieve him, that after preparatory treatment by tonics, quinine, and good feeding, we removed the whole mass, including both testicles. These latter could not be preserved, as there was no guide to their position in the tumours, and the fear of a heavy loss of blood forbade a prolonged search for them. The penis was not cut away. The combined weight of the two lobes amounted to twenty-seven pounds. As a necessary consequence of so extensive an operation, a very large raw surface, quite fifteen inches by ten inches, had to be left to heal by granulation. The patient rallied completely from the shock, his appetite became vigorous, his spirits rose, and granulation and contraction fairly began. On account of the amount of discharge and the great risk of contamination, he was removed after a week to a large airy verandah. The weather was warm at the time. In about ten days from the date of the operation, symptoms of tetanus set in, which, in spite of treatment, proved fatal after a fortnight. We can attribute the tetanus and fatal result in this case only to one of two things—either irritation of the spermatic nerve by a ligature which in the hurry of operation had been placed on the left cord, but which came away three or four days after its application; or to chilling of the wound by a squall of wind that came on suddenly one night after he had been removed to the verandah. We have as yet had no death immediately attributable to the operation itself.

Alcoholism in France.—In a paper on this subject, presented to the Académie de Médecine by M. Lunier, he observes—1. That wine is the true national drink, of which the mean annual quantity consumed during the last ten years has been 50,000,000 hectolitres—about 120 litres per inhabitant per annum. 2. The consumption of cider has diminished during the last twenty years from twenty-four to twenty litres per inhabitant. This is not to be regretted, as the ciders are of bad quality, leading to the taking of much brandy in order to digest them. 3. The consumption of beer has been constantly increasing, so that it has augmented from about 8·25 litres in 1825 to about twenty-two litres at the present time. 4. The consumption of alcohol has progressively increased during forty years: it was two litres per head in 1839, and is now nearly three litres. 5. The departments which consume most alcohol are those which do not consume wine. The contrast in this respect is most striking. Very little wine even is drunk in the departments where brandy is produced from wine. 6. The statistical facts confirm the opinion of M. Bergeron in 1870, that the alcohols of commerce are more mischievous in their action than those from wine. 7. As respects accidental deaths due to excess of drink, they are, for the most part, met with in the departments which consume most alcohol. They rarely occur in those in which most wine is drunk. 8. The results of the application of the law on drunkenness tend to the same conclusion. Prosecutions for drunkenness have been five times more numerous in departments which chiefly consume alcohol than in those which principally consume wine. 9. It is the same with cases of insanity due to alcohol, the proportion of these being almost everywhere in direct relation to the consumption of alcohol, and especially the alcohol of commerce. Almost the only exception is in La Vendée and Charente Inférieure, where white wines are almost exclusively consumed, these being as dangerous in this relation as eau-de-vie.—*Gaz. Hebd.*, October 19.

FROM ABROAD.

The University of Brussels.

It is gratifying to find that, notwithstanding all the efforts made and slanders circulated by the Ultramontane party (nowhere so rampant as in Belgium), this "free" University is pursuing a prosperous career. On the opening of the scholastic year 1877-78, M. Van Schoor, the Administrative Inspector, announced that the number of students registered during the academic year 1876-77 amounted to 877—viz., in the Faculty of Philosophy and Letters, 86; in the Faculty of Laws, 228; in the Faculty of Sciences, 178; in the Faculty of Medicine, 281; and for the Polytechnic School, 104. And this is no accidental success, for the number entering the University—in part in consequence of the great exertions made by the professors, and in part as a result of the war which the Ultramontanes have declared against lay teaching of any kind—is continually on the increase. Thus, in 1874 there were 537 students; in 1872, 583; in 1873, 594; in 1874, 686; in 1875, 715; and in 1876, 773. Besides these figures, which relate only to the four faculties, there have to be added since 1874, when the Polytechnic School was founded, 101 pupils for that year, 106 for 1875, and 104 for 1876, making a total for each of these years of 787, 821, and 877 students. This progress is in nowise due to laxity of the examinations, the proportion of rejections having sensibly increased this year, the professors being determined that the diplomas of the University shall not protect incapacity for fulfilling the functions of the State or undertaking the duties of the professions for which they are understood to offer solid guarantees.

Gonorrhœal Rheumatism.

From a clinical lecture by Prof. Gosselin on this subject, reported in *Gaz. des Hôp.*, No. 108, we take the following observations:—

A man, aged eighteen, was admitted to the Charité with acute pain in the right knee, accompanied by swelling and considerable effusion. The pain dated back five days, came on suddenly, without prior rheumatic history, and rapidly acquired its present intensity. Appetite and sleep had disappeared, and yet, in contrast with such an assemblage of symptoms, there was but little fever. The sudden appearance and rapid succession of these phenomena are to be noted as only occurring in two affections—ordinary rheumatic arthritis, and blenorrhagic arthritis. In the former of these it is rare to find such excessive pain and considerable swelling, and especially is it so for these to persist five days in one important joint without other joints being also affected. Even if other joints now become implicated, still the fact of this condition having persisted for five days shows that the case is not one of articular rheumatism. This localisation in one joint is a character of gonorrhœal arthritis; and on examining the man's urethra, obvious signs of inflammation were found. But in this man the gonorrhœa only dated a week back, while gonorrhœal arthritis usually appears only at about the fifteenth or twentieth day.

Much discussion has taken place in recent times as to whether such an affection as "gonorrhœal arthritis" really exists—that is, whether there is an articular affection having a special connexion with gonorrhœa, or whether the affection is not merely an attack of articular rheumatism coinciding with the urethral lesion. Lorain even maintained that there is a variety of rheumatism that coincides with a disease of the genito-urinary organs, and which he termed "uro-genital rheumatism." Both doctrines, in fact, are well founded, for it is indubitable that acute articular rheumatism may occur in the subjects of gonorrhœa, without our being able to say that the gonorrhœa has exerted on them the slightest influence, and which pursue their course just as do cases of ordinary acute rheumatism. Like in this, it may affect the heart and its membranes, and may terminate in the return of the parts affected to quite a normal condition. But there are excellent reasons for admitting that there is also an arthritis intimately connected with gonorrhœa, and due to a special intoxication proceeding from the urethra, the effects of which are manifested on an articulation. This is a theory not demonstrable, but it is a fact that there is a variety of arthritis proper to the subjects of gonorrhœa, and which differs essentially from other articular rheumatisms. It is characterised by its sudden onset, and the rapid appearance of the signs of severe inflammation, very great heat and swelling, the severest pain, and localisation in one joint, or, if several joints are affected, one of these (usually the knee) suffering with peculiar intensity. These inflammatory phenomena also present this peculiarity, that they are not in general complicated by cardiac lesions. Another characteristic of this special arthritis is that it is of much longer duration than acute rheumatism. While the latter may last for fifteen or twenty days, gonorrhœal arthritis will persist for ninety, one hundred, or one hundred and twenty days. The former terminates by resolution, leaving no traces of its presence in the joints; while the latter often ends in anchylosis. Congestive at first, it becomes plastic, giving rise to neo-membranous exudations, which become organised within the joint and in the substance of the synovial membrane, and are accompanied by destruction of the articular cartilages. Another characteristic is, especially when the knee is the seat of the arthritis, that it is very often accompanied by flexion of the joint, which, if not guarded against, leads to deformity of the limb. This vicious attitude, due to muscular contractions plays a very important part in the disease, disposed as it is to terminate in anchylosis. All these conditions existed markedly in the patient under consideration, except the muscular contraction, the absence of which was probably due to the recent occurrence of the affection. In him the pain especially was extremely severe, resisting all the various means employed for its relief. In many cases it thus resists the action of narcotics, and always returns very quickly after the operation of these has been exhausted.

It is of great importance that we should recognise this gonorrhœal form of arthritis, in order that it may be effectually treated. When, for example, it affects the hip-joint, it may lead to a spontaneous dislocation in consequence of enormous amount of effusion which accompanies it, and the which, unfortunately, it is impossible to ascertain. The researches of Petit, Bonnet, and Parise have sufficiently proved the possibility of this accident for our attention to be aroused in regard to it. What is of equal importance to be understood is that the pain may lead to a contraction of the muscles, which will give to the limb a vicious position; and, if we do not take care, it will remain fixed in such position, owing to the tendency of this variety of arthritis to terminate in complete or incomplete anchylosis, abolishing or diminishing the movements of the limb. What is to be done, then, in order to relieve the pain and prevent this termination? The first thing is to secure rest in a good position; and to this end the limb in this case has been rendered immovable on a splint, so as to prevent flexion. And it is perhaps because the limb has been placed in this forced extension that the patient complains of such excessive pain. It is certain, in fact, that flexion mitigates the pain; and it is in order to relieve this that patients instinctively adopt this vicious position. In these cases, also, Prof. Gosselin is in the habit of applying leeches, and would have resorted to them in the present one but for the fact that erysipelas was prevailing in the ward. He therefore substituted cupping, which is less often followed by this complication. The pain will be combated with narcotics, and especially morphia injections; and if the suffering is not abated, and seems to be connected with the enormous swelling due to the great effusion, puncture of the joint, as advised by some surgeons, may be tried. This is a procedure, however, which Prof. Gosselin has never yet had recourse to, fearing to add to the existing malady a traumatic lesion which might, in certain cases, favour the passage of a simple congestive to a purulent form of synovitis. Still, as this form of arthritis has very little disposition to terminate by resolution, the operation may be undertaken without much fear, care being taken to close the aperture and exert slight compression on the joint by means of a layer of cotton and a bandage. Moreover, copaiba, cubebs, and alum have been given to this patient, as to the ordinary subjects of gonorrhœa, in the hope that, by modifying the nature of the urethral discharge, the arthritis dependent on the urethra might also be at the same time modified. This, however, is a purely theoretical way of proceeding, and Prof. Gosselin is in possession of no fact which demonstrates in a positive manner its practical utility.

Discharge of Semen in Hanging.

In a paper published in the *Berliner Klinische Wochenschrift* (August 31), Dr. Müller-Benigna refers to a recent treatise by Dr. Huppert, which appeared in Eulenburg's *Vierteljahrschrift*, in which he comes to the conclusion, from his observations chiefly on epileptics, but also on persons hanged or who have died from suffocation from other causes, that the sudden and complete interruption of the access of air to the healthy respiratory and circulatory apparatus, occurring through the epileptic attack, in the process of hanging, or from other cause, may be attended with an effusion of semen into the urethra, although no ejaculation causes the expulsion of this. This he proves by an examination of the urine first passed after the epileptic paroxysm, and also from an examination of the contents of the urethra after death. Without expressing any opinion as to the regularity of this occurrence, Dr. Müller-Benigna reports a case which occurred a few years since confirmatory of the view.

A strong man, a prisoner, about forty years old, hung himself, and on inspection, about an hour after death, there was found neither turgescence of the genitals nor any moisture of the penis or surrounding part. At the autopsy, made twenty-four hours afterwards, at which all the signs of death from suffocation were very distinctly marked, there was also found under the urethral orifice about half a teaspoonful of seminal-looking fluid, which in the meantime had flowed out. Examined under the microscope, great numbers of spermatozoa in lively motion were observed, so that there could be no doubt as to the nature of the fluid. Had the first inspection of the body sufficed, or had the quantity of semen been so small as not to have issued from the urethra, then there would not have occurred any supposition that such effusion existed. This has probably been the case in many instances, and it certainly would be a matter of interest to examine the urethra in a great number of hanged persons, or of those who have died from other modes of rapid suffocation; and this may be very easily executed by making pressure along the course of the urethra from the perineum to its orifice, and examining by the microscope any fluid which issues.

There is nothing physiologically improbable in the position laid down by Huppert, that an effusion of semen takes place into the urethra in consequence of a sudden and complete interruption to the access of air. The semen, in consequence of the peristaltic movements of the vesiculæ seminales and vasa deferentia, is brought into the commencement of the urethra, whence it is carried on by the action of the bulbo-cavernosi and ischio-cavernosi muscles. Under the circumstances described, the peristaltic action of the vesiculæ is brought on by the suddenly induced venous condition of the blood—just as in suffocated animals the intestinal movements are accelerated—the muscular contraction not taking place.

A Sign of Hæmoptysis.—M. Constantine Paul observed at the Société de Thérapeutique that a sure prognostic sign of hæmoptysis is found in the recurrent pulse. If while the finger compresses the artery at the wrist, a pulsation is felt in the hand, we may feel certain that the patient will spit blood. During the last ten years that he has paid attention to the point, he has come to regard this sign as certain.—*Gaz. Hebd.*, October 19.

Paris Faculty of Medicine.—In addition to the regular courses of lectures at the Faculty for 1877-78, which we published last week, the following Professeurs-Agrégés have been appointed to undertake clinical courses:—M. E. Besnier, of the St. Louis, Diseases of the Skin; M. Archambault, of the Enfants Malades, Diseases of Children; M. Panas, of the Lariboisière, Diseases of the Eye; M. Tillaux, of the Lariboisière, Diseases of the Genito-Urinary Organs; M. Fournier, of the St. Louis, Secondary and Tertiary Syphilitic Diseases; M. Mauriac, of the Midi, Syphilitic and Venereal Diseases. It has been suggested that the two courses at the St. Louis ought to have been amalgamated, and a course on Diseases of Women given in lieu of one of them. The Director of the Assistant-Publique has also addressed a letter to the Director of the Salpétrière, requesting that two services of fifty or sixty beds each may be immediately provided at that Hospital, in order that Prof. Ball may commence his lectures on Insanity and on Diseases of the Nervous Centres. It is feared that these may somewhat interfere with the lectures delivered at that Hospital by Profs. Charcot and Voisin.

REVIEWS.

The Hair in Health and Disease. By E. Wyndham Cottle, M.A. Oxon., F.R.C.S. Eng., Senior Assistant-Surgeon to the Hospital for Diseases of the Skin, Blackfriars. London: J. and A. Churchill. 1877. Pp. 149.

This little volume is written "partly from notes by the late Mr. George Nayler." He had intended to produce a work of the kind, and had collected "much information" on the subject, when his death unfortunately stayed his labours. Mr. Wyndham Cottle, who had been a fellow-worker with him, has now completed alone what they had commenced together. A large portion of the volume is adapted, Mr. Cottle states, from the second edition of Mr. Nayler's work on Skin Diseases. The chapters of the volume treat of Alopecia, Canities, and Hirsuties, of the various forms of Tinea, of Pediculi, and of Hair Dyes. The book may be said, we suppose, to express the outcome of the observation and experience of Mr. George Nayler and Mr. Cottle, for scarce any notice is taken of other writers on the same subjects. A few foreign authorities are mentioned; but of living English writers Mr. Wilson alone, we believe, is even named, and that only in connexion with a case of canities exhibited by him at the Clinical Society.

Our Egyptian Obelisk: Cleopatra's Needle. By Erasmus Wilson, F.R.S. People's Edition. London: Brain and Co., Paternoster-row. 1877.

Mr. Erasmus Wilson, who never does anything by halves, is, *more suo*, not content with contributing with a magnificent generosity a few thousands sterling towards bringing "our Egyptian obelisk" to London, but he has also published this little pamphlet, to serve as an introduction of the obelisk, for the uses of the people. In the space of thirty-two pages he gives, with the aid of a few illustrations, a pleasantly readable and instructive description of Cleopatra's Needle, and a brief history of Egyptian monoliths in general. The *brochure* is extremely well and tastefully got up in every respect, and is a marvel of cheapness, its publishing price being only threepence. Mr. Wilson informs us that he has been led onwards, by an increasing interest in his subject, to write a fuller account of obelisks and their surroundings than he had at first contemplated; and that the publication of this only awaits the erection of Cleopatra's Needle in London. We trust that the public will soon be the happy possessors of both the famous Needle, and Mr. Wilson's "popular volume."

Archives of Dermatology. Vol. III., No. 3—April, 1877. L. Duncan Bulkley, A.M., M.D., Editor. New York: G. P. Putnam's Sons.

The April number of the *Archives* maintains the high standard of previous issues. It contains the details of a case of a bearded woman, by Dr. Duhring; a very good article on the nomenclature and classification of diseases of the skin, by Dr. Bulkley, "based on several modes of grouping diseases, etiological, clinical, pathological, and histological"; and, *inter alia*, an account of a method of tattooing small nævi, by Professor Sherwell, of Long Island Hospital Medical College, which may be useful in cases where the patients object to the radical cure by the galvanic cautery.

Under "Extracts and Translations" an excellent *résumé* of the present state of the doctrine of vegetable parasites of the skin, by Professor Moriz Kaposi, of Vienna, has been made available for English readers by Dr. Rohe, of Baltimore. The main argument of the article is that the idea of the identity of the fungi of favus, herpes tonsurans, and pityriasis versicolor is not supported by the scientific botany of the present day.

The digest of literature is, as usual, very complete, and we would especially direct attention to Section II., on Syphilis and Venereal Diseases, for valuable information on the hypodermic treatment of syphilis by mercuric albuminate and mercuric peptone, as proposed by Bamberger, of Vienna.

We hope the *Archives of Dermatology* will obtain in this country the support they well deserve.

Wyld's Famine Map of India.

We have received from Mr. James Wyld, Geographer to the Queen, of the Strand and Charing-cross, a map of India, showing the famine districts in the great famines of 1860-61,

1865-66, 1873-74, and 1877. The map does not show the limits of the provinces or the principal districts of the Indian peninsula, but it will be found very useful to all who desire to obtain quickly and easily a general idea of the relative positions of the districts affected by the famines mentioned. The existing railways are shown; and the population of each affected district, and its area in square miles, are given in round numbers, together with the average rainfall and some other meteorological data of importance and interest.

MANCHESTER.

October 24.

The New Infirmary Board—Opening of the Medical School—Meeting of the Medical Society—Alleged Death from Excessive Smoking.

The New Infirmary Board is the result of a compromise between the two opposing factions, the advocates and the opponents of removal. Though numerically equal, the parties are by no means evenly balanced as regards energy and business aptitude. The representatives of the outside party, or the non-removalists, are vastly more wideawake than the trustees who remain from the old Board to fight the battle of the removalists. The result of this is, that the Infirmary is forthwith to be enlarged and improved, and there is a danger lest the amount of money expended on these alterations should be so great as to afford a plausible excuse for delaying indefinitely the removal of the institution, which sooner or later is inevitable. The plain fact is that the present building cannot be enlarged sufficiently to meet the wants of the neighbourhood without completely occupying the Infirmary grounds, and building close up to the boundary-walls. This would be to deprive the city of a very large portion of the most valuable open space it possesses, and the merest tyro in sanitary science knows how important such air-purifying spaces are in the midst of a dense population. Our hopes rest, for the present, upon the restraining influence of the medical staff, with which, fortunately, the new Board shows every disposition to work harmoniously. Meantime, while the architects are preparing and presenting plans for the proposed improvements, and sub-committees are engaged in criticising and reporting upon them, the Board is resolutely setting to work to reduce the current expenditure. So thoroughly are these enthusiastic reformers bent upon this object, that even the supply of beer to the nurses has been made the subject of a special report, and the occasion of a somewhat amusing discussion. It is to be hoped that some of this newly found energy will be turned to account in speedily devising some plan for getting rid of the hideous wooden panic-sheds which were erected on three sides of the building in consequence of Mr. Netten Radcliffe's report. Originally intended to insure the immediate isolation of cases of erysipelas and allied affections, they are now used to a considerable extent as ordinary surgical wards—another proof of the utter inadequacy of the present accommodation.

The Medical School was opened this session without the usual introductory lecture. The predisposing causes of this innovation were, no doubt, the spreading conviction of the inutility of these addresses, and the example set by several of the metropolitan schools, and the exciting cause was the fearful uproar in which some of the students indulged during the "introductory" of last session. The registration for the winter session is highly encouraging, fifty-seven new students having entered their names.

The first meeting of the Medical Society for the present session was held on October 3, and several of the communications were of great interest. Dr. Dreschfeld showed two little boys, children of the same parents, suffering from sclerosis in patches, and gave a careful and concise account of the symptoms and pathology of that affection. Dr. Humphreys exhibited a younger child, in an earlier stage of the same disease, from the Sick Children's Hospital at Pendlebury. Dr. Ross showed a pathological preparation from a patient in whom a tumour of the cerebellum had been diagnosed during life. At the autopsy a glioma of the cerebellum was discovered, in the exact situation which had been predicted from the symptoms. Mr. Cullingworth briefly narrated two cases of abscess in both ovaries, and placed the preparations on the table. In one of the cases a large abscess of the right ovary had burst and discharged its contents between the peritoneal and muscular layers of the abdominal wall. The cavity thus formed extended above the level of the umbilicus, and from the anterior spine of one ilium to that of the other. During life it presented many of the signs of a suppurating ovarian cyst. The paper of the evening was read by Mr. Bishop, on the aid which may be derived, at the end of the first stage of labour, where the head has not yet descended, from irritation of the posterior vaginal wall by the fingers of the accoucheur. Vigorous uterine contractions are said to be capable of being thus induced by reflex action. It was pointed out by several subsequent speakers that the idea was not a new one, having been mentioned by Tyler Smith, Swayne, and others. Nevertheless, the Society congratulated Mr. Bishop on having re-investigated the subject, and tendered him a hearty vote of thanks for his paper.

An inquest, which has excited a good deal of interest, was held here four or five weeks ago (September 24), upon the body of a man, aged fifty-five, who had been found dead in bed. It was stated in evidence that the man had taken very little food, and had smoked to excess. A post-mortem examination showed absence of fat about the body, extensive disease of the heart and one lung, and corrugation (*sic*) of the stomach. The medical man who conducted the autopsy stated that the condition of the stomach was due to excessive smoking, and that death resulted from want of proper nourishment and poisoning by nicotine. The jury returned a verdict to that effect. Smokers became alarmed, and the agents of the Anti-Tobacco League were no doubt elated at the prospect of being able to add one more to their collection of deterrent anecdotes. In a few days, however, an able letter, pointing out the absurdity of the verdict, appeared in the *Manchester Guardian* from Dr. Dreschfeld, who some years ago was engaged in experiments on the physiological action of nicotine. He says, "None of these (specified post-mortem) changes have ever been traced to the inhalation of tobacco-smoke. . . . . Chronic nicotine poisoning from excessive smoking chiefly affects the nervous system, and produces symptoms which either leave no changes recognisable after death, or such changes as only a very minute examination can detect, such as alterations in the optic nerve and in the chemical reactions of the viscera. . . . . In this particular case there is no reason for attributing to nicotine any share whatever in causing death."

GENERAL CORRESPONDENCE.

"VIN DE BAUDON."

Letter from Messrs. Pagny, Wallace, and Co.

[To the Editor of the Medical Times and Gazette.]

Sir,—We regret that ignorance until to-day of the publication of Dr. Andrew Clark's letter in your issue of August 11 should have thus delayed the explanation due from us in respect to the use of his name in connexion with the "Vin de Baudon." Our advertisement is simply an abstract of the London Hospital Report published in your journal, and Dr. Clark's name being prominently connected with the case, and thereby made public, fully, we considered, justified us in appending it to our advertisement.

Had Dr. Clark made us acquainted with the facts of the case as stated in his letter, we should have rendered its publication unnecessary by having at once suppressed his name. We have apologised for having caused him unintentional annoyance; but as his letter as it stands is calculated to do us considerable injury, we beg you will favour us by publishing this explanation in your next issue. We are, &c.,

October 17, 1877. Pagny, Wallace, and Co.

CORRIGENDA.

Letter from Dr. Eugène Dupuy.

[To the Editor of the Medical Times and Gazette.]

Sir,—There are some clerical errors in my paper now in course of publication in the *Medical Times and Gazette*. It is through an inadvertence for which I am at a loss to account, and which I am glad to do amend for, for the sake of scientific accuracy, that the words beginning by "Portions of brain, etc.," lines 26, 27, and 28, column 2, page 85, have been incorporated in

the copy of my manuscript. They are to be considered "*non avenus*." Also page 86, the words "which had, etc.," to "knife, etc.," line 5, column 1, are "*non avenus*." Page 357, column 1, line 61, instead of "he begged," read "we beg." Page 358, column 2, line 11, after "brain" add "lesion." Page 358, line 15, after "influence" put a comma; instead of "C" put "c"; the sentence ends with "specifically," next line begins with "I," new sentence. I retain absolutely nothing of Dr. Bartholow's letter contained in your issue of September 29, except the notice of the errors above stated. I am always happy to rectify errors. The tirade contained in that letter of the Doctor on the humanitarian aspect of vivisection performed on feeble-minded people, and brutes of the lower species, I have no concern with. I believe that it is apparent for all that my meaning is to show that the Doctor's experiment could not be made to support the cerebral localisation theory, which I trust is now proved, and not to take him up as a very harsh man indeed.

I am, &c., EUGÈNE DUPUY, M.D.

37, West Thirty-third-street, New York, October 12.

REPORTS OF SOCIETIES.

THE PATHOLOGICAL SOCIETY.

TUESDAY, OCTOBER 16.

CHARLES MURCHISON, M.D., LL.D., F.R.S., President, in the Chair.

(*Concluded from page* 451.)

OBLITERATION OF THE AORTA.

DR. WICKHAM LEGG exhibited a specimen of obliteration of the aorta at the insertion of the ductus arteriosus. A man of twenty was brought dead into St. Bartholomew's Hospital. On examination the following condition was found:—The internal mammary arteries were as large as a goose-quill. The pericardium was full of blood from rupture of a dissecting aneurism of the aorta. The heart, which was of natural size, presented only two aortic valves. The aorta was much dilated, and highly atheromatous in its first portion; and gave off four branches above the point of obliteration, the last being the left subclavian, which took its origin from the constricted portion close above the obliteration. Below the seat of obliteration the aorta became of natural size almost immediately, large intercostal arteries springing from it. The ductus arteriosus was obliterated, but its attachment to the aorta would allow a fine bristle to be passed up for a line or two. The anastomosis between the internal mammaries and intercostals, and the mode of death, were usual in cases of obliteration of the aorta. Probably eighty cases of narrowing of the aorta were on record; but not more than fifteen of complete obliteration. With respect to the cause of this condition, some pathologists believed that the constriction arose in connexion with the closure of the ductus arteriosus post-partum; other pathologists believed that it was a congenital defect. In support of the former view there was the fact that in every case the constriction occurred at the insertion of the ductus arteriosus into the aorta, and also that in one instance the thrombus within the ductus was found spreading into the aorta. On the other hand, Rokitansky and Peacock contended that there was an original vice of constitution of the aortic arches in these cases. The ductus arteriosus was not always found closed, and probably did not close by thrombus, but by contraction. Dr. Peacock had further pointed out how frequently this contraction of the aorta was associated with some other congenital defect in the body, such as hare-lip, fissured-palate, and especially defects in the vascular system, such as imperfect septum ventriculorum, or defect in the number of the aortic valves—a defect present in Dr. Legg's case. The thymus gland was persistent in this case. Dr. Legg believed that both explanations might possibly apply in different cases.

DR. COUPLAND said that a similar case had been lately under observation at the Middlesex Hospital, and had been diagnosed multiple cirsoid aneurism in the back. The man died of fatty degeneration of the heart; and post-mortem a constriction of the aorta was found, not perfectly complete. Just below the ductus arteriosus it seemed as if a cord had been tied round the aorta. There was great enlargement of the aorta above and below. The first intercostal arteries were as large as the brachial, and the internal mammaries and other vessels were similarly enlarged.

MR. SYDNEY JONES said that he had shown a similar specimen at the Society twenty years ago, and briefly described it. In that case the transverse cervical artery was very large, on account of the anastomosis. The subject was a man of forty-five, and the aorta was completely blocked for a quarter of an inch.

MR. WAGSTAFFE was anxious to know whether there were any signs or symptoms which could be used *intra vitam* as diagnostic of contraction of the aorta.

DR. COUPLAND replied that, if there were none perfectly certain, he believed he could diagnose another case were it to come under his observation.

DR. LEGG said that Oppolzer diagnosed aortic contraction thirty years ago, and that the condition had frequently been diagnosed since, including once by Dr. Walshe.

CYSTINE CALCULI.

MR. CHRISTOPHER HEATH exhibited portions of cystine calculi, and reported the conclusion of the case, which he had previously brought before the Society, two years and a half ago. The present specimens consisted of two pieces of calculi removed post-mortem, and dust brought out by the lithotrite before death. The patient, a man of twenty-eight, had presented symptoms of calculus; and on lithotomy being performed, eighteen calculi had been removed. Two years afterwards the symptoms returned, and calculi were twice crushed. Some weeks later the man came in in a dying state. Post-mortem the bladder was found acutely inflamed, with masses of cystine in the bladder and ureters, and the kidneys were extremely diseased. The masses found post-mortem were much softer than those removed by operation.

THE PRESIDENT inquired whether there was any family history of cystine in the urine.

MR. HEATH replied in the negative.

DR. HARE asked whether cystine was always found in the urine. In several cases which he had himself observed, cystine never disappeared from the urine under any circumstances.

MR. HEATH replied that cystine was always present in the urine.

THE PRESIDENT said that he knew a case of a gentleman who had passed cystic oxide in his urine for five-and-twenty years, and had been operated on for calculus. He was still vigorous.

DESTRUCTIVE PNEUMONIA FROM PRESSURE ON BRONCHUS.

DR. PEARSON IRVINE exhibited a specimen of lung in this condition. A man of forty-three was admitted into Charing-cross Hospital in April, and died in July, of aneurism of the aorta. His illness dated from the previous Christmas, when it began with hoarseness. There was no history of disease of the chest, of syphilis, or of alcoholism. From Christmas till April he suffered from dyspnœa, hoarseness, and pains along the left side. On admission he presented the physical signs of aneurism of the ascending aorta. During his residence in the hospital there was gradually-developed dulness over the back, from apex to base of the left lung, with less extensive signs in front. The right lung was hyper-resonant. Death occurred rather suddenly. Post-mortem an aneurism was found as large as an orange on the ascending aorta. The left bronchus was compressed immediately below its origin; and the bronchial wall, including the cartilages, was ulcerated. The left lung was also compressed by the body of the aneurism, but was less diseased at this point than at any other. It occupied more of the thorax than normal, and was hard and dense. The pleura was greatly thickened, and the cut surface of the lung proved to be cribriform from apex to base. This appearance was due to the presence of cavities filled with grumous reddish fluid in immense quantities. The upper lobe presented less change than the rest, a portion of breathing-tissue remaining. The right lung was almost healthy. Dr. Irvine said that the point of interest in the case was the nature and cause of this condition of the left lung. Last year he showed a similar case, but more chronic; the present case was really acute. With respect to the cause, the nerves had been credited with an important share in its production. The explanation that Dr. Irvine would offer was that in the early stage of the disease there was an emphysema from greater impediment to exit than to entrance of air; that at last neither air nor secretions could escape; and that by the damming back of both air and secretions a destructive pneumonia was set up. The

aneurism in this case, as in his former case, was found empty post-mortem; and this seemed to him to be an important point—that an aneurism without clot might do more harm than an aneurism containing a clot. Dr. Pye-Smith showed a specimen of lung last session almost exactly like the present, as syphilitic in origin. Might not that specimen and others like it be due to disease of the bronchus, not to syphilis directly?

The President inquired what the nature of the fluid was that was found in the cavities.

Dr. Irvine replied that it contained a mixture of blood and pus-cells disintegrated.

Dr. Barlow said that he had lately seen a case, in a child, in which a pea had been impacted in a bronchus and led to ulceration. The secretions had gravitated and set up a condition of lung very similar to that of Dr. Irvine's specimen, only rather more chronic. He believed that Sir William Gull had first suggested that destructive pneumonia in cases of mediastinal tumour might be due to pressure upon the pneumogastric nerve. His own case supported Dr. Irvine's view.

Dr. Greenfield believed that this change on the lung was due to shutting up of the secretions and consequent ulceration. He had observed it with tumours pressing on the bronchus, in cases of foreign body in the air-passages, and in syphilitic disease of the same parts.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Thursday, October 23.

Charles West, M.D., President, in the Chair.

On Œdema (Myxœdema) in the Cretinoid Condition of Adult Women.

Dr. W. M. Ord described five cases of the above disease in which the symptom first apparent was general anasarca without albuminuria. The anasarca was, however, different from the anasarca of renal affection, in that while it was general the parts affected did not pit on pressure, and, as there was no gravitation of any fluid, remained equally swollen at all times. In all the cases there was remarkable thickening and broadening of the features, and slow articulation; there was marked slowness of perception, slowness of thought, and slowness of action, without any actual impairment of intellect. The cases all exhibited the pink tinge of the cheeks, and the spade-like state of the hands described by Sir William Gull in his paper on a cretinoid condition supervening in adult life in women; and it is remarked that all the cases seen by the author have been in women. The skin generally was harsh and dry, as well as swollen and semi-transparent. There was in all the cases an absence of natural perspiration. There were in none of the cases any indications, either in the urine or in the organs of circulation, of the existence of renal disease. But in two cases which ended fatally after several years of observation, renal symptoms appeared before death—that is to say, with the occurrence of fluid anasarca the urine became albuminous, the arteries became tense and thickened, and the heart overgrown. In one case a post-mortem examination was obtained. The kidneys were found to be of normal size, rather tough in consistence, and not notably discoloured. The cortical portion was a little wasted, but the capsule was not adherent. The arteries were everywhere greatly thickened, there was much atheroma in the larger vessels, and the heart was much hypertrophied on the left side, weighing sixteen ounces and a half. There were no other important naked-eye appearances excepting the thyroid gland, which was reduced to a third of the natural size, and was tough and fibrous-looking on section. Under the microscope a remarkable overgrowth of the fibrillar element of connective tissue was found in all parts of the body; the fibrils being separated from one another by much larger intervals than usual, and the interspace being filled by a transparent material yielding mucin, an excess of the normal cement, with excess of nuclei. Reviewing the cases, the singular train of nervous symptoms was attributed to failure of the action of the skin, and to general want of peripheric stimulation of the nerves. And this condition was traced again to the mucous œdema by which all nerve-ends were encased. It was argued that a steadily maintained stimulation of the central nervous system was a condition of the maintenance of health in the great nervous centres as in the body at large, and that in such cases as those described there was an isolation from external influences comparable in a less degree with what is effected by shaving and varnishing a rabbit. The symptoms observed in the cases under notice were compared one by one with the symptoms described by Sir William Gull in the paper referred to, and their identity was held to be established. They were then compared with those of cretinism, and again a remarkable agreement was demonstrated. Reference was also made to Mr. Curling's paper on two cases of absence of the thyroid in children suffering from mental infirmity, and to Dr. Hilton Fagge's paper on Sporadic Cretinism in England, where again, in conjunction with cretinoid symptoms in children, the thyroid gland was absent, or could not be felt. The thyroid gland in the case examined after death having been found to be practically annihilated, owing to the encroachment of the myxœdema upon its natural structure, this case was held to afford confirmation to Dr. Fagge's argument set forth in the above paper. In the last place, it was suggested that such a condition existing early in life, before the development of the intellect and of the organs related therewith, would cause arrest of development through failure of the guiding sensations and stimulations. It was held that the natural process of development of the central nervous organs is directly dependent upon exercise of these organs set going by impulses from the periphery, that the surroundings of the growing animal "lick it into shape" so to speak, and that the intrusion of an insulating medium will tend to arrest development in proportion to the completeness of insulation. Observation showed that many cretins were "œdematous," and that an œdematous state of the skin was often an indication in particular cases that the child so affected would become a cretin. The paper, therefore, suggested that more extended observation might possibly reveal some such connexion in cretinism as was there asserted of the cretinoid state of adult women. The ultimate course of the condition called myxœdema remained, the author said, unexplained.

OBSTETRICAL SOCIETY OF LONDON.

Wednesday, October 3.

Charles West, M.D., F.R.C.P., President, in the Chair.

Zwancke's Pessary.

Dr. Galabin showed a pessary (Zwancke) which had been worn for six years. The pessary was buried deeply in the vagina, amidst a large number of phosphatic calculi. The bladder, vagina, and rectum formed one cloaca.

Dr. Routh thought this form of pessary most convenient in practice. The injuries were due to abuse of the instrument.

Dr. Robert Barnes thought we should not trust women to remove and replace pessaries, so that it was our duty to select the least objectionable form. Zwancke's was a most objectionable instrument.

Dr. Hicks thought the Zwancke made of wire the most objectionable form.

The President had introduced Zwancke's pessary into England, and found it useful; it was before Hodge's was invented. He had not used it lately.

Dr. Wiltshire had seen nothing but harm from the instrument.

Dr. Hayes had seen evil results from other pessaries.

Dr. Godson had used Zwancke's pessary often, and had seen no harm result. He showed a boxwood disc pessary which had probably been worn for twenty-six years.

Dr. Ellis had seen ulceration and discharge following the introduction of a Hodge's pessary. A patient should be examined a week after introduction of pessary to see that it fits.

Obstetric Practice.

Dr. W. T. Green gave a synopsis of 1500 consecutive labours in his practice. Of the total number of cases attended, 300 were primiparæ, and 1200 multiparæ. Fourteen women gave birth to twins. There were 6 cases of placenta prævia: 3 of the mothers subsequently died; 2 children were born alive. There were 3 cases of hydatid mole. Of the twin births, in 4 the children were both males, in 6 both females, in 4 male and female. In every case where the twins were of the same sex there were 2 placentæ, and the membranes were distinct; while in cases where the infants were of different sexes there

was only 1 placenta, and the membranes were united. Forceps were used on 51 occasions, turning employed 12 times, and craniotomy had recourse to twice. The total deaths were 12 mothers and 73 infants. Of the latter 30 were cases in which the children were not of a viable age. The maternal deaths were due to post-partum hæmorrhage, placenta prævia, exhaustion, and puerperal fever. There were several cases of acute specific fevers during the puerperal period, which recovered. The author had not observed idiocy induced by complications during labour. He had used perchloride of iron to arrest hæmorrhage in placenta prævia, with good results.

Dr. Braxton Hicks would like to have had a fuller history of the cases which had recovered after puerperal illnesses, for more was to be learnt from them than from those that died.

Dr. Edis said that the maternal mortality was high, and required more explanation than was given in the paper. The number of still-born children was the usual percentage, but he thought that infant mortality throughout the country was too high, owing to want of employment of the forceps.

Dr. Barnes said the average of infant mortality in Dr. Green's practice was somewhat less than that in the Royal Maternity Charity, and could not be fairly referred to want of using the forceps.

Dr. Daly said he gave ergot in almost all cases. Dr. Green had not referred to external pressure as a means of helping delivery.

Dr. Heywood Smith asked if there was distinct proof that pelvic cellulitis results from hard labour and use of forceps oftener than from septic absorption.

Dr. Edis said he had no statistics in proof of it.

Dr. Chalmers had given ergot, but did not do so now, and does not think his cases last longer in consequence. It might be well for skilled accoucheurs to use the forceps frequently, but it would be bad in general practice.

The President said that the proportion of males to females (726 to 785) was the reverse of the usual proportion (105 to 100). Perhaps illegitimacy explained it. He had an impression that idiocy had a connexion with protracted, difficult, or instrumental labour.

Dr. Hayes thought that statistics could not decide the question of the frequency with which forceps or ergot should be used. Each case should be decided on its own merits. There are certain indications of the likelihood of the occurrence of post-partum hæmorrhage, and in such cases ergot may be given.

Dr. Galabin had examined the records of twin cases at Guy's Hospital during twelve years. He found all possible combinations of sex, etc., though, from the fact that double monsters are always of the same sex, it would be expected that twins, having a common amnial sac, would be of the same sex.

Dr. Green, in reply, said he had stated accurately the proportion of male and female children. There were only two illegitimate. He had observed a large proportion of the children for a long time, and he had not found reason to connect idiocy with any kind of labour. He had given ergot a fair trial; had never found it do good, but harm, giving rise to retention of contents of uterus. He had used the forceps in all the cases in which he thought them necessary.

The Forceps in certain Breech Presentations.

Dr. T. W. Agnew (Hobart Town, Tasmania) pointed out the great difficulty met with in delivering certain cases of breech presentation, and enumerated the objections raised to the use of the forceps in such cases, though other means failed. Though objections had been raised to their employment, the author thought that recourse might be had to them in some cases when other means had failed. Two such cases in which the instrument had been used with success were detailed.

Dr. Barnes said his experience on the point in question was abundant. He had tried the forceps, and had seen their inefficiency and their danger; they might compress the soft parts above the pelvis and the cord, thus causing asphyxia. Dr. Agnew used leverage—that was good. Breech presentations are of two kinds—that where the legs are bent is easy; the other, where the legs are straight, is very difficult. The breech is like a wedge, and the proper treatment is to decompose the wedge by bringing down a foot.

Dr. Poole suggested the propriety of dividing the symphysis pubes of the child when it is dead, in the difficult cases.

Dr. Hayes applied the forceps to the breech when the os was insufficiently dilated for the introduction of the hand. The instrument slipped, but the breech was dragged into the vagina. A foot was then seized, and delivery effected.

Dr. Barnes said anything might be done to diminish the size of the child when it was dead. He thought the lower the breech was, the more difficult it would be to seize a foot. He would not drag the breech lower down before seizing a foot.

ASSOCIATION OF MEDICAL OFFICERS OF HEALTH.

Friday, October 19.

Dr. Stevenson, President, in the Chair.

The Secretary having read the minutes of the final meeting last session, and of the special meeting in July for the election of officers during the current session,

Mr. Liddle proceeded to remark upon some of the defects of the Building Acts, especially with regard to the foundations of houses—builders being, under the existing Acts, at liberty to take away sand and gravel, and substitute for them decomposing refuse from ashpits. He hoped that some practical measure would be devised for building houses in accordance with sanitary science.

Dr. Tripe remarked that the Society had asked Mr. Sclater-Booth last year to make the general law with regard to infectious diseases uniform throughout the country. London should be on the same footing as the provinces as respects sanitary supervision. The Metropolitan Board of Works should be empowered to make by-laws in accordance with the Public Health Act of 1875. As respects the Building Acts, the medical officer of health has at present no power to prevent builders erecting houses on dust-heaps, or to provide for subsoil drainage. The metropolis is twenty-five years behind the provinces respecting sanitary legislation.

On the motion of Mr. Liddle and Dr. Tripe, these two subjects were referred to the Council for consideration and report.

President's Inaugural Address.

After briefly considering the advantages of an Association of Health Officers, and the work to be done by such an Association, especially that of supervision of sanitary legislation, Dr. Stevenson proceeded to comment upon the alleged sloth of local sanitary authorities. Ardent sanitarians, he said, are never tired of declaiming against the ignorance, the apathy, and the obstructiveness of these bodies. Where ignorance and obstructiveness are found in a local authority, that ignorance and obstructiveness is the product of the ignorance of the public electing such a body, and could not exist were it not in accord with the wishes or the apathy of the people at large who elect such representatives. So long as (*e.g.* in the metropolis) the educated ratepayers take no interest whatever in local affairs, and do not know the differences between a vestry and a board of guardians, a medical officer of health and a Poor-law medical officer, so long will local representatives be apathetic in putting into force sanitary enactments, and asking for improved and more advanced legislation. Happily, there are abundant signs of greater and increasing interest in hygiene on the part of the educated public. That great reflex organ of public educated opinion, the *Times*, is constantly directing attention to sanitary matters. It is our duty, as medical officers of health, not only to educate our own local boards, but also the public at large, in sanitary matters. One of the greatest obstacles to the universal recognition of sanitary needs and shortcomings has been the small interest displayed in hygiene by medical men in general. Preventive medicine is still in great measure an unrecognised subject of medical study, and as a consequence medical students become qualified practitioners without ever having studied or passed an examination in preventive medicine. If an acquaintance with preventive medicine is not demanded of candidates for medical diplomas: if the teaching of hygiene is ignored, nay, even scouted as a subject of medical education, how can a student be expected to pay any attention to it? May the time be not far distant when no man will be allowed to go into medical practice without an adequate acquaintance with hygiene. The increased prominence which sanitary matters have recently obtained with the public has in no small measure been due to the great interest displayed in them by ladies. Women have become very ardent knights of sanitation, and much good

may be expected to result from their exertions. Let anyone compare the sanitary state of any city—say, for instance, this metropolis—now with what it was some dozen years ago: the result will show how great has been the progress made. In no respect has an advance in the recoguition of the value of sanitary work been more apparent than in the means provided for the isolation of infectious diseases. In the small-pox epidemic of 1871 local sanitary authorities in the metropolis were, as a rule, very averse from providing accommodation for the non-pauper classes. In my own parish the matter had to be persistently pressed; and it was only when the crest of the epidemic wave was already passed that such accommodation was provided. In the last epidemic, on the contrary, every step which I thought it nccessary to advise was unhesitatingly adopted; so that whereas in 1871 great numbers of the non-pauper class suffering from small-pox were obliged to be treated at home, iu this last epidemic we had at all times ample accommodation for all who were in need of it. Here, then, we have an instance where the action of a sanitary authority was not behind public and even professional opinion. Most of the parishes in London now make arrangements with the London Fever Hospital for the reception of non-paupers. The Bolton Corporation, taking advantage of the Bolton Improvement Act of last session, has ordered a compulsory registration of infectious disease, so that the occupier of a house in which any inmate is known to be suffering from any infectious disease is required to give notice to the Corporation of the existence of such disease. Medical practitioners are also required to transmit to the Corporation a certificate whenever they meet in their practice with a case of such disease; and to remove all semblance of hardship, the Corporation will pay a fee to the medical man for such certificate. All honour to the Bolton Corporation for boldly trying this experiment! The results will be anxiously looked for. The compulsory registration of infectious disease is a point about which great diversity of opinion prevails, and the greatest opposition to its adoption would perhaps come from a section of the medical profession itself. Medical men say that they cannot afford to offend their patients by giving information of the existence of cases of contagious disease which they may have met with in their private practice, even if paid for giving such information by a public body. They say, and say, I think, justly, that the obligation to give information should rest with the heads of households, and that the duty of the medical attendant would be discharged were he to advise the friends of the sick person that the case is an infectious one. But if the ouus of giving information were laid upon the medical practitioner, who may be regarded as a public official, a truthful statement might well be demanded of him. To this it might be retorted that a heavy premium would here be offered to dishonesty, since a medical man who stoutly refused to inform, spite of penalties, or even a man who lied as to the nature of a disease, would be in great demand with the public. The Bolton Corporation has endeavoured to cut this Gordian knot by requiring a double registration of infectious diseases: not only is the person in charge of the patient, but also the medical attendant, required to give notice to the Corporation of the nature and locality of a case of infectious disease. We, as medical and surgical practitioners, are licensed for certain work. But since every privilege has, or ought to have, a corresponding obligation attached to it, we, in return for the privileges of exclusive legal practice conferred upou us as practitioners of medicine, must not suppose that, should Imperial interests demand it, we can refuse either legally or morally to give information of infectious disease iu our practices, should it be found that the public weal demands the information. The only real ground for the registration of infectious diseases is the danger to others of infection. Were there any other urgent reason it would be equally applicable to all diseases. The occasion of a recent tragedy has served to revive the idea of a registration of all forms of disease, and it has been thought that the revolting circumstances which have been revealed in connexion with the illness and confinement of an unfortunate woman furnish an additional argument in favour of the compulsory registration of all diseases over and above that afforded by the facilities a registration of diseases would afford for the isolation of infectious diseases; and it has been argued that, in the interests of sanitary science, and for the protection of the health of the individual, it is absolutely necessary that the registration of all disease should be made compulsory. If the interests of sanitary science were alone involved, all that is here alleged might be granted; but there are other interests very important and dear to Englishmen which have to be considered, and the day is, I believe, immeasurably distant when we shall have compulsory registration of all diseases. It may now be accepted that the normal relation of a medical officer of health to the sanitary authority uuder whom he works, and whose officer he is, will eventually be, in all cases, like that of the Poor-law medical officer. He will be appointed by the local authority, but not be removable without the sanction of the central authority—*i.e.*, a Government department—and the central will control the action of the local authority. For its successful working it is requisite that there should be perfect harmony and accord between the central and the local authority. There is a very widespread opinion in our profession that the relations of the Local Government Board to local authorities and to sanitary officers are by no means satisfactory; and that sanitation does not receive that full and cordial recognition to which it is entitled at the hands of the Local Government Board. I trust that the members of this Society, notwithstanding that a majority of its most active members are perhaps in no way directly under the supervision of the central authority, will use their best endeavours to secure a happier and more satisfactory state of affairs than at present exists. A Bill for consolidating the sanitary laws relating to the metropolis was introduced at a hopelessly late period of the session. There is little doubt that the Bill will be re-introduced; but it is doubtful whether, if the Government do not display more zeal and earnestness in sanitary legislation than they have of late done, the Bill will become law during the course of next year. The recent outbreak of cattle plague, and the discovery of several outbreaks of typhoid fever from impure milk-supply, have directed increasing attention to the necessity of greater care in the keeping of milch cows, and the collecting and storage of milk. I cannot help expressing an earnest hope that ere long some means will be found of effectually supervising the dairies both in town and country. The Cattle Plague Committee of the Metropolitan Board of Works has been led by its inquiries into the state of the metropolitan cowsheds to advise the Board to declare the keeping of cows to be a noxious business, and to frame by-laws for the regulation of the business of a cowkeeper. If this be done the supervision of the sheds will practically pass into the hands of the Metropolitan Board. The enactment of good by-laws will be most beneficial; but the transfer of the supervision into the hands of men who have no medical head to advise them on matters having a vital bearing on the health of the people will, if effected, be, I believe, by no means a step in advance.

In the debate following the reading of Dr. Stevenson's address,

Dr. Tripe, in proposing a vote of thanks to the President, said that he much preferred listening to a paper on a practical than on a theoretical or somewhat abstruse subject. It was very useful to the members of the Society to trace back the past progress of sanitary legislation, and to lead them up to the work yet required to be done by officers of health in their respective districts. There was no doubt that a large proportion of fever cases taken to the district asylums belonged to the non-pauper class. He could not but think that much valuable time had often been lost by the parish officers going about from one to another to ascertain who is to take the case. One corporation should have the removal of all fever cases, the non-paupers being located in a separate part of the building. As regards the reporting the existence of infectious disease in the house, he thought the occupier in many instances would rather incur the penalty of £10 than give information which would certainly damage their trade—such as publicans, drapers, etc. The plan adopted by the Bolton Corporation was the only practical method—*i.e.*, the medical officer and the occupier jointly reporting the case. He hoped to see shortly framed fresh by-laws for the regulation of cow-sheds, which should be uniform for the whole metropolis. At present 350 cubic feet of space are allowed in Shoreditch, and 400 feet in Hackney.

Mr. Liddle, in seconding the vote of thanks, said that there was gcueral complaint among local boards at the obstacles to progress set in their way by the Local Government Board. He was informed that the members of that Board had never met since that department of the Government was first started. All the business was carried on by the President and clerks in a very routine way. The medical officers of health should in all cases be required to abstain from practice, and be remunerated

accordingly, so as to prevent the petty jealousies often existing between them and their brethren in the profession. The central authority ought to be in more direct communication with the local authority, as an adviser rather than as controlling the acts of the district boards.

OBITUARY.

FRANCIS AUGUSTUS BURDETT BONNEY.

This gentleman, who died on the 13th inst., at his residence, Elm House, Brompton, in the seventy-fourth year of his age, was the son of Mr. J. A. Bonney, a solicitor in London, of good family, who, as the friend of the celebrated Horne Tooke, became involved in the State prosecutions of 1794.

Having received a sound preliminary education at Ealing School, he turned his attention to the study of physic, but the unexpected death of his father stopped for a time this desire on his part; he therefore, like many other good men, had recourse to his pen, and became an acceptable contributor, both in prose and verse, to the literary journals of the day, especially to the *European Magazine*. He subsequently commenced the study of medicine in earnest in Edinburgh, finishing in Paris; he was admitted L.R.C.S. Edin. in 1829, and L.S.A. in 1833, when he commenced the practice of his profession at Brentford. Some years later he removed to Chichester, but returned to London after some years, on his marriage with Miss Elliott, the proprietress of Elm House Lunatic Asylum. He was the author of some valuable papers in the *Medical Times and Gazette* and some of our contemporaries. His widow, two daughters, and three sons (two of the latter being Members of the Royal College of Surgeons of England) survive him to mourn the loss of a most indulgent and affectionate husband and parent.

MEDICAL NEWS.

University of Dublin.—Michaelmas Term Commencements.—A meeting of the Senate of the University was held in the Examination Hall of Trinity College, on Saturday, October 20, for the conferring of degrees, under the Presidency of the College *Caput*—the Right Hon. Montifort Longfield, LL.D., *Pro*-Vice-Chancellor; the Rev. H. Lloyd, D.D., Provost; and the Rev. Joseph A. Galbraith, M.A., Senior Master non-regent. The following degrees in Medicine and Surgery were conferred:—

Baccalaureus in Medicinâ.—Ricardus Henricus D'Olier Duckworth.
Magister in Chirargiâ.—Samuel Warren.
Doctores in Medicinâ.—Georgius Goode (in coloniis), Carolus Fredericus Murray.

Apothecaries' Hall.—The following gentleman passed his examination in the Science and Practice of Medicine, and received a certificate to practise, on Thursday, October 11:—

Pain, Alfred, Coultings, Bridgwater.

The following gentlemen passed, and received their certificates, on the 18th inst.:—

Culhane, Fredk. William Slater, Cranfield-road, Brockley.
Dale, Henry Ridley, The Poplars, St. George's-square, N.W.
Hoole, Henry, Walthamstow, Essex.
Robey, Jesse William, Etruria, Staffordshire.

The following gentleman on October 11 passed his Primary Professional Examination:—

Jacob, Henry Garrard, Charing-cross Hospital.

The following gentlemen passed on the 18th inst.:—

Hatton, George Stokes, St. Thomas's Hospital.
Lavis, Henry James Johnston, University College.
Lynn, Edward, Guy's Hospital.
Richardson, Charles Boards, St. Thomas's Hospital.

APPOINTMENTS.

*** The Editor will thank gentlemen to forward to the Publishing-office, as early as possible, information as to any new Appointments that take place.

Bennett, Storer.—Medical Tutor to the Dental Hospital of London.
Bennett, William H., F.R.C.S.—Surgeon to the Belgrave Hospital for Sick Children.
Lowndes, Frederick W., M.R.C.S. Eng.—Surgeon to the South Division of the Liverpool Borough Police Force, *vice* Dr. Newton, deceased.
Peacock, T. B., M.D., F.R.C.P.—Consulting Physician to the Training Hospital, Tottenham.
Rogers, Claude.—Demonstrator of Fillings to the Dental Hospital of London.

BIRTHS.

Butcher.—On October 22, at 70, London-street, Reading, the wife of W. Deane Butcher, M.R.C.S., of a daughter.
Caldwell.—On October 23, at Kennington-park, the wife of W. T. D. Caldwell, M.D., of a daughter.
Clifton.—On September 26, at Kamptee, in the Madras Presidency, the wife of Surgeon-Major R. W. Clifton, M.R.C.S. Eng., of a son.
Debenham.—On October 17, at Heath House, Stepney, the wife of Robert Debenham, M.R.C.S., of a son.
Elliot.—On October 18, at Cliffe House, Ruyton-of-the-Eleven-Towns, near Shrewsbury, the wife of Henry F. Elliot, L.R.C.P. Edin., of a daughter.
Irvine.—On October 6, at 3, Mansfield-street, Cavendish-square, W., the wife of J. Pearson Irvine, M.D., of a son, who survived his birth a short time only.
Johnston.—On October 22, the wife of John Johnston, M.R.C.S. Eng., of 3, Albion-place, Maidstone, of a son.
Orange.—On October 22, at Broadmoor, Wokingham, Berks, the wife of William Orange, M.D., of a daughter.
Thomson.—On September 20, at Simla, N.W.P., India, the wife of Murray Thomson, M.D., of a daughter.
Westcott.—On October 13, at Martock, Somerset, the wife of W. Wynn Westcott, M.B., of a daughter.

MARRIAGES.

Barry—Clare.—On October 20, at St. Stephen's, South Lambeth, Edmond Joseph Barry, M.D., of Lenham, Kent, to Constance, second surviving daughter of the late Thomas Clare, Esq., of Heather, Leicestershire.
Bird—Hewitt.—On October 18, at St. Mark's, Notting-hill, George Vernon, eldest son of P. Hinckes Bird, F.R.C.S., of 1, Norfolk-square, Hyde-park, W., to Lizzie Hewitt, of Bradbury House, Cambridge-gardens, North Kensington.
Blackmore—Gore.—On October 23, at St. George's Church, Hanover-square, Humphrey P. Blackmore, M.D., of Salisbury, to Augusta Sophia, second daughter of the late Colonel Henry Ross Gore, C.B.
Buchanan—Paterson.—On October 17, at 10, Queen's-terrace, Glasgow, William Stevenson Buchanan, Dundee, to Jane Campbell, younger daughter of Joshua Paterson, M.D.
Clay—Frost.—On October 23, at St. Mark's, Hamilton-terrace, N.W., Robert Hogarth Clay, M.D., of Plymouth, to Mrs. Mary Alice Frost, second daughter of the late John Gildart Jackson, Esq., of Hull.
Falconer—Sheppard.—On October 24, at St. Andrew's Church, Bath, John Egerton Falconer, Esq., eldest son of Randle Wilbraham Falconer, M.D., F.R.C.P., of Bath, to Isabella Charlotte, daughter of Philip Charles Sheppard, Esq., of Royal Crescent, Bath.
Edger—Hutton.—On October 3, at St. Marylebone Church, London, Warren Edger, of Dukinfield, Cheshire, eldest son of John Warren Edger, M.D., of Kirkby Stephen, Westmoreland, to Jane Taylor, eldest surviving daughter of the late Richard Hutton, of Gilling Lodge, Watford.
Fouracre—Osbaldeston.—On October 17, at the parish church, Islington, Robert Perriman Fouracre, M.R.C.S. Eng., of Hornsey-road, to Hester Jane, second daughter of M. D. Osbaldeston, solicitor, of Lincoln's-inn-fields and Hornsey-rise.
Madeley—Barton.—On October 16, at St. Michael's, Coventry, George Henry Madeley, M.R.C.S. Eng., Surgeon Royal Marine Light Infantry, to Katharine Helen, only daughter of the late George S. Barton, of Coventry.

DEATHS.

Basham, W. R., M.D., for many years Physician to the Westminster Hospital, at 17, Chester-street, Belgrave-square, on October 16, aged 73.
Cotton, Theresa Caroline Amelia, wife of George Cotton, M.R.C.S. Eng., of Northampton, at 47, Abington-street, on October 14.
De la Cour, George Gerald Herbert, infant son of G. F. de la Cour, M.D., at 282, Camden-road, N.W., on October 21, aged three weeks.
Elam, Shrofield, L.S.A., M.R.C.S., late of Tipton, Staffordshire, and Clare, South Australia, at Collingwood, Australia, on August 24.
Freeman, Henry Lankester, M.R.C.S., late of Saxmundham, at Woodbridge, on October 17, in his 82nd year.
Jackson, Rosa, wife of T. Carr Jackson, F.R.C.S., and youngest daughter of the late Thos. Wakefield, Esq., at 91, Harley-street, Cavendish-square, on October 23.
Latham, Mima Burns McDiarmid, wife of P. W. Latham, M.D., Downing Professor of Medicine at Cambridge, on October 20.
Neale, W. M., M.D., at Worksop, on October 14, aged 64.
Silvester, T. H., M.R.C.P. Lond., formerly of Clapham, Surrey, at Broadwater Grange, Tunbridge Wells, on October 16, in his 79th year.

VACANCIES.

In the following list the nature of the office vacant, the qualifications required in the Candidate, the person to whom application should be made and the day of election (as far as known) are stated in succession.

East Sussex, Hastings, and St. Leonards Infirmary.—Third Assistant-Surgeon. Candidates for the office must be Fellows or Members of the Royal College of Surgeons of London, Dublin, or Edinburgh. Applications, with testimonials, to the Secretary, endorsed "Application for Assistant-Surgeon," on or before November 10.

Worksop Dispensary.—Resident Surgeon. Candidates must be unmarried and doubly qualified. Applications, with testimonials, to J. Wilson Hamil, M.D., The Dispensary, Worksop, on or before October 27.

UNION AND PAROCHIAL MEDICAL SERVICE.

*** The area of each district is stated in acres. The population is computed according to the census of 1871.

RESIGNATIONS.

Burton-upon-Trent Union.—Mr. Alfred E. Prockter has resigned the Barton-under-Needwood District; area 12,892; population 3117; salary £45 per annum.

Erpingham Union.—Mr. J. Cooper has resigned the Cromer District; area 8818; population 4119; salary £66 per annum.

Thetford Union.—Mr. R. Thompson has resigned the Brandon District; area 14,486; population 2888; salary £52 7s. per annum.

APPOINTMENTS.

Aysgarth Union.—Edward Allen, M.B. Edin., L.R.C.S. Edin., to the Hawes District.

Dursley Union.—Francis J. Joynes, M.R.C.S. Eng., L.S.A., to the Third District.

Foleshill Union.—Ernest J. Pritchard, M.B. and C.M. Glasg., L.S.A. Lond., to the Shilton District.

Horncastle Union.—James C. Gray, L.R.C.P. and L.R.C.S. Edin., to the Tetford District.

St. Asaph Union.—Humphrey Roberts, L.R.C.P. Edin., M.R.C.S. Eng., to the Llanfairtalhaiarn District.

St. Thomas Union.—Arthur B. Ewen, M.R.C.S., L.S.A., to the Exmouth District.

Weymouth Union.—James Bartlett, L.S.A. Lond., L.R.C.P. Edin., L.F.P.&S. Glasg., to the Owermoigne District.

Royal College of Surgeons.—The annual registration of medical students is now, and we hope permanently, brought to a close at this institution, and the gross number amounts to 1919, including eighty-two dental students. Of the latter number an addition of nine is to be made to the Middlesex Hospital, bringing up the number of new entries to forty-four, against thirty-eight last year.

Treatment of Pertussis by Pulverised Ether.—Dr. Lubelski, of the Warsaw Civil Hospitals, recommends in the first two stages of pertussis the application to the neck, along the course of the pneumogastric nerve, of ether pulverisations. The first trial, made on his own child, aged seven, was followed by almost immediate relief. These pulverisations are, of course, only to be regarded as palliatives, especially applicable to children harassed by violent and frequent paroxysms.—*Gaz. Hebd.*, October 19.

Danger of Hair-Colouring.—In No. 38 of the *Veröffentlichungen* of the German Sanitary Board, caution is given against the use of hair-colouring preparations containing lead, and the results of Hager and Wittstein's analyses republished for general circulation. According to these, Allen's World's Hair-Restorer and Rossetter's Hair-Regenerator consist of strong solutions of the acetate of lead in glycerine and perfumed water, in which finely divided sulphur is suspended. Both preparations are characterised as highly dangerous to health.

Animal Vaccination in Italy.—The Milan Animal Vaccination Committee publishes the following statistics of the results that have been ascertained at the various animal vaccine centres in Italy. The conjoined numbers amount to 100,546 vaccinations, and 82,020 revaccinations—a total of 182,566 inoculations. Of the 100,546 vaccinations, 91,427 (90·93 per cent.) produced genuine results, 344 (0·34 per cent.) spurious results, and 1487 (8·72 per cent.) no results at all. Of the 82,020 revaccinations, 35,335 (43·08 per cent.) produced genuine results, 8129 (9·91 per cent.) spurious results, and 38,556 (47 per cent.) no results.—*Gaz. Med. Lombardia*, October 6.

Population of the German Empire.—The Imperial Statistical Bureau has just published the statistics of the progress of population in the different states of Germany. In 1871 the entire population amounted to 41,058,792 souls, and at the end of 1875 it had increased to 42,727,360, or an augmentation of 9·78 per 1000. It is in Prussia, in the kingdom of Saxony, and in the free cities, Hamburg, Bremen, and Lubeck, that the greatest increase has taken place, and then follow Bavaria, Würtemburg, Baden, Hesse, etc. In Prussia the increase has been 10·42 per cent., in Bavaria 8·04, in Baden 7·68. On the other hand, in Alsace-Lorraine, in Mecklenburg, and in Waldeck it has only been 6·67.—*Progrès Méd.*, Oct. 6.

Something New to Westerns.—Gold-leaf poisoning appears to be seldom practised at Kiukiang as a method of committing suicide, as I have heard of only one case during my three years' residence. In March, 1877, I was asked if an antidote could be furnished for this aristocratic method of poisoning. Being anxious to meet such a case, a favourable opinion was advanced if the patient could be brought for treatment. This, however, was not done, and how the case ended is still unknown. Gold-leaf, where it does not suffocate, must act simply as an irritant, and therefore I should consider that the rational treatment would be the continuous exhibition of alkalies, with demulcent drinks and emetics; but how far they might succeed in practice remains to be proved.—*Dr. Jardine, in the Chinese Customs Gazette.*

Worms in the Heart of Dogs.—During the past year there has been an alarming mortality among foreign dogs (at Kiukiang) of all kinds, and in nearly every case where the dog has been dissected, death has been found due to worms in the heart. The left ventricle has in some instances been almost completely filled with them; but I believe that as long as these creatures remain in the cavities, they are comparatively harmless, and that it is only when they obstruct the passage of blood through the orifices, or impede the action of the cardiac valves, that they prove fatal. The whole circulatory system has been examined on two occasions, as well as the blood microscopically, but no clue can be got to their origin.—*Ibid.*

Of late years, investigations into the diseases of animals have been made to an extent never before attempted. Many obscure forms have been brought to light, and the possibility of the communication to man of disease hitherto believed to be confined to animals has been fully established. Thus, by experiments on himself and others, Hertwig has proved that the "foot and mouth disease" is conveyed to man by milk yielded by animals affected with that malady. Stomatitis, and a vesicular eruption on the mucous membrane of the mouth, are among the symptoms. Side by side, however, with such inquiries as Hertwig's, other investigations have been pursued into the effect of various conditions upon infected milk. It has been set beyond doubt that milk loses infectious properties on boiling. Now, as in Shanghai many foreign children are fed on milk derived from all sorts of questionable sources—baffaloes and Chinese cows—the rule should be faithfully observed to boil all milk before it is used as food. I have noticed that aphthous ulceration of the mouth is far more common among the families of people who, while taking every reasonable care of their children's health, cannot afford to pay the high prices charged at the farm for milk of guaranteed quality.—*Dr. Jamieson, in the Chinese Customs Gazette.*

A Defence of Opium-Eating.—Struck by the exaggerated and sensational statements that have from time to time been published concerning the ill-effects of opium-eating, Mr. Vincent Richards (*Indian Med. Gaz.*, August) instituted a statistical inquiry at Balasore, in Orissa, where the habit of opium-eating is very general, and has much increased since the famine of 1866. The following are the conclusions at which he arrived:—1. That opium is taken habitually by about 8 to 10 per cent. of the adult population of Balasore, and that the average daily allowance for a man is seven grains, and for a woman five grains. 2. That moderation is the rule. 3. That moderate doses include from two to sixteen grains per diem, according to circumstances. 4. That opium-eating is much more common in unhealthy than in healthy localities, even though they are situated in the same district. 5. That the drug is sometimes taken in very large doses—thirty grains and upwards—without producing any very serious ill-effects, much depending on the constitution of the individual, and his habituation to its use. 6. That whatever the effects of the excessive use of the drug may be, when taken in moderation it is positively beneficial, where such diseases as fever, elephantiasis, rheumatism, etc., are present, and when food is scarce. 7. That the effects of even the most excessive use of opium are harmless, both to the individual and to society, compared with the excessive use of alcohol.

A distinguished French physician has recently communicated with me with a view of obtaining information regarding the condition of foreigners, especially with respect to their condition of anæmia or otherwise, after long residence in the East. Now that a considerable number of persons make

China their home, information upon this point must be much more accessible than it would have been ten or fifteen years ago. No doubt valuable facts bearing upon the query will be adduced by practitioners at the ports. Experience in Shanghai is tolerably uniform as to the excellent condition of health preserved by old residents who take good care of themselves, who avoid excesses, and who have been lucky enough to escape malarious fevers. Even among those who in their earlier days suffered from periodic fevers there are many who appear to have outlived their susceptibility. There are few of us that have actually entered upon old age, but there are many in advanced middle age. Of these latter—men who have lived twenty years and above in China—the majority would compare favourably for strength and endurance with a like number of the same age taken at random from the desks of London offices. This fact, which every resident can verify for himself, ought to have an important bearing on the calculation of life assurance rates, but the subject of life assurance in China has been so fully discussed in previous numbers of these reports that I now merely allude to it.—*Dr. Jamieson, in the Chinese Customs Gazette.*

THE principal part of the population of Swatow is due to the shipping, and from it the list of diseases is principally made up. Intermittent fever is common among sailors who sleep on the decks of their ships with very little covering, and who swim under the hot sun. Whether partially protected or not by a hat, a man who swims at an unseasonable time is almost certain to be prostrated by fever within twenty-four hours. Apart from these causes fever is rare, and ague is almost unknown.—*Dr. E. I. Scott, in the "Chinese Customs Gazette."*

NOTES, QUERIES, AND REPLIES.

He that questioneth much shall learn much.—*Bacon.*

Corrigendum.—Dr. Offenberg asks us to correct an error which crept into the article on "Hydrophobia Cured by Curare used Subcutaneously," which appeared in our number for October 6, 1877. At page 397, fourteen lines from bottom of left-hand column, in the sentence, "The action of a dose of curare only lasts from four to five *minutes*,"—for minutes, read *hours*.

"IDEATION IN UTERO."

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

SIR,—Will you have the goodness to tell me whether the phenomenon of "ideation in utero" is a possible one. In what book or books can I find a complete *résumé* of this subject? I trust you will pardon my taking this liberty, as I am very interested on all subjects that are related to that of mind. I enclose my card and subscribe myself Yours, &c., J. F. E.
University College, Gower-street, W.C., October 20.

*** Can any of our readers help the writer? Unfortunately we cannot. Perhaps some gentleman's recollections extend as far back: ours do not.

Scotch.—Dr. Joseph Dalton Hooker, C.B., accompanied Sir James Ross on his antarctic voyage, 1839. He succeeded his father as Director of the Kew Gardens in 1865.

*** The following is a copy of the verse to which the chimes of "Big Ben" are set:—

"Lord, through this hour
Be Thou my guide;
Then, by Thy power,
No foot shall slide."

A Young Fellow.—Competitors for the prizes must be members of the College. The competition is not open to members of the Council, although several successful competitors subsequently obtained that honour, and also the President's chair, as you will see from the following list:—Birkett (now President), Callaway, Cooper, Curling, Earle, Hodgson, Lawrence, Stanley, Stafford, Swan. Write to the Secretary, or to Mr. Stone, who will send particulars of the Collegial and Jacksonian Prize subjects for the present and ensuing year.

W. L. F.—Dr. Ahrens died on August, 1874, aged sixty-six. He was for many years Professor of Political Economy and Sociology at Leipzig, and was well known at Brussels and Paris by the courses of lectures on psychology and philosophy which he gave during his residence there, when, in consequence of his participation in the Göttingen disturbances in 1831, he had found himself obliged to fly from Germany. It was during his temporary occupancy of a chair of philosophy at the University of Brussels in 1834 that he published his "Cours de Psychologie" and his "Cours du Droit Naturel." He was also the author of other works.

THE LITERATURE OF VIVISECTION.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

SIR,—Supplementary to your reply to Dr. Mease's query regarding books on vivisection, I beg to say that, in 1842, a volume entitled "Vivisection Investigated and Vindicated, by George F. Etherington, M.D.," was published, the booksellers being Maclachlan, Stewart, and Co., Edinburgh, and Whittaker and Co., London. The volume consists of 197 pages divided into chapters, with an appendix of seventeen pages.
I am, &c., W. WHITELAW, M.D.
Wellington Place, Kirkintilloch, N.B., October 20.

M.D.—The recent report of the Board of Visitors of the Wisconsin University in the United States, referring to the co-education of the sexes, admits the intellectual proficiency of the young women studying in the University, but regrets their overworked appearance and ill-health, and concludes with the following observations:—"We are aware that the law organising the University provides that it shall be open for the education of men and women. It is not, therefore, necessary that both classes of students should be subjected to the same systematic course of training, mental drill being attained in a variety of ways, each leading to adequate results, and the thought impressed itself upon some of the members of the Board that the curriculum could be so ordered that both sexes might obtain university drill, adjusted in such a manner that each sex should be enabled to secure that form of education best fitted for his or her respective sphere, and that the system of compelling men and women to fare alike might be so modified as to preclude the possibility of causing disease. We are forced to the conviction that there is at present a marked disparity between the health of the men and women of the University, and that, as a class, the women present undoubted evidence of physical deterioration. If the Board of Referents, however, consider it expedient to alter the curriculum in any way, we would earnestly recommend that particular attention be paid to the physical well-being of the female students."

M. O. H.—A report in reference to the water-supply for Holmesfield and a number of the adjacent villages was presented to the Chesterfield Rural Sanitary Authority on Saturday. It recommended the construction of a reservoir near Fox-lane, Baslow, at a cost of £20,000, which would provide for 15,000,000 gallons, and supply 14,000 inhabitants.

Alexis.—The University of Pennsylvania (Philadelphia) added, about eighteen months ago, a scientific school to its other buildings. It was enabled to do this by a large bequest from a gentleman of Philadelphia. Scholarships have been established and thrown open to candidates educated at the free public schools. The Adriatic Society of the Natural Sciences was formed at Trieste in the early part of 1874, and amongst other sciences taught are chemistry, physics, meteorology, botany, and zoology. The Tuscan Society of the Natural Sciences was instituted in 1874 at Pisa.

Inquirer.—Mr. Cane, Poor-law Inspector, has contradicted, officially, the statements that there were people starving in Bolton. He attended a meeting of the Bolton Guardians for that purpose, and said that such statements tended to throw discredit on the Guardians of the Bolton Union, who are empowered to relieve all distress, even though caused by strikes.

Anti-Vaccination.—At the Leeds Police-court, on Saturday, Mr. J. Atkinson, Honorary Secretary of the Anti-Vaccination Society, was for the sixth time fined for refusing to have his children vaccinated. He did not appear, but sent the following letter to the authorities:—"To Mr. Thomas Holmes, Vaccination Spy, Guardians' Office, Leeds.—John Ewbank Atkinson is not going to be murdered to please you, or a thousand spies, tools, fools, guardians, Local Government Board, or anybody else. Take that for your answer, inform the *Mercury* of it, and take proceedings as soon as you like." At Ulverston, the Rev. John Postlethwaite, of Broughton-in-Furness, a member of the Ulverston Board of Guardians, was summoned for refusing compliance with an order of the magistrates to vaccinate his three children, and was fined 10s. and costs in each case. The defendant said he would sooner rot in prison than see his children rot from vaccination. The magistrates allowed him fourteen days.

Beneficence.—Mr. Harvie Farquhar, the Honorary Treasurer of the Victoria Hospital, Queen's-road, Chelsea, has made a donation of £1000 towards the £4000 required for the purchase of land adjoining the Gough House site.

J. J.—In connexion with the visit of the Prince of Wales to Ceylon, Mr. Rajapaksha has endowed a scholarship in the Colombo Academy, called the Prince of Wales Scholarship, with 10,000 rupees, and he has given a valuable plot of land opposite to the Borella Hospital as a site for the new Government Medical School.

Pro Bono Publico.—From the official report of the Local Government Board we find that the whole of the loans sanctioned by the General Board of Health during the ten years which followed the passing of the Public Health Act, 1848, amounted to £2,956,178; that those sanctioned by the Secretary of State during the next thirteen years reached a total of £7,363,366; and that those sanctioned by the Local Government Board during the five years which have elapsed from December 31, 1871, to December 31, 1876, have been no less than £7,770,348.

COMMUNICATIONS have been received from—

Dr. Offenberg; J. F. E., London; Dr. Byrom Bramwell, Newcastle; The Secretary of the Statistical Society, London; Dr. Althaus, London; Dr. Whitelaw, Kirkintilloch; Messrs. Cooper, London; The Registrar of the Royal College of Physicians, London; Mr. Beaver, Manchester; Dr. J. W. Moore, Dublin; The Secretary of the Obstetrical Society, London; Dr. Sawyer, Birmingham; Dr. Eugene Dupuy, New York; The Secretary of the Apothecaries' Hall, London; Mr. W. E. Poole, London; Dr. J. Mitchell Bruce, London; Dr. James Ross, Manchester; Dr. Herman, London; Mr. J. T. W. Bacot, Devon; Mr. C. J. Cullingworth, Manchester; Dr. Thomas Barlow, London; Mr. John Chatto, London; Mr. T. M. Stone, London; Dr. Cayley, London; Mr. B. R. Wheatley, London; Dr. Robert Lawson, Banstead Downs, Sutton, Surrey; Mr. Evan Marleit Boddy, Camberwell.

APPOINTMENTS FOR THE WEEK.

October 27. *Saturday* (*this day*).

Operations at St. Bartholomew's, 1½ p.m.; King's College, 2 p.m.; Royal Free, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.

29. *Monday*.

Operations at the Metropolitan Free, 2 p.m.; St. Mark's Hospital for Diseases of the Rectum, 2 p.m.; St. Peter's Hospital for Stone, 3 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.

Medical Society of London, 8½ p.m. Dr. Lee, "Maternal Impressions." Clinical Cases, and other Communications."

30. *Tuesday*.

Operations at Guy's, 1½ p.m.; Westminster, 2 p.m.; National Orthopædic, Great Portland-street, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; West London, 3 p.m.

31. *Wednesday*.

Operations at University College, 2 p.m.; St. Mary's, 1¼ p.m.; Middlesex, 1 p.m.; London, 2 p.m.; St. Bartholomew's, 1½ p.m.; Great Northern, 2 p.m.; Samaritan, 2½ p.m.; King's College (by Mr. Wood), 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.

November 1. *Thursday*.

Operations at St. George's, 1 p.m.; Central London Ophthalmic, 1 p.m.; Royal Orthopædic, 2 p.m.; University College, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; Hospital for Diseases of the Throat, 2 p.m.; Hospital for Women, 2 p.m.; Charing-cross, 2 p.m.; St. Thomas's (ophthalmic operations), 4 p.m.

Harveian Society, 8 p.m. Dr. W. H. Day, "Hypertrophy of Heart, with Chronic Albuminuria, in a Child." Mr. Edmund Owen, "Imperforate Rectum and Littré's Operation." Mr. T. Carr Jackson, "Lithotomy in a Patient aged 70." Dr. Ashburton Thompson, "Case of Death four and a half hours after Delivery."

2. *Friday*.

Operations at Central London Ophthalmic, 2 p.m.; Royal London Ophthalmic, 11 a.m.; South London Ophthalmic, 2 p.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. George's (ophthalmic operations), 1¼ p.m.; Guy's, 1½ p.m.

At the Royal Observatory, Greenwich, the mean reading of the barometer last week was 29·95 in. The lowest reading was 29·32 in. on Monday morning, and the highest 30·22 in. on Wednesday evening.

* The figures for the English and Scottish towns are the numbers enumerated in April, 1871, raised to the middle of 1877 by the addition of six years and a quarter's increase, calculated on the rate which prevailed between 1861 and 1871. The population of Dublin is taken as stationary at the number enumerated in April, 1871.

ORIGINAL LECTURES.

A CLINICAL LECTURE

ON THE RESULTS OF THE OPERATION OF EXCISION OF THE HIP.

By TIMOTHY HOLMES, M.A., F.R.C.S. Eng.,
Surgeon to, and Lecturer on Surgery at, St. George's Hospital.

In connexion with the subject of excision of the hip, a very interesting question is the utility of the limb when the cure has been long completed, in comparison with its state after the natural cure. I know of no work in which this point is more than just alluded to. I have given the details and drawings of a case, five years after recovery, in the "System of Surgery" (vol. v., pp. 688-691 of the second edition). A clinical lecture by Volkmann, on excision of the hip-joint, has recently been published by the New Sydenham Society, translated, or rather done into a kind of German-English, most painful to the reader, and not always intelligible. In this lecture the author does touch upon this point; but he appears not to have had any opportunity for actual measurement—at least, he gives no details of any observed cases. The conclusion to which he comes is, that growth will not be much checked; but this conclusion is made to rest on theoretical grounds only. He says, "It is a pity that only so very few cases are recorded in which children, who have undergone the operation of excision, have been under observation for years after healing has set in, and very seldom indeed up to the time when the growing process altogether has ceased; for hospital surgeons, to whom the cases often are sent from long distances, and, when cured, generally are lost sight of, are not well fitted for these continued observations. As far, however, as I can judge from a careful perusal of my cases, I may say, with regard to excision of the hip-joint, that the cessation of growth in the limb is not very considerable, certainly not more than we observe in cases of spontaneous cure." It is obvious that this opinion is of little value unless supported by the notes of cases in which the limbs were measured after they had attained their full growth.

As far as I am aware, no other writer has thought the matter worthy of notice; or, what is more probable, the difficulties in the way of finding hospital patients again, many years after their discharge, which Volkmann alludes to, has prevented other surgeons from investigating the point—for almost all cases of excision of the hip are performed in hospital practice.

The matter was suggested to me a short time since by my friend and late house-surgeon, Mr. Frost, at the suggestion of Mr. Folker, of Stoke-upon-Trent, who was desirous of discovering whether the femur, after excision of the hip, suffers any check to its growth, such as it often undergoes after excision of the knee.

In order, if possible, to resolve this question, I tried to procure the attendance of eight of my old patients at the Children's Hospital; but I only succeeded in finding three of them. I append short notes of the examination of these three patients. The exact dates of the operations could be procured, I believe, if necessary, but it seems to me hardly worth the trouble. They were all done before 1868, at which time I resigned my position at that Hospital:—

1. James T., aged twenty-three; operation about eleven years since. The entire limb is wasted, and the shortening, as measured from the anterior superior spine of the ilium to the sole of the foot, is over three inches; but the apparent shortening, when he stands up, as measured by a perpendicular from the anterior superior spine on either side to the ground, is not much over two inches, the pelvis being dropped on that side. Of the three inches of real shortening, only two inches belong to the femur, as measured from the ilium to the patella on either side; the other inch belongs to the leg, as measured from the patella to the internal malleolus. Not only the limb is wasted, but the whole of the affected (right) side of the trunk is smaller than the left side. Movement at the seat of the operation is free and painless, with a slight clicking sensation. The extent of each movement is shown by the figures in the "System of Surgery" above referred to, which were taken from this patient. He cannot stand on that leg alone, nor hop. He is a weakly young man, pale, and of sedentary habits, but can walk any ordinary distance, and do his day's work without inconvenience.

2. Louisa S., aged eighteen. The hip excised about twelve years ago. The limb is somewhat wasted. The shortening, as measured from the anterior superior spine to the patella, is three inches and a half, and measurement to the malleolus gives the same result. There is good union; free flexion and abduction; painless passive motion. She can just stand on the operated limb alone. Her general health is quite good, and she can walk as far as she likes, but her occupation is sedentary.

3. Lydia B., aged fifteen. The original operation was performed in early infancy, when she was about two years old, but some diseased bone was removed by a second operation some years afterwards. She wears a high-heeled boot, with a sole three inches thick; but the real shortening, as measured from the anterior superior spine to the patella and to the internal malleolus on either side, is rather less than two inches. She is a very fat girl, and the limb is well developed, though not so fat as the other. The union is close, so that in flexion the pelvis moves somewhat with the thigh; and this movement is not so extensive as abduction and extension are. Passive motion is quite painless. She can stand on the operated limb for about five minutes. Her work obliges her to walk at least four miles every day, which she does without fatigue. Her general health is perfect.

The above details show, as far as three cases can do so, that no check is given to the growth of the limb by the excision of the hip. The original notes of these cases are at the Hospital for Sick Children, and I have not taken the trouble to refer to them, since very probably the precise level at which the section of the femur was made in each case would not be found recorded. Nor does this seem to me a matter of any importance; for in every case of excision of the hip the level of the section must be below the epiphysial line. But the measurements of the above patients show that this is not followed by any progressive shortening of the limb, such as occurs after the excision of the knee, where it is not unusual to find six or eight inches of shortening in cases in which the diaphysis has been cut into. In the above instances no shortening was found beyond that which necessarily attends the operation, provided no reproduction of bone has occurred. The important point is involved in these last words. Dr. Sayre, of New York, has often written with regard to the subperiosteal method of excision as applied to the hip, and has affirmed that recovery takes place after this method of excision with little or no shortening. Mr. Croft, in the year 1873, showed at the Clinical Society a case in which this method of operation had been performed, and in which the real shortening appeared very small, although the limb was apparently shortened about two inches.(a) In that case, though the shortening was less than in any of the three above related, the movements of the new joint were not nearly so good as in those patients; in fact, it seemed that the limb was almost anchylosed to the pelvis. Mr. Barwell, however, stated in a debate at the same Society, that in a case in which Dr. Sayre had himself operated at Charing-cross by the subperiosteal method, the shortening was as great as usual.(b) This statement, joined (to speak quite frankly) to a certain amount of distrust of statements of the results of a grave operation so very favourable as Dr. Sayre's, and also to disappointment with the results of the subperiosteal method in other excisions, have led me to abstain hitherto from trying it in excision of the hip. The subperiosteal certainly involves more extensive incisions, and more free removal of bone than the ordinary operation; and the protracted manipulation necessary for the complete removal of the periosteum from a large extent of bone is, as I have found by experience, a frequent cause of inflammation and subsequent anchylosis. But I am quite open to conviction on this head, and if any evidence can be produced, which will bear examination, that the limb is left in a better state after the subperiosteal than after the ordinary excision, I shall be very glad to try it, though, if I waited till the operation could really be said to be necessary, I should certainly not expect to see thirty patients recover out of forty, and should be surprised if they all recovered without shortening. These are the results which Dr. Sayre (as quoted by Mr. Croft) claims for subperiosteal excision followed by extension of the limb; and, if I understand him rightly, the movements are also to be natural. We evidently, however, want more detailed notes of the condition of individual patients, as well as more exact accounts of the results of a long series of cases, including not merely the proportion of deaths, but also the state of the patient before operation, and the indications for the excision, before we can be in a position to judge how far the

(a) *Clinical Society's Transactions*, vol. vi., page 174.
(b) *Ibid.*, vol. viii., page 77.

results of the subperiosteal method are really superior, or otherwise, to those of the more common operation.

Another, and to my mind a still more interesting question, is whether the results of excision are superior to those of the natural cure. My own opinion is that they are not. It is quite true that the individual movements are more free. Extension and abduction are performed very freely, and over a considerable range, and flexion is usually also free—all which can hardly be the case after the natural cure,—but, if I may trust my own experience, the limb is hardly ever so firm or powerful in walking as we constantly see that it is after the natural cure by anchylosis, nor is the patient so active or so enduring.

From what I have myself seen of the operation, I should base its claims to adoption in suitable cases, not on its ultimate results being superior to the natural cure, but on its success in saving life in cases where the natural cure appears improbable.

And we cannot but admit that the question involved in the last few words is a very difficult one. We can never say that the natural cure is *impossible*, except in cases where recovery from the operation of excision is so also. And it must also be admitted that in cases of chronic disease, not only of the hip, but of other joints, many patients recover in whom a most unfavourable prognosis has been found. I cannot say that, in the numerous class of cases of hip disease, which appear to depend on injury rather than on any constitutional tendency, any case can be selected as incurable without operation, so long as the patient's general health is not greatly impaired. But we know the length of time and the amount of care which such cases require when carious bone has to be gradually removed by ulceration or necrosis, and deep-seated abscesses or long sinuses have to close up. Nor does our present hospital system enable us to meet the requirements of such cases at all adequately. Many patients require years, and some require many years, of the most sedulous care before they are well, or indeed out of danger of a fatal relapse. It is, I think, mainly because our general hospitals do not afford us opportunities for the prolonged treatment which such cases require, that we find ourselves obliged to resort occasionally to the operation of excision. In private practice, as far as I have seen, the operation is hardly ever practised, not because disease of the hip is rare—for it is, on the whole, tolerably common, both in town and country,—but because parents will not sanction an operation which cannot be represented as urgent or necessary; and because few surgeons in this country think so well of the operation as to recommend it in preference to the expectant treatment, when this can be carried out under the constant supervision of careful and intelligent parents or nurses, and with all the necessary appliances for prolonged rest, in proper hygienic conditions. I speak now of English practice, such as I have carried out myself and observed in the practice of others.

If our experience of the operation had led us to the same conclusions as Dr. Sayre, we should, no doubt, think it our duty to give different advice to the parents of our private patients.

In order that you may see how very differently this gentleman speaks of excision of the hip from the opinion I have just expressed, I will quote to you a few sentences from a "Lecture on Hip-Joint Disease" which formed the first of "A Series of American Clinical Lectures, edited by E. C. Seguin, M.D.," and published at New York in 1875. After describing the natural cure by the slow exfoliation of carious bone, Dr. Sayre proceeds, "In the most favourable cases healed by kind Nature in this way, they have been left with permanent deformity, and with a very much less useful limb than those which have been cured by exsection. I have now performed this operation over fifty times, and can therefore speak with positive assurance upon the subject. This operation is very simple indeed, and attended with no danger whatever." I need not quote the exact directions for the operation; it will be sufficient to say that Dr. Sayre prescribes an incision from four to six inches in length, according to circumstances, carried down to the bone, the periosteum of which is to be divided and raised in two triangular flaps, the joint completely opened, the femur forcibly thrown out from the joint, so as to tear it away from the periosteum on its internal aspect, the whole head, neck, trochanter and (if necessary) the shaft below the trochanter, removed with the saw, and the acetabulum dealt with as freely as its condition demands. The limb is then to be put on an extending splint in the straight position, to do which, if it have been long contracted, the adductors and tensor vaginæ femoris may require subcutaneous section, and dressed by filling the wound with Peruvian balsam applying a pad of oakum over it. Dr. Sayre adds—mediately after the patient is dressed in this way, an recovered from the anæsthetic, he is capable of being up (*sic*) against the wall, or riding out in a carria boat, and can take his daily exercise in this way. . . many of the cases which I have exsected, the motion has as perfect and complete as in the normal joint, and in on (Adolph Russell) the motion is greater in that joint than the opposite side, and the limb less than a quarter of an shorter than the other, although it was sawed three i below the top of the trochanter major, the head and having been entirely absorbed, and the acetabulum perfo Only one of my exsections has recovered by anchylosis that was from neglect in the after-treatment, I never h seen the patient after the operation for two years. . . the other cases that recovered have more or less good m and infinitely less deformity than those which have reco by Nature's process."

I am as little disposed to rude incredulity of the state of others as any man can be, but one cannot read this pa without seeing that it is chargeable with exaggeration a least. It is in the nature of things impossible that so severe an operation—one much more extensive, and invo more protracted and forcible manipulation than the ordi excision, such as you saw me perform the other day—ca volve "no danger whatever," especially when performe this operation always is, on a child weakened and exha by pain and suppuration. It is impossible that the pa can be ready to be placed in the erect position or taken carriage-airing as soon as he has recovered from the anæ tic.(c) So that, two of Dr. Sayre's general statements ap ing to me incredible, and the statements as to the compar results of the operation and natural cure being extre vague, I have hitherto left untried the sub-periosteal me in excision of the hip. I would remark that the reprodu of bone in isolated cases (such as the one of which alone Sayre gives anything like a precise account) happens excisions in which no care is taken to preserve the periost

A very different view of the prospects of the operation, with regard to its dangers and to its probable results, is g by Volkmann. He quotes a statistical paper by Herr Leis of Hamburg, who gives "the mortality after excisions on acc of caries at 63·6 per cent., deducting all uncertain cas well as those which had not been followed up to the he of the fistulæ." I have no doubt, however, that this i error—in fact, the method of computation is itself erron To exclude all the cases which were not followed up t healing of the fistulæ, in estimating the mortality of the o tion itself, evidently results in putting the death-rate too since in almost all these cases the patient had got ove direct results of the operation itself when the report was lished. In a large proportion of such cases the oper fails in consequence of the reappearance or persistence of ease in the bones; and in these, as a rule, the patient gradu succumbs from some of the complications of persistent supp tion. But it is quite erroneous to classify these deaths as d the operation; in fact, in estimating the immediate dang the operation itself, they ought to be reckoned as recov And of the 63 per cent. of deaths in the remaining cases, I no doubt that the majority were due to the disease, not t operation. But to say that so formidable a proceeding inv no danger whatever, is to bespeak distrust for any fu statements on the same subject. My own impression is the mortality from the direct and unquestionable results o operation is not great, but that many patients die from combined effect of the operation and disease, and that large number the operation fails to arrest the disease. I elsewhere given the proportion of real successes (that is, of in which a complete and permanent cure is obtained, as in three patients above referred to) conjecturally as abo quarter of the cases operated on. But this will, of co depend mainly upon the view which the surgeon takes of operation, and the period of the disease at which he justified in interfering. If the operation is performed ear the disease, doubtless the percentage of operative cures wi greater than if the excision be deferred until it is

(c) There is a sentence in Volkmann's lecture which may possib intended to describe some attempt to treat excision of the hip wit confinement to bed; but in consequence of the so-called translator's of familiarity with English, it is unintelligible. It runs thus—"Esm has lately actually raised these patients by applying a plaster-of- bandage to both legs, and which are then slung up, and only the trun far as the sacrum is supported by cushions."

rgently required. But whether the whole proportion of ures will be increased is a very different question. My own npression is that it will not. But figures are quite useless in olving this question—at least, figures without the notes of ne cases. It is more than probable, in my opinion, that by too arly operative interference lives might be sacrificed of children who would have recovered if left to Nature. Most people y this time are able to distinguish between the good statistics f an operation, and the good statistics of the surgical treatment f a given disease.

With regard to the utility of the limb Volkmann differs quite s much from Sayre as he does with regard to the danger of the peration. He says, "The result after excision of the hip-joint n cases of caries which have well healed, is, on the average, atisfactory with regard to its functions. Billroth's description of the same is painted too black, according to my opinion. Certainly half of the cases are afterwards able to walk without he assistance of a stick, and almost the second half will be nable to walk with the assistance of one: very seldom crutches re required for any length of time." This seems to me to ive a less favourable impression of the result than experience varrants. Almost all the cases of recovery after excision vhich I have seen—I think I might say all—have been able to valk quite nimbly and painlessly.

In conclusion let me say, with all due respect to the authors hat have written on this subject, that the statistics of excision f the hip which have been published by so many of them ppear to me worth nothing at all. They give no idea of he danger of the operation itself, and afford no assistance to he surgeon in making up his mind on the difficult question of ecommending or dissuading from the operation in any given case. And yet they are continually referred to by surgical writers, nore especially in Germany, as if they were of real value and mportance; and fresh collections are constantly made, at the xpense of much superfluous labour, as it seems to me, at least. The reason is, that these tables of figures are not accompanied by the notes of the cases upon which they are founded. For nstance, Leisrink (as above mentioned) estimates the mortality at more than 60 per cent.; and other authors have given estimates little less unfavourable. Sayre (as quoted by Croft) says that thirty cases out of forty recover, which would give a mortality of 25 per cent. Both statements may be true, if we assume that in Sayre's practice the operation was performed on many cases at an early stage of the disease, and when in everybody's judgment the natural cure was not improbable; while in Leisrink's series the operation had been put off till a much later period, when both the local and general conditions had become more unfavourable. But unless the necessary details are given, we have no right to assume that this is so, however probable it may appear; and if we are in ignorance of this essential particular, what is the use of the statistics? They are not only useless, but, far worse, they are misleading. A surgeon using Leisrink's might apply them as a proof of the great danger of the operation *per se;* and an argument for refusing to perform it in a case in which, nevertheless, it ought to have been employed. A surgeon using Sayre's might employ them as a motive for too hasty interference in a case where the patient might have obtained a better result by the natural process, without any danger at all. This is only one of the many departments of surgery in which the labours of so-called statisticians have retarded the growth of surgical knowledge instead of promoting it, because they will persist in using figures only, and ignoring facts.

THE authorities of the London Hospital have announced that the establishment at Woodford, in Essex, known as Mrs. Gladstone's Convalescent Home, will be closed from the 29th ult. until the 19th inst. The Home, which is occupied to a very large extent by convalescent patients from the London Hospital, is closed every year for a brief period for cleansing purposes.

GROWTH OF HAIR AFTER DEATH.—Dr. Caldwell, of Iowa, states that in 1862 he was present at the exhumation of a body which had been buried two years before. The coffin had sprung open at the joints, and the hair protruded through the openings. The hair of the head was found to measure eighteen inches, the whiskers eight inches, and the hair on the breast four to six inches. The man had been shaved before being buried. A similar circumstance occurred in 1847 in Mercer County, Pa., where a skeleton of a man who had been buried ten years exhibited hair as firm as in life, and eleven or twelve inches long.—*New York Med. Record*, August 18.

ORIGINAL COMMUNICATIONS.

ON THE DIAGNOSIS AND TREATMENT OF MISCARRIAGES.(a)

By A. E. AUST-LAWRENCE, M.D.,
Physician-Accoucheur to the Bristol General Hospital.

MR. PRESIDENT AND GENTLEMEN,—The subject which I intend bringing before your notice this evening is one the importance of which has been, I think, often much underrated; and when you hear the statistics which I will read to you, I believe you will agree with me that the "diagnosis and treatment of miscarriages" is not second in importance to any condition requiring our aid.

During the past two years I have had under my care at the Bristol General Hospital 450 women, of whom 390 were married, and out of this latter number 150 have had miscarriages, or nearly one-half: 59 miscarried once, 43 twice, 23 three times, 13 four times, 3 five times, 3 six times, 3 seven times, 1 nine times, 1 thirteen times, 1 fourteen times. Taking the whole number of married women, I found that the 390 gave birth to 1500 children, and had besides 356 miscarriages; giving a proportion of one miscarriage to about every four children born. You notice that each woman has an average of four children and one miscarriage.

Now, it is a serious thing in itself that there should be such a loss of fœtal life, but it is a far more serious thing when one considers the conditions which miscarriages often bring about,—conditions which follow miscarriages as surely as that they, if left unrelieved, will again produce abortion. These induced states are to a great extent capable of being removed, but as this applies to the preventive treatment, I shall not at present allude further to this part of the subject.

I ask your attention to the subject, then, on two chief grounds—one, the fœtal mortality; the other, the risks and dangers to the mother at the time of miscarriage, and the subsequent troubles she in many cases has to pass through.

Assuming, then, that you will agree with me that the subject is important, I will endeavour to lay it before you in as practical a manner as I can.

We will suppose that we are sent for to a case assumed to be a miscarriage. The very first question to settle is this—*Does or did pregnancy exist?* It may seem ridiculous to ask this, but those members here who have had to deal with many of these cases will agree with me that it is not sufficient to take the patient's own belief to be correct without running through our minds in all its bearings the question I have put. I have several times been asked to see women who were supposed to be on the verge of a miscarriage, or who had miscarried, and, meeting this question at the onset, have been enabled to save myself a great deal of trouble by being able to decide it in the negative. On the other hand, I have had cases where the reverse is the case.

I cannot possibly in this paper enter into the diagnosis of pregnancy; the points in reference to it are well known to you all. I will only say, do not rely on one symptom or sign, especially in those females of a doubtful age, who are so treacherous to doctors. I have seen cases where absence of catamenia (at the climacteric period), enlargement of the abdomen (due to flatulence), and escape of fluid from the uterus (in cases of catarrh of that organ), have been mistaken for *bonâ fide* miscarriage cases, and the embryo and placenta, etc., looked for in vain, whereas if my first question had been analysed the mistake would never have been made.

Having settled the first question in the affirmative—viz. that pregnancy exists—how are we to recognise that its course is about to be interrupted, or has already been brought to an untimely end? In this paper my remarks will refer to any interruption during the course of pregnancy, although they have more special reference to the earlier months.

I think that by paying attention to the following points we shall be aided in forming an opinion as to the nature of the case. The chief points to raise suspicion of miscarriage are *pain* and *hæmorrhage*. Now, if we can so isolate the kind of pain peculiar to miscarriage, and also the kind of hæmorrhage, we shall be in a position to form an opinion. We will discuss pain first of all, with a view of noting if there is anything

(a) A paper read at the meeting of the Bath and Bristol Branch of the British Medical Association, on April 12, 1877.

peculiar about it which may aid us in our diagnosis as to its cause and source.

Pain may be indicative of true uterine action accompanying the contractions of the uterus itself, and assuming a more or less rhythmical character, and intensified and increased in frequency by the application of the hand to the abdomen, or the finger examining the uterus per vaginam; the pain being felt in the back, thighs, and lower part of the abdomen.

Now, we must not expect to get this typical full-time pregnant-uterus pain if the miscarriage occurs in the early months of pregnancy, for the uterus is not so developed. The pain is more often a dull wearing ache in the loins, thighs, etc., than it is the true hypogastric and region-of-the-uterus pain. If I may state it in other words, it is more often that the reflected pains are most complained of, and not at the original seat. One gets a certain amount of uterine action *plus* the condition of congestion, and other conditions of the uterus, which are most probably bringing on the miscarriage.

Secondly, there is the spasmodic pain of the intestine, most frequently recognised by the condition of flatulence. There are the various intestinal pains due to the irritation of fæces. Then we might have peritoneal pain, especially where pregnancy is complicated with such conditions as ovarian disease, fibroids, etc. Then we frequently, in weak, irritable women, have, at what corresponds to a catamenial period, a neuralgic pain in the region of the ovaries; this, to a certain extent, is recognised by its situation. The pulse and temperature will help us in diagnosing pain of an inflammatory character; but do not be certain that because you have, say, a temperature of 101° and a pulse of 120, and general abdominal tenderness, that you are not going to have a miscarriage, for the condition I have here noted may so mask the uterine action as not to be recognised. I had a case with these conditions and no discharge from the uterus; the os uteri, being too high up to be reached by the finger, could not be examined without passing the hand into the vagina, which seemed hardly necessary in the absence of symptoms pointing to a miscarriage. I did not expect this woman to miscarry; yet she did, three hours after I left her; and, as it afterwards turned out, she was suffering from metritis, and had the placenta intimately connected with the uterus. Mind you, I did not expect her to miscarry simply from the constitutional disturbance, for we know what women will go through without miscarrying, and she had borne eight children, and never yet had a mishap.

I have only alluded to pain due to a few causes; others would suggest themselves to you, and would be referred to their proper causes. The ones I have alluded to are the most common one gets sent for about when people are pregnant and fear a miscarriage.

Another important sign is *hæmorrhage*. This, taken in conjunction with pain, is assumed by a good many to be tantamount to saying that there is a miscarriage about to occur, if it has not already taken place; but as we analysed the pain symptom, so we must the hæmorrhagic, which, according to its source, we will divide into intra-uterine and extra-uterine.

First we will consider the intra-uterine causes of hæmorrhage. During the first two or three months it is not uncommon for a little blood to escape at the menstrual period, especially in women of a lax fibre: this hæmorrhage is generally recognised by its corresponding to a period, and not being profuse or clotted. Then there is a form of hæmorrhage often due to a fibroid condition of the uterus, especially with interstitial fibroids. This does not necessarily correspond to a menstrual period, yet it often does; sometimes it is profuse, and yet the term of pregnancy goes on. I might say that sometimes, instead of getting a red discharge, we occasionally get an albuminous white one, which is the blood deprived of its coagulum, which is retained in utero, and frequently sets up uterine action, and so brings on miscarriage. This kind of discharge is a very dangerous one, as it is so often overlooked, and not recognised as a blood discharge, which to all intents and purposes it is. It is this kind of discharge that we see now and then in premature detachment of the placenta, the blood-stained serum draining down between the membranes and the uterus, leaving behind its coagulum. I have seen two cases where this was the case; the patients were anæmic to a degree, and on evacuating the uterus, enormous clots were turned out.

Another form of hæmorrhage is the one most commonly seen; it accompanies the separation of the fœtal structures from the uterus, it is more or less clotted, comes away in gu and often in it one recognises signs of membrane, etc.; however, this is a sero-sanguineous discharge lasting some and then becoming true blood. This in some cases las weeks.

I now come to the extra-uterine sources of hæmorrhag very common one is due to a granular condition of the o cervix uteri—a state of epithelial denudation, with hypertr of the papillæ, often erroneously called ulceration. Thi common cause of hæmorrhage, especially in pregnant wo The great vascularity of the uterus finds relief by an o from the vessels of the cervix. Sometimes the hæmorrh very great from this source, sufficient to produce well-m anæmia, and, as a result of this, miscarriages Yet I seen several cases where women had supposed they had carried, on account of the hæmorrhage from this source, at the time of my seeing them they were still pregnant. condition can be recognised by the finger or speculum minute; as also can another state, viz., cancer, the hæmor from which is so often mistaken for catamenial flow or carriage. Of course, recognising products of conceptio the discharges will aid in the diagnosis.

The next question is *treatment*. And here, at the onse are met with the important consideration, Is it to be palli or radical?

Having fully analysed the conditions of pain and hæ rhage, and come to the conclusion that the pain is indic in this case of uterine action, and not due to any of the causes mentioned; that the bleeding, if any, is not d either of the extra-uterine conditions, but is, in all p bility, from the decidua, we are justified in attempti palliative treatment—provided that the hæmorrhage is slight, and we do not recognise in the discharge any pro of conception. Keep the patient perfectly quiet; the supine, with the pelvis raised above the level of the tr the room cool, etc. Give a full dose of opium or ch bromide of potassium, or Indian hemp. Gallic aci valuable, as also is ergot in small doses. If this has desired effect in warding off the miscarriage (which occa ally it has), then well and good; but if the hæmor increases, either with or without pain; if the woman is ciently far gone that you can be sure of the death of the fo or if it is in the early stage, and the hæmorrhage is g then the question of radical treatment must be met.

I consider the main element in treating miscarriages palliative proceeding consists in recognising the cause of mishap, and treating that when possible. I have averted carriages in cases where there has been retroflexion and displacements of the uterus, as well as uterine disease treating that cause, even when the pain has been decid uterine and the hæmorrhage decidual.

The *radical treatment* divides into three chief stages, vi (1) Stopping the hæmorrhage; (2) dilating the cervix; (3) emptying the uterus.

We will take the first. How are we to stop the hæmor when medicines have failed to do so? The answer undoub to this is, by plugging the cervix uteri—not the vagina it can possibly plug the cervix—and I cannot realise the c tion where this is impossible. If you have a speculum, of lint, and a probe, you can do it. However, the best wa plug the cervix is by means of a sponge-tent, which effe double purpose—it stops the bleeding and dilates the ce If you cannot get in a sponge-tent, pass a sea-ta tent, which you can make as small as you like. also fulfils two purposes. If you fail in plugging cervix uteri, then you must plug the vagina, either sponge, pieces of lint, or a silk handkerchief; but, as a avoid plugging the vagina if you can possibly help it cervix is the canal you want expanding; if you plug that can effect this object, and at the same time restrain hæmorrhage with far greater certainty than you can plugging the vagina. One frequently sees it recommend pass the tent over night, and go in the morning to remov this generally means twelve hours, but six hours is sufficient time to allow. A well-made tent will do all it in that time, and it is not wise to keep a tent in too long.

By plugging the cervix we fulfil two of our indicat The third is to empty the uterus, and this is done by uterus contracting in a good many cases, detaching the em its placenta and membranes, and saving us any further tro But frequently our trouble begins here. Either the gr part or a portion of the embryo remains inside, and will

expelled by the uterine contractions, and we must remove —which I can say, from my experience, is far easier said an done.

The process of removing divides itself into two parts—) detachment, and (2) removal of the detached portion.

Now, for the first part, I say decidedly, do not use instruents to detach portions of fœtal structure from the uterine alls. Use only the fingers; they will do the work when inruments fail, and by the bi-manual process we are cognisant what we are doing. The only instrument I think we are stified in using for detaching any portion of fœtal structres (I allude especially to the placenta) is the wire écraseur, d in certain cases it is a very valuable aid, especially where e connexion between the placenta and the uterus is so intiate that one cannot peel it off, and the portion projects. Then e plan of Dr. Barnes and others, of applying the écraseur d shaving off the projecting portion, is accompanied with od results: it breaks up the connexion; and in those cases here you are only able to remove a portion, the hæmorrhage equently ceases.

Now as to the way of using our hands in these cases when e are about to attempt detachment. Some cases are so mple that by passing one finger into the uterus we can ach the fundus and sweep out the contents, at once effecting tachment and expulsion, but I am sorry to say these cases ve been few and far between in my practice, and I am sure hers will say the same.

Failing this simple plan, I think the best mode of proceedg is as follows:—Place the patient in the ordinary obstetric sition on the left side; flex the thighs well to relax the dominal walls; give chloroform just to insensibility to pain; en with the left or right hand press down the uterus, and ith the index finger of the other hand passed into the uterine vity, try and detach the fœtal structures. Often it is ecessary, in order to reach the fundus of the uterus, to pass e hand into the vagina.

It is a question now of the very greatest patience in a large mber of our cases. Do not as you detach a bit be in a hurry pull that bit away—let it be a guide for you; keep the finger ose to the uterine wall, then you are not so likely to dig into e uterine structure. If you can manage it, work from ove down, as it is often the easiest way; but each case must e treated on its own merits. Having fully dilated the cervical nal, and being able to reach the fundus uteri, we ought to e able to complete the process of detaching and removing the mbryo, unless there is very intimate adhesion to the uterus. n this case we must be content to detach and remove what e can, and use disinfectant injections, when in a few days e portions generally become detached and expelled. We e cases now and then where it is impossible to push the erus down so that the finger can reach the fundus: this ndition is often met with in women where the cervix uteri long, and here it is necessary to pull down the cervix with a naculum; this straightens the canal, and gives us a good deal control over the uterus. In using the tenaculum, mind and et a good hold and take charge of it yourself, and get some ne else to push down the uterus.

The tenaculum is often a very valuable aid in introducing nts, especially when the uterus is malposed, and if you tempt to pass a tent through a speculum it is in most cases necessity. We will suppose that we now have detached hat we can—frequently the removal is easy; but sometimes, wing to the feeble uterine action, and the possibility of only eing able to get one finger into the uterus, the removal is oublesome. We now can, with advantage, use an ordinary air of long speculum forceps, or small ovum forceps, bearing mind we use them simply for removal, and not to detach ortions from the uterine cavity.

Having either partially, or in most cases entirely, emptied the erus, frequently the hæmorrhage ceases. Should it not, at nce use the hypodermic injection of ergotin; and I might say ere that in giving ergot to check uterine hæmorrhage the ypodermic injection is most valuable. The formula I use is ne given by Professor Simpson, of Edinburgh, which is made y mixing one part of ergotin and three parts of water gether, and adding ten or twelve grains of chloral to each halfnce of the mixture. The quantity to be used for an injection ten drops. I have used this several times, and with the very est result. So highly do I value this method of giving ergot nd other drugs, that I always carry the hypodermic syringe nd suitable preparations with me to every midwifery case nd miscarriage case I go to, and on several occasions I have been very thankful of having them with me—notably in a case of post-partum hæmorrhage, where the action of the ergotin was well marked in less than five minutes from the time of administration. If this does not answer, we must wipe out the uterine cavity with liq. ferri perchlor., or inject slowly a solution consisting of two drachms of liq. ferri perchlor. in two ounces of water. I generally use a No. 12 gum-elastic catheter, and connect this with a glass syringe by means of a piece of indiarubber tubing. If you maintain a free opening from the uterus—which you can do by passing alongside your catheter another one of the same size (so that as you inject through one it runs out through the other),—and inject very slowly, I do not think you run much risk.

If you swab out the cavity with the iron solution you are frequently bound to use some means to keep open the cervix uteri. The various intra-cervical specula will effect this, but what is very serviceable is the following plan:—Pass right through the cervical canal a pair of narrow-bladed forceps, expand them, and then the cervical canal cannot close, and you can pass the cotton-wool soaked in the solution without any difficulty.

Having emptied the uterus and stopped the hæmorrhage, we must then consider the immediate after-treatment.

In those cases where we have been obliged to leave portions of the embryo in the uterus, it is an excellent plan to inject daily, until the uterus is clear, a weak solution of iodine, about one drachm of tincture to ten ounces of water. This must be sent right into the cavity of the uterus by means of a catheter, as before described. This should always be done in every case if the discharge is offensive. I generally, in addition, order the nurse to wash out the vagina two or three times a day with Condy's fluid and water. The intra-uterine iodine injection I always do myself.

The other treatment is pretty much the same as after confinement, bearing in mind that we intend, if possible, to prevent our patient having the same trouble again.

This brings me to the *preventive* treatment, upon which I cannot do more than very lightly touch, as it involves questions ranging through almost the whole of uterine pathology.

One common cause of trouble is the condition known as sub-involution, characterised by a more or less continuous discharge of sometimes blood, but more often of muco-purulent matter, with the uterus enlarged. This is often complicated with metritis, endometritis, etc. In fact, the treatment of sub-involution frequently resolves itself into the treatment of various and distinct uterine diseases which have arisen as complications of that state.

The condition of endometritis itself is one often mistaken for miscarriages, as there is frequently more or less constant hæmorrhage. I have frequently dilated the cervix uteri in these cases, and passed the finger into the uterus, and found nothing but a rough granular state of the mucous membrane, which the local application of nitric acid or liquor ferri perchlor. has cured. This condition is often due to syphilis, and it is necessary when it is so to give the specific treatment for that condition.

In cases of pregnancy with interstitial fibroids it is useful to give small doses of ergot and bromide of potassium, and to maintain as much as possible the recumbent position. Avoid constipation of the bowels. A few leeches now and then to the perineum or groins will be useful in some cases, as also drawing blood from the cervix uteri by puncturing; this determining an extra- rather than an intra-uterine hæmorrhage.

In uterine displacement we must adopt the appropriate treatment, having special reference to position.

To sum up, the preventive treatment involves that, in most cases, of some lesion of the pelvic organs or blood dyscrasia, which can be found if looked for, and treated successfully. It is because this condition is allowed to remain unrelieved that we hear of women so frequently miscarrying. I feel sure that by attending to this part of the treatment, and carrying out the other indications laid down in this paper, we shall not hear of so many miscarriages, nor, when they do occur, shall we hear of women "flooding for weeks," which at present is not an uncommon occurrence.

The following brief notes of cases will serve to recapitulate the chief points of my paper:—

Case 1.—I was asked by a gentleman to see, with him, Mrs. H., who had been losing blood for six weeks slightly, but rather profusely on the morning I was called in. The history was, that previous to the loss of blood she had missed three periods, and believed herself pregnant. An examination

revealed an enlarged uterus with a patent external os; but the finger could not be passed into the uterus. I passed a sponge-tent, and in six hours removed it, and was able to pass my finger into the uterus and remove a dead and partially decomposed three-months fœtus. The hæmorrhage ceased, and the woman did well.

Case 2.—Mrs. B. had passed a fœtus of about three months some eight weeks previous to my seeing her; during the whole of this interval hæmorrhage had been going on, in spite of all medicinal treatment. The cervix was dilated, and I removed, after detaching with some difficulty, a piece of placenta. The hæmorrhage ceased, and the patient did well.

Case 3 refers to one where it was impossible to remove the placenta, as Dr. Swayne can vouch for, as he saw the case with me. I allude to it as showing the great value of intra-uterine injection of iodine, for by following out the plan I have detailed the placenta was discharged without fetor or symptoms of septicæmia.

I must apologise for taking up so much of the time of the meeting, but I feel, even now, that I have but imperfectly stated the case, considering its very great importance.

A CRITICAL REVIEW OF THE

PREVAILING THEORIES CONCERNING THE PHYSIOLOGY AND THE PATHOLOGY OF THE BRAIN:

LOCALISATION OF FUNCTIONS, AND MODE OF PRODUCTION OF SYMPTOMS.

By EUGÈNE DUPUY, M.D. Paris, of New York;
Corresponding Member of the Paris Société de Biologie; Member of the American Neurological Association, etc.

Part II.

(*Concluded from page* 358.)

It is impossible for me to examine in detail all the various subjects comprised in the study of cerebral physiology, and chiefly those which Dr. Ferrier has examined in his work, without writing a volume. I have no inclination and no aptitude for that work, but I must, however, say something on the chapter of Dr. Ferrier's volume, "The Hemispheres considered Psychologically." First, any candid reader will readily perceive that those metaphysical deductions do not spring from the author's experiments, nor even from the deductions or theories which might legitimately be derived from them even if they were accepted to prove what their author claims. Secondly, it appears to me that he has given one illustration—a capital one—which destroys from the very foundation the theory of localisation of functions: I allude to the case of Laura Bridgman, quoted several times by Dr. Ferrier himself.

That person, deaf, dumb, and blind, communicates with the outer world by means of digital language. It has been observed that, just as some persons when deeply thinking allow their lips unconsciously to move as if they were speaking, and indeed that some others when thinking whisper audibly, and in some instances speak aloud, so Laura Bridgman likewise is seen to have unconscious movements of the fingers, just as if she were communicating with somebody, when she is in reality only thinking. The same thing happens when she is dreaming.

Now, it is clear to everyone that by an educational process of long duration the would-be motor centres in the convolutions (to please localisers) must have acquired also the faculties inherent to the speech-centre which in her case were deficient; or if it be said that the speech-centre was intact, that there was no aphasia, but trouble of the external organs of speech, then it must be conceded again that a channel has been established between the speech-centre and the finger-centres for the conveyance of the translation of thought into digital language. It can even be argued that in her, if a larynx could be constructed at the end of her fingers, she would actually speak phonetic language just as an educated parrot. The conclusion to draw from this is that there is no part of the cortex specially or specifically endowed with a certain function, but that any such part can become endowed. I know the experiments of Carville and Duret, which, according to them, enable them to establish the theory of "*suppléance*"—*i.e.*, vicarious, supplementary functions established in the neighbourhood. But it is known also to all those who have made experiments on the brain such as Carville and Duret have published,(a) that in dog they have "taken away the *centre* for the legs in the *rig* hemisphere; the voluntary motor paralysis showed itself usual. After six or eight days the animal had entirely recover power in its *left* leg. They (we) then took away the centre f the legs in the left hemisphere. Evidently, if the '*suppléanc* (supplementary function) of the two hemispheres existed, par lysis of the *left* leg ought to have appeared. It did not. T dog was paralysed on the right side just as if he had had lesion of the left hemisphere before." It is evident in th case that the *left* leg must have derived its nerve-impulse fro some centre not situated in the *left* hemisphere, nor, certainl from a regeneration of its own *right* centre. Therefore so portion of the cortex in the neighbourhood must have acquir *that* function which it had not before, according to the theo of those who teach that the cortex contains centres.

I believe that I have said enough on this subject to sho that there are other facts in science besides those taken noti of by Dr. Ferrier in his treatise, and that even the fac analysed by him can be shown to prove the contrary of t theory which he has established. I will observe here, agai that unless one starts with the idea that there are motor centr in the cortex cerebri, it is impossible to succeed in establishi their existence in that tissue, which, after all, may be as w endowed with a sensory function as with any other.(b)

I shall now proceed to state very briefly what I consider be the explanation of the experimental results of Hitzi Ferrier, and others.

First. I must state that it has not yet been proved by a means that the cortex cerebri in any portion of its extent c be irritated by any means, mechanical, physical, or chemic and that even if we were to suppose that the electricity us by experimenters excites the fibres which are in communic tion with the cortical cells, and which unite them with low centres, we could gain no knowledge as to the nature of t function of those cortical cells, because a nerve-fibre w conduct in either sense, afferently or efferently.(c)

Second. An experiment which shows that when both centr for the two anterior legs are destroyed, the animal very so uses its limbs as well as before the experiment, sugges the idea that the transient paresis which resulted immediate after the experiment, instead of being a withdrawal influence of a centre, is, on the contrary, an irritative influen exerted by the lesion. The subsequent disappearance of paresis, and the cicatrisation of the brain-tissue, show that fa plainly.

Third. When, an animal being deeply narcotised, an ir tation of the exposed sciatic nerve gives rise to most viole contractions in the muscles of the leg, whilst all reflex actio have disappeared, if the cortex cerebri then does not respo to electricity it is wrong to say that it is because it has fi lost excitability, as Drs. Ferrier, Carville, and Duret preten after Flourens. There are many experiments which go again this. Here is one very striking, which I have had occasion make several times, and which Onimus has specially noted one of his papers. If from a large healthy frog the rig hemisphere is taken away, the animal presents this well-know appearance, that its left side takes the position usual to a brai less frog; the tonicity of all its muscles is increased on that o side, the anterior and the posterior legs are held closer a firmer against the body, which is itself inclined on that sid If now chloroform is administered, all changes. The left si becomes weaker than the right side, which its tonic contra tion made it overpower; that effect becomes more and mo apparent as the narcotic effect advances, until both sides the body are equally influenced by the anæsthetic; the frog c then no longer rest on its anterior limbs, and its posterior on are in a state of revolution. At the same time that the effec of the narcosis pass away, the leg of the sound side in corr spondence with the existing hemisphere assumes by degre its normal position, and comes near the body; whilst those the right side, which are deprived of their cortical centres, a yet in extension and revolution. A little later, that one al resumes its former position as before the narcosis, and one time the position of all four limbs is identical; bu when the narcotic effect has entirely passed away, t limbs which are in relation with the side of the hemisphe

operated upon are again in a state of stronger *tonus*, and the body of the animal is again more inclined towards the side opposite to the destroyed hemisphere. That experiment also shows that the cephalic centres are the first to recover their excitability. In the cat and the rat the effect *is exactly identical, mutatis mutandis;* so that, in the experiment for the elucidation of the problem of localisation of functions, if there is any one part of the cerebrum which does not react when electricity is used (the animal being absolutely narcotised), it must be the lower centres, *i.e.*, the corpora striata and thalami optici. But this last fact is not proved; on the contrary, if in an animal so deeply chloroformed the electrodes are applied directly on those ganglia, we do have general contractions. If the cortex cerebri has any influence on motion, it must be in the sense of a sensitive centre, and not as a motor, because from the foregoing we see a radical difference between it and the other ganglia.

Fourth. The objection that the movements which arise from electrical stimulation of the cortex (which the foregoing experiments and arguments would enable us to consider sensitive, and which are thus of a reflex nature) cannot be reflex,(d) because a reflex "movement is rarely limited to the same group of muscles," is worthless, as everybody knows that no movements are more limited than reflex movements. Indeed, let those who pretend that all actions performed by a brainless frog are purely reflex and have nothing intelligent or psychic, study the beautiful harmony of movements of a frog so prepared. After the ablation of the medulla oblongata, reflex movements are still very localised.

Fifth. The argument derived from this fact, that it can be foretold that on irritating such a point of one convolution in a brain, or in the brains of all animals of one species, or in any convoluted brain, care being taken to ascertain homologous points in all, such a movement will arise in one limb,(e) does not prove the irritated cortical area to be motor at all. It must be kept in mind that no other agent but electricity will produce the phenomena under consideration, and that electricity, as I have experimentally proved, travels and diffuses. Now, when making use of a physical agent, every time that we shall have identical circumstances we shall also have identical results; and allowing that the electricity diffuses to the base of the brain,(f) to different ganglia, etc., it is natural that in all convoluted brains we should have the same results, and be able to foretell them; but the mere fact that when the sulci in different brains (species) assume a different direction, the point to be irritated to produce one given movement also varies—showing that always a constant relation of the area of the cortex of the brain with the base of the brain or the ganglia must be an element for obtaining the sought-for result—destroys the only objection, as shown by the different situations of some centres in the brain of the cat, the ape, the dog, etc.

Sixth. The fact that irritation of the same area(g) of dura mater will give rise to localised movement in a certain group of muscles identical with that following irritation of the cortex,(h) and that even mechanical irritation will give the same results, is contrary to the theory of Hitzig, Ferrier, Carville, and Duret.

Seventh. The fact that irritation of the cortex after the manner of the forenamed experimenters has given rise, when the leg centres only were acted upon, to peristaltic movements of the intestines, to hyper-secretion of saliva, to increase in the blood-pressure, to contraction of the spleen,(i) etc., tends to show that if the opinion of Hitzig and Ferrier and others is to be maintained, that the cortex is a motor centre, we must *ipso facto* admit that those *same* centres of motion are centres also for the different functions just enumerated.

Moreover, within the last year Dr. Brown-Séquard has shown that burning of the cortex in a large area will bring on paresis—in some instances on the same side, in others on the opposite,—and always vaso-motor paralysis.(k) Bochefontaine has also given some reasons for believing that the elements acted upon are not those which make up the cortex; and Eulenburg and Landois(l) have shown that in irritation of the cortex the so-called motor areas act very much like vaso-motor centres.

I had already in 1875 advanced the view (which appeared to me to be well substantiated by experiments) that the phenomena which we saw in those experiments were reflex, being the results of vaso-motor influences.

The facts and arguments detailed above had satisfied me that the cortex cerebri was no part in the process which produced the phenomena of contraction of groups of muscles after irritation of certain areas with electricity; and I discovered that those points of the cortex which are called "ideo-motor" are those to which a comparatively larger artery from the pia mater penetrates, not into the cortex, but deeper, into the white strands beneath; also that the only spot in the homologue of the angular gyrus of man in the dog which does similarly give rise to movement and to hypersecretion of saliva, is also the one at which there is such an arterial arrangement. I have given details on that subject elsewhere.(m) Those vessels are provided with nerve-fibres, which go along with them, or singly, into the brain-tissue. The arteries also send smaller twigs, which ramify like roots of trees into the cortex alone, but everywhere in it; whilst those with which I am concerned have no office with the cortex.

I had found by my former experiments(n) that substances which diminish or increase reflex action by acting through the vascular system, also increase or diminish the intensity of the phenomena observed in the experiments under consideration; and taking notice that the cerebral pia mater contains a very great number of ganglion cells and fibres which are those of which I have just spoken above, and which are in relation with other cells found in the tissues under the convolutions, I came to the conclusion that the movements observed after irritation of the cortex cerebri are of the same nature as those which are seen when the four main arteries of the brain are simultaneously tied. That, in fact, we had in one limb what Kussmaul and Tenner have observed in the whole animal in their experiment.

I have noted that the time, from the instant of applying the electrodes to the cortex to the actual production of the movement, is sensibly the same as that which is required to stop the bleeding of a small artery in the spinal cord laid bare, when a branch of a communicating nerve is irritated with electricity, and that this is fifteen or seventeen times longer than the period required for the performance of a voluntary action, and nearly once longer than for the performance of an ordinary reflex action, which, according to Professor Schiff,(o) is between eleven and thirteen times longer than for a voluntary one.

Against this view some objections have been raised. Dr. Brown-Séquard(p) has stated that the elements arising from the pia mater have certainly nothing to do with the process, because he has seen the same vaso-motor effects follow the burning, by the actual cautery, of the cortex after peeling off the pia mater as before. To this argument I have found this answer: that the mere peeling off of that membrane induces vaso-motor phenomena, so that the subsequent application of the cautery to the denuded cortex adds nothing to the results.

Those strands of fibres with which the bloodvessels have some office are in connexion with the spinal cord, the medulla, the pons, and the basal ganglia (apparently), if I am to judge by the direction of their course.

One word more before ending, about consciousness. I am not prepared to deal with that huge subject metaphysically. I will only say a few words about it because I have undertaken to review the subject of the functions of the brain in the same manner as Dr. Ferrier has done it. If I do not accept his views, I wish it to be understood that the hypothesis which I will give is a mere hypothesis, and nothing more. I must say in the beginning, however, that I agree with Dr. Ferrier and with many others that "we may succeed in determining the exact nature of the molecular changes which occur in the brain-cells when a sensation is experienced; but this will not bring us one whit nearer the explanation of the ultimate nature of that which constitutes the sensation." Montaigne has written long ago—"Cette apparence de verisimilitude qui les faict prendre plutôt à gauche qu'a droicte, augmentez la; cette once de verisimilitude qui incline la balance, multipliez la de cent, de mille onces; il en adviendra enfin que la balance prendra parti tout a faict, et arrestera un chois et une vérité

entière. Mais comment se laissent ils plier à la vraysemblance, s'ils ne connaissent le vray? Comment connaissent ils la semblance de ce de quoi ils ne connaissent pas l'essence?"(q)

This being the case, I beg leave to state that in the beginning of this review I have said that instead of stating that "the brain is the organ of the mind, and that mental operations are possible only in and through the brain, is now so thoroughly well established and recognised, that we may without further question start from this as an ultimate fact;"(r) but that there is good reason, on the contrary, for believing that the lower centres so called, the spinal centres, also are the organs of mind to some degree. Vulpian, when commenting on reflex actions in a frog deprived of its brain, keeping in his mind the beautiful adaptations of purposiveness of its movements, says—"What would an animal still possessing its cerebrum do more?" Yet he has concluded that there was no will in the actions of that frog! How do we know? What is will? Professor Dugès, of Montpellier, as I have already said, found, after experimenting on the *Mantis religiosa*, that when the head and prothorax have been taken away, the posterior portion, retaining its four limbs, resisted all efforts made to overthrow it, and manifested anger by trepidations of wings. On the anterior portion of the animal he removed the head, so that the animal consisted of nothing more but the prothorax. That portion of the body lived for more than one hour, agitated its limbs, and sometimes caught the fingers of the experimenter, and inserted its fins in the flesh.

I have seen a salamander deprived of what represents its cerebrum, and kept in a cool and dark place during summer, and placed in a dish covered with a plate, for several days change its place without being excited to do so by any circumstances that I could appreciate.

Those facts, and the reasonings which can be deduced from them, authorise me, I believe, to state that Dr. Ferrier is not right when he says "that it must follow from (? his) experimental data that mental operations in the last analysis must be merely the subjective side of sensory and motor substrata."(s)

We must not accept either this other proposition of his, that the physiological activity of the brain is not, however, altogether co-extensive with its psychological functions.(t) It is through the obligation he has been all through his work to beg the question that he has written the postulate which is followed by this, that the "brain as an organ of motion and sensation, or presentative consciousness, is a single organ composed of two halves; the braiu as an organ of ideation, or representative consciousness, is a dual organ, each hemisphere complete in itself." He has been bound to make that distinction, although there is no ground for it, because, as he says himself, "when one hemisphere is removed or destroyed by disease, motion and sensation are abolished unilaterally, but mental operations are still capable of being carried on in their completeness through the agency of one hemisphere." If the view is taken that diseases of the brain do not arise from the fact that a centre has been destroyed, but that the diseased portion of nerve-matter does start the symptoms, in the same manner that washing the pleural sac in the operation of empyema, in some instances brings on an attack of paralysis of the arm on the corresponding side, which passes away to recur again after every washing—as shown by Leudet aud others—of course this view of Ferrier's is still more unacceptable. I will state first that it so happens that when gross lesions of the brain do give rise to psychic alterations, it is in the lower centres that the lesion exists, aud not only in the cortex. Trousseau repeatedly asked himself why the patient suffering from hæmorrhage on the brain always cried, whilst when only aphasia, only lesion of the convolution existed, no crying was observed. Lesions of the upper part of the pons, chiefly of the anterior right part, are very prolific of emotional symptoms. The emotional state is a psychic one; and Dr. Brown-Séquard aud Professor Charcot have noted that fact so often noticed by Trousseau. Dr. E. C. Seguin has two years ago written a good paper on that subject. Dr. Fleury(u) has shown that there is a difference as to frequency of emotional symptoms, according as the right or the left hemisphere is diseased. It is necessary that Dr. Ferrier should prove that consciousness and ideation are two such different things—that is to say, that one can exist without the other—as if the mere fact of ideating does not prove consciousness of the ideating process, which is equivalent to saying that a thing can be without being, before we can adopt the distinction he has drawn.

I believe that sensation being a factor of consciousness, it is not unreasonable to suppose that we can conceive consciousness to be that which is at work, or rather which is developed from anatomical elements, when the brainless frog executes all the movements so well observed by Pflüger; the *Mantis religiosa*, without head and without posterior segment, reduced to its prothorax alone, and the salamander without cerebral ganglion, execute purposive actions.

(q) That appearance of verisimilitude which impels them to incline to the right rather than to the left—augment it; that ounce of verisimilitude which bends the scale—multiply it by a hundred, by a thousand more ounces: it will come to pass at last that the scale will incline altogether, and will thus fix upon a choice, and a whole truth. But how do they allow themselves to believe in a similitude of a truth if they know not the truth itself? How can they know the like of that of which they know not the essence?—Michel Montaigne, "Essais," liv. ii. chap. xii.

REPORTS OF HOSPITAL PRACTICE IN MEDICINE AND SURGERY.

CASES OF NERVOUS DISEASE.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC.

Case 1.—*Local Cerebral Anæmia—Bilateral Symmetry in Neuro-vascular Diseases.*

Remarks by Dr. Gowers.—A bilateral character of symptoms in central disease of the nervous system suggests, first, and rightly if the symptoms came on at once, an affection of some part of the cerebro-spinal axis in which the conducting tracts or the centres arc in such close contiguity that a single lesion might produce the symptoms. Thus, bilateral affection of the limbs suggests the idea of disease in the spinal cord or pons Varolii. But it is important to remember that a similar distribution of symptoms occasionally results from disease of identical regions in the cerebral hemispheres or central ganglia. Such bilateral disease may result in one or two different ways. The identical relation of certain regions of nerve-tissue in the hemispheres to general morbid influences may cause a symmetrical affection of the two sides. We see an illustration of this effect in albuminuric retinitis, which, except in its slighter forms, is rarely unilateral. In cerebral atrophy, and in some forms of spinal and medulla diseases, the same thing may be observed. But there is a second and more frequent cause of this bilateral symmetry of cerebral disease. Many of the gravest cerebral affections are primarily diseases of the blood-vessels—neuro-vascular diseases, as they may be called. Such are cerebral softening and cerebral hæmorrhage. Bilateral symmetry of these diseases may be determined by the similarity of the distribution of the vessels of the two sides. This correspondence of vascular distribution is often very close; it may be noticed in the resemblauce of the arraugement of the retinal vessels in the two eyes. The effect of this bilateral vascular symmetry is, that any general cause of vascular disease acts in an identical way on the vessels of each side, and gives rise to symmetrical changes. This may be seen, rarely, in cases of embolism. Emboli of similar size entering the two middle cerebral arteries may be arrested at a similar position on each side, and thus may cause disease of functionally identical regions in each hemisphere. This was the case in an observation published by Dr. Barlow, in which such a mechanism gave rise to a bilateral paralysis of the tongue. A similar effect is seen with greater frequency in degeneration of the cerebral vessels. We are able to understand its mechanism better now that we know to how large an extent vascular degeneration is determined by mechanical strain—that it is the high intravascular pressure and imperfect support which determines the occurrence of degeneratiou in the arteries at the basc of the brain. Symmetry of vascular arrangement means symmetry of strain, and frequeutly causes symmetry in the resulting degeneration, and ultimate cerebral disease. This is seen sometimes in the branches of the internal carotid, but more frequently in those of the basilar artery. The pressure in the two internal carotids is often not quite equal, but that in the branches of the basilar on each side is

often very nearly equal, and its effect is correspondingly symmetrical. It was so in the case which suggested these remarks. By this mechanism a bilateral affection of functionally identical regions results from the operation of the simplest mechanical conditions. It is probable that the hereditary transmission of a tendency to cerebral softening and cerebral hæmorrhage is in part at least, the effect of the transmission of a similar vascular arrangement. The fact that certain peculiarities in the distribution of vessels in internal organs is transmitted is often observable with the ophthalmoscope. A parent, for instance, has a certain peculiar arrangement of the branches of the central artery of the retina, and precisely the same peculiarity may be observed in that parent's child. Thus, a similarity in cerebral vascular supply may determine undue pressure at certain localities, with the result that "atheroma" or "endarteritis deformans" occur there, and produce similar effects on the cerebral tissue.

The case which suggested these remarks was that of a man aged sixty-five, who came to the hospital complaining of some right-sided weakness and disordered sensations in the leg—numbness, coldness. On examination with the dynamometer, it was found that both arms were weak, and equally so, and no difference in the sensibility of the two sides could be made out. There was no evidence of cardiac or renal disease. A few weeks later, word was brought that he had become gradually weaker, and had died. A partial post-mortem examination was obtained by Mr. Sankey. There was no hæmorrhage or softening to be discovered in the brain. The large arteries presented a moderate amount of atheroma, not interfering with their branches except in one situation. On each posterior cerebral artery, at the spot at which the vessel passes over the crus and supplies branches to the optic thalamus, was an area of extreme atheroma, about an inch in length, and involving the whole circumference of the vessel. On examination of the optic thalami, it was found that each presented in the central region an area, about the size of a nut, of very marked pallor, and that this region was limited on every side by a narrow zone of hyperæmia. It was unsoftened, but under the microscope the nerve-elements were beginning to degenerate, and a few granule corpuscles were seen. The area affected corresponded exactly to the distribution of the arterial branches from the diseased portion of the posterior cerebrals.

The case illustrates several of the points above mentioned, especially the way in which disease of vessels (probably largely determined by mechanical conditions) resulted in symmetrical disease of the cerebral tissue. It affords, also, an interesting example of the effects of local cerebral anæmia in the production of symptoms. It is not often that this can be observed, since the obstruction is usually so complete that necrobiotic softening occurs. It is such local cerebral anæmia which causes the well-known "prodromata" of acute softening.

GREAT NORTHERN HOSPITAL.

Case 2.—Delirium Tremens treated by Chloral, Hypodermically and by Mouth—Ulcers following the Hypodermic Injections.

(Under the care of Dr. CHOLMELEY.)

[From notes supplied by T. H. GILLAM, House-Surgeon.]

N. B., a master carpet-beater, aged about forty, was admitted into this hospital on September 18, suffering from premonitory symptoms of delirium tremens. From his history it was learnt that he had delirium tremens two years ago, that he was a great drinker, chiefly of spirits, and that he had been suffering for some months from melæna and hæmatemesis. When admitted, his trembling hands and general confusion of ideas and manner indicated that he was going to have another attack. He was a spare, thin man. The capillaries of his face were much congested. Ordered milk diet, with beef-tea, and no stimulants.

September 19.—No sleep. Had twenty grains of chloral in night. Now very refractory, sitting up, and it is with difficulty he can be kept in bed; very excited, and is determined to leave the hospital if he can manage it. Bowels have acted; motion nearly all blood. 10 p.m.: Has been in strait-jacket since 3 p.m., at which time he tried to get out of the window. High delirium, and extremely violent, sweating profusely. Has passed no water; will take no nourishment. Ordered twenty grains of chloral at once, and twenty grains more if not asleep at 4 a.m.

20th.—10 a.m.: Has not had any sleep; talking and calling out incessantly throughout the night; eyes very bloodshot; face crimson and suffused; pulse 126, running. Water drawn off by catheter, highly coloured, very albuminous. Bowels not open. Will take neither food nor medicine. A beef-tea enema with brandy (two ounces) administered, but returned immediately; twenty-four minims of a saturated solution (gr. j. ad ℥ j.) of chloral hydrate hypodermically injected into legs. 2 p.m.: Certainly worse; has had no sleep; pulse feeble and running; bathed in sweat. Thirty-two minims of the same solution of chloral injected hypodermically, as before. As the patient was evidently becoming exhausted by the violence of the delirium and want of sleep, and would now swallow, it was determined to give full doses of chloral every hour until sleep was produced. He was therefore ordered forty grains of chloral the first hour, and twenty grains every hour afterwards until sleep should be procured.

21st.—1 a.m.: Still the same busy delirium; no sleep since the 18th inst. Bowels constipated; sweating profusely; voice husky; pulse very feeble, about 136. Has taken nourishment since 4 p.m. yesterday. 6 a.m.: after taking (in a space of five hours) 120 grains of chloral, the patient fell into a profound sleep, from which he awoke at 2 p.m., much refreshed, and at times almost rational. He now rapidly recovered from this very severe attack, and on the 27th was discharged, cured.

Remarks.—Two or three points are especially worthy of note in this case. In the height of delirium the urine was, as has been stated, highly albuminous. When the patient had nearly recovered, the urine was examined more than once, and no albumen was detected; and on two or three occasions later on it was carefully tested, but not a trace of albumen was found. The condition of the patient seemed to make it imperatively necessary to induce sleep by means of drugs, but the amount of albumen in the urine rendered it at the least very desirable to avoid the exhibition of opium in any form, and chloral hydrate was therefore selected as the hypnotic; and a concentrated solution of this was given hypodermically, by seven injections, three in one leg, and four in the other, each injection containing six or eight grains. No local evil consequences followed during the patient's stay in hospital, and though sleep was not induced by the injections, yet after them the man could be persuaded to take both medicine and food by the mouth, so that probably they had that good effect. About ten days after the patient went out the points of injection began to be irritable and painful; and a week later still, he, on being seen at the hospital, complained of severe pain and discomfort. On examination it was found that each spot was covered by a dark red, dry, thin scab, formed apparently of hardened epidermis. This was easily rubbed off, and discovered a circular spot of cutis of a perfectly dead-white colour, slightly moist, and entirely devoid of sensibility. Each white spot was encircled by a narrow line of vividly red, slightly swollen, and highly sensitive and painful skin. There being at that time no vacant bed in the hospital, the man could not be readmitted, but he was enjoined to take to his bed at home, or at any rate to keep the legs up, and to apply poultices or water-dressing. A few days later the dead-white cutis at each place of injection had sloughed away, leaving very inflamed and irritable-looking ulcers, varying in size from a florin to a fourpenny-piece, having clean, circular, punched-out looking borders, with greyish sloughs at the bases, and very painful. The patient was then taken into hospital, and with rest in bed and the simplest local treatment—vasiline and moist warmth—the ulcers cleaned; the edges became undermined a little, but healthy granulations formed, the sores began to contract, and healing has gone on steadily, though rather slowly. The appearance of the ulcers at one time was strongly suggestive of a syphilitic taint; but there is no history of syphilis, and no specific treatment has been required. The sodden and unhealthy condition of the tissues generally in this alcohol-saturated patient had probably some share in causing the ulcers, but the solution of chloral used for injection was no doubt too highly concentrated It is remarkable, however, that so many days intervened before the appearance of any local mischief.

CHILDREN'S HOSPITAL, PENDLEBURY, MANCHESTER.

Case 3.—Disseminated Selerosis of Brain and Spinal Cord in a Child.

(Under the care of Dr. H. HUMPHREYS.)

Annie J. S., aged three years and six months, was admitted into the Children's Hospital, Pendlebury, on September 1, 1877.

Family History.—Parents both healthy; their first child was stillborn; one child died, aged thirteen months, of measles; one, aged five months, is quite healthy. Patient was quite healthy until ten months before admission. She is said to have been an intelligent child, and often used to be sent on

errands. About ten months ago she was knocked down by a horse. She did not lose her senses at the time, but she bled at the mouth. She appeared to recover completely from the accident. Two months afterwards, however, she had a fit lasting about half an hour. In this she turned black, and was convulsed. On the day following it was noticed that her limbs shook when she attempted to use them either to feed herself or to walk. The limbs continued to shake for two months, when she was taken to the dispensary and galvanised; after this the limbs became steadier. There was no impairment of speech at this time. Five months after the first one, she had a series of fits lasting three hours and a half. After these her intelligence appears to have been much impaired. She would say very little, and take very little notice of things. She would, however, ask for things she wanted. The shaking of her limbs did not increase much after these fits. The last fit occurred fourteen days before admission, and lasted a quarter of an hour. Her bowels are generally costive. She does not vomit unless she has had something to disagree with her.

On Admission.—She is a large child for her age, and weighs thirty-five pounds; her bones are massive, and muscles well developed; her head is of moderate size, the forehead perhaps a little deficient in breadth. She has a dazed look; her lower lip hangs down. She can sit up steadily in bed, but directly she attempts any voluntary movement her limbs and head begin to shake. She cannot stand, but begins to shake very much when she is raised into the upright position. When she is supported she makes an attempt to walk, but the movements of the muscles of the lower limbs are incoördinate, and so she flounders about. Her tongue is protruded with great difficulty, with much shaking, and generally with a slight deviation of the tip to the left. She has the greatest difficulty in getting anything up to her mouth—her arm shakes very much in the attempt. She swallows fairly well; occasionally a little milk runs back out of her mouth. She is clean in her habits. She does not seem to understand much of what is said to her. She speaks in a drawling, plaintive voice. She can look steadily with her eyes; there is no nystagmus; her sight appears to be fairly good. An ophthalmoscopic examination, made under chloroform, showed that the optic discs are well defined; the colour is pale grey, the arteries are perfectly thread-like, and the veins small. The muscles react well to faradism. Treatment: Five grains of iodide of potassium to be administered three times a day.

October 1.—There appears to be some improvement in her condition. She does not shake so much as she used to do when raised up. When supported she manages to walk a little more steadily. Her toes always touch the ground before the heel in this movement. Her tendency is to fall forward. When seated on the floor she manages to shuffle along in a very dexterous way, pushing out first one leg and then the other. She never answers any question. She is always asking the same question, viz., "Is daddy coming?" Sometimes she shouts out "T-t-t-ics," meaning toys. When a watch is held to her ear she gives a look of great satisfaction, and says, "T-t-tick-er." The above words are about the only ones she ever uses. She is an amiable child, very lively, and at times boisterous.

6th.—Had a fit yesterday evening, which is thus described by the nurse who witnessed the attack:—First her eyes turned to the left, then the left arm was drawn up, and next the left leg; then she stiffened out all over, and then became convulsed. At this stage the Lady Superintendent saw the patient. She says that the legs were kept wide apart and stiffened out, but that the feet were moving upon the ankles; that the right arm was kept up against the head, and the left down against the body, and that both hands were moving upon the wrists; that she kept her eyes turned to the left; that her mouth went to the left side, and her face twitched; and that after this state of things had continued a few seconds, she passed into a deep sleep.

Remarks by Dr. Humphreys.—Most of the symptoms of disseminated sclerosis are well marked in this child. As to her age, out of forty-one cases collected by Jaccoud the youngest age was two years. The age of the patient under consideration appears to be the second youngest on record, as far as I can ascertain. In this case there have been well-marked epileptiform attacks, one of which occurred in the hospital under the observation of the nurses. Such attacks, according to Charcot's article, have not as yet been described in the disease in question. Nystagmus is absent, although there is well-marked atrophy of the optic discs. Lastly, the muscular development of the child is very fine.

SATURDAY, NOVEMBER 3, 1877.

THE ARTISANS' DWELLINGS COMPANY FRAUDS.

The recent action against certain late officers of the Artisans' Dwellings Company for conspiring to defraud the Company, must have been watched with special interest by members of the medical profession. At the least, as well acquainted as any other class of men with the overcrowded, wretchedly unhealthy, and in every essential ill-appointed dwellings in which the lower ranks of our population are driven to herd together, medical men know better than any other class can know of what vital importance room-space, fresh air, pure water in plenty, cleanliness, and light—all the physical surroundings, in short, that can help to make a dwelling into a home—are to the physical, moral, and mental development of mankind. They have consequently noted with great delight and satisfaction every step taken by the Legislature or by private enterprise towards supplying our artisans and labourers of all kinds with improved dwellings; and it may be fairly supposed that they felt some special degree of interest in the success of the Artisans' Dwellings Company, as its late chairman, Dr. Baxter Langley, is a legally qualified and registered medical man, though not a medical practitioner. The primary object of the Company was, as is well known, a philanthropic one, and its supporters and shareholders did not look for more, at the first, than a moderate rate of interest on the capital employed. Profit on the operations of the Company was, in fact, rather a secondary consideration; but that it should pay its way, and return a reasonable rate of interest as an investment, was a matter of great importance for the encouragement of similar undertakings. The Company was formed in 1866 for the purposes of purchasing land in the neighbourhood of London, and erecting upon it model residences for artisans; and special faith was probably placed in its soundness and trustworthiness

by artisans and others, because, while many highly influential persons belonged to it, its Chairman, Dr. Baxter Langley, and its Secretary and Manager, Mr. Swindlehurst, were widely known as men who were identified with the movement for improving the condition of the working-classes. All went apparently well till the present year, when circumstances led to an investigation by some independent gentlemen into the affairs of tho Company, and as one of the results of that investigation the recent prosecution was instituted. It is sufficient here to say that it was proved to the satisfaction of the jury and the presiding judge that estates bought in 1874 and 1876 by Mr. Saffery, an estate agent, at one price, were sold to the Company at a much higher price, and that the profits were shared in by the Chairman and the Secretary, and by at least one other officer of the Company, a Mr. John Shawe Lowe, one of the directors, who did not surrender to take his trial. The profit on the resale of one estate to the Company seems to have been over £9000, and on another £13,000. The defendants were found guilty, and, on the count of a conspiracy to defraud the Company, Dr. Langley and Mr. Swindlehurst have been sentenced to eighteen months' imprisonment with hard labour, and Mr. Saffery to twelve months'. It was urged in defence of the prisoners that similar transactions are of everyday occurrence in the City of London, and that, nevertheless, this was the first case of the kind that had ever come before the law courts; and that therefore the defendants had no reason to suppose that they were doing anything illegal. But it is very difficult to believe that, at any rate, a man of Dr. Langley's education and position could have believed that he had any right, moral or legal, to line his own pockets at the expense of a company in which he held a position—a highly responsible position—of trust. We must be thankful that the prosecution was successful, for had it failed the failure must have had a most disastrous effect on all enterprises like that of the Artisans' Dwellings Company, to say nothing of the effect on commercial morality in general. The fraud committed was a most heinous breach of trust, and to some it may seem that the sentence is comparatively a light one. But no one will so deem it who considers the effects of it, for it entails absolute ruin of character and prospects. As regards two of the prisoners we have no special interest, but Dr. Langley is a man widely known to the profession as a medical agent, carrying on a large business for the sale of practices, the arrangement of partnerships, and so on. He was educated at King's College, and is a Member of the Royal College of Surgeons of England; he received some years ago a degree in Laws from America; he is author of several works in professional and general literature; and he was a busy politician, so well known and so far trusted in, that not very long ago some 5000 of the Liberal electors of Greenwich supported with their votes his pretension to represent them in Parliament. And he has now forfeited everything an ambitious man can care for, and is hopelessly disgraced in the eyes of all honest men. Considering all this, it will be allowed that his punishment is terribly heavy. That it is, however, in any measure too heavy, we cannot feel; and we must hope that it will act, as all punishment is intended to do, as an effective deterrent to all placed in similar positions of trust and confidence. If it is, as may be feared and has been said, true that offences like his are of common occurrence, that deplorable fact could not in any degree justify or excuse him; while the lesson taught by his detection and punishment was all the more needed for the vindication and the refining of commercial morality.

THE RADCLIFFE INFIRMARY, OXFORD.

The relations between the Committee of Management and the Governors of the Radcliffe Infirmary, and their Senior Surgeon, Mr. E. L. Hussey, are unhappily at present severely strained on more than one point. The matters on which the differences between them have arisen were discussed at the Quarterly General Court of Governors, held at tho Infirmary on October 24, and one of these is a subject of more than local interest. On the part of the Committee of Management it was stated to the Court of Governors that some months ago the Senior Surgeon to the Infirmary, Mr. Hussey, was elected to the office of City Coroner, and in that capacity has already had "to sit" upon one of his own patients. A man suffering from a wound inflicted by his wife was taken to the Infirmary, and there died, having been one of Mr. Hussey's own patients. An inquest was held by Mr. Hussey, as City Coroner, the jury returning a verdict of wilful murder against the wife. The woman was acquitted at the Assizes; but the Judge (Baron Huddleston), to quote the statement of the Committee of Management, "pointed out to Mr. Hussey the indecency of uniting in his own person the two offices of Coroner and Surgeon to the Infirmary." "One would have thought," continues the statement, "that an opinion pronounced on such an occasion, by a person of such eminence and authority, would have had an immediate effect on Mr. Hussey's mind; but such, unfortunately, was not the case." Unfortunately, too, for him, a short time after, another patient died in the Infirmary, during an operation. Again we quote the words of the statement of the Committee, read by the Treasurer at the Quarterly Court:—"After three months more we had another illustration [of the anomalous position in which Mr. Hussey was placed]. The patient of one of his colleagues died whilst under the influence of an anæsthetic. In such cases it has been the custom in this Infirmary to hold an inquest, as it is in all the London hospitals. Mr. Hussey, who was cognisant of all the circumstances, held no inquest, but he took the opportunity to inform the Committee, in writing, of his opinion that the way in which anæsthetics were administered in the Infirmary was dangerous to life. Thus the indecency of sitting in judgment on his colleague was avoided, but at the sacrifice of the rights of the patient and his friends, the public, and the institution." The Committee having in vain called upon Mr. Hussey to explain why he considered "the manner of giving an anæsthetic to be attended with great dangers to life," as well as to suggest a remedy for the evil complained of, now asked the Governors to take the matter into their own hands. With Mr. Hussey as Coroner they had of course nothing they could do, but with him as Surgeon to the Infirmary they had some power; and the Treasurer therefore proposed the following resolution:—"That it is the opinion of this Committee that Mr. Hussey should be requested to make his option as to his retaining the one or the other of the offices of the City Coroner and Surgeon to the Infirmary within a period of one month from the date of the Quarterly Court. And that the Court do at its rising adjourn till November 21, to receive Mr. Hussey's answer." A long discussion on the matter followed, and it was proposed as an amendment—"That Mr. Hussey be requested to appoint a Deputy Coroner in all cases connected with the Infirmary"; but this was rejected, and in the end the original resolution was carried by a majority of ten, thirteen voting for the motion and three against it. It was unfortunate that the question about the way in which chloroform is given at the Infirmary was mixed up with the Coronership question, as it seems that the way in which Mr. Hussey has acted with regard to the giving of anæsthetics has excited not a little dissatisfaction. But there can be no real difference of opinion as to the impropriety of one of the professional staff of the Infirmary being in the position of having to hold inquests on Infirmary patients. The appointment of City Coroner is an honour, as showing that the holder of it has won the favour and confidence of a large part, at any rate, of his fellow-citizens, and Mr. Hussey may well have felt strongly tempted to accept it. But his doing so was surely a

most unfortunate mistake, though it no doubt never occurred to him that he would very probably be placing himself in a highly undesirable and difficult position. We do not find it anywhere stated, however, that anyone objected, on this score, to Mr. Hussey's election at the time. And it is a fact that another of the Surgeons to the Infirmary, Mr. Symonds, is University Coroner. But, though it is improbable that the University Coroner will have to hold an inquest on an Infirmary patient, yet it would seem that such a possibility did present itself, for a solicitor was appointed co-Coroner with Mr. Symonds; and the duties of University Coroner are certainly not heavy enough to explain the double appointment. Perhaps, however, the University only desired to express in that way their opinion that a Coroner ought to be both a medical man and a lawyer?—though we are not aware that the co-Coroners sit together. It does appear strange, however, that Mr. Hussey did not, at any rate, after Baron Huddlestone's severe comment, either resign the Coronership, or avail himself of the power of appointing a deputy. It was stated during the discussion that Mr. Hussey holds that he can only appoint a deputy to act for him in case of illness or unavoidable accident; but in correction of this it was asserted that, at the Assizes, the Clerk of the Peace declared that the Act of Parliament gives the Coroner full power to appoint a deputy, and, it was added, Mr. Hussey had shown no inclination to do so; and this, no doubt, caused the rejection of the amendment to the resolution on the matter. The resolution was seconded and strongly supported by Professor Rolleston, and we agree with him in thinking that the position in which Mr. Hussey has placed himself is wholly wrong, though we think he rather strained the point when he spoke of it as an "immoral arrangement," meaning thereby that it is immoral "to put a man into an office, the very essence of which is to bring him into a position that puts a strain upon his conscience"; and we cannot but think that the way in which the learned Professor dragged in Prince Leopold's name was an offence against good taste. In the other matter spoken of, Mr. Hussey seems, from his own letters which were read to the Court, to have dealt rather hardly with the Committee of Management, and with the officer who administers anæsthetics in the Infirmary. He wrote to the Committee, calling their attention "to the manner in which an anæsthetic is given" in the Infirmary, and saying, "I think the manner of giving it is attended with great danger to life." The Committee asked for an explanation of the manner in which the mode of administration is dangerous, and requested Mr. Hussey to enlighten them either by letter or by his personal attendance and advice; but, so far as we gather from the correspondence, all they have obtained from Mr. Hussey is the information, in writing, that "the use of the instrument with which an anæsthetic is given is attended with danger to life"; and that "the remedy is obvious—to have another instrument, and to direct the officer appointed to the duty to look to the medical officers for his instructions." Mr. Hussey has not complied with the request of the Committee, that he would give them his personal assistance, and would tell them what instrument he would recommend for use. The Committee, and the rest of the medical staff of the Infirmary, apparently feel, not unnaturally, that when their Senior Surgeon, who holds also the office of Coroner, makes such an observation as he has done on the way in which an anæsthetic is given, they have some right to an explanation from him; and we think that most people will be apt to agree with them. The consideration of the matter was adjourned, we believe, till the next meeting of the Court. Mr. Hussey has for many years held a position in Oxford, and at the Radcliffe Infirmary, of which any man might be proud; and we trust he will find the way to put himself right with his colleagues and the Governors of this institution.

THE WEEK.

TOPICS OF THE DAY.

At a meeting of the Willesden Local Board held last week, Dr. Danford Thomas submitted a special report, showing that in a stable with a loft over it, situated in a mews out of Denmark-road, four children were lying ill with scarlet fever, occupying the loft with their parents. The loft contained scarcely any furniture—only a chair and a mattress. Upon the latter, which was on the floor, and unsupplied with bedclothes, lay the four children, covered only by their own garments. Dr. Ring had attended them as paupers, and he considered that the condition they were in was highly dangerous to life. The father accounted for the state of poverty in which the family was placed by the fact of his having had a distress warrant for rent recently served upon him. Dr. Ring thought that the children ought to be removed for hospital treatment, and therefore applied to the relieving officer, who stated that the Guardians had no place to which to remove them. He then applied to the sanitary officer, who communicated with Dr. Thomas on the subject, and the latter gentleman immediately wrote to the Guardians, asking if they had made any provision for the isolation and hospital treatment of their infectious poor. In his report Dr. Thomas reminded the Board that the London Fever Hospital has refused to receive patients who are paupers, and he specially urged upon them the necessity of their making provision for contagious cases, as has already been done by several of the metropolitan parishes. Mr. Wood said that such a shocking state of things reflected most unsatisfactorily upon the parties concerned, and he thought the Guardians should at once, without a single moment's delay, have the report before them and act upon it. Taking into consideration the time which has elapsed since the notice from the Local Government Board on the subject of erecting hospitals for infectious diseases in each parish was issued, it is to be regretted that any of the metropolitan districts should still be found to be unprovided with these buildings.

An inquest held by Dr. Hardwicke last week, at the "Buffalo's Head," Marylebone, on the body of James Dooley, aged two years and a half, of Westmoreland-street, elicited a charge of carelessness in dispensing medicines which should not be allowed to exist at the present day. Deceased had been under treatment for nine weeks for ophthalmia, medicine and a belladonna lotion for the eyes being prescribed. The lotion was put in a large bottle by the dispenser at the Marylebone General Dispensary, Welbeck-street, but, according to the mother's statement, it was not labelled as "poison." On Saturday morning last the mother administered to deceased a dose from the lotion bottle, believing it to be the medicine bottle, there being a similarity in the two bottles. She presently saw a great change come over the child, and finding out her mistake, ran with it to the dispensary, where it was seen by the medical officer, who at once gave it an emetic. Deceased, however, got worse, and died at ten the same evening, having been delirious nearly all day. The cause of death was pronounced to be poisoning by atropine. The dispenser of the eye-lotion would not admit that the word "poison" was not on the bottle; and, singularly enough, no effort seems to have been made to produce the bottle in court. The jury eventually returned the following special verdict:—"That the deceased was poisoned by atropine, contained in an eye-lotion, which lotion was given by the mother in mistake for medicine, and the death was from misadventure. The jury are further of opinion that carelessness was shown by the dispenser of the eye-lotion in not affixing a label with 'poison' written or printed on the bottle, and that the bottle was not a proper one for a small quantity of lotion as prescribed."

The ship *Gauntlet*, Captain Lucas, which, as we announced last week, arrived at Plymouth, on her voyage from London to Plymouth, with scarlet fever on board, is now free from her emigrants, the people having been transferred to the Government hulk *Pique*, which has been lent by the Admiralty for the purpose, and is moored in Plymouth Sound. The ship will now be fumigated and thoroughly disinfected. No fresh cases have occurred on board since the landing of the two previously reported, and if all goes well the emigrants will return to the ship, which will be allowed to proceed on her voyage at the expiration of fourteen days from the last case having made its appearance.

In a special report to the Uxbridge Rural Sanitary Authority, Mr. C. Roberts, the Medical Officer of Health, states that seventy cases of scarlet fever have been treated in the hospital opened at Southall last Christmas. Of these only four proved fatal. He denies that the continued spread of the disease in Southall —the principal seat of it—is attributable to the patients' clothing not being properly disinfected before their discharge, as has been rumoured. There have been about 300 cases in the neighbourhood since the first outbreak, the majority of the sufferers having been treated at their own homes. Twenty-nine cases have occurred at the St. Marylebone Workhouse Schools, the sanitary arrangements of which Mr. Roberts describes as in every way perfect.

It is stated that Marlborough House has recently been so thoroughly inspected that all anxiety on the score of its bad or defective drainage may now be dismissed. At Sandringham, since the illness of the Prince of Wales, a special supply of pure water is furnished for the Royal table from two springs on the estate, which, though small, produce very pure water. The house has also been thoroughly ventilated, and the drains examined by Mr. Rawlinson, under whose direction all the cesspools have been removed.

We understand that the following points have been suggested by the Grand Committee of St. Thomas's Hospital as a basis on which the Governors of the institution should remodel the control portion of the establishment:—1. That a House Committee be appointed, to consist of the treasurer, almoners, and six governors, two of whom shall be gentlemen who have filled the posts of Physician or Surgeon to the Hospital. The House Committee to have full power to make all regulations necessary for its proceedings, and for the attendance on the Committee of the officers of the Hospital, and of a representative of the medical and surgical staff and school. 2. That the treasurer be appointed for the term of five years, but to be then eligible for re-election. 3. To adopt the principle of paying a salary to the treasurer, who should reside in the house provided and furnished for him in the Hospital, and who would be enabled to devote more time and personal attention to the Hospital than can be expected if he is not paid, and who, being able to exercise a thorough supervision of the Hospital, may thus obviate the necessity of appointing a superintendent.

At their sitting at Canterbury, on Saturday last, the county magistrates made an order upon the South-Eastern Railway Company to abate a nuisance which they allowed to exist in their harbour at Whitstable. The proceedings were instituted by the Local Sanitary Authority, who alleged that the harbour was used by about 200 ships, that the whole of the sewage from them went into the harbour, and that no means were taken by the Company to cleanse the harbour. It was stated that three was an outbreak of typhoid fever at Whitstable in August, and it was considered attributable to the nuisance in question. The sewage from the town also runs into the harbour, and the company defended the action on the ground that the Commissioners of Sewers, who superintended the drainage, were the parties really liable.

We have received a copy of the Report of the Inspector of Lunatic Asylums on the Hospitals for the Insane in the Colony of Victoria for the year ended December 31 last, by which it appears that the total number of registered lunatic patients in the colony at that date was 2635, which is an increase of 78 upon the preceding year. This increase, however, is stated to be less than that of the two preceding years, the number added to the registers in both 1874 and 1875 having been 99. This may be regarded as a satisfactory result, especially when the increased population of the colony is taken into account. Moreover, the mortality in Victorian asylums is shown to be lower than that in similar establishments in England, and has remained so during the last ten years. The colony, it would seem, has adopted the arrangement of having lunacy wards attached to hospitals, which, according to the Report, has been found to work satisfactorily. The aggregate admissions to all the wards during the past year were 98; of these 36 were discharged cured, 2 improved, 56 were eventually transferred to public asylums, and 2 died, leaving 3 under treatment at the end of the year. The Report points out that owing to this arrangement thirty-six persons were enabled to reach recovery, who would otherwise have been unavoidably subjected to the annoyance of being sent to an asylum for treatment; further, much expense was spared, and the asylum space was relieved to the extent of accommodation which would have been needed for these thirty-six patients. It is intended, if found practicable, to extend the usefulness of these lunacy wards in hospitals in the future.

Last Sunday, in Birmingham, the annual collection was made in the various churches and chapels in aid of the local medical charities fund, which is this year to be appropriated to the needs of the General Hospital. The returns received up to the present time show a total of nearly £2800, which is about £200 below the corresponding total last year, the falling off being generally attributed to the depression of trade, and the collection recently made for the Indian Famine Fund.

A serious outbreak of scarlet fever is reported to have taken place at the Albert Memorial College, Framlingham, forty pupils being confined in the sanatorium. It is expected that the College will be temporarily closed. Another serious outbreak is recorded at Witham, in Essex, where thirty children are now suffering, and six have died. All the schools in the neighbourhood have been closed, and operations are in progress to disinfect the houses.

ROYAL COLLEGE OF PHYSICIANS, LONDON.

At a meeting of the Royal College of Physicians, held on October 25, besides various matters of ordinary business, a letter was received from the Chairman of the Conference of Representatives of the Medical Authorities engaged in the formation of a Conjoint Scheme for Examination in England requesting the College to appoint two members of the Committee of Reference, in order that the Committee may at once proceed with the duties assigned to them by the Scheme. The College ordered the letter to be referred to the Council, that they may nominate two Fellows for appointment on the Committee, and consider the question of an honorarium.

THE INDIAN FAMINE.

The Mansion House Indian Famine Relief Fund now amounts to more than £430,000. The latest returns from Madras state that from January last the increased death-rate in the famine-affected district has more than averaged 50,000 monthly. This is exclusive of the great mortality in Mysore. In July, with the beginning of the last half-year, mortality took a sudden spring upwards, 113,494 deaths being registered, as against 33,442, the average for the same month during the last five years. This shows an increase of 80,052, all famine victims.

In the week ended October 2, 628,259 persons were on the relief works, and 1,603,721 were being fed gratuitously by the Government. In nearly all the districts, cholera, fever, and small-pox prevailed. This did not take into account the terrible suffering caused by high prices—300 and 400 per cent. above normal rates. About 2,131,482 are on the hands of the Government, being 13·27 per cent. of the population of the distressed district. Children had very largely benefited by the funds from England. Children in very great numbers had suffered, and were suffering, from the usual consequences of chronic starvation, and unless means can be devised to supply the children of the industrious poor with food in excess of the means of the parents, many must die before food supplies return to their normal value. Those who had visited relief camps and had noticed the wasted appearance of the children would never be able to shake off the saddening impressions excited. Dr. Cornish, the Sanitary Commissioner, says:—"Big boys will bring little boys, and, though lank and hungry, and casting longing eyes on the food, are only intent on seeing their charges get their allotted ration. For six weeks past, a little girl of ten or eleven has been bringing up two sickly children twice a day, nursing them with the tenderest care, and never asking for bite or sip on her own account. She showed no signs of starvation until the last few days, when I noticed that she was beginning to go down, and I have asked the lady in charge of the nursery to bring her on the list of those to whom one good meal a day may mean the salvation of life. I hold the view that there is a great and wide field for the exercise of private charity in the part of feeding such children as these." Our readers will be interested also in the passage which we give below from a letter written on September 29, by the Duke of Buckingham, the Governor of Madras, to a relative in England. It was quoted at a meeting of the Committee of the Manchester and Salford Indian Relief Fund, and points out the special need and value of private charitable assistance. The Duke says:—"We here are very grateful for the response England has made to the appeal, and Government can find work for the able and can give food to the weak and sick, but Government cannot pry into the homes of those who do not seek for aid, but are fading away in a vain attempt to feed a dozen on the scanty pay of one, and still wish to keep out of the abyss of pauperism; and to keep, then, these on the brink from falling, or to keep together the household goods, few enough, but still valuable in their eyes, of the small cottar farmer and the fairly well-to-do labourer is what charity can and Government cannot do; yet by doing it one of the greatest helps will be given towards meeting the remaining period of the famine year. The people are patience exemplified in life and in death."

THE PENGE CASE.

Most of our readers will have learned by this time the ultimate decision of the Home Secretary in this miserable affair. Alice Rhodes has received, according to the laws which govern British justice, a "free pardon" for a crime it is now allowed she never committed—a free pardon for having done nothing unlawful! The three Stauntons have been sent into penal servitude for life; but this, it is hardly probable, will be carried out in its entirety—at all events, in the case of Mrs. Staunton. Of this part of the decision we see little to complain. The negligence displayed by these people was so gross as to deserve ample punishment; but the taking away of life is a serious matter. Have these results been brought about by the intensity of public feeling that a great wrong was likely to be done, and by the determination of the medical profession that, though certain of their brethren had erred in skill and judgment, people who might be innocent should not lose their lives? But the terrible thing is this, that no new fact has been brought out since the trial which was not attainable before. We have on the trial a judge acting as an advocate, certainly not as *advocatus diaboli*, and a jury in hot haste to get home to bed, rushing to a conclusion which one of them afterwards admits was wrong. There has seldom been a trial which has more signally betrayed the imperfections of our law, or more forcibly impressed men's minds that law and justice are not always commensurable.

AN ILLEGAL USE OF METHYLATED SPIRIT.

The Law and Parliamentary Committee of the Pharmaceutical Society have recently brought under the notice of the Council the fact that some chemists used methylated spirit in the preparation of certain tinctures, such as that of opium; and the question was raised as to whether such chemists should be prosecuted. Some doubt was felt as to the possibility of obtaining a conviction under the Pharmacy Act in such cases, and it was suggested that the Council should bring the matter officially before the Inland Revenue authorities. It was eventually decided not to take any steps with regard to the subject. It was felt that the honest tradesman was placed in an unfair position if an unscrupulous neighbour used methylated spirit in the manufacture of tinctures for internal use, but some members of the Council expressed the hope that "no occasion might arise for vexatious interference by revenue officers." Some complaints appear, however, to have been made to the Board of Inland Revenue, and an order has been issued notifying to manufacturing chemists "that the use of methylated spirit in the preparation of 'absolute alcohol' is clearly illegal, as involving the purification of the spirit"; and that any person discovered in future to be carrying on any such process will be proceeded against.

GLASGOW AND ABERDEEN MEDICAL GRADUATES' DINNER.

The second annual dinner of the medical graduates of Glasgow and Aberdeen was held on Thursday, October 25, at the Pall-mall Restaurant, under the presidency of Dr. Allen Thomson. Professor Lister was among the guests, and Dr. Matthews Duncan was present in the capacity of an Aberdeen medical graduate. Professor Lister and Dr. Matthews Duncan were specially toasted and welcomed to London, and each acknowledged in warm terms the cordial reception he had met with, not only from fellow-graduates and Scotchmen, but from all circles in London. Dr. Andrew Clark, who occupied the vice-chair, proposed the health of the chairman. He paid a most eloquent tribute to the learning and sincerity which characterised Professor Allen Thomson as a teacher, and expressed his own sense of gratitude, which an interval of thirty years had only served to deepen, for the instruction he himself had gained when a student in his class. In the name of the Glasgow and Aberdeen medical graduates he warmly welcomed him to London, and hoped he might be spared for many years to enjoy the repose he had so justly earned, and to add a lustre to scientific London society. We fear somewhat that, though all is here *couleur de rose*, the second annual dinner of the Glasgow and Aberdeen graduates may be fraught with evil. The following is an extract from the circular sent out convening the dinner meeting:—"We may state that this dinner is not in connexion with, nor is it in any sense in antagonism or opposition to, a proposed Association of the Universities, but is of a purely social and friendly character." It is signed as follows:—"John Couper, F.R.C.S., 80, Grosvenor-street, Grosvenor-square, W.; John Brunton, M.D., 21, Euston-road, N.W.—(Glasgow). Fancourt Barnes, M.D., 39, Weymouth-street, Portland-place, W.; Stephen Mackenzie, M.D., 26, Finsbury-square, E.C.—(Aberdeen)." We believe that it is strongly desired by many graduates to form a general association of all *alumni* and graduates of one or both Universities, as may be determined. We have been told that matters had been arranged thus: a

meeting of graduates was to be called some time in November, to decide whether the proposed Association was to consist of Aberdeen and Glasgow graduates of all kinds, of Glasgow and Aberdeen medical graduates only, or whether the Universities should each have an association of its own. There are two bonds between certain members of the two Universities—first of all, the members of the General Council of either University unite in electing a member of Parliament; secondly, as a certain number of both Universities belong to the medical profession, it has been proposed to make a purely medical association, made up of medical graduates belonging to the two—this, we have been told, partly at least with the view of returning a medical member of Parliament for the two Universities. These are matters with which, upon the whole, we have not much to do—they are, so to speak, household; but at the same time this second *annual* dinner seems very much like forcing the hand, not of opponents, but of men who would be allies. Of course there is another way of explaining it.

THE TREASURERSHIP OF ST. THOMAS'S HOSPITAL.

Elsewhere in our columns will be found the recommendations of the Grand Committee of St. Thomas's Hospital with reference especially to the office of Treasurer. They are of a character to command attention, and the most careful consideration and discussion. No single office is of equal importance, as regards the future prosperity and well-being of the Hospital, to that of Treasurer, and we can hardly imagine that anyone can seriously dispute the principle, formulated by the Grand Committee, that the Treasurer ought to be a paid, resident officer, who shall be able to devote ample time and attention to the Hospital, and to exercise a thorough supervision of it. When this shall have been agreed to by a General Court of the Governors, the next step to be taken—and one the importance of which cannot easily be exaggerated—will be the selection of a man to fill the post of Treasurer. Three men have been already spoken of, though we do not know whether they are all actually candidates for the appointment—viz., Mr. Alderman Stone, Captain Galton, and Mr. Simon, C.B. They are all able men, and distinguished in their chosen walks in life, but we are not aware that, with the exception perhaps of Mr. Simon, any one of them has any practical knowledge of hospital administration and management, though of the great ability he has shown throughout his long official life it would be difficult indeed to speak too highly. Captain Douglas Galton has made for himself a high reputation as an architect, and by his knowledge of all the details of scientific hospital construction; and Mr. Alderman Stone is, we believe, or rather was, a successful solicitor. But we hear that a fourth gentleman has presented himself for the appointment, than whom it would not be easy to find a more fitting candidate. Dr. Norman Chevers has had large and great experience in very similar work in India; for many years he managed, with marked success, the Medical School and Hospital in Calcutta; he was secretary to the Medical Board; he had large official work in serving other appointments; and he has won, as we hardly need note, high reputation as a physician and an author. He has retired from Indian service, and in full health and vigour can devote himself entirely to the service of St Thomas's Hospital. If Mr. Simon really desires the vacant appointment, it will, perhaps, hardly be possible for the Governors to pass over his great claims and eminent qualifications; but they are, at any rate, fortunate in having before them such a candidate as Dr. Chevers. We are speaking of the qualifications of Mr. Simon and Dr. Chevers for the Treasurership without any very definite knowledge of what the Treasurer's duties are to be; but if he is to undertake all that seems to be laid on him by the speeches and resolutions passed at the meeting of Governors on the 31st ult., we doubt if any one man can be found equal to the office.

COMPRESSED OXYGEN AS A TEST OF CELLULAR POTENCY.

Professor Paul Bert, of Paris, has lately utilised a former discovery of his, that compressed oxygen destroys organised (cellular) ferments, as well as living cells in general; whereas it has no effect on chemical (liquid) ferments, to determine whether certain poisonous animal ferments owe their properties to the presence of cells, or not. He found (*Comptes-Rendus*, lxxxiv., p. 1130), that the poison of the scorpion, fresh, dried, or redissolved in water, resisted the action of compressed oxygen, and that vaccine lymph could be exposed for a week to oxygen at a pressure of fifty atmospheres, without losing its peculiar influence. In the same way, the virus of glanders, and that of malignant pustule, remained unaffected. Hence Bert concludes that all these poisons are independent of living cells; and that even if the corpuscular elements which their liquids contain appear, as Chauveau maintains, to be the seat of the fermentative material, this is only because the latter adheres to them by simple attraction—just as, for example, hæmoglobin is retained by the blood corpuscles.

THE EDINBURGH INFIRMARY STAFF.

By the transfer of Mr. Annandale to the Chair of Clinical Surgery, a vacancy occurs in the surgical staff of the Edinburgh Infirmary. It is not the least of the privileges attached to this chair, that its occupant becomes, *ipso facto*, a Surgeon to the Royal Infirmary—a post which he holds whilst he holds the chair—with special wards and service of his own. The other Surgeons, except the Professor of Surgery, hold office only for a limited period. It was partly on this account that the friends of Mr. Heron Watson made such efforts to secure his appointment. For the vacancy thus occurring we hear of Dr. John Bishop as a likely candidate. This gentleman has long enjoyed exceptional opportunities of acquiring experience, both under Syme and Lister, and is an out-and-out advocate of the antiseptic system.

At a recent meeting of the managers of the Infirmary, Dr James Affleck was appointed an Assistant-Physician. The report of Mr. Charles Barry, of London, on the works of the new Infirmary was laid on the table, and it was resolved by the meeting to abide by it.

SOCIETY FOR RELIEF OF WIDOWS AND ORPHANS OF MEDICAL MEN.

A general meeting of the Society was held, by kind permission of the Royal Medical and Chirurgical Society, in their rooms, Berners-street, on Friday last, October 26, at half-past eight o'clock. The chair was taken punctually by the President, Sir George Burrows, Bart. From the half-yearly statement read, it appeared that a sum of £1298 10s. had been distributed amongst fifty-eight widows, twelve orphans, and four orphans on the Copeland Fund. The expenses of the half-year had been £109 14s. 9d. It was announced that the directors, having a sufficient sum in hand, had determined to give a present at Christmas to the widows and orphans now receiving grants; the total amount of the present would be £326. During the half-year fresh applications had been received from four widows and two orphans; thirteen members had died, and seven new members had been elected. Dr. Harvey Kimpton Owen was elected a Vice-President, in the place of George Cooper, Esq., deceased. A legacy of of £500 from Mrs. Mary Davis Parker was reported, and also £250 from the executors of the late James Graham, Esq. A vote of thanks to the chairman closed the meeting.

A Productive Collecting-Box.—Since the collecting-box for donations to the Indian Famine Fund was placed outside the Mansion House no less a sum than £958 has been contributed to it, anonymously, by passers-by. The largest sum collected in one day was £33 15s. 8d., and the smallest £6 8s. 4d.

THE SICK AND WOUNDED IN THE RUSSO-TURKISH WAR.

The following extracts from reports furnished to the Stafford House Committee have been obligingly sent to us for publication; and as they may be of much interest to some of our readers, we are glad to be able to find space for them:—

Extract of a Letter from Mr. Barrington Kennett; dated Pera, September 19, 1877.

The reports speak for themselves. I need not comment upon the awful misery and distress among the wounded in every district. It is with feelings of the greatest reluctance that, for want of funds, I find myself unable to extend or even strengthen our different sections. Please make every exertion to secure further subscriptions at this critical moment.

All our sections are working extremely well, and Neylan, at Philippopolis, and Moore at Adrianople, have secured for themselves high and responsible positions.

I regret to have to report that Neylan is returning temporarily invalided with dysentery, as also Drs. Beresford and Lake, but I hope they will be able to return to their positions.

An excellent position having been offered to the last batch of our doctors sent out, involving the condition that the Red Crescent defray all expenses of their pay and passage, etc., I have accepted the conditions. I will send you details by next mail.

I leave to-morrow with large ambulance destined for Plevna.

I have attached Stoney permanently to our staff as assistant-commissioner. He will represent the Stafford House Committee at Constantinople during my absence.

Mr. Pratt is working well and energetically in the Varna and Shumla district.

Our soup-kitchens are still working well; over 4000 wounded have been received and attended to at each of them.

The ranks of the Red Crescent have recently received a great addition in the person of Baron Mundy.

No. 1.—*Report of Ambulances with Mehemet Ali Pasha's Army.*

Shumla, September 12, 1877.

(W.) Pratt's Section, Mehemet Ali's Head-Quarters.
(To the Stafford House Committee.)

In accordance with Mr. Kennett's instructions, I beg to inform you that I left Shumla on the date of my last report (September 2) for Varna, by a train in which there were eighty severely wounded men. There were no Turkish surgeons to meet them on their arrival at Varna, and Dr. Hayes and myself had, with the aid of his transport drivers, with our own hands carried out of the trucks and placed on the transport waggons more than two-thirds of their number before the Turkish surgeons and their carriages arrived.

The Red Crescent Hospital under Drs. Konvaros and Cullen (Stafford House) is full and working well.

On September 4 I left Varna for Rasgrad, and thence on horseback to the front with Drs. Cheyne and Jolly (National Aid Society). We arrived late—the fighting at Atlava and Rasilovo was just over; we had time, however, to collect some twelve severely wounded men, and place them in a transport out of the rain for the night. The next morning their wounds were dressed by Dr. Wattie. We on the same morning found a large number of slightly wounded men at Chevasa; we dressed some of their wounds, the remainder were attended to by Drs. Wattie, Busby, and Lake, after their severer cases had been disposed of.

The same day I rode to Yeni-Kieni, and brought back with me Drs. McQuean and Beresford and their transport to Chevasa.

We found Messrs. Wattie and Busby. Before night the lighter cases remaining were dressed and transported to the Turkish Hospital, and the severer ones not admitting removal remain at present under the care of Drs. McQuean and Beresford, an empty house having been prepared as a temporary hospital.

During the few days that Drs. McQuean and Beresford were at Yeni-Kieni they were not allowed to perform any operations by the Turkish surgeons there; men with undressed wounds being sent to Shumla and Eski-Djuma. Dr. McQuean will report, however, to Mr. Kennett with regard to this.

I visited Dr. Wattie's ambulance in camp opposite Atlava. Dr. Lake was suffering severely from dysentery. [I ordered him back.—V.B.K.] He was very anxious to remain, in expectation of more work, but as Drs. Wattie and Busby both agreed that it was advisable that he should do so, at my suggestion he left the next morning for Varna with a convoy of sick. He has since written to offer his services at the Imperial Hospital at Varna, where help is very much required. He has stipulated for the care of wounded men only, and for independent action with regard to treatment in his own wards.

Dr. Wattie will report to Mr. Kennett as to the large number of wounded that have passed through their hands lately.

I have appropriated an empty house at Yeni-Kieni as a store for Dr. Cruikshank (National Aid Society) and Stafford House Ambulances. As this village is protected by a very strong and fortified position, it is not likely to be again in possession of the Russians.

As Dr. Barker is now engaged elsewhere, I have sent the stores destined for Eski-Djuma to Yeni-Kieni. I visited the Government Hospital yesterday, and as several very bad cases had disappeared, it did not appear to be in such an offensive condition as I described in my last report. They are still without disinfectants. On the two chief doctors writing me that they were in great need of certain medicines, which they could not procure immediately, I gave them a small quantity,

and some hospital requisites that they were obviously in need of. I have done the same at Yeni-Kieni.

The voluntary aid given to Mehemet Ali Pasha's army may be thus described :—Drs. Cruikshank, Cheyne, and Jolly (National Aid Society), in camp with south wing ; Drs. Wattie, Busby, and Boyd (Lord Blantyre), with their transport, in camp with north wing ; Drs. Beresford and McQuean, with transport, in village in rear of centre, with orders to move forward in whatever direction the fighting next takes place ; Dr. Hayes, in charge of railway transport from Rustchuk to Varna, which is doing excellent service. The Varna and Rustchuk hospitals are both now full. I proceed to the latter to-morrow.

(Signed) E. R. Pratt, S. H. Assistant-Commissioner.

(X.) *Extract from Letter from Dr. Lake; dated Varna, September* 13, 1877.

I find that there are so many hundred wounded—some of their cases we dressed at the front, others so interesting surgically, and all left to the careless and indifferent treatment of the uneducated Turkish surgeons here—that Mr. Pratt, Dr. Hayes, Dr. Schofield, and myself, have all deemed it a wise and prudent step that I should take over a ward of, say, twenty-five or thirty, or more, under my own care and treatment, assisted by Hayes, independently of the Turkish surgeons. By this arrangement Hayes and myself would be able to work into one another's hands, and would form an important, useful, rear permanent hospital. The other three men would still remain at the front.

(*To be continued.*)

FROM ABROAD.

Prof. Billroth on a Case of Gasteroraphia.

In the *Wiener Med. Wochenschrift* for September 22, Prof. Billroth relates the following interesting case :—

"In the twentieth volume of the *Archiv für Klinische Chirurgie*, Dr. Wölfler described the case of a young woman, aged twenty-five, in whom I had closed a fistulous opening in the stomach of the size of a florin (*Silbergulden*), by means of a granulating flap. I was in hope that this flap would resist the digesting power of the gastric juice, if the granulating, highly vascular surface of the flap, becoming covered in the course of time with epithelium, assumed the condition of a cicatrix, and consequently became much less vascular. In this hope I was encouraged by the fact that we sometimes meet with pretty considerable cicatrices as residua of former ulcers of the stomach, which lie depressed below the level of the mucous membrane, and possess much fewer and smaller bloodvessels than the latter. Unfortunately, my expectation was not confirmed, for at the end of three months the fistula reopened, and so completely had the flap of skin become digested that it was as large as ever. Thus I had not been able to effect a durable closure of this large fistulous opening, but the ease with which union was accomplished showed that the physiological principle upon which I proceeded was correct.

"Referring to the former account of the case for the details, it may be stated that following a cold abscess which had formed in front of the lower ribs, and after adhesion had occurred between the stomach and the diaphragm and the wall of the abdomen, perforation took place at the same time into the stomach and externally. When the patient was again admitted to my clinic, the fistula was closed by a plug, kept on by a broad bandage, but the closure was only exact when she lay on her back, the contents of the stomach continually escaping when she was erect. Her nutrition had been excellent while the fistula was closed, but she had now become again very thin. The edges of this large fistula were always red and sensitive, and her condition upon the whole was so unsupportable that she ardently desired an attempt to be made for its definitive closure, even if this were attended with some danger. . . . After further meditation on the case, I resolved to attempt the closure, or at all events the diminution of the fistula, by means of the actual cautery or powerful caustic, applying this around the fistulous orifice, so as to give rise to a circular cicatrix. By producing a second and smaller cicatricial ring under the first, and another still smaller under this, and so on, until the mucous membrane and muscular layer were reached, a funnel-cicatrix might be formed by the contraction so produced, the terminal end of which might be afterwards obliterated. Between November 10, 1876, and February 7, 1877, six such cauterisations were made by means of Paquelin's thermo-cautery ; and although these were very intense, they were followed by very insignificent reaction, and never by any peritoneal irritation. The eschars always separated very rapidly ; the shreds, in place of being discharged, undergoing digestion. Unfortunately, however, the cicatricial contraction was so slight that the attempt to effect the closure in this manner had to be abandoned. At a later period it became evident that the prevention of contraction was caused by the enormous and firm adhesions of the stomach to the wall of the abdomen."

Prof. Billroth goes on to relate other procedures which he employed. One of these, which was resorted to on February 22 and March 9, consisted in detaching a portion of the mucous and serous membranes, and attempting to effect a union with the subjacent tissues and the skin. This having failed, on March 16 he performed Middeldorff's operation of forming a large flap, which, while retaining its union with the surrounding skin, was brought so as to cover the fistula, except at a slight aperture, which was easily closed by compression. The lower edge of this flap united easily, but the upper one underwent digestion, so that the fistula was soon again exposed, and, notwithstanding all endeavours, things were brought to a state pretty much as before any operation had been attempted.

"I have thus minutely detailed all these unsuccessful attempts to close the fistula in order to show that I did not proceed to gasteroraphy until I had exhausted all other relatively dangerless methods with which I am acquainted. The patient was a most sensible person, and submitted to all that was done for her with inexhaustible patience. Notwithstanding the best hospital diet, however, she was becoming emaciated ; and partly on account of this, and partly because long after the last operation the circumference of the fistula remained in an irritable condition, further attempts were called for. In the meantime I had listened at the last Surgical Congress to the communications of Schönborn and Trendelenburg upon the successful formation of a gastric fistula in cases of stricture of the œsophagus, which, together with a similar case of Verneuil's, showed that with our present operative procedures it is possible to bring a plastic healing process in the stomach to a successful issue, although the flow of the gastric fluid over the fresh surfaces could not be entirely prevented. I cannot conceal that, among the many interesting occurrences at this Congress, these operations produced the greatest effect upon me, and encouraged me to undertake gasteroraphy in my case.

"This I performed on June 13, in the following manner :—After the stomach had been repeatedly washed out with water, I began, after incision of the mucous membrane, to separate, by means of the finger and a raspatorium, the stomach with all its membranes from its adhesions to the abdominal wall. So excessively firm were these that considerable force was required to effect this ; but the bleeding was insignificant. This separation around the edges of the fistula, in order that they might be brought together without any tension, had to be carried farther and farther, until at last it amounted on all sides to six or seven centimetres. I found myself at the upper, outer, and inner portions still within the region of the adhesions ; and it was only below that I reached the peritoneal cavity. Finally, I was enabled to draw the stomach so far forward that it became possible to sew up the fistula by means of twelve deep and three superficial silk sutures, which penetrated through the serous and muscular coats, so that serous membrane laid almost applied to serous membrane. A simple flap was formed from some healthy skin below the lower edge of the fistula, and applied over the external opening, and united by sutures, some drainage-tubes being inserted. The wound was dressed by Lister's procedure, and for the first three days the patient took only water. During the next week she took milk, after which some meat diet and wine—at first sparingly, and then more abundantly—were allowed. A fortnight after the operation she had the full hospital diet, with any extra articles she wished for. The patient, who at first was very hungry and felt feeble, soon regained her strength.

"From the time of the completion of the operation not a drop of fluid or a morsel of food ever issued from the fistula. Not only did the wound of the stomach heal by primary intention (so that I have nothing to say concerning the sutures, which were cut close), but the flap of skin did so almost

completely also, pus being discharged for some time through the drainage-tubes. There were never any peritoneal symptoms. A month after the operation the wound had completely closed, the wound caused by the removal of the flap not yet being quite healed. On July 27 the patient was dismissed completely recovered, in the best health, and in a good condition as regards nutrition. It is not probable that the fistula will re-open again; but, at all events, I shall after some time make inquiries concerning the patient, and, if her condition undergoes any change, I will make it public. This rare case may, with respect to the various operative procedures connected with it, serve as a type for similar cases. Excision of a portion of a carcinomatous stomach would only be to take a bolder step in the same direction—just as, recently, Czerny has proceeded from œsophagotomy to the removal of a cancerous portion of the œsophagus, with the happiest success. Gussenbauer and Winiwarter (*Archiv für Klin. Chir.*, Band. ix.) have already executed the necessary preliminary work."

The American Dermatological Association.

The New World is as prolific as the Old in the generation of new Congresses and Associations; and the *Boston Medical and Surgical Journal* of September 13 contains a report of the first annual meeting of the American Dermatological Association, which took place at Niagara on September 4 to 6, under the presidency of Dr. White of Boston. The first object of the introductory address which he delivered was the justification of the existence of the Association; for there are many persons in the United States, as well as in Europe, who seriously doubt the propriety of this process of splitting-up of medical science into so many divisions, and treating each as an entity of paramount importance. A stand against it has been made recently at Munich, where the project of holding what was called a Gynæcological Congress or Conference was defeated on the ground that gynæcologists surely ought to rest content with forming one of the already too numerous twenty-five sections of the German Association for Naturalists and Physicians. A kind of congress-epidemic is just now prevailing; and certainly the recent jubilee meeting of the German Association, held at Munich, was a proper occasion to call to mind, as Professor v. Pettenkofer and other speakers did, the original idea which animated Oken, when, amid so many difficultics and obstacles, he succeeded in founding this parent of migratory congresses. He sought to develope the bond of union which ought to prevail amongst those who were pursuing the various departments of science, which, if lost sight of, risks the production of the one-sidedness and limited scope consequent on excessive division of labour.

However, we must let Dr. White state his own case. The objects of this new Association are, he says—"1. The affording opportunities for a more intimate personal acquaintance among American dermatologists, thus obviating the tendency to harsh judgments upon necessary differences through ignorance of personalities. 2. To average the varying views upon etiology and treatment by oral discussion in each other's presence, and thus to elaborate a common basis for work. 3. To ascertain by observant study, and by the collection of statistical data, the peculiarities of cutaneous diseases at present existing in our own country, the establishment of a standing committee for this purpose being desirable; and to investigate the new diseases, leprosy, etc., which, though now rare, are yet to be expected here in time. 4. The establishment of a common nomenclature in dermatology. 5. To foster the interests of dermatology in its general relations with the medical profession and with the public. The objects of the Association show the need of its existence. There are peculiar difficulties and very inappropriate rewards in this speciality of medicine. The medical profession has yet to learn that diseases of the skin are like other diseases, all being subject to the same laws, and all affecting organs composed of similar tissues. Physicians either lack interest in these maladies, or, regarding them as incurable, leave them to chance; or, again, pandering to popular prejudice, will talk of 'humours' and of diseases 'coming out' or 'striking in,' thus frightening patients into resignation; or will undertake unjustifiably the treatment of maladies of which they are ignorant, merely because they anticipate less evil from mismanagement than they would in the case of maladies of the eye or ear, for instance. Even physicians who consult a specialist seem surprised that these diseases subsequently remain apparently as intractable as before, forgetting that the pathological conditions may vary from day to day in an organ so exposed, thus calling for a coincident change, perhaps temporary only, in the plan of treatment. There is a necessity for special teachers in the medical schools. There exists the need of better opportunities of instruction by means of special clinics, either in special hospitals or in special wards in established institutions. The neglect of existing institutions to do common justice to patients suffering from these diseases is an outrage against reason and humanity. On the other hand, relatively speaking, there has been great progress during the last twenty-five years in the proper teaching of this speciality, and the present condition of dermatology in America is flourishing."

REVIEWS.

On the Prognosis in Cases of Valvular Disease of the Heart. By Thomas B. Peacock, M.D., F.R.C.P., Hon. Consulting Physician to St. Thomas's Hospital. London: J. and A. Churchill. 1877. Pp. 55.

This handsomely got-up monogram is a revised reprint of a paper in the *St. Thomas's Hospital Reports* for 1871, and will be very gladly welcomed by the profession in its new and separate form. The day has long gone by since there was any need to commend to the profession a work on diseases of the heart by Dr. Peacock. He is an accepted authority on the subject; and this short essay is characterised by all his usual learning, accuracy and minuteness of observation, and practical skill. The work does not treat only, or chiefly, of prognosis. The different forms of valvular disease are described, and illustrated by cases and engravings, the sources of danger are noted and classified, and some consideration is bestowed on treatment. Dr. Peacock considers that the order in which valvular diseases should be placed, as indicating their relative danger, is as follows—the first placed being the more serious affections:—Aortic regurgitant disease, mitral regurgitant, mitral obstructive, and aortic obstructive, disease. The other elements for the formation of prognosis are:—1st. The cause of the disease, its duration, and the rapidity with which the symptoms have advanced, as indicating its probable nature or its active or passive character. 2nd. The degree of impediment to the circulation which it occasions, and the power of the heart to overcome such obstruction, as indicated by the force and regularity of its beat, and by the relation which it bears to the pulse at the wrist, and the amount of congestion in the lungs and other organs and in the general system. 3rd. The presence or absence of serious complications, as of the lungs, liver, brain, kidneys, etc., and the existence of dropsical symptoms, or of a gouty or rheumatic condition. 4th. The circumstances in which the individual is placed, as affording the means of obtaining rest of body and mind, and protection against atmospheric changes, together with the proper regulation of diet and facilities for medical treatment. The work is a valuable and clearly written outcome of Dr. Peacock's experience in the subject treated of.

An Immense Dose of Chloral.—Dr. Bishop relates a case of delirium tremens, in which the patient, a man thirty-two years of age, after sixty hours of absence of sleep, took *one hundred and sixty-five grains* of chloral (found by trial in other cases to possess its full efficacy), and slept for thirty-six hours, without any alarming symptoms—such as diminished temperature, sighing respiration, slow or feeble pulse, or pallor of the countenance.—*Boston Med. and Surg. Jour.*, September 6.

Case of Anosmia from a Blow on the Occiput.—In the *Boston Medical and Surgical Journal* for September 13 Dr. Knight relates the case of a man, forty-two years old who, three weeks after having been thrown out of a gig striking the back of his head, found the sense of smell was completely gone; the perception of flavour was also gone,—which was of great consequence to the patient, he having to taste tea as a teadealer. He was unconscious for twelve hours after the accident (which occurred three years before); and blood flowed from the nose and one ear, in which he also had great pain. Since then he has had no pain or cerebral symptoms, and his hearing is good. On testing the sense of smell, it was found to be insensible to the strongest odours, such as assafœtida or peppermint introduced into the nostril. Dr. Knight cites twenty-one other similar cases of anosmia from injury of the head which are on record.

IRELAND.

Dublin, October 30.

THE OPENING OF THE SESSION 1877-78: ROYAL COLLEGE OF SURGEONS; ST. VINCENT'S HOSPITAL.

THE Introductory Lecture of the present winter session was delivered in the Lecture Theatre of the School of Surgery, Royal College of Surgeons, on Monday, October 29. The lecturer was Dr. Charles A. Cameron, Diplomate in Sanitary Science, University of Cambridge, Professor of Chemistry and of Hygiene to the College. The subject of his address was "The Pathology and Propagation of Contagion." The chair was taken by Dr. Robert McDonnell, F.R.S., President of the College, who was supported on the right hand by Dr. Gordon, President of the King and Queen's College of Physicians; and on the left by Dr. Philip C. Smyly, Vice-President of the College of Surgeons. Having referred to the recent losses sustained by the School of Surgery in the lamented deaths of Dr. John Cronyn, the Professor of Midwifery, and of Mr. Henry Wilson, the Professor of Ophthalmic Surgery, Dr. Cameron proceeded to treat of the lower forms of life and their relations to disease. He discussed the question of spontaneous generation at considerable length, alluding to the opinions of Van Helmont, and to the experiments of Needham, Spallanzani, Appert, Schwann, Schultz, and Pasteur. He went on to say, "Quite recently, Dr. Bastian, of London, had with great pertinacity sought to demonstrate experimentally not only that living things spring into existence out of putrid matter, but that they are actually formed out of certain mineral substances containing nitrogen; as, for example, mixtures of tartrate of ammonia and phosphate of soda. There are, therefore, three doctrines entertained in reference to the beginnings of life. First, there is *Archebiosis*, according to which the lower forms of animal and vegetable life spontaneously arise from mineral substances placed under favourable conditions; *Heterogenesis*, which holds that low forms of life arise during the decay of organised matter, such as flesh or vegetable albumen; and *Panspermism*, which maintains that the most lowly forms of life are derived by direct descent from ancestors of the same, or nearly the same, nature." Dr. Cameron criticised the details of Dr. Bastian's experiments, and pointed out not only possible, but also highly probable sources of fallacy. The controversy with respect to spontaneous generation had, by encouraging experimental researches, led to the discovery of many of those forms of life which existed upon the borders of the invisible world. Some of these tiny objects were termed bacteria, which were by many believed to be the cause of fermentation, and even to constitute the contagium of such diseases as scarlatina and typhoid fever. The lecturer next described the diseases which were propagated directly from the sick to the healthy, and those which were indirectly propagated. Dr. Grimshaw's investigations as to the prevalence of cholera over the gravelly subsoil and along the dried-up or diverted watercourses of Dublin and its environs, were detailed, and beautiful experiments were shown to prove that, as Pettenkofer maintained, foul air may enter dwelling-houses from the soil by mere pressure of wind upon the surface of the ground outside the houses. The contagious nature of tuberculosis could now scarcely be doubted. There were two forms of phthisis, one of which, and that the most common, was contagious, though perhaps not very actively so. It was, therefore, injudicious to place phthisical patients next patients affected with other diseases, and, above all, it was desirable to afford to the former a very large amount of cubic space and ample ventilating openings. The experiments of Gerlach, Director of the Berlin Veterinary School, Leisering, of the Dresden Veterinary School, Klebs, and other pathologists, show that those who eat the flesh of phthisical cows are liable to contract tubercular disease, tubercular matter being contagious. As tubercular disease is common amongst Irish cattle, their flesh and milk probably occasion much pulmonary consumption in man. The modes by which the more commonly occurring contagious diseases are propagated were explained, and the lecturer concluded by expressing his opinion that, broadly, contagious diseases were all "filth diseases," and could only be destroyed by the most rigid national and private cleanliness. The lecturer was frequently applauded.

The clinical session at St. Vincent's Hospital, Stephen's-green, Dublin, was inaugurated on Monday, October 29, when Dr. Mapother gave the opening address in the presence of a large and appreciative audience. He selected as his topic "The Lives and Writings of O'Ferrall and Bellingham,"—the first two medical officers of the Hospital. As his interesting and instructive address is to appear at length in the *Dublin Journal of Medical Science* for November, it is only necessary to allude to it thus briefly in this letter.

GENERAL CORRESPONDENCE.

DISLOCATIONS OF THE HEAD OF THE THIGH-BONE INTO THE OBTURATOR FORAMEN.

LETTER FROM MR. W. RIVINGTON.

[To the Editor of the Medical Times and Gazette.]

SIR,—In the interesting clinical lecture on Dislocations of the Femur into the Obturator Foramen, by Mr. Holmes, which appeared in your impression last week, there are one or two remarks which personal observation enables me to confirm. Mr. Holmes calls attention to the absence of lengthening, and to the tension of the adductor muscles found in the case on which his remarks were based. A few months ago a similar case came under my care at the London Hospital. I have not by me the notes of the case, as they were sent to a contemporary, but both of the conditions specified were present. There was apparent lengthening, but real shortening to the extent of a quarter to half an inch. Being rather surprised to find shortening in a case of obturator dislocation—an injury always described as being characterised by lengthening—I made some experiments on the dead body, and found that when the head of the bone is actually over the thyroid membrane there is no lengthening in the measurement from the anterior superior spine to the inner malleolus. Lengthening can only occur in those cases in which the head is either below the acetabulum near the tuberosity of the ischium, or at some distance from the foramen; and I cannot avoid the conclusion that in those cases in which lengthening has been described, either, as Mr. Holmes suggests, apparent lengthening from obliquity of the pelvis has been mistaken for real lengthening; or the head of the bone has been at a lower level than the obturator foramen, as in the case reported by Mr. Luke, and quoted by Mr. Holmes in his recent work on Surgery—a case which I had the good fortune to see.

With regard to the tension of the adductors, which was accompanied by tension of the ham-string muscles, I attributed it, as Mr. Holmes does, to the irritation occasioned by the displacement. I am, &c., WALTER RIVINGTON,
Surgeon to the London Hospital.

22, Finsbury-square, October 30.

THE BENEFICENCE OF SCOTCH GROCERS.

[To the Editor of the Medical Times and Gazette.]

SIR,—An extract from your journal appears in the *Edinburgh Courant*, of yesterday's date, in which mention is made of "the evils of the system of granting licences to grocers for the sale of intoxicating liquors." Therein you jauntily hold up the grocers to scorn because one of them is reported to have "sold drink to a woman, with whom he drank it in his back shop"! Sir, the grocer will come out of this inquiry with a better character than the medical profession could were every case in which a medical man prostitutes his professional skill to such cases as procuring abortions, either in back shops or private houses!

A few months ago a certain Dr. —— appeared in the Divorce Court as co-respondent in a case in which one of his patients was actually divorced from her husband for something worse than drinking in a back shop. Do you apply the same principle, then, to your own profession? And, if so, why not hold them up to scorn? Further, the grocer (licensed) sells—in this country at least—the best quality of spirits and wines, which are both food and drink; and, therefore, the people prefer to get the best article as well as the best value for their money from the grocer.

I am of opinion, from a large experience in England, that if a better class of goods were sold there (better wines and spirits), it would be of great advantage to the English in

regard both to their health and morals. And of this I am certain, viz., that one positive result would be less illness, less crime, and a smaller consumption of doctors' drugs—which, as a rule, are neither food nor drink, but positive poisons.

Be kind enough to print this, as it is of public—ay, national—importance; but it is not easy to break through pride of caste, self-interest, or ignorance.

I enclose my card. I am, &c., An ex-Grocer.

Star Hotel, Ayr, N.B., October 23.

[We have been deeply touched with the beautiful simplicity of this letter "of national importance." The reading of it has been to us a real and, we trust, a lasting pleasure. May it equally gratify and delight our readers! The "ex-Grocer" has our heartfelt thanks.—Ed. *Med. Times and Gaz.*]

REPORTS OF SOCIETIES.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Thursday, October 23.

Charles West, M.D., President, in the Chair.

(*Concluded from page* 476.)

On Œdema (Myxœdema) in the Cretinoid Condition of Adult Women.

Dr. Hilton Fagge had come to the conclusion that the cases described by Sir William Gull and Dr. Ord were really cases of sporadic cretinism, as seen in England. In one of his own cases the appearance and features were similar to those seen in the patient exhibited. As to the distinctions between sporadic and endemic cretinism, they were various; but in the first place, in sporadic cretinism there were two masses of fatty tissue in the posterior triangles of the neck, not to be found in endemic cretinism. Dr. Fletcher Beach had shown a specimen from a child which had died after some weeks' diarrhœa and wasting. Here the fatty masses had formerly existed, but had disappeared. Possibly, in ordinary cretins, were they well fed, the fatty masses might appear. Another point of distinction lay in the base of the skull. This had been described by Virchow in a case of his own, where the patient was twenty-one years of age; the condition was somewhat different from that described, but that might result from ossification of the sutures preventing growth. Thirdly, there was the goître of endemic cretins, whilst amongst sporadic cretins in this country the thyroid was often absent. He thought the formation of goître contributed to cretinism, especially in the next generation. In many Alpine valleys the deterioration of race was so great that families seldom survived the fifth generation. He could hardly agree with Dr. Ord that the myxœdema was the primary part of the cretinism leading to the fibroid state and atrophy of the thyroid.

Dr. Heywood Smith inquired whether there was any catamenial irregularity among women of this class, and also as to the condition of the uterus in those who had borne children.

The President considered it would be premature to apply the term "cretinoid" to this class. The disease was rare in England, and even abroad where goître was very common. The condition occurred among all classes, rich and poor. He had recently had such a child under his care, in which the condition was improving. Other children, under two years of age, with a cretinoid appearance, deficient intelligence, and cyanosed skin, he had also seen. Any diseased state interfering with the nutrition of the child, as did cyanosis, might give it a cretinoid appearance. From Sir W. Gull's and Dr. Ord's cases, it appeared that the disease might come on, the mind lose its force, and the face its intelligence. These cases should stimulate inquiry; but few things tended more to retard discovery than the hasty endeavour to affix to such cases an import they could hardly have.

Dr. Ord, in reply, said that in the cases he had seen there was at first no cretinism. There was a dropsical appearance, without kidney mischief, but with a lethargic condition of the nervous system. After death the thyroid gland was found changed into a mucous, yielding, pulpy tissue. As regards the name, it might be useful or it might be abused; but he thought a distinct name should be given to the condition under discussion. Possibly the name "cretinoid" was stronger than circumstances warranted; but "myxœdema" only described the actual condition of affairs. He merely desired to draw attention to the parallelism of such cases with certain aspects of cretinism.

CLINICAL SOCIETY OF LONDON.

Friday, October 26.

Thomas Bryant, F.R.C.S., Vice-President, in the Chair.

A Case of Hysteria, with Contraction of the Lower Limbs, Anæsthesia, and Ischæmia, in a Boy.

Dr. Henry Thompson communicated the report of this case. The patient, aged fourteen, son of a French father and English mother, was admitted into the Middlesex Hospital on May 10, 1877. He had always been delicate, but had had no definite illness until two months before admission, when he began to lose flesh, became low-spirited, and complained of vertical headache. He had occasional paroxysms of laughing and crying, accompanied by a loose barking cough and globus. For a month he had been unable to walk, owing to paresis, rigidity, and distortion of his lower limbs. On admission, his pulse, temperature, and respirations were normal, and remained nearly so throughout the case. His voice was almost inaudible, but was strengthened by weak faradism. The legs were firmly flexed upon the thighs, and the feet extended as in talipes equinus. The genital organs were ill developed. Anæsthesia and ischæmia were prominent symptoms from first to last; and on May 18, experiments were made to define those conditions, with the following results. At the time of observation he was very impassive, but the senses of sight and hearing were normally acute. There was complete cutaneous and deep anæsthesia to ordinary and painful impressions on his cheeks, forearms, and legs—in fact, over the whole body,—the punctures being made down to the bone; and none of the punctures were followed by any bleeding. Faradism being applied to the right forearm, the seats of puncture began to bleed, but the anæsthesia persisted. Gold coins were then applied, and it was noticed that, after their application for ten minutes, sensation returned over those regions, and punctures produced bleeding; the range of sensibility gradually diminishing in every direction from the area over which the coin was placed. These experiments were repeated on the 19th, 21st, 29th, and on several subsequent occasions, with invariably the same result. Like observations were made with other metals, insulated and non-insulated, and with wood, with the boy's attention drawn to it, or, on the other hand, wholly without his knowledge: but only with the gold could the above results be obtained. On one or two occasions the gold failed, but never when it had been applied so long as ten minutes. Once a puncture made into the leg when he was asleep produced pain and free bleeding. In about a month after admission he had so far recovered the use of his limbs as to be able to walk about with the aid of a stick. It was not until fully three months after his admission that the anæsthesia and ischæmia passed away; and he left the hospital on August 25, able to walk fairly well, and with his sensibility and capacity for bleeding everywhere normal. With the exception of being treated for two severe attacks of bronchitis, shower-baths, faradism, valerian, cod-liver oil, and iron were the only remedies adopted. Dr. Thompson pointed out that the case was one of pure and simple hysteria in a boy, who was singularly intelligent, thoroughly truthful, straightforward, and uncomplaining, but who appeared to have been foolishly indulged by an over-fond mother, and was of rather an effeminate disposition, and was possessed of ill-developed genital organs. Possibly the latter was the main element in his predisposition. The symptoms included paresis and contractions; anæsthesia, amounting to analgesia, which, unlike the majority of cases, was distributed equally on both sides. Thirdly, there was the strange feature of ischæmia; and, lastly, the influence of the gold coins. The author of the paper then dwelt at some length upon the nature of this influence; he considered that what is known as the "moral" theory, which has the support of Dr. Russell Reynolds, although, no doubt, an element in this, as in every other case of hysteria, could not altogether explain the result of this experimentation. Thus, the gold was operative when the boy was told, and believed, it was silver; and the silver was

inoperative, although the boy believed it to be gold. On the other hand, so far as the anæsthesia was concerned, a puncture made when the boy was fast asleep was evidently felt, and produced bleeding.

Dr. Althaus said that the case described in the paper was particularly interesting just at this time when the investigations of Charcot and his pupils at the Salpétrière had drawn considerable attention to the phenomena of anæsthesia in hysterical persons. During a recent visit to Paris, Dr. Althaus had carefully examined the cases in M. Charcot's wards, and had come to the conclusion that the phenomena described were all genuine, and could not possibly have been produced by shamming on the part of the patients. The anæsthesia and analgesia in them were so profound that they were utterly unaware of long and sharp needles being thrust not only through the skin, but the cellular tissue, muscles, periosteum, and even into the cranial bones. There were at the same time a low temperature, loss of muscular power, and anæsthesia of the special senses, which had not been alluded to in Dr. Thompson's paper. There was also complete ischæmia, so that needles could be rapidly pulled out of the flesh of the patients without the slightest hæmorrhage occurring. It was at the present time impossible to explain why all these symptoms should yield in a very short time to the application of metallic plates; and M. Charcot had himself given up all attempts at explanation for the present. There was, however, no doubt of the fact that, when gold and other coins or plates were applied to the skin of the affected parts, the sensation returned, that profuse capillary hæmorrhage occurred from punctures, and that the special senses recovered their functions. At the same time, the temperature rose by 8° or 10°, and the muscular force, as measured by the dynamometer, increased considerably. With regard to shamming, Dr. Althaus could not understand how, by any amount of artfulness, the patients could prevent hæmorrhage from punctures, or could, when they remained all the time under observation, cause the thermometer to rise by 10°. With regard to Dr. Russell Reynolds's explanation, that the recovery of function was owing to mental impression rather than to the application of a special therapeutical measure, this would account for many phenomena, but not for all; it could, for instance, not explain why sensation should in some persons only return after the application of copper, while in others it would only return after gold or iron. It had been shown that the application of all oxidisable metals gave rise to the development of galvanic currents, which varied in power according to their affinity to oxygen. In these researches a Du Bois-Reymond's galvanometer multiplier of 25,000 convolutions was used. The needle remained unaffected only with platinum, but gave a deflection of 3° with pure gold, 10° with gold coins, and 15° with copper; and a feeble galvanic current, corresponding in strength to that evolved by the metals, was equally effective in restoring sensation. Phenomena of this kind had, however, not only been observed in hysterical women, but also in cases of undoubted structural disease of the nervous centres; as, for instance, in a case of hemiplegia owing to cerebral hæmorrhage, in which there had been hemianæsthesia and hemichorea for several years, and in which the application of iron restored sensation—copper, gold, and zinc having remained inactive. A curious fact was, that while in the hysterical patients the effects of these applications were temporary, they were more or less permanent in cases of structural disease of the brain and spinal cord. Dr. Althaus finally described the curious phenomena of transfer of sensibility and nervous force altogether from one side to the other, which occurred in the patients alluded to during the application of the metals; and expressed his opinion that those who studied these perplexing phenomena would neither ridicule nor deny them; but that much further observation was necessary for assigning to these their proper place in the pathology of the nervous system.

Dr. Broadbent had seen most of the facts described by Dr. Althaus. All the young females under his care with this affection had been engaged in sewing. He had had a case similar to Dr. Thompson's, the report of which he had sent in to the Society for reading and discussion, and which he would now shortly relate. She had hysterical anæsthesia of both legs below the knee, and had been treated by a metallic band, a cure resulting. The patient, a housemaid, aged seventeen, was admitted into St. Mary's Hospital in July, 1877. She had enjoyed good health up to the age of fifteen, when the catamenia were established, but then began to suffer from pain in the back and side, and headache at each period, and for four months had been unable to keep a situation on account of increased suffering. She never had hysterical attacks. Muscular weakness in the arms and loss of sensation in the legs gradually came on; and, on admission, pinching or pricking of the legs below the knees or of the feet was not felt. She did not even perceive that anything was being done when a pin was pushed under the toe-nails. She stood with the feet close together, or walked when the eyes were closed. The limbs were cold, and did not bleed when pricked. Sensibility was normal above the knees and on the rest of the body. There was a little tenderness on pressure over both ovaries, more on the left side. Compound galbanum pill was given, but no improvement in the condition of the legs had taken place after many days. A metallic band or garter was then ordered to be put round the right leg, just below the knee. Sensation gradually returned, and in six days (though not in a few minutes) was normal in this limb, while the left was still absolutely insensible. The band was now shifted to the left leg, upon which sensation returned in it; and thirty-one days after admission the patient left the hospital well. The treatment was suggested by the effects of the application of plates of gold or other metals in hysterical hemianæsthesia, as described by Professor Charcot. In these cases, sensation returned in fifteen or twenty minutes; and it appeared to be important that a particular metal should be employed in a given case, gold being the metal most generally useful. Feeble galvanic currents were found to be set up by the contact of the metal with the skin; and it was supposed that in these might reside the agency by which the result was effected. In his (Dr. Broadbent's) case no care was taken in the selection of the metal, and no test was applied to estimate the strength of the galvanic currents set up. The cure was attributed by Dr. Broadbent to expectant attention; the girl's attention was called to the leg by the presence of the metal band, and this, with the anticipation of the favourable result, brought it about. The attention directed strongly to a part could induce a pain there; why, then, should it not be able to produce improvement in the sensation at the same part? Dr. Broadbent did not understand the value of one metal over another in these cases; nor did he know if the result in his case was simply due to expectant attention or to some galvanic impulse.

Mr. Brudenell Carter said that many years ago he had had his attention particularly drawn to cases of hysteria. He had heard frequent use made that night of the word "facts"; but facts which rested on the testimony of hysterical patients were not worthy of much credence. Statements from such patients as to colour, etc., must be received with much caution. Elliotson, when working amongst them, was only too easily deceived. As Dr. Risdon Bennett had pointed out, there was a large class of hysterical women who had no higher delight than that of trying to deceive their doctors, whose whole scientific education made them guileless, and perhaps only too easily duped. Mr. Maskelyne had lately said that one reason why Fellows of the Royal Society did not detect tricks was because the tricks were of such a nature as to be detectable by schoolboys rather than by scientific men, with their minds trained to appreciate phenomena of an entirely different kind. We ought to be careful in regard to such cases, and avoid the follies of the wise.

Dr. Coupland said that it seemed to him difficult to suppose that "ischæmia," at any rate, could be produced by any amount of shamming.

Dr. Glover thought that sensation was much more real than doctors were apt to think it; and that hysteria was a much more real disease than it was generally considered to be. He had lately seen a man apparently asleep, who did not respond nor open his eyes when spoken to. His right eye was as insensible to touch as if he had been under chloroform; yet that man had shortly before left his bed to micturate. He could scarcely feel the prick of a pin on his right hand, but felt it well on the left. He had also a decided loss of power on one side of the face on the afternoon of the day when he had been visited. At mesmeric experiments he had seen young men have needles thrust beneath their nails without exhibiting any sign of feeling.

Dr. Barlow thought that Mr. Carter's observations would be much more useful if he would examine these cases himself. They had been most minutely inquired into in Paris by sceptical scientific men. Let us look at them, and not attempt to explain them offhand, nor take refuge in the supposition

that they were all sham. In hysterical patients the larynx might often be most readily examined, as if there were a kind of anæsthesia about the fauces. In one such patient he had constantly seen down the trachea to the bifurcation of the bronchi.

Mr. B. T. Lowne said that, if one placed a cold body on the skin, it produced vascular congestion at the part, by which it was possible the blood might be caused to be poured out.

Mr. Howse inquired if this curious sequence of phenomena were visible at the very first sitting with the patient, or if they were only developed at subsequent sittings.

Dr. Althaus did not think it was imagination or shamming of the patient which produced the curious results witnessed upon the application of the coins. If it were imagination, why should not a copper coin have the same influence as a gold one? In all the cases he had seen, the results differed as the metal of the coins that were used varied.

A Case of Injury to the Lower Part of the Spinal Cord, followed by Wasting and Contraction of the Muscles of the Lower Extremities.

Mr. Lawson read a communication he had received from Dr. Aikman, of Guernsey, on this case. A lad, aged twenty-one, fell about twelve feet on March 30, 1877. With the exception of severe nocturnal pains, which were not allayed by full doses of opium or of chloral, he presented no evidence of spinal injury for four months after the date of his accident, about which time atrophy of the muscles of the left leg set in. At present, his left leg is much atrophied; the muscles on the front of the leg not responding even to the electric stimulus, while the sural muscles and the flexor muscles of the foot remain in tonic spasm, even when the patient is fully under the influence of chloroform. No treatment having done any good, suggestions are asked for.

Dr. Buzzard thought further particulars of the case were required. The history pointed to some hæmorrhage in the lower part of the spinal canal due to the fall, with the mention of great pain in the back. There was none as to stiffness over the vertebræ. The patient gradually recovered from the first effects of the injury. A fortnight afterwards wasting occurred; the débris of the extravasated blood in the cord had doubtless then set up neuritis and destroyed the conductility of the motor nerves to the muscles. Thus atrophy of the muscles was brought about, which was progressive. In such a case the application of the continuous constant voltaic current, if slowly interrupted, would bring about contraction of the muscles, and gradually cure the patient.

Mr. Lawson said that the muscles of the calf of the leg were in a state of continuous contraction, and were atrophied.

Dr. Buzzard said there might be more or less atrophy and yet contraction. Some muscles would be more, others less, contracted if there were irritation, and the stronger ones would overcome the weaker.

Dr. Althaus remarked that the boy could walk after the accident for two or three weeks. He therefore thought his symptoms were due to spinal myelitis. With hæmorrhage into his cord he would not have walked. Myelitis was also accompanied by great pain in the back. He regretted that no mention was made of the use of the continuous current. Even when the interrupted current failed, the continuous current would often make the muscles react.

Cerebro-Spinal Unilateral Sclerosis.

Dr. Dowse read a report of this case, and exhibited some well-executed photographic drawings, showing its pathology. The patient, a woman, aged forty-one, was admitted into the Central London Sick Asylum at Highgate, on January 12, 1872, and died on September 23, 1876, so that she was under Dr. Dowse's observation for more than four years. She was completely devoid of voluntary motor power. In the year 1870 she was seized with a fit of unconsciousness, followed by left hemiplegia. In the year 1872 she was seized with right hemiplegia, and, three months after this, she came under Dr. Dowse's care in the following condition. There was complete paralysis of voluntary power of every muscle in the body, so far as one could judge; and as the nurse placed her at night, so she was to be seen, in precisely the same position, in the morning. Dr. Dowse said that he was really doubtful whether there was or not any voluntary or even muscular automatic power; but after repeated observations, month after month and year after year, no movement of a voluntary nature could be detected, excepting upon one occasion, when she answered some few questions clearly and intelligibly, showing that most probably her reason was not affected. There was complete anæsthesia of the entire body, with flexed contractions of the four extremities, which were in a constant state of rhythmical agitation. There were apparently no trophic changes, and there was no appearance of a bed-sore until within a month of her death. There was no marked adipose or muscular wasting, and the muscles contracted readily to Stöhrer's galvanic continuous current. The countenance was mask-like and devoid of expression. When she was spoken to about her home, the tears would flow freely down her cheeks; but no sign of emotion was ever visible beyond this. When agitated, the tremor of the limbs increased; and when asked to perform any act, it was clearly seen that an attempt was made to carry it out, but the will was unequal and powerless to execute. It was difficult to say how far the special senses were involved. The application of strong ammonia to the nostrils caused at first what was considered to be a voluntary movement of the head, but repeated applications did not produce the same effect. The sense of sight was thought to be good, and the ophthalmoscope gave no evidence of retinal changes. Both pupils were usually contracted, but more so the right. There was marked trismus, and no ordinary power could depress the lower jaw, yet when food was brought to her the rigidity became in a measure relaxed, although there was no direct masticatory power. There was marked paralysis of the facial muscles (bilateral), evidently from central causation. The sense of hearing was normal. When semi-solid food was given, it was necessary to place it well into the mouth, otherwise it would return, showing clearly that she had no voluntary power over the labial muscles. Sensation of the tongue and the special sense of taste were in like manner obliterated, as far as one could ascertain. The voluntary power over the tongue appeared to be greater than that over any other member of the body, for she would at times get it to the lower row of teeth, but it was never protruded. These were what might be noted as the objective signs presented by this patient, and so in a manner she vegetated until she died. What her sufferings might have been, it is impossible to say; for she had no voluntary power whatever to make these conditions manifest, even if they had an existence. The post-mortem appearances were then noted; and the evidence was to the effect that the general surface of the convolution of the hemispheres was normal. The motor ganglia on the left side were free from any gross lesion; but on the right side, a brownish-looking degenerative change was seen to extend from the internal capsule of the corpus striatum, running along the under surface of the optic thalamus, through the right crus cerebri, into the under and inner part of the right half of the pons Varolii, involving the right floor of the fourth ventricle. The drawings, from sections made by Dr. Kesteven, showed the sclerosis of the right half of the pons, advancing in successive stages through the anterior pyramids, and then crossing over in direct relationship with the decussating fibres to the left lateral column of the spiual cord. Dr. Dowse remarked that it was now a recognised pathological fact, which had been more particularly demonstrated by M. Charcot, that lesions of the brain, when they succeeded in promoting consecutive degenerative changes, did so in direct harmony with what may be termed a direct histo-pathological law. He said it was interesting to follow out M. Charcot's statements concerning the association which existed between sclerosis of the lateral columns of the cord and hysteria, both with and without tremor; and had it not been for the marked facial paralysis in this case, he should certainly have felt inclined to look upon it as of an hysterical character; the more especially as there was such general and profound anæsthesia.

Dr. Buzzard said there were interesting points of similitude in the case to those witnessed in many cases of hysteria. He had seen girls suffering from cerebro-spinal sclerosis who had been told that they had hysteria, and who consequently had evidently endured great hardships at the hands of non-sympathisers. This case did at first greatly resemble many cases of hysteria.

The Entrance Science Scholarships given this year at St. Thomas's Hospital Medical School have been awarded as follows, viz.:—The Scholarship of £60 to Mr. Wansborough Jones, B.A. Oxon. and B.Sc. Lond.; and that of £40 to Mr. A. E. Wells, of the University of London.

OBITUARY.

WILLIAM RICHARD BASHAM, M.D., F.R.C.P.

Dr. Basham, who was for many years Senior Physician to the Westminster Hospital, died rather unexpectedly, at his residence in Chester-street, on October 16. It will be remembered that on February 13, this year, while attending the meeting of the Weekly Board of the Governors of his Hospital, he was seized with hemiplegia of the left side, and that, retaining consciousness, he was at his own request at once put to bed in a private room in the Hospital. There he remained, slowly recovering, till, in May we believe, he was removed to his house in Chester-street. Later on in the year he was able to be removed into the country; whence he returned to London, and attempted to resume practice at the beginning of October. Dr. Basham was born in 1804, and was seventy-three years old at the time of his death, but he was not so old as a physician as the date of his birth would suggest, for he entered the profession rather later in life than is generally the case. Intended at first for business, he began the work of life in a banking-house, and it was not till 1831 that he turned his attention to medicine. In that year he entered as a student at Westminster Hospital, then situated in a small street at Westminster, and with that institution he was connected, through various offices, for almost all the rest of his life. He received his medical education there, in what may without offence to anyone be called the most brilliant days of the Hospital—the time when Lynn, Sir Anthony Carlisle, Anthony White, Hale Thompson, Guthrie, and John Bright were on its staff; and Dr. Basham did full credit to his teachers, and was an honour to his school and hospital, ever keeping himself well forward in the ranks of modern and scientific physicians. In 1834 he took his M.D. degree in the University of Edinburgh, and, returning to the Westminster Hospital, filled the office of Clinical Assistant there in 1834 and 1835. He then went for about three years on a voyage to China and India, in the service of the old East India Company. In 1838 he became a Member of the Royal College of Physicians in London. He was appointed Physician to the Westminster Hospital in 1843, on the resignation of Dr. Bright; in 1849 he became joint Lecturer on Medicine with the late Dr. Hamilton Roe; and from the retirement of that physician in 1855, till 1871, Dr. Basham alone held the lecturership. He was elected a Fellow of the College of Physicians in 1850; served as Censor in 1864-66, and again in 1873; gave the Croonian Lectures in 1864; and was Examiner in Medicine in 1870-71. Especially well known as a worker at the subject of renal affections, his first work was published in 1858, under the title, "On Dropsy connected with Disease of the Kidneys, Heart, Lungs, and Liver; and on some other Diseases of the Liver without Dropsy." His Croonian Lectures, afterwards published, were on "The Significance of Dropsy as a Symptom in Renal, Cardiac, and Pulmonary Diseases." In 1870 he published a small work entitled, "Renal Diseases, a Clinical Guide to their Diagnosis and Treatment"; and in 1872 his last work, the title of which is, "Aids to the Diagnosis of Diseases of the Kidneys." His works are illustrated with faithful and accurate drawings from the microscope, the work of his own pencil, for he was a good microscopist and a skilled draughtsman. Dr. Basham was a learned and shrewd physician, a most careful and accurate observer, and to the end of his active life an earnest student. He had a highly and widely cultivated mind, and was, we are told, a skilled botanist, chemist, microscopist, and artist; and his powerful—if we may be permitted to say so, somewhat roughly hewn—exterior framed in a most kind and generous heart, an active keen intellect and sound judgment, and retentive and ready memory.

JOHN DAVIDSON M'CREADY, M.B. Dub., F.K.Q.C.P.

The death of this highly esteemed and veteran member of the profession occurred after a few hours' illness on Saturday, October 27. Dr. M'Cready was amongst the most senior of the Fellows of the King and Queen's College of Physicians, having been elected to the Fellowship on June 8, 1829. He had previously (1827) taken the degree of Bachelor of Medicine in the University of Dublin. For many years he was Physician to the General Dispensary, Fleet-street, Dublin, before the establishment of the existing Poor-law system. In this capacity he laboured unceasingly and fearlessly during the cholera epidemic of 1832. From 1833 to 1872, when he retired from active professional life, he held the appointment of Physician to the Training-Schools of the Commissioners of National Education. As to the man himself, we cannot do better than quote the Dublin *Freeman's Journal*, which, in an obituary notice, speaks thus of him:—"Dr. M'Cready was eminent among those who knew him for the unostentatious and single-minded benevolence of his character, as well as for the blameless integrity of his private and public life. For many years before the passing of the Act rendering vaccination compulsory in Ireland, he vaccinated gratuitously thousands of the children of the poor of Dublin who came to his house. He was a native of the county Down, and was educated at the Belfast Academical Institution. He was a good classical scholar and a keen lover of the topography of Ireland." He died in his seventy-ninth year.

MEDICAL NEWS.

Royal College of Physicians of London.—On October 25 the following gentlemen passed their examination and were admitted Licentiates:—

Boulting, William, Belmont House, Heath-street, N.W.
Brown, John, 12, Colebrook-row, N.
Coley, Frederic Collins, 6, Morden-road, S.E.
Collier, Herbert, Bohemia House, Turnham-green, W.
Druitt, Lionel, 8, Strathmore-gardens, W.
Lockwood, John Parker, New Hampton.
Masters, John Alfred, Maidenstone-hill, S.E.
Prentis, Charles, 11, Upper Phillimore-place, W.
Price, Henry Elthington, Melrose, Stamford-hill, N.
Prideaux, Thomas Engledue Pegamus, Scarborough.
Steedman, Percy Andrew, Charing-cross Hospital, W.C.
Thurston, Edgar, King's College Hospital, W.C.
Tyrrell, Walter, Bethlem Hospital, S.E.
Wilmot, Thomas, Fenton, Newark.

The following candidate, having passed in Medicine and Midwifery, will receive the College Licence on obtaining a qualification in Surgery recognised by this College:—

Pointon, James, Birkenhead.

On October 25 the following gentlemen passed their examination and were admitted Members:—

Steel, Graham, M.D. Edin., Edinburgh.
Barratt, Joseph Gillman, M.D. St. And., 8, Cleveland-gardens, W.
Buszard, Frank, M.D. Lond., Northampton.
De Tatham, Hamilton, M.D. Brussels, Junior United Service Club, S.W.
Smith, Robert Shingleton, M.D. Lond., Clifton.
Smith, David Boyes, M.D. Edin., 16, Holles-street, W.

Royal College of Surgeons of England.—The following gentlemen, having undergone the necessary examinations on the 26th and 30th ult., were admitted Licentiates in Dental Surgery, viz.:—

Bellaby, Frederick, Nottingham, diploma of Membership dated May 23, 1877.
Browning, Daniel, Crawford-street, Portman-square.
Thomson, Walter Scott, Denmark-hill, S.E.
Williams, Harold, Belgrave-road, N.W.

Two candidates, having failed to acquit themselves to the satisfaction of the Board, were referred to their studies. The following were the questions on Anatomy and Physiology, and Pathology and Surgery, which were submitted to the candidates at the above examination on the 26th inst., viz.:—1. Mention the bones which articulate with, and the nerves which pass through, the foramina of the superior maxillary and palate bones. 2. Describe the functions of the tongue.—1. Describe the growth, structure, and treatment of simple epulis. 2. How would you recognise and treat abscess of the antrum? What are the exciting causes of this disease?—The following were the questions on Dental Anatomy and Physiology, and Dental Surgery and Pathology, submitted on the same occasion, viz.:—1. Describe specimens 1, 2, 3 under the microscope—(1) tooth germ before calcification; (2) enamel showing the lines of Retzius and dentine, and interglobular spaces—some of the dentical tubule passing into the enamel; (3) exostosis. 2. (*a.*) Describe and contrast the appearance of the temporary and permanent teeth generally. (*b.*) How would you distinguish between the superior and inferior permanent canine teeth? (*c.*) Describe the crowns of the permanent incisor teeth immediately after protrusion through the gums. 3. What are the principal features which distinguish the teeth and jaws of man from those of the orang?—1. What is meant by the impaction of permanent teeth in the substance of the maxillary

bones? Which of the teeth most frequently exhibit this condition? What is the common course of such cases, and what evil results may arise? 2. What (1) do you consider to be the best anæsthetics for dental operations? Describe (2) the usual effects upon the patient in the order of their occurrence, and also those which you would consider alarming, and their treatment. Mention (3) the reasons which would induce you to prohibit the use of anæsthetics; and give (4) the probable theory of their action. 3. Describe the characteristic symptoms of ulcerative stomatitis, of chronic inflammation (false scurvy) and true scurvy of the gums.

APOTHECARIES' HALL.—The following gentlemen passed their examination in the Science and Practice of Medicine, and received certificates to practise, on Thursday, October 25:—

Aldrich, Arthur Worlledge, Mildenhall, Suffolk.
Baker, Fredk. Grenfell, Cambridge-gardens, Notting-hill.
Jeffreys, James Graham, Richmond, Surrey.
Nundy, Edward, Rotherham Hospital.
Rogers, Maurice Cohen, 23, Wimpole-street, W.

The following gentleman also on the same day passed his Primary Professional Examination:—

Wray, George Bury, University College Hospital.

APPOINTMENT.

*** The Editor will thank gentlemen to forward to the Publishing-office, as early as possible, information as to any new Appointments that take place.

ROBERTSON, FREDERICK FREER LESLIE, M.B.—House-Physician to the Royal Hospital for Diseases of the Chest, City-road, E.C.

NAVAL, MILITARY, &c., APPOINTMENTS.

WAR OFFICE.—MEDICAL DEPARTMENT.—Deputy Surgeon-General Vere Webb retires upon half-pay, with the honorary rank of Surgeon-General. The undermentioned Surgeons to be Surgeons-Major:—John Joseph O'Reilly, William McWalters, Robert Nelson Mally, William Alister Catherwood, M.D., William Johnston, M.D., George Bridges Mouat, M.D., Henry Joseph O'Brien, M.B., Philip Lefeuvre Kilroy, John Edward Purdon, M.B., Edward Connellan, Henry William Alexander Mackinnon, John FitzGerald Brodie.

BALMORAL.—Her Majesty in Council has been pleased, by and with the advice of her Privy Council, to appoint Andrew Fergus, M.D., President of the Faculty of Physicians and Surgeons of Glasgow, to be for five years a member for Scotland of the General Council of Medical Education and Registration in the United Kingdom, in the place of Joseph Lister, resigned.

BIRTHS.

BELL.—On October 30, at Starr-hill, Rochester, the wife of J. Vincent Bell, M.D., of a daughter.

LONGHURST.—On October 28, at Hammersmith, the wife of Alexander K. Longhurst, M.R.C.S., L.S.A., of a son.

MOORE.—On October 28, at Coventry, the wife of Milner M. Moore, L.R.C.P. Lond., of a son.

MOSSE.—On September 28, at Mona, near Kingston, Jamaica, the wife of Deputy Surgeon-General Charles B. Mosse, C.B., L.K.Q.C.P. Ire., of a son.

ROGERS.—On October 26, at Kensington, the wife of Hildyard Rogers, M.R.C.S., of a son.

TWORT.—On October 22, at 2, Staff-villas, Camberley, Surrey, the wife of W. H. Twort, M.R.C.S. Eng., of a son.

VENNING.—On October 26, at 87, Sloane-street, the wife of Edgcombe Venning, F.R.C.S., of a son.

MARRIAGES.

BURTT—SPICER.—On October 24, at the parish church, Clifton, Giles Richard Burtt, L.R.C.P. Edin., M.R.C.S. Eng., to Frances Jones, only daughter of the late Northcote William Spicer, Esq., of Chard, Somerset.

MUIRHEAD—BALFOUR.—On October 23, at Edinburgh, William Muir Muirhead, M.D., of Assam, to Madeline Drummond, second daughter of J. H. Balfour, M.D., Professor of Medicine and Botany at the University of Edinburgh.

SAMPSON—STEELE.—On October 29, at Dorchester, Dorset, Henry Moore Sampson, L.R.C.P. Edin., M.R.C.S.E., of Painswick, Gloucestershire, son of John Sampson, of Brympton, Yeovil, to Laura Augusta, sixth daughter of Edward Steele, of Wollaston House, Dorchester.

SNAPE—POYNTER.—On October 25, at North Shoebury Church, Frank Theodore, third son of R. F. Snape, F.R.C.S., of Bolton-le-Moors, Lancashire, to Georgiana Browning, third daughter of Samuel Poynter, Esq., of The Crouchmans, North Shoebury.

VACHELL—EVANS.—On October 25, at St. John's Church, Westminster, Charles Tanfield Vachell, M.D., of Cardiff, to Winifred, younger daughter of the Rev. J. W. Evans, M.A., Vicar of Costessey, Norfolk.

DEATHS.

BARFOOT, EDWARD, M.R.C.S., at 117, Barnsbury-road, Islington, on October 24, aged 76.

STEELE, EDWARD HARRY, M.R.C.S., L.S.A., eldest son of Edward Steele, of Wollaston House, Dorchester, at Peckham, Surrey, on October 16, aged 31 years.

VACANCIES.

In the following list the nature of the office vacant, the qualifications required in the Candidate, the person to whom application should be made and the day of election (as far as known) are stated in succession.

EAST SUSSEX, HASTINGS, AND ST. LEONARDS INFIRMARY.—Third Assistant-Surgeon. Candidates for the office must be Fellows or Members of the Royal College of Surgeons of London, Dublin, or Edinburgh. Applications, with testimonials, to the Secretary, endorsed "Application for Assistant-Surgeon," on or before November 10.

EVELINA HOSPITAL FOR SICK CHILDREN, SOUTHWARK-BRIDGE-ROAD, S.E.—Registrar and Chloroformist. Candidates must possess a recognised qualification. Applications, with testimonials, to the Committee of Management, at the Hospital, on or before November 9.

MIDDLESEX COUNTY LUNATIC ASYLUM, COLNEY HATCH.—Assistant Medical Officer in the Female Department. Candidates must be registered, single, and not less than twenty-five years of age. Applications, on a printed form, which may be obtained of the Medical Superintendent of the Female Department, at the Asylum, with not more than three testimonials of recent date, to John S. Skaife, Clerk to the Committee of Visitors, on or before November 10.

UNION AND PAROCHIAL MEDICAL SERVICE.

*** The area of each district is stated in acres. The population is computed according to the census of 1871.

RESIGNATIONS.

Alnwick Union.—Dr. Magill has resigned the Embleton District; area 18,658; population 2776; salary £30 per annum.

Bradford (Yorks) Union.—The Horton West District is vacant; salary £80 per annum.

Poole Union.—Mr. H. D. Ellis has resigned the Workhouse; salary £40 per annum.

Richmond (Yorks) Union.—Mr. R. Atkinson has resigned the Richmond Rural District; area 12,859; population 985; salary £10 per annum.

Wolverhampton Union.—Mr. A. Hands has resigned the Seventh District; area 2085; population 8000; salary £40 per annum.

APPOINTMENTS.

Barrow-upon-Soar Union—Charles W. Drew, M.R.C.S. Eng., L.R.C.P. Edin., to the Quorndon District.

Bury St. Edmunds Incorporation.—F. W. Clarke, M.R.C.S. Eng., L.S.A. to the fourth District.

Horncastle Union.—Thos. Hunter, L.R.C.P. Edin., L.F.P. & S. Glasg., to the Revesby District.

Launceston Union.—Harry Davis, L.R.C.P. Lond., M.R.C.S., L.S.A., to the Fifth District.

Southmolton Union.—Timothy Daly, L.R.C.S. Edin., L.R.C.P. Edin., to the Seventh District.

SANITARY INSTITUTE OF GREAT BRITAIN.—The first examination of Surveyors and Inspectors of Nuisances took place on Monday, October 29, at the rooms of the Medical Society of London. Eight candidates presented themselves, five of whom were successful in obtaining certificates of competence, namely:—Mr. H. Robinson, surveyor, Ulverston; Mr. J. Parker, surveyor, Bridgwater; Mr. F. Booker, inspector of nuisances, Bradford; Mr. W. S. Prebbles, inspector of nuisances, Blackburn; Mr. Thomas Blanchard, inspector of nuisances, Evesham. Fifteen candidates have already entered their names for the next examination.

ANEURISM OF THE AORTA OPENING INTO THE PULMONARY ARTERY.—Dr. Laveran read, before the Hospital Medical Society, the case of a man twenty-nine years of age, who, after suffering for several years marked oppression of breathing, was suddenly seized with great dyspnœa, and exhibited all the signs of aortic insufficiency and contraction of the mitral valve. At the autopsy the aorta was found thickened, rough, and red, but with no lesions of its orifice, although the valves were thickened. Above the orifice an aperture, three or four centimetres in diameter, was found opening into an aneurismal sac, which communicated with the pulmonary artery. It was, then, an example of an aneurism at the base of the aorta which had burst into the pulmonary artery—a fact of such rarity that M. Laveran has only found two other cases recorded in the *Bulletins of the Anatomical Society.—Gaz. Hebd.*, October 26.

AN INDUSTRIAL HOME FOR FEMALE DRUNKARDS.—On Monday last the Lord Mayor presided over a meeting, held at the Mansion House, in support of an appeal to establish an industrial home for women who are habitual drunkards. In moving the first resolution, affirming the evils of drunkenness, Dr. Alfred Carpenter urged that women, once becoming drunkards, sooner lose their self-respect than men. As an encouragement to the promoters of the scheme, he stated that 33 per cent. of the women received into institutions in America, similar to the one now proposed to be established, left completely cured of their cravings for drink. The Chaplain of Newgate, the Rev. E. Brooke, the Rev. Mr. Horsley, the Chaplain of the House of Detention, and Dr. Irons, addressed the

meeting. Mr. S. Morley, in the course of a speech supporting the movement, remarked that, in his opinion, it was high time that an influential deputation should wait upon the Home Secretary, and impress upon him that it was no longer possible for the State to neglect an opportunity for grappling with this national evil; and a resolution to that effect was eventually carried. Upon the motion of the Rev. Ernest Wilberforce, seconded by Captain Toynbee, it was decided to establish an industrial home for the reformation of women and girls addicted to drink; and during the proceedings it was stated that £4000, of which £300 had already been obtained, was needed to make the movement a success. The proceedings terminated in the usual manner.

THE HEALTH OF THE PORT OF LONDON.—The half-yearly report of Dr. Harry Leach, the Medical Officer of Health for the Port of London, for the period ending June 30 last, recently published, shows an increase in usefulness, due in a great measure to the system and organisation which four years' experience have enabled the authorities to bring to bear on the subject. As Dr. Leach remarks in his report, one of the chief duties of a port sanitary authority is most undoubtedly the initiation and maintenance of a system calculated in as complete a manner as possible to prevent the introduction of contagious and infectious diseases into the country by means of shipping; and when it appears that scarlet fever has been discovered and promptly dealt with in a vessel from Melbourne, measles in a first-class steamship from Calcutta, erysipelas in an emigrant ship from Antwerp, and small-pox in various coasting craft, it must be conceded that these duties have been very satisfactorily carried out. Dr. Leach admits that no special event has occurred during the six months now under consideration, so that the substance of the report is almost purely statistical; but in it he regrets that the exertions of the Committee and managers of the school-ships stationed in the Thames have been unable to provide hospital accommodation for these vessels, more especially as the epidemic on the *Cornwall* two years ago cost the school-ship society £3000, and the events of that outbreak showed most distinctly how much inconvenience and increase of sickness were caused by the absence of any proper means for promptly isolating the sick and suspected boys.

DEATH FROM SHOCK.—M. Le Dentu having stated at the Paris Society of Surgery that a patient upon whom he had performed amputation at the hip-joint died twenty-six hours afterwards of "traumatic shock," having lost but little blood, Prof. Verneuil expressed a wish that this term should be suppressed or better defined. "Traumatic shock" is made the result of many causes, the patient being said to die of it when he dies some hours after the operation. Among twenty English cases you are sure to find one that dies of shock; and the term has been especially abused in regard to amputation at the hip. "Shock" is not admitted by all surgeons, and in most cases it is synonymous with acute anæmia—a condition easily produced in some persons who have little blood to lose. M. Desprès observed that we sometimes meet with cases in which there are no wounds at all, the patients being covered with contusions, and having their limbs broken without any large vessels being ruptured. They are in a state of extreme prostration, and often succumb from what may be termed correctly "traumatic shock." It is not requisite that the blood should issue from the body to induce acute anæmia, it sufficing for it to have quitted the vessels. M. Le Dentu observed that the influence of the nervous system in extensive injuries cannot be denied. A patient who loses much blood by a small wound does not die, or dies much more slowly than the subjects of operations. Prof. Verneuil did not deny the effect of injuries on the nervous system; but he wishes that a different name should be given to each depressing action. After amputation at the hip the patients die usually of acute anæmia; and of 136 so operated upon, forty have died within the first twenty-four hours—no other operation furnishing such a result.—*Gaz. Hebd.*, October 26.

NOTES, QUERIES, AND REPLIES.

He that questioneth much shall learn much.—*Bacon.*

Dr. John Drysdale.—Received with thanks.

Economist.—The total expenses of the five Middlesex coroners for the past quarter were £2373 7s. 9d.

Dens-Sap.—The following gentlemen constitute the Dental Board of the College of Surgeons, viz.:—Messrs. F. Le G. Clark, F.R.S., Chairman; William S. Savory, F.R.S.; John Birkett; S. J. A. Salter, F.R.S.; T. A. Rogers; and H. J. Barrett.

Botanist.—It is stated that Sir Joseph Hooker, who has recently returned from his tour in the United States, is of opinion that the key to the botany of these States is to be found in Colorado.

Good Templar.—There were no less than nine different measures, dealing with the question of intemperance, brought before Parliament last session.

Hydrophobia.—At the meeting of the Liverpool Town Council on Monday, a memorial was presented, largely signed by doctors and others, calling attention to a recent shocking case of hydrophobia, and urging that stringent precautions should be taken to prevent stray dogs from infesting the streets.

Humanitas.—John Howard, the philanthropist, whose grand object was to put a stop to that infectious distemper (now believed to have been typhus), the gaol fever, which raged in some places like the plague, died on a tour in Russia. In visiting an hospital at Cherson, then recently founded on the Black Sea, he caught a malignant fever, which carried him off in January, 1790, after an illness of about twelve days. His remains were buried in the garden of a villa in the neighbourhood, and a monument to his memory was erected at the national expense in St. Paul's Cathedral.

Egoism.—Mrs. H. More's remark was—"I used to wonder why people should be so fond of the company of their physician, till I recollected that he is the only person with whom one dares talk continually of one's self without interruption, contradiction, or censure."

L. O. P.—"The average mortality of any given country is less fluctuating than the mean temperature of its climate, and the remark holds good with respect even to violent deaths; and yet upon how many tumultuous passions, wayward thoughts and states in man, and upon what multiplied circumstances, does each death, murder, and fatal accident depend! Not only, then, must the same moral and physical causes be in constant operation, but the annual amount or force of each, taking one year with another, will not vary to any considerable extent."

Nemo.—The Metropolitan Asylums District Board have now under their control two asylums and four hospitals, with a temporary asylum at Clapton, one building at Darenth, and the training-ship *Exmouth*.

Hygeia.—The district surveyor has power over the foundations of buildings, under the Metropolitan Buildings Act, 1855 (Schedule 1, structure of buildings), viz.:—"Every building shall be enclosed with walls constructed of brick, stone, or other hard and incombustible materials, and the foundation shall rest on the solid ground, or upon concrete, or upon other solid substructure."

Grumbler.—It has been stated by a contemporary that the prohibition of exchanges among army medical officers has been rescinded, and those who have suffered impairment of health in the Service may now try to suit themselves as respects climate.

Goliath.—Yon-Shan, the coming Chinee, is stated to be eight feet three inches in his socks, and as he has not finished growing, he stands a chance of rivalling the historic Irish giant, Patrick Colter, who measured eight feet seven inches. He will be the tallest man in giants we have had since O'Brien, another gigantic Celt, who died in 1783, and whose skeleton is, we believe, in the Museum of the Royal College of Surgeons.

Gourmand.—Cheese was known to the Greeks and Romans much earlier than butter, according to Beckmann, for he found no notice of the latter in Aristotle, though the first is frequently mentioned. The ancient proverb was that—"Cheese is bad, because it digests everything but itself."

Meteorologist.—Mr. H. F. Blanford returned to India in 1874, as head of the Meteorological Department. By this appointment the Government of India have shown their appreciation of the importance of a central office, through which useful meteorological work in India may be organised, and uniformity of the observations in the different provinces secured.

G. L.—According to reports that have been received from Bulgaria, the medical staff of the Russian troops there consists of 849 doctors, 146 chemists, 123 veterinary surgeons, and 3285 assistants, besides the sanitary corps of the guards, the medical men of the Red Cross Society, and the Sisters of Charity.

BOOKS AND PAMPHLETS RECEIVED—

Report of the Chief Surgeon on the Health of the Metropolitan Police Force during the Year 1876—Annual Report on the Lock Hospitals of the Madras Presidency for the Year 1876—Cassell's History of India, part 23—Lawson Tait, F.R.C.S., A Letter on Hospital Mortality, addressed to the Governors of the Birmingham General Hospital—Vivisection viewed under the Light of Divine Revelation, an essay, by M.A., Cambridge—Jonathan Hutchinson, F.R.C.S., Illustrations of Clinical Surgery, fasciculus ix.—C. F. Maunder, Fistula in Ano—Julius Althaus, M.D., M.R.C.P. Lond., Diseases of the Nervous System, their Prevalence and Pathology.

PERIODICALS AND NEWSPAPERS RECEIVED

Lancet—British Medical Journal—Medical Press and Circular—Berliner Klinische Wochenschrift—Centralblatt für Chirurgie—Gazette des Hôpitaux—Gazette Médicale—Gazette Hebdomadaire—Le Progrès Médical—Bulletin de l'Académie de Médecine—Pharmaceutical Journal—Wiener Medizinische Wochenschrift—Medical Examiner—The Louisville Medical News—Boston Medical and Surgical Journal—Nature—Philadelphia Medical Times—Iron—Cincinnati Clinic—Veterinarian—New York Sanitarian—Nordiskt Medicinskt Arkiv—Students' Journal—Leisure Hour—Sunday at Home—Toronto Sanitary Journal—American Practitioner—La Province Médicale—National Anti-Compulsory Vaccination Reporter—Hardwicke's Science Gossip.

COMMUNICATIONS have been received from—

Mr. W. E. Poole, London; Mr. E. Nettleship, London; Dr. W. B. Gowers, London; Mr. Timothy Holmes, London; Mr. B. R. Wheatley, London; Dr. William Cayley, London; Dr. Julius Althaus, London; Dr. Thomas Barlow, London; Mr. T. M. Stone, London; Dr. A. E. Aust-Lawrence, Clifton, Bristol; The Registrar of the Royal College of Physicians, London; Mr. Wm. F. Crane, London; Mr. E. Drake, London; Mr. Teevan, London; The Secretary of the Apothecaries' Hall, London; Mr. Lawson Tait, Birmingham; Dr. Burdon Sanderson, London; Mr. C. Rivington, London; The Secretary of the Society for the Relief of Widows and Orphans of Medical Men; The Secretary of the Clinical Society; Council of the Sanitary Institute of Great Britain; The Secretary to the Royal Institution; Mr. R. H. A. Schofield, London; Mr. John Chatto, London.

APPOINTMENTS FOR THE WEEK.

November 3. *Saturday* (*this day*).

Operations at St. Bartholomew's, 1½ p.m.; King's College, 2 p.m.; Royal Free, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.

5. *Monday.*

Operations at the Metropolitan Free, 2 p.m.; St. Mark's Hospital for Diseases of the Rectum, 2 p.m.; St. Peter's Hospital for Stone, 3 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.

Medical Society of London, 8½ p.m. General Meeting. Dr. Greenhalgh, "On the Treatment of Dysmenorrhœa and other Uterine Affections by a New Form of Pessary."

Royal Institution, 2 p.m. General Monthly Meeting.

6. *Tuesday.*

Operations at Guy's, 1½ p.m.; Westminster, 2 p.m.; National Orthopædic, Great Portland-street, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; West London, 3 p.m.

Pathological Society, 8½ p.m. Dr. Peacock—Aneurism of the Aorta opening externally. Dr. P. Irvine—Two Cases of Abdominal Aneurism. Mr. Wagstaffe—Aortic Aneurism bursting into the Pericardium, following a cured Popliteal Aneurism. Dr. Crisp—1. Case of Imperforate Anus; 2. Miliary Tuberculosis in an Infant aged three months. Mr. A. Doran—1. Perforation of a Diverticulum in the Jejunum; 2. Large Single Cyst of the Testicle. Mr. Davies-Colley—Congenital Occlusion of the Small Intestine. Mr. H. Cripps—Cancer of the Rectum. Dr. Dowse—The Pathology of a Case of Paralysis Agitans. Dr. Burney Yeo—Cyst connected with the Liver. And other Specimens.

7. *Wednesday.*

Operations at University College, 2 p.m.; St. Mary's, 1¼ p.m.; Middlesex, 1 p.m.; London, 2 p.m.; St. Bartholomew's, 1½ p.m.; Great Northern, 2 p.m.; Samaritan, 2½ p.m.; King's College (by Mr. Wood), 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.

Obstetrical Society, 8 p.m. Dr. Galabin, "On the Choice of the Leg in Version." And other Papers.

8. *Thursday.*

Operations at St. George's, 1 p.m.; Central London Ophthalmic, 1 p.m.; Royal Orthopædic, 2 p.m.; University College, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; Hospital for Diseases of the Throat, 2 p.m.; Hospital for Women, 2 p.m.; Charing-cross, 2 p.m.; St. Thomas's (ophthalmic operations), 4 p.m.

9. *Friday.*

Operations at Central London Ophthalmic, 2 p.m.; Royal London Ophthalmic, 11 a.m.; South London Ophthalmic, 2 p.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. George's (ophthalmic operations), 1¼ p.m.; Guy's, 1½ p.m.

Clinical Society, 8½ p.m. Mr. Bellamy, "A Case of Urethral Calculus." Mr. Sydney Jones, "A Case of Urethral Calculus." Dr. Gowers, "A Case of Unilateral Injury to the Spinal Cord." Dr. J. Burney Walker, "A Case of Left Hemiplegia and Hemi-Anæsthesia, associated with Loss of Speech; Recovery." (Communicated, with Remarks, by Dr. Broadbent.)

VITAL STATISTICS OF LONDON.

Week ending Saturday, October 27, 1877.

At the Royal Observatory, Greenwich, the mean reading of the barometer last week was 29·50 in. The highest reading was 29·95 in. at the beginning of the week, and the lowest 29·05 in. on Thursday afternoon.

* The figures for the English and Scottish towns are the numbe enumerated in April, 1871, raised to the middle of 1877 by the additio of six years and a quarter's increase, calculated on the rate which pr vailed between 1861 and 1871. The population of Dublin is taken stationary at the number enumerated in April, 1871.

ORIGINAL LECTURES.

A CLINICAL LECTURE
ON A CASE OF
ULCERATIVE OR INFECTING ENDOCARDITIS SIMULATING TYPHOID FEVER.

DELIVERED AT THE MIDDLESEX HOSPITAL.

By WILLIAM CAYLEY, M.D.,
Physician and Lecturer on Medicine at the Middlesex Hospital;
Physician to the London Fever Hospital.

GENTLEMEN,—I propose to-day to bring under your notice a case of a not very common form of disease, which is generally known as ulcerative endocarditis, though the name is not happily chosen. I will first narrate the facts of the case, and then make some remarks on the pathology and diagnosis of the affection.

The patient was a boy in Hertford ward, aged nine years, who was admitted on September 25, and died on October 3. His previous history is briefly this:—He has never suffered from rheumatism in any form, but about six years ago he had a severe attack of small-pox, since which he has been more or less subject to palpitation, shortness of breath on exertion, and cough. We are therefore, I think, justified in dating the valvular disease of the heart, with which he was affected on his admission, to this attack. Endocarditis, especially of the ulcerative form, is an occasional, though rare, complication of small-pox; pericarditis is much more common. This patient, as it appeared on post-mortem examination, had evidently suffered from both. In January, 1874, he was admitted into this Hospital with symptoms much resembling those of tubercular meningitis—vomiting, pain in the head, muscular twitchings, clenching of the hands, retraction of the abdomen, irregular pulse, and fever. It was then noticed that there was a systolic apex-murmur. These threatening symptoms soon subsided, and he was discharged in about three weeks. On September 16, eleven days before his admission, he was taken ill with pains in the head and chest, and vomiting. He complained of vertigo, and is stated to have fainted several times during the day. The following day he had rigors. He continued to vomit and to complain of his head and chest, and his appetite quite failed. The pain in his head and chest continued up to his admission, but the vomiting gradually ceased.

State on Admission.—An anæmic, delicate-looking boy, much pitted with the small-pox. Expression rather heavy, but there was no delirium. His chief complaint was pain in the præcordia and frontal headache. He coughed frequently, and expectorated a little glairy mucus. There was a marked convergent strabismus of old standing; the pupils were moderately dilated and active. On examination with the ophthalmoscope nothing abnormal was seen in the fundus. There were slight choreic twitchings of the left arm and side of the face. The tongue presented very marked features: the centre was red and transversely fissured; on each side was a strip coated with white fur, and the tip and edges were again red. There was no distension of the belly, or tenderness on pressure, or gurgling in the iliac fossa. No eruption was visible on the skin, which felt pungently hot; the *tâches cérébrales* of Trousseau were only slightly marked. This symptom is evoked by drawing the back of the nail across the skin, and consists in the appearance of a red stripe, bordered on each side by a narrower white anæmic one. Trousseau regarded it as a sign of meningitis, though it is also met with in many febrile conditions, and is especially frequent in typhoid fever. I have, indeed, come to regard its absence as a strong indication against the existence of typhoid fever, and on more than one occasion have found this a guide in making a diagnosis. In typhoid fever this sign often lasts for some time after convalescence has set in, and I regard its persistence as an indication that the intestinal ulcers are not yet healed, and that, therefore, the patient is still liable to relapse and to the complications attending unhealed ulcers. The spleen was enlarged; the dulness extended from an inch below the level of the nipple to below the margin of the costal cartilage—a space of about three inches. Pulse 134; respirations 48; temperature 104° (in the evening it fell to 101·2°). On physical examination of the thorax, nothing amiss was discovered with the lungs except some bronchial râles, which were universally present. The heart was much hypertrophied; the apex beat in the sixth interspace, half an inch external to the mammary line. The impulse was accompanied by a distinct thrill. At the apex there was a loud, rough systolic murmur, which also occupied the presystolic period, and was distinctly heard at the back. At the base a soft systolic, and a prolonged diastolic murmur were audible. The heart had a triple cantering rhythm like that of pericarditis. This was caused, no doubt, by some rough patches and fibrous tags which were found on post-mortem examination, the result of past inflammation. Urine, specific gravity 1030, contained no blood or albumen, and an abundance of chlorides. The next day the motions were observed to be solid, and of a dark colour.

The diagnosis which was now made was the correct one, that the patient was suffering from ulcerative endocarditis; though later, for insufficient reasons, the case became regarded as probably typhoid fever complicated by heart disease.

The next morning (September 27) the pulse was 132; respirations 36; temperature 104° (nearly 3° higher than the temperature of the preceding evening). Fever of this inverse type, I need hardly say, rarely occurs in typhoid, in which there is almost always a decided morning remission, though it is common enough in pyæmia, with which ulcerative endocarditis is closely allied. Patient still complained much of præcordial pain and headache. His belly was now rather swollen and tense, and there was slight general tenderness. He was ordered infusion of digitalis ℥ss. ter die. In the evening his pulse was 120; respirations 48; temperature 104·2°. Four leeches were ordered to the præcordial region; this gave great relief to the præcordial pain and distress. September 27: Pulse 108; temperature 101·2°; patient feels better; the præcordial pain and headache have much abated. During the day he had three loose light-coloured stools. In the evening his temperature rose again to 104·2°. At 10 p.m. he was ordered ten grains of quinine. This was followed by a rapid fall of the temperature. At midnight it was 101·2°; at 3 a.m. on the 28th, 99°; at 6 a.m., 99·4°; at 9 a.m., 100·6°. He was now wandering, and said he felt quite well. His tongue was more fissured and rather dry. At 2 p.m. his temperature was 104°. Ordered thirty grains of salicylate of soda; this he vomited. At 3 p.m. ten grains of quinine were again administered in two doses. At 3.30, temperature, 103°; at 9.30, 104°. September 29: At 6.30 a.m., temperature 101·4°; at 9.30, pulse 120, respirations 36, temperature 102·4°. Patient's condition seems somewhat improved, and he is free from pain. The heart has lost the cantering rhythm, but the physical signs are otherwise little altered. During the day his nose bled freely, and he had several loose light-yellow stools. At 5.20 p.m. the temperature was 102·6°; at 8 p.m., 104·2°. Ten grains of quinine were again administered. At midnight the temperature was 100·2°; at 7 a.m. on the 30th it was 102·6°; at 10 a.m., 104·8°. During the night the bowels were opened several times; the motions were liquid, of a light yellow colour and alkaline reaction. His pulse was now 144; respirations 60, and he dilated his nostrils. The teeth were covered with sordes. There was a frequent hard cough, with scanty glairy expectoration, streaked but not mixed with blood. Bronchitic râles were everywhere audible, but there was no dulness or fine crepitation. Belly swollen and generally rather tender. Urine free from blood and albumen.

I now began to regard the case as probably one of typhoid fever. The symptoms which induced me to change my original opinion were the characters of the stools and the absence of blood and albumen from the urine (these are almost always present in ulcerative endocarditis), and also the occurrence of epistaxis. The *tâches cérébrales* were now well marked. At 11 a.m. he was given ten grains of quinine, divided as before, into two doses. At 1 p.m. his temperature was 102°; at 6, 101·4°; at 7, 103°. He was now given a bath of a temperature of 80°. After about five minutes he began to shiver, and his pulse became very small. He was taken out and given ten grains of quinine. At 11.30 his temperature had gone up to 104°. He passed a restless, disturbed night. The next morning, at 9.30, his temperature was 104·2°. There was now gurgling in the right iliac fossa. He was ordered a second bath at 80°. He remained in it eighteen minutes without any shivering. When taken out his temperature was 103°. Ten grains of quinine were given, and at 3 p.m. his temperature was 101·8°. At 4.30 the temperature had again risen to 104°. A third bath was given at 80°. He remained in it twelve minutes, when he began to shiver, and was therefore taken out. While in the bath the temperature rose to 105°; when taken out it fell to 103·8°. At 7.30 the temperature was 105°. A fourth bath of fifteen minutes' duration was given. Half

an hour after being taken out the temperature was 101·2°. At 10.25 the temperature was 105°. A fifth bath of twenty-five minutes' duration was given, after which the temperature fell to 100·8°; but at 1 a.m. it had risen to 104·4°. A sixth bath was given of twelve minutes' duration, when he began to shiver. In the bath the temperature rose to 105·7°. After being taken out it fell to 102°. He was given twelve grains of quinine. After the baths he generally fell asleep, and his tongue, which had become dry, used to get moist. At 8 a.m. on October 2 the temperature had again risen to 104°. There was now great prostration, a dry brown tongue, sordes on teeth, subsultus tendinum, and much stupor. He continued in much the same condition all day, half unconscious, with muttering delirium, and finally passed into a state of profound coma. The diarrhœa continued. He died the next day at 8.40 p.m. Shortly before his death, while sweating profusely, his temperature rose to 107°; shortly after death to 108·4°.

Stimulants were freely administered as the signs of depression increased. At first four ounces of port were given daily, then brandy, the amount of which was gradually increased to six and eight ounces daily, and at last to half an ounce every hour, though he often refused all nourishment. Nutrient enemata were then tried. Opium was also administered by the bowel to check the diarrhœa.

Post-mortem Examination.—The pia mater of the convexity was very vascular, and studded here and there over the frontal lobes, and still more thickly over the inferior and inner aspect of the occipital lobes of the cerebrum, with dark red patches of effused blood, varying in size from a pin's head to a shilling. In the centre of many of the smaller of these patches an opaque yellowish-white spot was visible, surrounded by the zone of hæmorrhage. On microscopical examination these spots were found to consist of fine molecular matter. There was no effusion of lymph in the pia mater. The brain itself was generally hyperæmic, but there were no abnormal deposits of any kind in it. The fluid in the ventricles and at the base was somewhat increased. The lungs were studded with minute sub-pleural ecchymoses; they were everywhere crepitant, but universally congested, especially their depending parts. They were quite free from any abnormal deposits. The pericardium contained about three ounces of clear fluid. There were no sub-serous ecchymoses or signs of recent inflammation, but on the anterior surface of the heart was a thick, rough, fibrous patch, with fibrous processes attached to it. The right cavities of the heart were filled with loose black clot. The valves were normal. The left ventricle was hypertrophied. Both the aortic and mitral valves were thickened and fringed with vegetations, but there was no ulceration or loss of substance. The chordæ tendineæ of the mitral valve were shortened and thickened. Covering the auricular aspect of the mitral valve, and extending over the wall of the auricle as far as the mouth of one of the pulmonary veins, was a friable reddish-brown granular layer of fibrine or lymph, fragments of which could be readily detached. On microscopic examination of this, it was found to consist mainly of rather highly refractile molecules, among which were many rod shaped bodies, presumably bacteria. Abdomen: On opening the abdomen the intestines were seen to be studded with numerous ecchymoses, varying in size from a pin's head to a sixpenny-piece; they were sub-serous, and many of them presented opaque yellowish-white spots in their centre, like those of the pia mater. The mucous membrane of the intestinal canal presented nothing abnormal; there was no ulceration or infiltration of Peyer's or the solitary glands. The spleen was much enlarged, softened, and presented at one point a large wedge-shaped block of consolidation and hæmorrhage of recent appearance. The kidneys presented very remarkable characters; their surfaces were thickly spotted with minute hæmorrhagic infarctions, in the centre of many of which a yellow spot was visible. On sections, similar deposits were seen scattered through their substance, together with a few old caseous blocks of wedge shape. Microscopic examination showed these yellow spots to consist of molecular matter, together with numerous rods; but I found swarms of bacteria in other parts of the kidney, and elsewhere, due, I suppose, to decomposition. A more minute examination of the kidney was subsequently made with the assistance of Dr. Coupland, and the renal epithelium was found in part filled with highly refractile granules, which were unaffected either by liquor potassæ or acetic acid.

The disease known as ulcerative endocarditis, of which this is a well-marked example, was first described by the late Dr. Senhouse Kirkes, who published a case in the *Edinburgh Medical and Surgical Journal* in 1853; and it has since bee carefully investigated by many pathologists, German as wel as English, especially Virchow. The name is not happil chosen, as we often have ulceration of the endocardium i rheumatic and other affections, without the characteristi symptoms and effects of the disease; and we meet with all th phenomena of the disease, as in this case, without any ulcer tion. Professor Rosenstein, in "Ziemssen's Handbuch," as it called, though it consists of some two dozen bulky volumes, term it "diphtheritic endocarditis"; and considers the soft, friabl layer of lymph or fibrine which is deposited on the inflame endocardium as similar in its nature to the false membran on the mucous surfaces in diphtheria, both being largely com posed of the lower forms of fungi, bacteria, and micrococc The term "diphtheritic" is, however, employed in so many di ferent senses, and has already given rise to so much confusio that I think it very undesirable to extend its use. I myse should prefer the name "infecting endocarditis," as one of th most prominent results is the infection of the blood wit some morbid poison.

The disease is characterised by producing multiple embolism for the most part of the miliary form, and a condition of th blood which at present we must call by the general name blood-poisoning, the indications of which are rigors, feve prostration, delirium, stupor. Embolisms are, of course, liab to occur in ordinary endocarditis, but here the principal co sequences are due to the local effects of the embolism; th miliary form, too, is less frequent, and the seat of the embo isms is not quite the same. In the brain the emboli due detachment of vegetations in ordinary endocarditis usual get lodged in a branch of the middle cerebral artery, and pr duce hæmorrhage, and softening of the anterior part of th optic thalamus or corpus striatum, and, as a consequence, hem plegia. In infecting endocarditis the embolisms are mo common, as in this case, in the pia mater of the hemisphere and from their small size do not necessarily cause any chara teristic signs of cerebral lesion. The intestine, too, is mu more frequently the seat of embolism in infecting than simple endocarditis.

In both forms the kidneys and spleen are the most comm seats of embolism.

The symptoms of the disease differ greatly in different cas but are conveniently divided by Professor Rosenstein into tw main forms—the pyæmic and the typhoid. The pyæmic fo more resembles ordinary pyæmia, with which it is often ass ciated. There are recurrent rigors, fever of a remittent intermittent type, and local suppurations due to embolisms.

The symptoms of the typhoid form were well exemplified this case. At the outset, rigors; often vomiting, which m continue through the whole course of the disease; high fe of an irregular type, the remissions and exacerbations oft occurring at irregular times, and not necessarily morning a evening, as is usually the case in typhoid. Often there profuse sweating. Together with these symptoms there headache, vertigo, great prostration, dry brown tongue, sor on the teeth, delirium, stupor passing into coma. Diarrhœa often present, due no doubt to the intestinal embolisms, a the motions may contain blood. The spleen is enlarged, a the urine is almost always albuminous, and often bloody; the present case this symptom was absent, though the kidn were studded with miliary embolisms.

On auscultation of the heart we find the signs of valvu incompetency, and often also of obstruction of the orifices, the bruits thus produced are liable to vary from day to d from the progress of the ulceration.

Infecting endocarditis does not appear to attack pers previously in good health. It may occur in pyæmia; it also met with in the puerperal state, in which case, accord to Professor Rosenstein, there is often a diphtheritic infla mation of the genital mucous membrane. It sometim complicates the specific fevers, as small-pox or diphthe Sometimes the endocarditis of acute rheumatism takes t form; and occasionally, as in the present case, it supervene chronic valvular disease. If the disease be really due to infection of the blood by bacteria, it is difficult to underst how, in the latter instances, this is effected.

The principal points of distinction between the typhoid f of infecting endocarditis and typhoid fever are these:—Fi the physical signs of the cardiac lesion. Endocarditis is likely to occur as a complication of typhoid, though, of cou typhoid fever may attack persons suffering from chr valvular disease. Next, the presence of one of the affecti which are known to give rise to this form of endocarditis. T there are the more sudden onset, the rapid course, the mar

gors, and the more irregular type of fever. The frequency the pulse, and especially of the respirations, is usually much eater than in typhoid: this great frequency of the respira- ons was well marked in this case, and was out of all proportion the pulmonary lesions, as appeared both by the physical gns during life and the post-mortem condition. Any local mptoms of embolism would, of course, tend to confirm the agnosis. The presence of blood and albumen in the urine, dicating embolism of the kidney, is a very important sign, ough albuminuria is not uncommon in typhoid. Why this gn was absent in my case I am unable to explain. The rose ots of typhoid are of course absent. The delirium, the dry acked tongue, the sordes on the teeth, the prostration, the arrhœa, the enlargement of the spleen, are common to both seases.

The disease appears necessarily to tend to a fatal issue, and not amenable to treatment. On the view that it is due to an fection of the blood by bacteria, it has been proposed to give e sulpho-carbolates, quinine in large doses, salicine and sali- lic acid, which are destructive to these organisms. As this se was regarded as probably one of typhoid fever, the patient as treated by the "antipyretic method," as it is called—that by reducing the temperature by tepid baths and large doses quinine. Though I have not succeeded in obtaining the lliant results which have attended this mode of treatment Germany, I nevertheless regard it as the best way of treat- typhoid with high temperatures. Here the temperature isted the treatment in a remarkable manner, and the chilling ect of the baths was very transient. In typhoid the tem- rature seldom resists the effects of a few successive baths l a large dose of quinine or salicylate of soda, which usually duce a reduction lasting for twelve or even twenty-four irs, and by repetitions of this treatment the temperature y be kept at a moderate height throughout the course of fever. In this case I did not venture to give baths below , as they were not very well borne, soon causing shivering l depression of the circulation. The use of stimulants was icated by the great prostration, which, however, they were verless to remove.

ORIGINAL COMMUNICATIONS.

ON SYPHILITIC AFFECTIONS OF THE NERVOUS SYSTEM.

By JULIUS ALTHAUS, M.D., M.R.C.P.,
sician to the Hospital for Epilepsy and Paralysis, Regent's-park, etc.

THOROUGH knowledge of those nervous diseases which are duced by the subtle poison of syphilis is of the greatest ctical importance, as they yield much more readily to ific treatment than the corresponding idiopathic affections the nervous system, and, unless thoroughly recognised, not be efficiently treated. An incorrect diagnosis in such s will often doom a patient to destruction, while a true gnition of his state may save his life and restore his lth.

euro-syphilitic affections belong generally to the later ions of the secondary stage, or to the tertiary period of complaint. They are invariably preceded by a hard cting sore, and usually by secondary symptoms affecting skin and fauces. They may, however, appear as the first ifestations of infection of the system, in from twelve ths to twenty years from the appearance of the primary ction, and have been now and then seen to follow the first and sore throat. They are observed at all ages, but most uently between twenty and forty years; and this is of nostic importance, as hemiplegia or paraplegia coming on outhful persons is in nine cases out of ten of syphilitic in. The male sex is more liable to them than the female, hich is in accordance with the fact that constitutional ilis is altogether more frequent in men than in women.

erve-syphilis appears to affect with preference those persons hom there is the neuropathic constitution, either hereditary cquired. There is almost always a family history of apo- y, epilepsy, chorea, megrim, or other nervous maladies, frequently the patient himself has previously suffered neuralgia or fits. Persons who have put an undue strain heir nervous power, either by excessive mental labour, or ree indulgence in alcohol and the sexual appetite, are more e, when rendered syphilitic, to become subject to nervous dies than those in whom there have been no such ante- cedents. Injury, such as a blow on the head or a fall, and depressing emotions, act frequently as exciting causes of these diseases. Finally, an unsystematic and too soon interrupted treatment of the primary affection has to be looked upon as a powerfully predisposing cause of nerve-syphilis.

Syphilis affects with preference the brain and cranial nerves, but does not spare the spinal cord. Anatomically, we find that the characteristic lesions are not meningitis or encephalitis, as was formerly believed, but repeated attacks of hyperæmia, tumour, and disease of the arteries.

1. The congestive form of cerebral syphilis shows hardly any striking features on the post-mortem table, more especially where the case ends fatally at an early stage of the complaint, from such complications as cystitis, decubitus, phthisis, or pneumonia. When the disease has lasted for a considerable time, the membranes of the brain are seen to have lost their transparency, and there is slight wasting of the cerebral convolutions,—which latter, however, is not sufficient to explain the severe symptoms which have been observed during life. The lesions are the same, although in a slighter degree, as those which are found in general paralysis of the insane, and affect more particularly Hitzig and Ferrier's psycho-motor centres in the cineritious substance of the anterior lobes. In some of these cases the cervical sympathetic nerve has been found in a state of pigmentary degeneration, and it is probable that disease of the superior cervical ganglion of that nerve may have an important influence in the production of the repeated attacks of hyperæmia by which this form of brain-syphilis is characterised.

The symptoms which are observed under these circumstances resemble very closely those of general paralysis of the insane. They are at first indefinite, come and go, and a change in the mind and temper is the most characteristic feature. There is excitement or depression, with some confusion of thoughts, fussiness, and ambitious ideas or delusions. Apart from a general feeling of *malaise*, the patient does not complain of being ill. As time goes on, there is loss of energy, debility, embarrassed speech partaking of the nature of aphasia, and being cortical rather than medullary in its kind. The size of the pupils is unequal; the tongue is tremulous when protruded; there is tottering gait, and pins-and-needles and numbness in the extremities are complained of. When the symptoms on the part of the nervous system become more marked, there is often a simultaneous outbreak of fresh syphilitic manifestations on the skin, mucous membrane, or periosteum. The intellect and memory now suffer more decidedly, and symptoms of paralysis appear from time to time—viz., aphasia, agraphia, hemiplegia, and paraplegia. Such symptoms may last at first only for a few hours or days, but they gradually become more permanent. The general debility increases *pari passu;* and unless an energetic anti-syphilitic treatment be previously followed, the patient dies within a few years from the outbreak of the disease, from cystitis, decubitus, and general marasmus.

2. The second manifestation of cerebral syphilis is the syphilitic tumour, gumma, or syphiloma, which presents itself in two varieties, these being probably only different stages of development of the same deposit. There are the soft and hard varieties; the soft tumour being the earlier, and the hard swelling the later phenomenon. The soft tumour consists of a reddish-grey jelly, from which on section a small quantity of pinkish liquid is seen to escape. Its histological elements are round cells and nuclei, mixed with spindle and stellated cells, and few but large capillary vessels. The outline of such tumours is not well defined, and they seem gradually to merge into the surrounding normal tissue. They are chiefly found in the subarachnoid space, and grow from thence to the surface of the brain; but they also occur in the dura mater, and are in this situation generally harder than when situated in the soft and moist tissue of the pia.

The hard tumour is in many respects similar to tubercle. It is dry, yellow, of a cheesy consistency, and on section homogeneous. It occurs interspersed into the reddish-grey jelly which I have just described, or as a well-defined tumour of variable size. It consists histologically of a granulated substance otherwise devoid of structure. There are no blood-vessels or spindle-cells, but now and then heaps of pigmentary granules and crystals and oil-globules near the periphery. Its size varies from that of an almond kernel to that of a pigeon's or even a hen's egg, and its shape is frequently adapted to that of the spaces in which it is discovered. It is seen between the two layers of the dura mater, which are much thickened, and more especially in the falx cerebri. The skull-bone which corresponds to its situation is generally in a state of dry caries, and appears rough and attenuated, while the other

portions of the skull are normal. The yellow hard tumour is probably owing to contraction and atrophy of the soft gumma. It is likewise found in the subarachnoid space, and from thence proceeds to the bloodvessels, nerves, and cerebral tissue itself. Occasionally, all the membranes and the cineritious substance are grown together into a uniform mass, and cannot be separated; and the two varieties of tumours are then seen together. Soft jelly is embedded between the dura and the surface of the brain, and one or several dry yellow tumours are lying in the fissures between the convolutions. The surrounding brain-tissue is in a state of red or white softening, or a portion of the cortical and medullary matter is changed into the same cheesy mass of which the tumour itself consists. Under the influence of anti-syphilitic treatment, nearly the whole of these changes may be repaired, and cicatricial patches are then discovered on the surface of the hemispheres.

At the base of the brain there is occasionally a diffuse infiltration with grey jelly, which can no longer be called a tumour, but must be looked upon as gummatous meningitis. The effusion in such instances is seen to spread from the olfactory bulb to the posterior portion of the cerebellum, and may even invade the cortex.

The symptoms of cerebral syphiloma differ considerably from those of syphilitic hyperæmia; and one that is hardly ever wanting, and also the first to appear, is a peculiar kind of headache, which appears chiefly at night, and is relieved towards morning. It is intolerably severe, and occurs in paroxysms which last for a few weeks, after which there is a remission, which is again succeeded by a fresh outbreak of it. Unless specific treatment is adopted, this may go on for years. The seat of the headache is mostly at the sides of the head, but it may also be frontal and occipital. It is sometimes localised in a very small area, and then generally increased by pressure; and it is owing to a gummatous deposit on the internal surface of the skull-bones, which irritates the periosteum and the dura mater. Sleeplessness is another symptom which is generally caused by the pain, but also occurs during free intervals; and it is apt to raise our suspicion, because it is mostly found in young persons, in whom insomnia is otherwise very rare.

After these symptoms have continued for a variable time, epileptiform attacks are apt to supervene, which sometimes resemble in every way an ordinary epileptic seizure. Unilateral convulsion, without loss of consciousness, is often connected with this condition; the muscular spasm starts from the thumb or first finger, or the foot, or the face, and affects only the arm or the leg of the same side, but becomes bilateral where the nerve nuclei of the two sides are associated; or there may be a regular epileptic seizure, *i.e.*, general convulsions and coma. When the hemispasm is on the right side, showing affection of the left hemisphere, temporary aphasia may be produced, and there may be hemiplegia with this, or left hemiplegia without aphasia. This hemispasm is due to irritation of the convolutions of the opposite hemisphere. When such fits succeed each other more or less rapidly, the mind becomes affected. There is irritability of temper: the patient is sometimes in a state of hysteria, laughing and crying alternately without any adequate cause; he is generally depressed in spirits; the memory is impaired, and the current of thoughts considerably retarded; the speech is embarrassed; the patient is unable to finish a sentence, and sometimes stops for a minute without being able to go on; he tries to held himself with gestures, but even this aid after a time forsakes him, and complete aphasia, agraphia, and amimia may become developed.

In such cases there is no hemiplegia or any other form of actual paralysis; but there is paresis, such as we are apt to connect with disease of Hitzig and Ferrier's psycho-motor centres. The patient is still able to walk, to dress and feed himself, but he is clumsy in doing so; the foot drags on the ground; he becomes gradually more helpless; there are frequent epileptic fits, and sometimes he does not awake from the coma; or decubitus is developed, leading to blood-poisoning; or death supervenes from total exhaustion of the nervous force.

The symptoms just described arise from syphiloma of the subarachnoid space, which gradually involves the cortex of the brain and the adjacent medullary matter. Where the third left frontal convolution and its neighbourhood are suffering, aphasia and agraphia will be the result. Where the anterior lobes are affected, there will be symptoms of paresis; while irritation of the posterior lobes causes melancholia, without much, if any, loss of motor power. But whatever portion of the cineritious structure is affected, syphilitic epilepsy will be the most prominent symptom.

The cerebral nerves generally suffer in exact proportion the seat of the syphiloma, which causes irritation, and final destruction, of the nerve-trunk. The gummatous tumo sometimes grows right round a nerve, and compresses it, it squeezes it against the bone; or an exostosis may occur the osseous canal through which the nerve has to pass. It quite true that a nerve is occasionally discovered passing rig through a syphiloma at the base, without having lost its fu tion or structure; but such cases are exceptional.

The general sequence of events is neuritis, followed atrophy. The nerve appears at first reddish and soften its sheath is thickened; and at a later period it is wasted a changed into a thin thread. Sometimes the sheath of the ne appears perfectly normal, but on opening it the nervous s stance is seen to have disappeared, and to be replaced b reddish or yellow mass, corresponding in structure to the s and hard syphiloma. In other instances the syphiloma gr directly from the pia mater along the bloodvessels into nervous substance, more particularly into the chiasma of optic nerves, causing atrophy of the same. Finally, there n be no structural lesion, although symptoms of paralysis, an thesia, and neuralgia may have been present during life. Hughlings-Jackson(a) is therefore incorrect in stating t the pathogenesis of these cases is nothing but a squeezing nerve-fibres by overgrowth of the connective-tissue eleme this is only one of several causes.

Amongst the cranial nerves the third is most frequen affected by syphilis, and the most common symptoms ptosis, external strabismus, and paralytic dilatation of pupil. Vertigo is occasionally a symptom of paralysis of nerve. Syphilitic neuro-retinitis and simple retinitis are common. There is effusion of serum into the layers of retina, which is sometimes slight and sometimes considera and is generally preceded by hyperæmia. The outline of disc is rendered indistinct and hazy, and the neighbourhoo the yellow spot is particularly affected. Sometimes vitreous humour becomes turbid, and prevents a thoro ophthalmoscopic examination. Where the effusion t place rapidly, the sight may be quickly destroyed; bu most cases it occurs slowly. It is not unfrequently associa with irido-choroiditis. Dr. Hughlings-Jackson has poi out that double optic neuritis may often be recognised by ophthalmoscope before vision suffers, and that it may be some time the only symptom, or be accompanied with slight symptoms as to be hardly noticed.

The portio dura and the fifth and sixth nerves may like suffer; there is then inability to close the eye, neuralgi the face, with lachrymation, paralysis of mastication, internal strabismus.

3. The third and last form of cerebral syphilis is disease o arteries, which affects with preference the carotids, the c of Willis, the Sylvian artery, and that of the corpus callo The first symptom of disease is, that the artery becomes transparent and loses its pink colour, assuming instead of white-greyish appearance. At the same time the vessel its cylindrical shape and becomes quite round, while its co hardened, and gives a cartilaginous sensation to the fi The diameter of the vessel is very much reduced by the d sition of a moist grey substance, which later on becomes and dry, and what remains of a free canal is often blocke by thrombosis, so that ultimately the whole artery is cha into a solid cord. This deposit takes place chiefly betwee endothelium and the elastic fibres of the vessel. At fi appears to consist of endothelial cells, which multiply siderably, and develope into connective tissue. This gr goes on in a longitudinal as well as in a transverse direc and the degeneration is therefore apt to spread to the bra of the artery.

Heubner and Cohnheim have distinguished two spher cerebral nutrition, which differ considerably from one and viz., the basal and the cortical sphere. In syphilitic disea cerebral arteries, these considerations become of paran importance. The basal sphere comprises the vertebral, ba and carotid arteries, the circle of Willis, and the comm ment of the anterior, middle, and posterior cerebral ar All these vessels give off small branches vertically, penetrate directly into the cerebral matter, become divide terminal, and then proceed through the capillary vessel the smaller veins. It is particularly in this basal s which supplies the central ganglia, that plugging o arteries from deposit and subsequent thrombosis becon dangerous to the nutrition of the parts; for as there

(a) *Journal of Mental Science*, July, 1875, page 5.

astomosis, the various forms of necrobiosis, such as red, low, and white softening, are easily produced, the results ng generally syphilitic hemiplegia.

In the cortical sphere of nutrition, on the other hand, the gging of arteries is not of the same vital importance, ause the peripheral part of the bloodvessel may still be pplied with blood by anastomosis in the pia mater. The tical arteries run for a long time in the pia mater without ving off any branches to the cerebral substance; they divide the pia, become constantly smaller, and anastomose so roughly with their fellows, that a kind of network is esta-shed, by means of which not only the smaller branches, but o the principal arteries, are made to communicate with each ner. The cerebral matter only receives small capillary ssels from this large vascular net after it has been allowed spread over a considerable surface. Although, therefore, e danger of starvation is much less in the cortex than in the ntral ganglia, nevertheless a rapid plugging cannot pass thout causing mischief, inasmuch as it decreases the pressure those vessels; while, if collateral circulation is established, e pressure may be suddenly increased above the normal ndard. The cineritious substance is thus exposed to consider-le vicissitudes of circulation, and the temporary apoplectic zures which are so common in this form of syphilis find in em a satisfactory explanation.

In both spheres of nutrition, however—the basal as well as e cortical,—simple narrowing of the arterial tubes, without tual plugging of the same, must have a deleterious influence the nutrition of the entire brain. It increases the resistance ered to the current of blood, which becomes further retarded the rigidity of the tube, which has lost its elasticity. The erchange of oxygen and of nutritive material is therefore nsiderably lessened, which explains the loss of energy, the pairment of the mental functions, and the somnolence which found in a number of these cases.

Where the basal sphere of nutrition suffers, the symptoms e generally rapidly developed. It is not by any means rare at, after a few insignificant premonitory symptoms, there is sudden stroke of apoplexy, which proves fatal. The sym-oms of this form of apoplexy are in all respects similar to ose of ordinary apoplexy from cerebral hæmorrhage. Mul-le thrombosis of several important basal arteries is discovered st-mortem.

In other cases there are premonitory symptoms chiefly on e part of the cranial nerves. These are ptosis, double vision, akness of sight from optic neuritis, anæsthesia, and neu-gia in certain branches of the fifth nerve, spasm in the portio ra and sixth nerve, etc. These symptoms may come on, as were, spontaneously, or after mental and physical efforts, citement, and indulgence in alcohol and the sexual appetite. ter a time there is a somewhat slowly produced attack of miplegia, with or without aphasia, and without loss of con-ousness. If collateral circulation is established the patient y gradually improve; or he sinks into a somnolent condition embling that of typhoid fever. There are headache, confusion, siness; the patient has a staring, absent look, and a morose pression of the countenance. He will on occasions pass his ter or fæces in the middle of the room, and does other things ich show absence of the feeling of shame; but on being ked to he generally becomes more reasonable. He will often use food, and die in the first or subsequent attacks; yet ere all these symptoms have been present an immense provement may by proper treatment be brought about in the tient's condition.

When there has been true hemiplegia, recovery is generally perfect, even under the best treatment. There are, however, nporary kinds of hemiplegia, which only persist for a day two, and where the starvation of cerebral tissue is evidently too short duration to cause any great degree of softening. some cases hemiplegia is followed by Türck's sclerosis of e lateral columns of the spinal cord, just as after ordinary ebral hæmorrhage.

Syphilitic Affections of the Spinal Cord.

These are much more rare than the corresponding diseases the brain and cranial nerves, and there are as yet only few st-mortem examinations of such cases put on record.

The syphiloma occurs in its two forms—viz., as jelly and as eese—in the pia mater and the subarachnoid space. The rec membranes are found grown together with each other d with the surface of the cord. There are, however, not cumscribed tumours as in the brain, but a kind of infiltra-n of the meninges and lymphatic spaces by gummatous usions, which appear small, multiple, and disseminated. Where the membranes grow together with the periosteum of vertebræ and the surface of the cord, there is generally pro-liferation of the neuroglia and wasting of the white columns. Some cases in which the symptoms of acute ascending spinal paralysis are observed during life seem to be owing to hyper-æmia simply, as no real structural alterations of the cord have been discovered.

In this latter case the symptoms generally commence at an early period—viz., in the first year,—and are accompanied by the usual early manifestations of constitutional syphilis. The first symptom is sudden paraplegia, with incontinence of urine and the fæces. There is no pain in the spine, and no anæsthesia of the limbs. Decubitus soon becomes developed, and the patient dies within a few weeks from the beginning of these symptoms.

More frequently, however, paralysis comes on in the later periods of the disease, after many other symptoms have existed for a long time. There is muddy pallor of the skin, and a disagreable smell about the patient, who is generally feeble and in a state of constant *malaise*. He experiences pain at different points of the spine, which is increased by pressure; and also pain, pins and needles, numbness and stiffness, in the lower extremities. These symptoms come and go, and then there is all of a sudden an attack of paraplegia or hemi-paraplegia. Where the seat of the disease is in the lower portion of the dorsal cord, there is also paralysis of the sphincters. If the case is not well treated, the paralysis remains stationary, and ultimately decubitus is developed, which shortly leads to a fatal result. By proper treatment, however, the patient may get well in a very short time. Some years ago I was consulted by a patient of this kind, only two days after the paraplegia had become developed. He was carried into my consulting-room on the back of a cabman, and had completely lost power over the lower extremities, but only slightly over the sphincters: there was no anæsthesia. Under full doses of iodide of potassium the patient improved most rapidly, and walked briskly into my room a week after I had first seen him. He did, however, not perfectly recover, as a slight degree of weakness in the left leg has remained up to this day.

Where the cervical spine is affected, matters are more serious. There is then not only paraplegia and paralysis of the sphincters, but also of the thoracic and abdominal muscles, the upper extremities, and the diaphragm. Asphyxia from paralysis of the phrenic nerve, or pneumonia, generally carry the patients off in a short time, unless, as we have seen it, the remedy proves stronger than the disease. But in cases of this class we cannot look forward to perfect recovery, as the posterior columns of the cord generally become disorganised beyond thorough repair, and a state resembling locomotor ataxy may remain for life.

ON CHINESE HÆMATOZOA. (a)

By PATRICK MANSON, M.D.

Allusion has often been made to a condition known at Amoy as "worms in the heart," to which the European dog in China is peculiarly liable. Anyone who has had much acquaintance with dogs in China must be aware of their liability to sudden and apparently unaccountable death; and the medical practitioner is often asked to perform a post-mortem examination with the view of clearing up or confirming the suspicion of poisoning which is so commonly entertained in such cases. Ten chances to one the cause of death is found to be plugging of the pulmonary artery, or mechanical interference with the action of the valves of the heart, by a mass of filariæ occupying the artery and cavities of the right side. I have had many opportunities of seeing this affection, and I am aware that a similar disease is known in America, France, and Italy, and probably elsewhere, and that the "worm" has been more or less carefully described by various authors.

Besides the usual and well-known external pests, there is a large number of different parasites infesting both foreign and Chinese dogs. I am familiar with at least five species occupying the alimentary canal—viz., two kinds of tænia, a thread-worm inhabiting the small intestine, and two round worms like the human lumbricus. In addition to these is the heart-worm, variously named *Filaria canis cordis* or *Filaria immitis*, and a new species, not hitherto described as existing in the dog in China, the *Filaria sanguinolenta*. The latter was discovered by Dr. Lewis in the pariah dog of Calcutta, and most of his observations I have been able to confirm. I propose to

(a) From the *Customs Gazette*.

describe both *Filaria immitis* and *Filaria sanguinolenta*, as an acquaintance with the appearance and habits of both is necessary to understand the lesions they produce, and to prevent mistakes and false conclusions on an important point in the history of *Filaria immitis*—viz., the process by which it obtains access to the circulation of its host.

Filaria Immitis.

Its Prevalence.—The extent of this is difficult to estimate without much and laborious investigation; but if I say that one-half of all dogs in China (my remarks apply especially to Amoy), whether native or foreign, are the hosts of this parasite, I believe I am within the truth; two out of three is nearer it, and is not, I think, an over-statement. Anyone can satisfy himself on this point by examining with the microscope the blood of the first half-dozen dogs he can procure, and to do so it is not necessary to kill the animals.

Mode of Examining the Blood for Embryos.—The plan I adopt is to make a small incision with a sharp knife on the inner surface of the ear, where the skin is not covered by hair, and from this to express sufficient blood to supply six or eight slides. These I carefully search with a low power, and the probability is, that in one or all of them one or more immature filariæ will be discovered. From observations thus made, and in some cases confirmed by post-mortem examination, I conclude that dogs of all ages, and probably every breed, are liable to be attacked by the parasite I am describing.

The Embryo Filaria.—The immature hæmatozoon thus discovered, according to my measurements is about $\frac{1}{100}$th of an inch in length, by $\frac{1}{3000}$th of an inch in breadth, and, as far as I can make out, is quite structureless. On close examination with a high power, something like a mouth can be seen at the blunt extremity, which appears to be alternately protruded and retracted. The body attains its greatest diameter a short distance from this point, and maintains the same thickness for about two-thirds of its length; beyond this point it gradually tapers off to the long and filiform tail. In freshly drawn blood the animalcule is in constant motion, wriggling about amongst the blood-corpuscles with a snake-like movement, and lashing out most vigorously with its supple and slender tail. It never seems to be at rest, and retains its activity as long as the blood continues fluid, often for many hours. It never seems to attach itself to the blood-corpuscles or to the surface of the slide. I have never seen any sign of growth or development in the many specimens I have examined, the measurements and appearance of all being exactly alike. So numerous are these creatures in some specimens of blood, that I have seen as many as five in full activity in one small field of the microscope. From this some idea may be formed of the vast numbers existing in the total circulation in such a case, and one cannot but wonder that it is possible for a dog, containing such a prodigious number of parasites, to live. I know many dogs thus infested, and who have probably been so for many years, yet they seem in no way inconvenienced by their guests, have attained a good old age, and are fat and well nourished. If a dog whose blood is thus infested dies or is killed, the parents of these microscopic filariæ are found coiled up in the right ventricle of the heart for the most part, sometimes extending through the tricuspid valve into the auricle, and even into the superior vena cava, and very generally through the semilunar valves far into the pulmonary artery and its branches. I have never found them, or anything resembling them, in any other vessel, though careful search has been made in all the larger veins. In the heart their bodies are found after death, surrounded for the most part with a dark, soft, grumous clot, which, on microscopic examination, is found to be swarming with the embryos above described. Their number varies very much. Sometimes there are only three or four, while in other instances the heart and pulmonary artery are actually stuffed with them, so that one can hardly understand how the circulation can possibly be carried on. The largest number I have counted was forty-one, and in this instance some were probably overlooked, as they extended into the smaller branches of the pulmonary artery, and escaped detection.

On opening the heart, the worms are found massed together in a bundle like a coil of thick catgut that has been some time steeping in water. The few sluggish movements they exhibit after the death of their host form a striking contrast to the liveliness of their progeny. On unravelling and extending them, they can be separated into two kinds: one sort, the larger and plumper, measure from 8 to 13 inches in length, by $\frac{1}{30}$th of an inch in diameter; the other (the smaller), 5 to 7 inches in length by $\frac{1}{40}$th of an inch in diameter. The former is the female, and is characterised by her superior dimensions and only slightly curved caudal extremity; the latter is the male, and is easily recognised by his fine tail, curled up near its extremity like a corkscrew or the tendril of a creeper. The colour of both is a milky opalescent white, with generally a long, and at places convoluted, thin red streak, most marked near the head, running nearly the whole length of the body—this is the alimentary canal. They feel like whipcord when rolled between the fingers, and can bear considerable strain without breaking. If the body of the female is snapped or cut across, three slender threads can be drawn from one of the severed ends—these are the alimentary canal and the two uterine tubes. On the male being similarly treated, only two threads are observed, the alimentary canal and the testicle. As a rule, the females are more numerous than the males. In one instance I found four females but no male. The general proportion is about one male to two females. In the instance above mentioned, in which forty-one worms were found together, thirteen were males and twenty-eight females.

Anatomy of the Mature Worm.—The coverings appear to be two in number—the tegumentary, a very delicate diagonally striped membrane, continuous at the mouth and anus with the lining of the alimentary canal; and the fibro-muscular, or inner coat, of strong and coarse longitudinal fibres, strengthened about the head by numerous diagonal bands. The alimentary canal commences by a funnel-shaped mouth placed slightly to one side of the extreme end of the animal. This funnel-shaped opening contracting towards its apex leads to the pharynx, and this to the œsophagus, which, running for a short distance directly backwards, terminates in a valvular-like opening in the intestine, about a quarter of an inch from the mouth. This, the main part of the alimentary canal, traverses the whole of the remaining length of the animal, to terminate in an anus placed not quite at the tip of the incurvated tail. For the most part, the course of this tube is straight, but at intervals it winds round the uterine or seminal tubes. It is rather narrower near the anus than elsewhere, but its dimensions seem to depend on the quantity of food, represented by a dark red granular matter, with which it is more or less filled. The œsophagus is usually empty and contracted. The anatomy of the alimentary canal is about the same in both sexes. The vagina opens at a point close to the union of the œsophagus and intestine. It is a narrow muscular tube, which, after a short and convoluted course, first forward and then backwards, bifurcates. The two tubes thus formed gradually increase in diameter, and constitute the uterus. These two uterine tubes occupy the greater part of the animal and extend from within half an inch of the head to an inch and a half of the tail. Their course is usually straight and parallel, but at intervals they are twisted round each other. Each terminates quite abruptly in a very delicate vessel, which, after a short and nearly straight course again gradually expands to about half the diameter of the uterine tubes, and after many turns, doublings, and convolutions, ends, close to the tail, in the delicate ovarian tube. The course of the latter is short and tortuous, and terminates abruptly. The contents of the female reproductive organs form a very beautiful and striking object for microscopic study, and from them, with a very little care, the whole history of the development of the embryo can be ascertained. To obtain specimens at different stages of development, it is only necessary to divide the body at short intervals with a sharp instrument, and examine the fluid which exudes from the severed ends. If a section is made near the tail it is sometimes possible to draw or press out the very termination of the ovarian tubes, and after adding a little water to observe the earliest appearances of the embryo. One is a globular transparent cell, from $\frac{1}{3000}$th to $\frac{1}{2000}$th of an inch in diameter, with a distinct nucleus and nucleolus. A little farther down the ovary, mixed with the clear globular cells are others of a granular appearance and elongated form measuring $\frac{1}{750}$th by $\frac{1}{2000}$th of an inch, with a nucleus and nucleolus dimly visible. Some of them are drawn out into a spine at one end or both, and when massed together, as they often are, resemble a columnar epithelium. Still farther down, the cells enlarge, the circular to $\frac{1}{1000}$th, the spindle-shaped to $\frac{1}{500}$th by $\frac{1}{1500}$th of an inch, and are mixed with abundance of bright shining granules, measuring about $\frac{1}{5000}$ of an inch, resembling what is seen in the spermatic fluid of the male worm. About this point the nucleus is seen to be divided, and as the examination advances into the uterine tubes, division and subdivision of this nucleus proceeds, the cell increasing in size to $\frac{1}{750}$th by $\frac{1}{1000}$th of an inch, and acquiring the oval form which it maintains till its maturity. The continued and minute subdivision of the nucleus, a mulber

lass is formed inside the envelope or shell. An indentation is ien observed at one point; this indentation deepens, and by egrees the semblance of the free embryo is shaped from the lass. When this process is perfected, the egg measures $\frac{1}{300}$th y $\frac{1}{500}$th of an inch. As its development advances, the embryo ses its granular appearance, and exhibits some amount of iovement. Its movements gradually become more active, till wards the vaginal end of the uterus the shell is burst, and hrivels up into an irregular granular membrane, and the mbryo struggles out and swims about with all the vigour it fterwards displays when an independent organism in the lood. The liberated embryo measures from $\frac{1}{4000}$th to $\frac{1}{3000}$th in readth by $\frac{1}{100}$th of an inch in length.

Close to the extremity of the tail of the mature male orm, and on its under surface, are two very delicate spicules nclosed in a sheath and apparently retractile. Their common heath is close to the anus. One spicule is longer than the ther, being attached higher up the body. Besides these, here is a double row of delicate pedunculated papillæ, ix on each side of the anus; and farther back than these, hree minute serrations, and at the very extremity of the tail wo very small tubercles. I presume that these spicules, and erhaps papillæ, communicate with the testicle by means of a as deferens, but this communication I have not been able to race, owing to the thickness and opacity of the fibro-muscular bat of the tail in the male worm. The testicle is easily made ut; it is a long, simple tube occupying the greater part of he body; it terminates opposite the union of œsophagus and ntestine, by the last few lines of it doubling back and gra- ually tapering down to a point. The contents of the spermatic ube consist of a clear colourless fluid, in which minute shining longated bodies are suspended. If the male is cut across ear his caudal extremity, a drop of this fluid exudes. The permatozoa measure about $\frac{1}{6000}$th of an inch in length.

How does Filaria immitis enter the circulation? We have een the two extremes, so to speak, of the parasite's life—the inute structureless embryo, and the mature elaborately rganised parent a foot in length. But I have met with no ntermediate form; yet such there must be. Where to look or it I cannot suggest. I have searched in all the visceral nd cervical veins, but without discovering a trace of such a orm. Spleen, liver, kidneys, lungs, brain—all the viscera, in act, in every instance in which I have dissected them, have ielded no information. Dr. Jamieson has suggested that the arge water filariæ he had under observation for some time ight be the heart-worm of the dog, but this is extremely nlikely, if not impossible. Of the two hundred or more pecies of filariæ known to naturalists, many live an indepen- ent life, and never become parasitic. Such were probably the pecimens he watched. They are found in abundance in stag- ant water, moist earth, and in a variety of different media. Many, however, are parasitic in birds, fishes, quadrupeds and olluscs, free in the intestine or embedded in different tissues. uch, as a rule, are swallowed with the food, having pre- iously undergone some advance in development in the body f another animal, in water, in moist earth, or on vegetables hich the final host consumes. The degree of development ffected in these temporary media consists essentially in he elaboration of an alimentary canal, and a boring appa- atus wherewith to penetrate the tissues and assist the animal n its progress to its future resting-place. Now, in the case f the Filaria immitis, after a residence more or less pro- onged in some suitable medium, it is swallowed, or in some ther way obtains access to the tissues of the dog; then, by neans of the boring apparatus with which it has become rovided, it penetrates, and working its way to some spot in r near a vein, it rests for a time, loses all trace of its boring pparatus, and grows from probably a microscopic animal to length of many inches, and becomes provided with a com- lete set of reproductive organs. This accomplished, it finds s way along the vein to its final resting-place—the right ide of the heart,—where the important function, reproduction f its species, is performed. I cannot tell whether the parasite ver dies before its host, or if it dies what becomes of it, or hat effect its death has on the dog. In what animal or other nedium the first step in development is gone through, I can nly guess at; and what the spot or tissue it lies *perdu* in till finally enters the circulation, I cannot find out. Both these oints it would be interesting and important to ascertain. hat the latter is not the heart I feel certain, as imperfect nimals of a much smaller size and at different stages of evelopment would be found there. Such I have never seen. he smallest female I have measured has been over seven nches in length, and all I have examined have been sexually mature. It cannot be in the arterial system, as to get at the right side of the heart the capillaries must be traversed; and it cannot be on the distal side of the portal circulation, as it would be arrested in the liver. The receptaculum chyli, thoracic duct, or the venous system, exclusive of that passing into the liver, must be the channel by which the heart is reached, and the places where the immature animal should be searched for.

Diseases produced by Filaria Immitis.—One must be careful not to attribute to this cause the death of every dog in whose heart worms are found. We have seen that nearly two-thirds of all dogs are thus affected, and that for the most part host and parasite are apparently in good health. But I think there are at least two forms of disease fairly attributable to Filaria immitis.

The position the worm occupies in the circulation is about the safest so large and fertile an animal could select. Were the left side of the heart its habitat, the consequences to the host would surely be much more formidable; for in such case, the animal, escaping from the ventricle (as is its habit), would pass into some small but important artery, and all the evils of embolism would follow. Or even if the unhatched eggs were to escape in any number, as I suppose they sometimes do, there would be the same danger from capillary plugging in the brain, spinal cord, and elsewhere. The capillaries of the lungs, however, act as a filter, and all products of generation too large to pass capillaries,—all the results of death if such a thing occurs, and the wandering parasite itself should he, as he so frequently does, leave the heart,—all these are arrested there; the free embryo, of a diameter smaller than a blood corpuscle, too small to do harm by its size, alone passes through. As a consequence of this filtration, the lungs may themselves be injured; and I put down tubercle, or tuberculoid disease, as an occasional result of this process. I have met with an appearance closely resembling miliary tuberculosis in the lungs of filaria-stricken dogs, and in many cases where no distinct tubercular appearance exists, the lungs feel, when squeezed between the fingers, as if they contained numerous minute particles of gravel.

The most frequent and important effects, however, are those that may be attributed purely to the mechanical interference with the valves of the heart, and the capacity of the pulmonary artery and branches. But it is astonishing how very considerable the bulk of the bunch or rope of worms extending through the tricuspid and pulmonary valves may become. In many instances it must be impossible for the valves to close properly, or for more than one-third of the full stream of blood to be transmitted by the pulmonary artery. Such an animal must, of course, be short-winded, and perhaps liable to attacks of syncope, especially on exertion or excitement, when the demands on the circulation are greatest. And it is after some occurrence, such as a fight, that death most frequently occurs. Possibly, then, the energetic working of the ventricle has forced one or two more worms suddenly into the pulmonary artery, or entangled them among the valves or chordæ tendineæ, and death may come suddenly, or only after a day or two, during which breathlessness and other signs of failing circulation point to the probable cause of illness.

(*To be continued.*)

THE RESULTS OF THE MEDICAL EXAMINATIONS IN PRUSSIA.—Of the 346 students of the nine Prussian universities who were submitted to examination for the year 1876-77, there were 220 who passed with the designation "good," forty-nine with "very good," and seven with "remarkably good." The rejections amounted to seventy.—*Deutsch. Med. Woch.*, October 20.

THE STATURE OF MAN.—The question of the medium stature of man is one that has much excited the curiosity of anthropologists, and concerning which extremely divergent opinions have prevailed. According to an investigation into the subject, published recently in the *Révue d'Anthropologie*, the tallest man ever yet met with was a Finlander, who measured 2·88 mètres, and the shortest a dwarf, measuring only 0·43 mètres. Between these two extremes numerous are the differences, as influenced by climate, habits, manners, etc. It is among the Patagonians that the highest medium height (1·78) is attained, while the bushmen of Eastern Africa are the shortest (1·35) of men. The medium between these extremes would be 1·60; but the *Révue* is of the opinion, derived from the tables hitherto published, that the central point of departure should be 1·65. The measurements do not apply to women.—*Union Méd.*, November 1.

REPORTS OF HOSPITAL PRACTICE IN MEDICINE AND SURGERY.

THE GREAT NORTHERN HOSPITAL.

GENERAL PARALYSIS, FOLLOWING EXPOSURE TO COLD AND WET—RECOVERY UNDER TREATMENT BY PERCHLORIDE OF MERCURY AND BARK.

(Under the care of Dr. CHOLMELEY.)

[From notes by Mr. T. H. GILLAM, House-Surgeon.]

W. B., aged thirty-eight, married, a knife-grinder by occupation, was admitted on February 25 into No. 2 Male Ward.

History.—Always had good health till a week ago, when, after long exposure to wet and cold, he was seized with "stabbing" pains in the fingers and legs. This sensation was on the following day replaced by tingling and numbness, which have daily increased. Family history good; no history of rheumatism or syphilis. Gonorrhœa six years ago.

Present Condition.—Patient is a strong and healthy-looking man; well nourished. Complexion rather dark red. Skin soft and moist. Temperature 99·2° in axilla; tongue furred. Bowels have been very confined during last week; appetite good. Urine normal in quantity; specific gravity 1012, acid; no albumen, phosphates, or sugar. Chest and abdomen normal. The veins of both legs are varicose, and are said to have been so for many years. On the right leg are some superficial cicatrices of old ulcers, not of a specific character. No evidence of clotting in femoral or iliac veins. There is hyperæsthesia over the inner side of both calves, pressure creating great soreness and pain. He is able to walk, but his gait is unsteady; and he feels unsafe, and as if at any moment his legs may "give under him."

At first he was kept simply at rest in bed, with good diet, and no medicine except aperients. The constipation was very obstinate, though ordinarily, the patient said, the bowels were easily acted on. At first slight improvement took place; but after two days the paretic condition began again to increase, and on March 3 the man was unable to stand. His legs and feet felt to him "dead" and cold, though to the hand they were warm. The hyperæsthesia over the inside of the calves had almost disappeared. He complained of numbness in the arms and hands, especially on the right side, and of tingling in the hands. He was now given the iodide of potassium. March 5: Worse in all respects. Ordered potass. iodidi grs. v., ammon. chloridi grs. x., every three hours, day and night. This treatment was persevered with till March 16, but the patient continued to get steadily worse. On March 14 he was unable to make any movement in bed; the lower limbs were absolutely paralysed, and hyperasthesia had everywhere disappeared, there being complete insensibility to touch as well as loss of motor power. The abdominal parietes were also numb; there was complete loss of power and sensibility in the arms and hands on both sides; the urine and fæces passed involuntarily, and the patient was very low and emaciated. The tongue was furred and tremulous. The pulse varied from 68 to 76, regular and weak. The temperature ranged from 98° to 99·2°. Constipation had been replaced by diarrhœa. On March 15 the former medicine was omitted, and the patient was given liq. hydrargyri perchloridi ℥ss., and tinct. cinchon. co. ℥ss., every three hours, in water. He seemed then in a very hopeless condition; and the stomach and intestinal canal were so irritable that all the nourishment taken passed off almost immediately per anum, in spite of the employment of starch and opium enemata. The patient suffered greatly also from sleeplessness, over which neither chloral nor the bromide of potassium, given at night, seemed to have any effect. March 18: Decided improvement. He "feels stronger." The pulse is 80, and of better volume and power; temperature 98·1°. The urine does not pass involuntarily, and there is very slight power in the legs. On the 17th there seemed to be some loss of power on one side of the face, but this certainly does not now exist; the diarrhœa is so severe that the medicine is to-day discontinued. On the 19th the mixture was resumed, five minims of tincture of opium being added to each dose. The diarrhœa quite ceased on that day, and on the 21st the opium was omitted. From the 18th the improvement in the general condition was steady and rapid. On the 23rd the patient could move the toes and feet, and the legs slightly; he could also move his fingers, and give a feeble grasp with the hands. On April 3 he could just manage to get in and out of bed without help. On the 13th he was able to walk slowly up and down the ward with the help of a walking-stick; he had at this time "twitchings" in the right calf, but no severe spasms or pains anywhere. On March 25 the dose of the liq. hydrarg. perchlor. was altered to one drachm given every four hours, and this was continued till April 30; then it was gradually reduced, and on May 3 changed for quassia and iron. There was never the slightest soreness of the gums, nor any salivation. On May 6 the man was discharged perfectly well.

It may be added that on one occasion after the patient's admission the electric irritability of the muscles and nerves was tested by both the continuous and the interrupted current, with the view of assisting the diagnosis whether the paralysis was *rheumatic*, or in other form *peripheral*, or *central*. It was found that faradic irritability was diminished, but not abolished; and that galvanic irritability was not increased, but also diminished in a similar proportion to the faradic.

NEWCASTLE-ON-TYNE INFIRMARY.

PUERPERAL FEVER—BRIGHT'S DISEASE—THROMBOSIS OF THE FEMORAL VEIN—PUERPERAL CHOROIDITIS—DEATH.

(Under the care of Dr. BYROM BRAMWELL.)

MRS. A., aged thirty-three, was admitted on March 18, 1875, suffering from fever, œdema of the left leg, and loss of vision.

Previous History.—Patient was a healthy woman until two years ago, when she was laid up for three weeks after her confinement with general dropsy. She remained fairly well until a fortnight ago (March 4), when she was again confined. The labour was difficult, owing to the large size of the child. On March 5 she had a rigor, and felt a severe pain in the lower part of the abdomen. On March 7 the right thigh became painful and swollen; she was feverish. On March 11 an abscess, which had formed in the front of the right thigh, burst. The same evening she *suddenly* felt a severe pain in both eyes: the eyes began to water; vision became dim; she thought she saw people pointing swords and pistols at her. On March 12 she completely lost her eyesight, and has not been able to see since. For the last week she has felt a pain in the chest, and has had a cough.

Condition on Admission.—She is quite sensible. Pulse 130, temperature 102·2° Fahr. The tongue is dry and tremulous. She complains of great thirst. The right thigh is much swollen, hard, and brawny. There is a dirty, sloughing-looking ulcer over the lower end of Scarpa's triangle. The feet and legs are œdematous. The urine contains a large quantity of albumen and casts. She is totally blind. The conjunctivæ are much swollen; the pupils irregular. The conjunctivæ are so clouded that ophthalmoscopic examination is impossible. The skin of the face is red and erythematous. The heart sounds are normal, but weak. There is some dulness over both bases posteriorly. Crepitant râles are heard all over the back of the chest. The uterus seems normal, but there has been no discharge since March 5, the day after her confinement.

The treatment consisted in the administration of beef-tea, milk, wine, the tincture of the muriate of iron in half-drachm doses, and quinine.

On March 20 she complained of pain in the right knee and wrist-joints. The parts were slightly swollen. She gradually sank, and died on March 25.

The post-mortem was made twenty-four hours after death. The pericardium and both pleural cavities contained a considerable amount of clear serous fluid. Both lungs were adherent posteriorly. There was a small deposit of tubercle in the left apex. The lower half of the left lung was in a state of pneumonic consolidation. The other portion of both lungs were highly œdematous. The heart was of natural size, its valves healthy, the muscular substance pale. Both kidneys were large and pale, the cortical substance much increased. The right femoral vein was plugged with a firm clot, which was adherent to the sides of the vessel. All the tissues of the eyeball were in a state of purulent inflammation. No emboli were found on microscopical examination (the tissues were much disorganised). There was no pus in any of the joints. The uterus and ovaries were healthy.

Remarks.—The case has been detailed at some length, as it is particularly interesting from the eye affection. Dr. Clifford Allbutt, in his work on the Ophthalmoscope (page 104,

alludes to the condition as one of great rarity. He describes its causation as follows:—"The purulent inflammation begins in the chorio-capillaries, and is apparently due to capillary infarctions, which soften and break up into pyoid forms. From this layer the inflammation extends to the stroma of the choroid, which proliferates and runs down into pus and fat; and thence the retina, the pars ciliaris, the vitreous humour, and even the capsule of the lens, are invaded. The process seems to recede before perforation takes place."

BULLOUS SCARLET FEVER (SCARLATINA PEMPHIGOIDEA, OR PUSTULOSA).

(Under the care of Dr. BYROM BRAMWELL.)

A. B., male, aged thirty-six, a joiner, was admitted on April 12, 1875, suffering from a cutaneous eruption and sore throat. He complained of great debility.

Previous History.—His present illness commenced a week ago with headache, sore throat, and aching in the bones. Several children were laid up in the house where he was at work, with "red rash and sore throat." He has not had syphilis.

Present Condition.—Is very heavy and stupid-looking. Says he is deaf, and "feels quite dazed in the head." On the skin there are several spots which present the characters of pemphigus. In some places the vesicles have been broken and a running sore remains. On the left hand and arm there is a good deal of loose epidermis. On both legs there are many small ecchymoses. On the nates there are some red, angry-looking spots, and some other spots covered with scabs. The scabbed spots are chiefly situated in the fold between the nates, and around the anus. The tongue is perfectly clean, moist, and abnormally red. The throat is considerably inflamed. There is an ash-coloured slough on the uvula and on the back of the pharynx. The pus from the vesicles and surrounding skin was examined microscopically, but nothing abnormal was detected. The blood too was normal. The temperature was 99·8° Fahr.; the pulse 68. The splenic dulness was slightly increased. The other organs and systems were normal.

Treatment.—A mixture containing iron and quinine was prescribed, and the throat was brushed over with a solution of nitrate of silver.

On April 29 he was so much better that he was allowed to sit up. The skin was beginning to desquamate from the whole body.

On May 6 he was quite well, the desquamation still continuing. The temperature never exceeded 101·3° Fahr., nor the pulse 90.

WEST LONDON HOSPITAL.

A CASE OF TIGHT URETHRAL STRICTURE, ILLUSTRATING THE VALUE OF FILIFORM BOUGIES IN THE TREATMENT.

(Under the care of Mr. TEEVAN.)

GEORGE W., a labourer, twenty-eight years old, was admitted into the Hospital on September 4, 1877.

History.—The patient stated that he had contracted gonorrhœa when fourteen years old, and that it was treated by medicines only. It gradually dwindled into a gleet, which hung about him for a long time. Six years ago he had another attack of the complaint, which followed an almost similar course to the first one.

State on Admission.—The patient, who was a healthy-looking man, complained that he was incessantly obliged to make water, and that he could only pass his urine in drops after much straining.

Treatment.—The patient was put to bed the day he was admitted, and at 3 p.m. Mr. Teevan managed to introduce a very fine filiform bougie, which was tied in for twenty-four hours. On September 7 a larger bougie was passed, and tied in for twelve hours. On September 9 a filiform conducting bougie was introduced, and a No. 7 (Charrière = No. 3) silver catheter having been screwed on to it, it followed the "bougie conductrice" into the bladder, and drew off the urine. On the 15th a No. 10 (Charrière) olivary catheter was passed, and tied in for twenty-seven hours, when it was withdrawn, and No. 13 was introduced, but not left in. No. 16 was passed on the 20th. The patient left the hospital the same day, able to make a good stream, and to hold his urine for four hours. He was requested to attend as an out-patient, in order that the dilatation might be carried up to No. 20, when he would be taught to use the instrument himself. The strictures were two in number, one being situated just in front of the root of the penis, and the other at the sub-pubic curve.

Mr. Teevan remarked that the value of filiform bougies in the treatment of stricture could hardly be overrated, for they rendered permeable strictures which were impermeable to catheters; they enabled catheters to be slid over them; and when screwed on to urethrotomes or catheters they conducted them into the bladder. Not only were filiform bougies most useful in the treatment of stricture, but they were invaluable in cases of retention of urine. It was perhaps not generally known that in order to relieve retention it was not necessary to introduce a catheter, for if a fine filiform bougie were passed and left in for a few minutes, urine would usually flow on its withdrawal, so that many cases of stoppage from strictures so tight and narrow that they would not admit any catheter, soft or metal, could be relieved by the smaller bougie. When a bougie was tied in, a patient would often ask how he would be able to urinate, as the instrument was solid; and he could be told that the water would flow by the sides of the bougie. Such annoyances as bleeding, pain, or rigors were almost unknown when filiform bougies were used. Their very weakness constituted a great recommendation, as no injury could be inflicted by them.

SATURDAY, NOVEMBER 10, 1877.

HYDROPHOBIA.

PROVIDED that the public alarm excited by the growing prevalence of hydrophobia in England does not degrade into unreasoning panic, we shall certainly not regret that the public have been well frightened; since not a little good may come out of it, at least till the present alarm shall have been forgotten. We are all apt to laugh kindly at, if we do not criticise, the late Lord Macaulay's assumption, or affected assumption, that all that he knew must be common knowledge, as conveyed in his oft-used phrase, "Every schoolboy knows," as the introduction to some choice or little-known piece of historical or other lore. But are we not all really somewhat too ready to think that any information which we ourselves have for years possessed, concerning subjects of common and public import or interest, must be common information, must

be things that everybody knows? Hydrophobia has for untold years been a subject of public interest; its mode of communication, the means of preventing it, and the way in which persons bitten by mad dogs should be treated, at once and when the disease attacks (if it should attack) them, have all been treated of over and over again, not only in medical works, but in the daily papers; yet the study of the innumerable letters and of some of the leading articles that are now taking up so much space in the public journals shows that even educated people know almost nothing, and apparently think that the profession know as little, on all matters concerning the disease. We have no intention of entering now into the whole subject of hydrophobia, but mean only to point out some facts regarding it; and to say a few words on the employment of curara in the treatment of the disease in the human subject.

So far as we know, the disease never arises now except by direct inoculation from an animal suffering from it. We have no proof whatever that it can originate spontaneously in man, or in the dog or any other animal. We know that in the vast majority of cases it arises from the bite of a rabid dog. Some cases are traceable to the bite of a cat, but these are comparatively rare—so rare that in considering measures of prevention they need not be taken much into account. We know that after inoculation the disease remains latent for a considerable, and almost indefinite, period—generally for some weeks, sometimes for several months. But Youatt, one of the greatest authorities on the subject, says that there is only one acknowledged case on record in which the disease appeared in the dog after the seventh month from the bite. The idea presents itself, therefore, that the disease might be stamped out by the isolation of every animal subject to it, or at least of every dog, for a length of time exceeding the longest known period of incubation; and it has been actually suggested that it may be necessary to pass "a law making it compulsory that every dog in the land should be kept in a state of isolation for the space of half a year." From what we have said above, it is evident that the period of isolation must, to make such a measure perfect, last at the least for more than seven months; but the utter impracticability of such a proceeding is so patent that it is not worthy of consideration. The slightest thought will convince anyone of the absolute impossibility of carrying out such a measure perfectly in Great Britain; while if not carried out absolutely perfectly, it might altogether fail in stamping out the disease, even for a time; and, moreover, it might at any time be again imported from abroad. We know that the degree of prevalence of hydrophobia has varied very much in different years. In the five years, 1850-54, the number of deaths from it in England and Wales averaged less than one for each million of the population; during the two succeeding terms of five years the average decreased, and in 1862 there was only one death from hydrophobia in all England and Wales. Since 1864 the average mortality from it has again increased, steadily as regards each quinquennial period, though irregularly as regards each year separately. In 1866 the number of deaths from it exceeded 30; then they sank, but in 1869 rose again to 18, in 1870 to 32, and in 1871 to 56; in the next two years they were 39 and 28, but rose to 61 in 1874, and in 1875 were 47. We are not disposed to attempt to connect the drop in the number of deaths with the passing of the Dog Act of 1872, or the increase since 1873 with any carelessness in the working of that Act; but it is a fact that hydrophobia has been most common in those parts of the kingdom where dogs are most numerous, and in which it may be supposed that masterless or unowned dogs are most common. Thus, in 1875, out of the 47 deaths from the disease, 16 occurred in Lancashire, 10 in Yorkshire, 5 in Staffordshire, and 6 in London. Mr. Fleming, the Veterinary Surgeon to the 2nd Life Guards, in a letter to the *Times*, says that he some years ago predicted the late increase of the malady, unless measures should be adopted to check it. What measures can and ought to be taken for that purpose is a matter for the consideration of the Government; but we may venture to say that a rigid carrying out of even the present Dog Act would largely lessen the risk of the disease, by doing away with great numbers of the stray, unowned dogs,—the "curs" and "mongrels" that roam at large, and by which the disease is chiefly spread. We know, next, that a large proportion of the persons bitten by rabid dogs escape hydrophobia; and the reason of this is, most probably, that very many of the bites are on covered parts of the body, so that the teeth of the attacking dog have been wiped free from saliva before the skin was reached: for we know that dogs can be inoculated with rabies by the saliva of a rabid dog, or of a person who has hydrophobia; and we know that the disease has been communicated to man by the contact of the saliva of a mad dog with an abraded part of the skin, without any bite.

Then, with regard to the prophylaxis of the disease, the prevention of it in bitten persons. We may fairly say that we know that the prompt and thoroughly efficient cauterisation, or more certainly still the excision and cauterisation, of the bitten part will insure safety; and we certainly know of nothing else that will. Mr. Youatt has told us that he has employed lunar caustic on upwards of 400 persons, and four times on himself, after bites from dogs decidedly rabid, and in not one of these instances did rabies occur. Cauterisation is often, however, employed inefficiently, or too late; the disease is developed afterwards, and then it is said that cauterisation has failed. In every case of bite by a mad dog a ligature of some sort should, if possible, be applied immediately and firmly above the bitten part—that is, between it and the body; and that, as promptly as possible, the bite should be excised and freely cauterised, or at least cauterised. The agent employed does not much matter—it may be the nitrate of silver or lunar caustic, nitric acid, sulphuric acid, the actual cautery or red-hot iron, etc.,—but the cauterisation must be thorough.

Lastly, as to treatment when the disease is developed. We have no proof that any case of true hydrophobia has ever been cured, unless it is the case we reported in our number of October 6, and which has been since again reported in the *Times*. Alleged specifics have again and again been brought forward, been tried, and been found wanting; and now, as on all former occasions when public attention has been directed to the malady, methods of treatment are recommended that have been thoroughly tested not only years, but ages ago. The eliminative plan of treatment, by drugs, sweating, etc. has been tried in vain so far back as the days of Celsus. Van Swieten and others have tried mercurials; and it has been stated that the Chinese believe that a combination of musk and cinnabar is an infallible cure for the disease. But with us, at any rate, every case has hitherto proved fatal. The case which we have alluded to—Dr. Offenburg's case,—which was treated by curara, does seem to have been a genuine case of hydrophobia, and it terminated in recovery. Curara is a resinous substance said to be used by the Indians of South America for the purpose of poisoning their arrows; and believed to be the watery extract of a climbing plant belonging to the genus Strychnos; but this is doubtful, as the properties of curara are the opposite of those possessed by strychnia. It is soluble in water, and may be introduced with impunity into the alimentary canal, except in very large doses; but if introduced into a puncture in the skin it rapidly kills by paralysing every muscle in the body. Its use in hydrophobia, therefore, is grounded on the rational principle of arresting the spasms by or through which the disease kills, and so curing or gaining time for recovery. Its physiological action has been studied by Bernard (*Compt.-Rend.*, lx., 1327)

and many others; and it has been employed with success in the treatment of tetanus. We reported in our pages (vol. i., page 336) of the present year, a case of tetanus treated successfully, chiefly by curare, in Guy's Hospital by Mr. Durham. The drug ought, therefore, to be fully tried. But it must be tried with great skill and care, as well as with boldness. It is an heroic remedy. If used timidly it will fail, and if employed too boldly it may kill. In the case in which Dr. Offenburg used it, about one-third of a grain was injected hypodermically, and repeated, at intervals of fifteen minutes or longer, according to the effect, till the physiological action was well obtained, and this action was kept up as long as was necessary. At one time the physiological effect was so complete as to affect the muscles of respiration, and artificial respiration was necessary. This must be watched for, but need not excite serious alarm, for, as was taught years ago by the late Sir Benjamin Brodie's experiments with woorara (another name for curara), artificial respiration will maintain life in an animal poisoned by the drug. Under the treatment so boldly and skilfully carried out in Dr. Offenburg's case, the spasms gradually lessened in frequency and intensity, and finally disappeared after the eighth day. We have been at some pains to find out, for the information of our readers, where the drug can be procured, and find that it can be obtained, at a very moderate price, from Messrs. Hopkins and Williams, wholesale druggists, of Hatton-garden; Messrs. Morson and Son, of Southampton-row, W.C.; Messrs. Savory and Moore, New Bond-street; and the General Apothecaries' Company, Oxford-street and Berners-street; and no doubt from other first-class druggists. Messrs. Savory and Moore supply gelatine discs containing it for hypodermic injection; each disc as usually made by them contains only one-hundredth of a grain of the drug, but they can easily be made very much stronger, and are very manageable. The best method of administration will probably be either to use the gelatine discs, or to prepare an aqueous solution of a given strength—say one part of the drug to ten of hot or boiling water,—and then filter it. M. Du Cazal, in his experiments with it, found that it is not wholly soluble in water, and that the unfiltered solution excites great and lasting irritation at the points of injection, while the filtered solution is free from this inconvenience, and produces the whole effect of the poison.

We ought to say that Mr. Fleming states that he published an account of Dr. Offenburg's case in the *Veterinary Journal* in July, 1876; and that a case of hydrophobia, in which curara was employed with apparently some good effect, is reported in the *Boston Medical and Surgical Journal* for May 17 of the present year. It was not successful, but the curara treatment was not fully carried out, and many other drugs also were employed, as morphia, chloroform, and nitrite of amyl. The nitrite of amyl appears to have been of decided service in quelling the spasms. Lastly, it may be observed, for the information of anti-vivisectionists, that what was hitherto known of the effects of curara has been learned by means of experiments on animals; and that one of the difficulties in the way of its prompt and efficient use arises from the Vivisection Act. The drug as we receive it varies greatly in strength, and it can be very easily and quickly tested on frogs. But no one but a licensed experimenter can do this now, and the strength of any specimen of the drug can only be tested without licence on man himself. Two dangers may therefore, in a severe or advanced case, await the unfortunate patient: the surgeon, anxious to get quickly the physiological action of the drug, may have got an unusually potent sample of it, of which an ordinarily moderate dose may prove to be a dangerous one; or, fearing such a result, he may have to waste invaluable time in cautiously testing on his patient the strength of the specimen in use. In the helmsman's anxiety to avoid Scylla his barque may be lost in Charybdis.

THE MANAGEMENT OF ST. THOMAS'S HOSPITAL.

St. Thomas's Hospital has now for a long time been under what we might call a cloud. For many years it existed in a state of semi-hibernation in the Surrey Gardens, and since its removal to its present site its resources have been so crippled, that though 500 beds are available, only 350 have been occupied, thus reducing the Hospital, notwithstanding its pretensions externally, to the level of one of the second-rate London hospitals, as far as the number of its beds is concerned. At last, however, it has dawned upon the minds of some of the governors that such a position is unbecoming in what should be a great public charity; and since the death of the late Treasurer, various schemes have been proposed for its regeneration. At last these schemes took the form of a special report from the Grand Committee to the whole body of governors. A meeting was held last week to consider this report. It was largely and influentially attended, but the report of the proceedings seems to remind us—*mal-àpropos* as it may be where grave aldermen are concerned—of the palmy days of St. Pancras. The gist of the report was this—either that the new Treasurer should be a paid officer of the Hospital, and should attend to its business, residing in the Hospital and looking after its administration; or that, with a Treasurer of the old school, an Acting Resident Superintendent should be appointed to look after the Hospital and Medical School, to keep the minutes of the House Committee, and to conduct its correspondence. This Superintendent *should not be a medical man*. The House Committee above referred to is to consist of the treasurer, almoners, and six governors, two of whom are to be gentlemen who *have been* either Physicians or Surgeons to the Hospital. This Committee are to have full power to make all regulations for their own proceedings, but their business is defined in the report of the Grand Committee. They are to meet weekly, and keep a constant supervision over the medical, surgical, and apothecaries' departments, the nursing, the supply of food, and the sanitary condition of the Hospital generally, as well as of the several wards and the Medical School; and in order that the House Committee may be kept in regular communication with the medical staff, a representative from it is to attend all the meetings, but shall not have the power of voting; and the meetings shall also be attended by the steward and matron, and by any other officer the Committee may think advisable. Every man may look on this scheme as pleases him, but to us as medical men the constitution of the Committee is peculiarly interesting. First of all, two of its members must be former Physicians or Surgeons to the Hospital. Well, we might say, can the Hospital always dispose of the services of two such gentlemen? if so, are they the most eligible representatives of their class, or are they not likely to be *laudatores temporis acti?* Why not appoint at once two representatives of the Hospital Staff and School, instead of thus beating about the bush? True, they may say, but we are to provide for the attendance of such representative, but he has to have no vote—a dignified position truly, for the attendance of the steward and matron is to be provided for in like manner. We suppose that it is out of respect for this unfortunate representative's feelings that the Superintendent, a man of power and authority, is recommended to be *not a medical man!*

Next came the resolutions with regard to the appointment of Treasurer. Here the City was up in arms: to poach on their privileges was a crime indeed! Some respectable and successful tradesman must forsooth be appointed to this purely honorary and unpaid-for post. Curiously enough, we have heard, and we should be glad to be contradicted, that the unpaid post of treasurer to some of our hospitals—St. Thomas's may be among them—is really very lucrative, inasmuch as the treasurer receives the interest on all hospital deposits or current

accounts (which may be kept at his own private banker's) as a solatium for his trouble. There can be no doubt of the enormous power and influence the treasurer yields in many ways; and it is high time he were no longer an autocrat, appointing and ruling the staff with a rod of iron. As to the question of a paid treasurer, who is to do everything—that we hold to be sheer nonsense? With estates like those belonging to St. Thomas's Hospital there is plenty of room for out-of-door management. To master the domestic details of a large hospital requires a man who knows something as to the requirements of patients, doctors, nurses, and students. How is a layman to acquire this knowledge? It certainly does not come by nature. But when it is suggested that this layman shall also look after the affairs of the Medical School, we find the proposed arrangement somewhat too absurd. It is plain that the aldermanic body is resolved to do its best to put in one of their own number as Treasurer; and to Alderman Stone himself we can find no objection. But three things are quite plain to us: (1) that St. Thomas's Hospital and estates sadly want more careful supervision; (2) that neither Alderman Stone nor anybody else can do the double work of external and domestic management efficiently; and (3) that it is far more difficult to get a good and efficient Hospital Superintendent than an Honorary Treasurer. However, we shall see. It may be that St. Thomas's shall yet revive—with good management, it is certain that it will do so. Meanwhile, can it be wondered at that people do not care to bestow their money on an institution managed as this has been.

THE WEEK.

TOPICS OF THE DAY.

A visit of inspection was paid last week by several members of the Metropolitan Board of Works to the West Kent Main Drainage Works at Dartford. We explained the full intention of the present scheme some time ago, when the undertaking was commenced; it will be remembered that it consists of a main sewer fifteen miles long, which begins at Beckenham, and passing through Lewisham, Mottingham, Eltham, Bexley, Crayford, and Dartford, finally discharges itself into the Thames at Long Reach. The works were commenced about nine months ago, and since that time good progress has been made, the total length of sewer already constructed being about three miles and three-quarters; and according to the present rate of progress it is expected that the whole will be completed by the end of the year 1878. The time of completion is anxiously looked forward to by the various districts affected, and it is anticipated that the scheme will eventually prove to be the outfall for a much larger district than is at present arranged for. This contingency has been foreseen and provided against by Sir Joseph Bazalgette, who prepared the scheme, and who is the consulting engineer: in designing the works he has provided sufficient capacity throughout to enable them to meet any extraneous demands which may at any time be made upon them.

There has been recently opened at Leicester a new coffee and cocoa house, on temperance principles. The house is well lit, and is made as much as possible to resemble an ordinary public-house. It contains a handsome billiard-room, and provision is made for games, such as chess, bagatelle, and dominoes. The Mayor, Canon Vaughan, and others were present at the opening. The house has been built, at the suggestion of the Church of England Temperance Society, by a company with a capital of £10,000, the shares being fixed at £1 each, of which only five shillings has been called up.

It is almost incredible that in the present day anyone should be found to object to the utilisation of our metropolitan churchyards, yet at the Consistorial Court of London, held before Dr. Tristram, the Chancellor of the Diocese, a question was raised last week as to the appropriation of the disused burying-ground of St. Matthew, Bethnal-green. The rector and churchwardens had presented a petition for a faculty, or licence, to erect in the churchyard a mortuary and rooms for post-mortem examinations, together with a coroner's court. Some objections have, however, been made on the part of the inhabitants, and the question has been raised on pleadings. Counsel appeared for both the petitioners and objectors; it was stated that the proceedings were closed, and the parties wished to know whether the Court could proceed on affidavits and require witnesses to attend for cross-examination, or whether the case would be heard on *vivâ voce* evidence. The learned Chancellor remarked that the question raised was certainly an important one, and he would appoint the hearing before Christmas on *vivâ voce* evidence. We shall be glad to hear that the objections have failed, and that a faculty has been granted for the erection of these much-required buildings.

At the annual meeting of the promoters of the Hospital Saturday and Sunday collections at Liverpool, held in that town last week under the presidency of the Mayor, Alderman A. B. Walker, it was stated that the amounts contributed in the past five years were as follows:—1873, £9821; 1874, £11,185; 1875, £9716; 1876, £9946; and 1877, £10,019. The Mayor remarked that he felt justified in assuming that the institution might be depended upon to yield at least £10,000 a year, which, capitalised at 5 per cent., represented the magnificent sum of £200,000. The Liverpool hospitals are certainly to be congratulated on the munificent spirit which distinguishes the dwellers in their city; these results, as compared with the annual metropolitan collections for a similar purpose, do not redound to the credit of the first city in the world as regards its charitable impulses.

A useful, if practicable (?), suggestion for diminishing the risk of infectious diseases in private families has been put forward by Dr. McGrigor Croft, one of the Marylebone Guardians; this is to the effect that, in engaging female servants, ladies should make a point of inquiring whether any sickness had prevailed in the families they had just left, and, if so, of what nature. In the event of their seeking employment from private lodgings or institutes, the same question might be asked. He remarks that many instances occur of scarlet fever, small-pox, etc., breaking out in families immediately after the advent of a new servant, who undoubtedly imported the disease. We fear that a great deal of deception would be practised, and many difficulties occur, in obtaining this information; but so, too, it is not easy to find out the nature of the sanitary arrangements of Sarah's own home and of the places she visits on her "Sunday out." Surely it is given to some men to be useful above their fellows.

The present disastrous famine in India has aroused public attention to the question whether it would not be possible to adopt some means for preventing the recurrence of such a deplorable catastrophe; and at a meeting of the Liverpool Chamber of Commerce, held last week, a resolution was adopted, which, whilst deploring the famine and the inadequacy of existing appliances for grappling effectually with so great an evil, expressed a belief that it is incumbent on Ministers to "advise her Majesty to appoint a Royal Commission of skilled men competent to inquire into and report upon the remedial measures best calculated to ward off or to alleviate the horrors attendant upon such a visitation, and especially to direct their inquiries as to the value of works of irrigation and water transit as a principal means of preventing famine." In the discussion, irrigation and canals were strongly advocated, and regret was expressed that Parliament devoted so little time to Indian affairs. How about the rain?

After a somewhat long period of retirement from public agitation, the opponents of the Contagious Diseases Acts have once more come to the front. A meeting, stated to be con-

vened by the National Association for the Repeal of the Contagious Diseases Acts was held last week at the Cannon-street Hotel, the object of the convenors being to lay before the public the result of the deliberations of the Congress lately held in Geneva "for the abolition of Government regulation of prostitution." Mr. William Shaen occupied the chair, and amongst those present were the Right Hon. James Stansfeld, M.P., Mr. W. Fowler, Professor James Stuart, and Professor Sheldon Amos, with representatives of the movement from several provincial towns. Mr. B. Scott moved the following resolution, which was seconded by Mr. W. Ashurst, and carried unanimously:—"That this meeting rejoices to hear of the remarkable success of the first Congress of the British and Continental Federation for the Abolition of Government Regulation of Vice, held in Geneva in September last, and is of opinion that the resolutions so carefully considered and unanimously adopted by the Sections of Morals, Hygiene, Benevolence, etc., will be productive of great good." A second resolution, pledging the meeting to support the National Association in its efforts to insure success for the repeal Bill of Sir Harcourt Johnstone, was then proposed by Mr. Stansfeld, who contended that the obnoxious Acts stimulated the demand for prostitution, and so increased the supply, and, therefore, the danger they pretended to do away with. This resolution was also carried unanimously, and the meeting then separated.

Some little time since we reported that the Lords Commissioners of her Majesty's Treasury, in a letter to the Sheerness Board of Health characterised as "unsatisfactory and insufficient" the explanations tendered by that Board respecting the quashing of a general district rate after a considerable portion of it had been collected—among others, from the Government. The Sheerness Board decided on that occasion to write to the Treasury, asking why the explanations they offered were not considered satisfactory, the Chairman going further, and counselling a petition to Parliament if the Treasury did not withdraw the words used. The Lords Commissioners of the Treasury have now replied to this letter, stating that they can only repeat their opinion that the explanations were unsatisfactory. The Board referred the letter to a committee to report upon.

A somewhat singular cause of death was elicited at an inquest which was held on Monday last, before Dr. Hardwicke, at Stoke Newington-green-road, South Hornsey, on the body of John William Digby, aged seventy-six. The widow of the deceased said he was a tutor, and enjoyed very good health. On Sunday week last, whilst they were dining, she heard a peculiar noise as of choking, and perceived that the deceased had swallowed his artificial teeth. She at once put her fingers into his mouth, but to no purpose. Dr. Welsh, who was called in, attempted to remove the teeth, but he failed to do so; after which, Mr. Durham, of Guy's Hospital, was summoned, but also failed to accomplish their removal. Morphia was administered, but the deceased grew worse, and expired on the following Wednesday. Dr. Welsh deposed that he attended the deceased, and found that he could not get the teeth up. He had made a post-mortem examination, and found that death had resulted from shock, and injury to the throat. The reason why the teeth could not be removed was because the crooked portion of the plate had caught in the muscles of the throat. The jury returned a verdict of accidental death.

An outbreak of small-pox in the Isle of Man appears to be of rather a serious character. Since July 18 there have been 102 cases in Douglas, twenty-eight of which have been fatal.

The Medical Officer to the Kingston-on-Thames Sanitary Authority, Dr. Price Jones, has reported to that Board that the water of the Lammas Well, on the property of Mr. Money Wigram, at Esher, should not be used for drinking purposes unless well filtered. One of the Esher Guardians stated that the water of the well in question was always drunk by her Majesty when staying at Claremont. The Board resolved to send a copy of the analysis made by Dr. Price Jones to Mr. Money Wigram.

At the meeting of the Metropolitan District Asylums Board, held on Saturday last, the usual fortnightly returns from the various small-pox hospitals under the control of the managers were announced to be as follows:—Admitted, 98; died, 16; discharged, 60; remaining under treatment, 184. In the previous fortnight the numbers were:—Admitted, 81; died, 21; discharged, 44; remaining under treatment, 162: or an increase in the last fortnight of 22.

DIMINUTION OF THE GASTRIC HYDROCHLORIC ACID IN FEBRILE CONDITIONS.

An interesting illustration of the relation of the hydrochloric acid of gastric juice to the febrile process is afforded by a case reported by Dr. Von den Velden, assistant to Professor Kussmaul, at Strasburg, in the *Berl. Klin. Woch.* (No. 42, 1877). The patient, a man of sixty, had suffered from gastric symptoms for about ten years, which latterly assumed the character of those of dilatation of the stomach, pain in the epigastrium, repeated vomiting, etc., which reduced his strength to such a degree that he was obliged to enter the hospital for relief. He was admitted on February 27, 1877, and treated with the stomach-pump with great benefit, and the disappearance of the vomiting. The fluid which was pumped out (in the morning, before breakfast) was generally quite clear and ranged in quantity between 100 and 700 cubic centimetres. At first it contained sarcinæ and torulæ, with abundance of peptones, and a gradually diminishing amount of undigested food. The percentage of hydrochloric acid was determined by Resch's colour test (described in the *Zeitschrift für Phys. Chemie*, Bd. i. 3), and varied between 0·025, 0·03, 0·05, 0·13, 0·15, 0·16, and in one instance 0·3 per cent. In May, when the patient's improvement had become so great that he was about to leave the hospital, he began to suffer from diarrhœa, and on June 7, headache, fever, and general *malaise* ushered in an attack of typhoid fever (source not stated), which ran a normal course, and terminated about the twenty-second day. During the attack the stomach-pump was used daily before breakfast, and the liquid removed carefully examined. In quantity it was less than previously, and scarcely reached 100 cubic centimetres. The main difference in its composition revealed by analysis was *the absence of free hydrochloric acid*, although its reaction was faintly acid, probably from the presence of lactic or acetic acid. A flake of fibrin remained quite undigested whilst in some of the filtered liquid in the cold; whereas the addition of an equal volume of 0·2 per cent. dilute hydrochloric acid caused its rapid disappearance. On the cessation of fever, on June 7, Dr. Von den Velden naturally expected that hydrochloric acid would again be found in the gastric liquid. He had, however, to wait until the *eighth* day after the temperature had become normal before traces of it reappeared. On the *ninth* day 0·08 per cent. was detected, and from this time onwards the percentage ranged between the limits mentioned above. It might be objected that since in this case the gastric contents were removed before food had been ingested, the absence of acid might depend on the absence of a stimulus to its secretion; but this objection fails, because the patient happened one morning to breakfast before being pumped, and still not a trace of free hydrochloric acid was present. The absence of acid was also not due to the patient's diet during the period of fever, for the latter consisted, *inter alia*, of milk, *bouillon* containing eggs, and other nitrogenised substances, in the presence of which acid juice would normally be secreted. Lastly, there was no increased secretion of alkaline mucus which would mask the free acid by neutralising it as soon as secreted. This case confirms the observations of Pavy, Hoppe-

Seyler, Manassein, Leube, Uffelmann, and others, that it is the acid, and not the pepsin, of the gastric juice which suffers diminution in fever, and it suggests the more extensive use of hydrochloric acid during the period of elevated temperature.

THE QUARTERLY REPORT OF THE REGISTRAR-GENERAL TO SEPTEMBER LAST.

The quarterly return of the Registrar-General, of births, deaths, and marriages registered in England during the period ended September 30 last, has just been made public. The figures show the births of 276,968 children, and the deaths of 144,528 persons of both sexes; the recorded natural increase of population thus being 132,440. The death-rate of the quarter was no less than 3·1 per 1000 below the average rate in the ten preceding corresponding quarters, and was mainly due to the low summer temperature, which favoured exceptionally low rates of infant mortality, and especially of mortality from diarrhœa.

The comparison of the health of England with that of the principal cities abroad may not prove uninteresting. A summary of the weekly returns received by the Registrar-General from various local authorities abroad shows that the average annual death-rate during the third quarter of the present year, in thirty Indian and foreign cities, was 31·8 per 1000, against 20·5 in twenty of the largest English towns. The population of these thirty foreign cities is estimated at rather more than eleven millions. The lowest death-rates in these cities were 19·0 and 21·0 in Christiania and Copenhagen; whereas the rate was equal to 51·0 in Alexandria, 53·2 in Bombay, and 125·4 in Madras. The 12,419 deaths in Madras included 3010 from dysentery, 1131 from cholera, and 943 from small-pox; thns, excessive zymotic fatality is partly attributed by the Medical Officer to the immigration of crowds of half-starved fugitives from the surrounding famine-stricken districts. In Calcutta 218, and in Bombay 1129 deaths were referred to cholera. Typhoid fever caused 322 deaths in Paris during the quarter, against 386 and 212 in the two preceding quarters; in Paris the annual death-rate from this disease was equal to 0·65 per 1000, while it was only 0·23 in London. In St. Petersburg and Philadelphia typhoid fever was especially fatal. Small-pox was more or less prevalent in Madras, Brussels, and Vienna, though in each of these towns the fatal cases showed a considerable decline from those in the preceding three months. In Berlin 269 deaths resulted from scarlet fever; this disease also prevailed in Stockholm, Brooklyn, and Philadelphia. To diarrhœa or diarrhœal diseases 3111 deaths were referred in Berlin, 460 in Munich, 2675 in New York, and 1193 in Brooklyn. Whooping-cough caused 130 deaths in Alexandria.

HEALTH OF ST. GEORGE'S, HANOVER-SQUARE.

In his annual report on the sanitary condition of the parish of St. George's, Hanover-square, for the year 1876, Dr. W. H. Corfield, the Medical Officer of Health, remarks that the year in question was a very healthy one for the parish, and indeed for London generally, in spite of the fact that an epidemic of small-pox was prevalent. The corrected death-rate for his district shows a result of 18·2 per 1000 per annum, or lower than either last year or the year before. The deaths of children under one year were also less than in either of the three preceding years, and the percentages of such deaths to the registered births—except in one instance—and to the total deaths were also less than in either of those years, which must be pronounced to be satisfactory; and Dr. Corfield states that the infantile mortality of the parish, though small, would be still less were it not for the infanticides committed in the Parks and in the Serpentine. Allusion is made to the fact that only two out of twenty-two deaths from scarlet fever, and only one out of thirty-three deaths from "fever," were reported to the inspector, showing strongly the necessity for the Medical Officer of Health being provided at once with a return of all deaths from infectious diseases. Dr. Corfield would appear to have succeeded in impressing this important fact upon the authorities of his parish, as he states that "this has since been done, so that I now receive immediate information, and am able to take measures to prevent the spread of these diseases." Even a West-end parish like St. George's, Hanover-square, is not without some blots in the shape of low and unsanitary courts and alleys. In the beginning of the year 1876 Dr. Corfield made a special report on the condition of Street's-buildings, May's-buildings, and Lancashire-court, which resulted in his reporting the latter locality to the Metropolitan Board of Works as a suitable area to be dealt with under the Artisans' and Labourers' Dwellings Act; the Board, however, declined to deal with it, and various sanitary improvements have since been carried out at several of the houses.

PROVINCIAL STUDENTS.

The following is an abstract of the annual return of the Royal College of Surgeons, of gentlemen pursuing their professional studies at our recognised provincial schools, which has just been made to Mr. John Birkett, the Government Inspector:—

	1877	1876.	1875.
Owens College, Manchester . . .	11(	110	119
Leeds School of Medicine . . .	6(	54	45
Liverpool Infirmary School of Medicine .	5(	53	63
Cambridge University School . .	2(	42	36
Durham University College of Medicine	3(	31	28
Bristol Medical School	3(	40	31
Queen's College, Birmingham . .	5(	34	59
Sheffield Medical School . . .	2(	17	17
Totals . . .	41	381	398

It will be seen that this session Queen's Collge, Birmingham, has an increase of twenty-three over the las, followed by the Leeds School of Medicine with fifteen, Durham University College of Medicine six, Sheffield Medical School five, and Owens College, Manchester, four. There is a decrease of fourteen at the Cambridge School, of six at the Bristol Medical School (owing, no doubt, to the circumstance we recently published), and of three at the Liverpool Infirmary School of Medicine. Perhaps the following totals of medical students at provincial schools from 1867 to 1877, inclusive, will be interesting to many of our metropolitan as well as provincial teachers:—

In 1867 there were	257	students	In 1872 there were	402	students
1868	,,	284	,,	1873	,,	455	,,
1869	,,	330	,,	1874	,,	453	,,
1870	,,	357	,,	1875	,,	398	,,
1871	,,	368	,,	1876	,,	381	,,

In 1877 there are 413 students.

The following comparative table, showing the numbers of metropolitan and provincial students respectively during the past decade, will no doubt be read with great interest by town and country teachers and their pupils:—

	Metropolitan.	Provincial.	Total.
1868 . . .	1,194	284	1,478
1869 . . .	1,241	330	1,571
1870 . . .	1,298	357	1,655
1871 . . .	1,475	368	1,843
1872 . . .	1,496	402	1,898
1873 . . .	1,650	455	2,105
1874 . . .	1,745	453	2,198
1875 . . .	1,769	398	2,167
1876 . . .	1,744	381	2,125
1877 . . .	1,923	413	2,336

KING AND QUEEN'S COLLEGE OF PHYSICIANS IN IRELAND

At the monthly business meeting of the College, held on Friday, November 2, the Fellows present being twenty-one

in number, an adjourned debate took place, and was concluded on a motion by Dr. Grimshaw, seconded by Dr. James Little, that the following resolution, passed on February 21, 1868, be repealed:—"That in future no King's Professor in the School of Physic shall be allowed to hold an appointment as medical officer to any clinical hospital other than that of Sir Patrick Dun. This rule not to affect existing arrangements." The College was equally divided on the question, and the motion was carried by the casting vote of the President, who, before putting the motion, and while speaking strongly in favour of a rule which would prevent a Physician or Surgeon holding two clinical hospital appointments—pluralism,—observed that by that rule the King's Professors were left no option as to whether they should continue to hold appointments in other hospitals, or should of necessity surrender such appointments and become members of the staff of Sir Patrick Dun's Hospital. In his reply, Dr. Grimshaw showed clearly that "The School of Physic Amendment Act" (30th Vic., cap. 9) provided that the College of Physicians should have power to appoint Physicians to Sir P. Dun's Hospital should the King's Professors not wish to undertake clinical duties in that institution. If, as outsiders, we may give an opinion on the points at issue, we cannot but express our regret that the relations between the School of Physic in Ireland and Sir P. Dun's Hospital should be so close as to demand the compulsory service of the Professors in the School as Physicians and Surgeons to the Hospital. In our opinion, it by no means follows that the best school lecturers necessarily make the best clinical teachers. And further, we think it inimical to the interests of the School of Physic that its Professors should be obliged to accept office only on pain of forfeiting their previous hospital appointments and of becoming members of the staff of a small, albeit a well-appointed, institution like Sir P. Dun's Hospital, where the opportunities for clinical research are of necessity extremely limited.

ARMY MEDICAL EXCHANGES.

We fear that one or two of our contemporaries have been rather premature in announcing that one of the most substantial grounds of discontent amongst army medical officers has been removed—namely, prohibition of exchanges. As far as we can learn, the rule of considering every individual case upon its own merits is still in force. There may perhaps be a disposition to forward the views of officers as much as possible when the interests of the service are not compromised, but we believe we are right in stating that exchanges for the persistent evasion of foreign service would still most certainly be refused; and we can only hope, in the absence of any official declaration on the subject, that this is the only class of exchanges against which the authorities at the Army Medical Department will now set their faces.

THE INDIAN FAMINE.

The latest news from India with regard to the famine and the food-supply prospects is as satisfactory as possible. A telegram, received at the India Office from the Viceroy, dated November 3, states that in the Madras Presidency the north-east monsoon has burst favourably everywhere except in Ganjam; that, with the exception of the same district, the crop prospects are good, rainfall sufficient, and prices of food falling. The numbers of persons on the relief works and receiving gratuitous relief were steadily decreasing, and the condition of the people was improving. The reports from all other parts of India were also good, excepting that in Scinde "harvests are short." And the most telling proof possible of the happy change since the rains came was received by the Executive Committee of the Mansion House during their meeting on the 5th inst., in the shape of a telegram, dated that day, from the Duke of Buckingham, the Governor of Madras, to the Lord Mayor, announcing that the Executive Relief Committee concurred with him in thinking that "under the present favourable prospects, we gratefully say that the collection may cease." A telegram was also received from the Secretary of the Relief Committee, stating—"With reference to the Governor's telegram, please remember that we shall continue active operations with the munificent funds supplied to us till January or February." The Mansion House Fund is therefore now closed, and the Committee will only continue to receive donations already promised or collected by local committees, or from other sources. The funds entrusted to the Lord Mayor already amount to £451,000, and considerable sums have still to be received; so that whether the Fund reaches or not the half-million spoken of, a grand and most pregnant proof has been thus given to our fellow-subjects in India that we in England do feel a most real and practical interest in their welfare, and are ready to give them prompt and most material aid in their distress.

MEDICAL SOCIETY OF THE KING AND QUEEN'S COLLEGE OF PHYSICIANS IN IRELAND.

The annual general meeting of this Society was held on Wednesday evening, October 31, in the Hall of the College of Physicians, Kildare-street, Dublin. The chair was taken by Dr. Thomas Fitzpatrick, Honorary Fellow of the College. The election of officers and Council for the session of 1877-78 resulted as follows:—*President:* Samuel Gordon, M.D., President of the College (*ex officio*). *Vice-Presidents:* James Little, M.D., Vice-President of the College (*ex officio*); Sir Dominic J. Corrigan, Bart., M.D., ex-President; William Stokes, M.D., D.C.L., F.R.S., ex-President; Alfred Hudson, M.D., ex-President. *Council:* J. Hawtrey Benson, M.D., F.C.P.; James Foulis Duncan, M.D., F.C.P.; John Magee Finney, M.D., F.C.P.; Arthur Wynne Foot, M.D., F.C.P.; Thomas Wrigley Grimshaw, M.D., F.C.P.; Reuben J. Harvey, M.D.; Thomas Hayden, F.C.P.; Henry Kennedy, M.B., F.C.P.; Stephen Myles MacSwiney, M.D., F.C.P.; John William Moore, M.D., F.C.P.; Walter George Smith, M.D., F.C.P. *Honorary Secretary:* George Frederick Duffey, M.D., F.C.P. The report of the Council for the past session was read by Dr. Duffey, Hon. Secretary, and was unanimously adopted. It contained a recommendation that, in future, discussions on clinical cases or observations should occasionally take place at the meetings of the Society. The opening meetings for the present session will be held on Wednesday evening, November 14, when the President (Dr. Gordon) will give an inaugural address.

The General Hospital, Birmingham.—At a meeting of the Committee, held yesterday, Philip Bindley, M.B. Lond., and Robert Saundby, M.D. Edin., were elected Assistant-Physicians to this Hospital; and Wm. G. Archer, M.A., M.B. Cantab., M.R.C.S., and Thomas F. Chavasse, M.B., C.M. Edin., M.R.C.S., Assistant-Surgeons, for attendance upon out-patients. It was resolved to declare the recently created offices of Obstetric Officer and Ophthalmic Surgeon vacant; the election to take place on the 28th inst.

Surgical Society of Ireland.—The ballot for the election of a Council for the session 1877-78 took place at the Royal College of Surgeons, Stephen's-green, on Monday, November 5. The following are the new officers of the Society:—*President:* Robert McDonnell, F.R.S., President of the College. *Vice-President:* Philip Crampton Smyly, Vice-President of the College. *Council:* John Barker, Charles Benson, Philip Bevan, Richard George Butcher, William Colles, Anthony H. Corley, Henry Gray Croly, Edward Hamilton, James Stannus Hughes, Archibald H. Jacob, Benjamin Francis McDowell, Rawdon Macnamara, Edward Dillon Mapother, Humphrey Minchin, George Hornidge Porter, Benjamin Wills Richardson, M. Harry Stapleton, William Stokes, Jolliffe Tufnell, Henry J. Tyrrell, Albert Walsh. *Honorary Secretaries:* Benjamin Wills Richardson, Jolliffe Tufnell. The first meeting of the Society will take place on Friday evening, the 23rd inst.

VIRCHOW ON THE PENGE CASE.

We have received, through the courtesy of Professor Virchow, a copy of his pamphlet (a *Separat-Abdruck* from the *Berlin. Klin. Wochensehrift*) on the "Penge Case," and we have much pleasure in laying a translation of it before our readers; and it will be observed that the celebrated German pathological teacher supports the doctrine we advocated in our leading article of October 6 on the subject. We hope, now that public attention has been so strongly drawn to the shortcomings of our post-mortem system (if we may be allowed the expression), that the necessary alterations will soon be officially initiated, and that the humiliating spectacle of another "Penge Case" will thus be avoided. We would take this opportunity of reminding our readers that Virchow has recently published a little work on "Post-mortem Examinations, with especial reference to Medico-Legal Practice"(a) (the translation of which first appeared in these columns), to which we would again draw attention:—

The English medical journals have during the past two or three weeks contained a number of leading articles, special reports, and individual opinions, all with the same heading —"The Penge Case." The case in point is a criminal one, in which the indictment declares that the death of Harriet Staunton, of Penge, in the county of Kent, was brought about through starvation. The unusual sensation which this case created, and which found expression even in political papers, is to be explained chiefly by the energetic opposition which this indictment met with among medical men. The exhaustive arguments of Drs. Greenfield and J. F. Payne are to be found in the *British Medical Journal* of October 6, pages 495 and 497, and in the *Lancet* of the same date, page 492. It was these arguments which induced an English medical man to request me to express my opinion concerning the case, as he feared that the excitement of the public mind in his own country was too great to allow of a thoroughly unprejudiced opinion on the part of English medical men.

Indeed, to read the editorial comments of the *Lancet* and *British Medical Journal* side by side, amply suffices to show how totally opposed are the views of the various parties. Thus, while the editor of the *British Medical Journal* congratulates the court on its verdict of guilty, and sees in the summing-up of the judge a vindication of English justice, the *Lancet* organises a petition praying for the intervention of the Secretary of State, and for a pardon for the condemned prisoners, lest they should fall victims to an unjust sentence. As the papers announced, this petition has been successful; therefore the following criticisms are directed to the purely scientific aspect of the case, as indeed it is right that they should be.

Nevertheless, I would have kept silence if the points at issue had referred to this individual case alone. On the contrary, this case seems to me peculiarly suited to bring on for discussion the cardinal questions of the position of medical men in medico-legal cases in general, and especially as regards the methodical performance of *post-mortem* examinations. I can do this the more unrestrainedly, inasmuch as the *Medical Times and Gazette* (also in a leading article on October 6, page 392) has already arrived at the same conclusions as those which I am now about to formulate. This article condemns in the strongest language the unskilfulness with which the post-mortem examination was made, and demands a reform in the system of giving medical evidence in England. The writer, speaking of the medical evidence, says, "It shows the utter folly of leaving such inquiries in the hands of men not specially trained to, and skilled in, such inquiries"; and concludes with, "It is high time the system of medical evidence in criminal cases was reformed."

If we review without prejudice the medical technicalities which the case presents, we find that there are two chief points of reproach.

The first, which, by the way, is admitted on all hands, relates to the manner in which the autopsy was made, and to the drawing up of the report (protocol)—that is, of the written notes of the result of the autopsy. If the former was in the highest degree unsatisfactory, the latter was certainly culpably careless. The original protocol is to be found in the *British Medical Journal* (page 495). At all events, to judge from its general form, we must accept as such the "Notes of a post-mortem examination the body of Harriet Staunton," at the commencement of which Dr. Wilkinson, Dr. Longrigg, and various other persons, among which several medical men are named, are stated to have been present. In the *Lancet* (page 512) the same Dr. Wilkinson, on his own responsibility, gives an extract from his own notes, taken during the autopsy, *which differ in essential points from those already mentioned.* For instance, in the protocol it says:—

"On removal of skull-cap, *adhesions* were found between this and the dura mater and *arachnoid or fibrous (and serous) membranes enclosing the brain*, and between this last and the pia mater (or internal membrane of the brain itself), *showing the existence of previous inflammation*"; while in Dr. Wilkinson's summary it is recorded, "There was no trace of meningitis, *no adhesion*, and no effusion."

If ever a case demonstrated how necessary are the strict regulations of our criminal procedure as regards *post-mortem* examinations and the method of reporting them, surely it is this one. A portion of the French press protested with great vehemence against such minute and despotic instructions, on the occasion of the publication of the new Prussian regulations, in which they were contained, and many of our own medical men in Prussia are only too much inclined to agree. But, notwithstanding, whoever forms his opinion on something else than mere theory, whoever has had personal opportunity of seeing how the entire worth of a technical medical examination may almost be destroyed owing to a superficial and careless *post-mortem* examination, and still more to an ambiguous and unintelligible manner of recording the same, will not for one moment doubt that it is desirable, both in the interests of justice and still more in those of the medical profession, that a definite method of proceeding in all criminal cases should be imposed on us as an obligatory duty. What must a judge or statesman, or even the public, think of professional men who not only are not able to agree as to facts, but who afterwards differently depose as to facts which they have jointly observed?

THE SICK AND WOUNDED IN THE RUSSO-TURKISH WAR.

(*Concluded from page* 499.)

(Y.) *Extract from Dr. McQuean's Letter from Cherissa.*

September 13, 1877.

On August 29, Dr. Beresford and myself, accompanied by Mr. Pratt, arrived at Yeni-Kieni with the intention of forming a temporary hospital there, and of using our waggons to transport the wounded from the field to our hospital, and from there as soon as possible to the nearest large hospital in the rear. We found a Turkish hospial already established in the best houses of the village, so that we had some difficulty in securing suitable places for our hospital, but at last fixed upon a house capable of containing twelve beds, and a large hay-shed, which we had cleared out, capable of containing twenty or twenty-five beds.

On the 31st we set out with our arabas and cacolets, horses and work, over the battle-feld of the previous day along with Dr. Cruikshank and Dr. Roy, but found no wounded.

The few sick or wounded that came into the village were taken to the Turkish hospital, where they lay without anything being done for them—several cases of gunshot wounds with bullets unextracted, smashed fingers requiring amputation, etc. When asked why they did not operate, they said they had not proper instruments, and afterwards that they had received orders not to operate; and though we begged to be allowed to operate or to take charge of the cases, we were always put off for a day or two, and then the cases sent off to Eski-Djuma untouched.

On the 4th we had five sick soldiers in our hospital. We transported from the Turkish hospital at Yeni-Kieni to Eski-Djuma on the 30th nine sick and wounded, and on the 3rd twenty sick and wounded.

On the evening of the 6th Mr. Pratt arrived from Cherissa,

where he had seen numbers of wounded unattended to, so, as there was no work at Yeni-Kieni, we started off early next morning, and arrived here late in the afternoon. We found numbers of wounded lying about the streets in a deplorable state, with undressed wounds and unset fractures. We got them as comfortably housed as possible, with mattresses and blankets for the bad cases, and distributed bread.

Early next morning we dressed seven fresh cases and performed amputation of the thigh on a poor fellow we found the evening before, lying on the bare floor of a room, suffering great agony from a gunshot smash of the leg, the wound being in a bad state, swarming with maggots.

We fortunately were able to buy a supply of bread from a passing cart; sent off an araba to Rasgrad for two sheep to make soup for the wounded.

On the 9th we were able to secure seven arabas, and transported fourteen sick and wounded to Rasgrad (six or seven hours from here), and in the course of the day we treated thirteen sick and wounded, and sent them off the next morning to Rasgrad. On the 10th we treated seven fresh sick cases, and on the 11th one.

To-day Dr. Beresford has taken all the cases from here to Rasgrad. These include the amputation case, which has been doing famously.

Dr. Beresford and I have almost come to the conclusion, after consultation with Busby, Wattie, and Cruikshank, that we must get up our tents and join a division, as it is impracticable to work in the villages.

(Z.) *Hayes' Section (from Dr. Hayes).*

[Copy.] Varna, September 13.

[*Note.*—This report was written in answer to one suggesting the advisability of suspending the Varna Town Transport. It is doing extremely good work, and want of funds alone will compel me to abandon it.—V. B. K.]

I have the honour to acknowledge receipt of your memorandum dated 11th inst., also a list of cases and contents. Yesterday I had the cases sent up in the boat, and to-day they were sent up the line addressed to Dr. Busby.

I note your opinion that a large town transport is unnecessary at Varna, "and that we must cut down that item of our expenditure." If you send me an order to abolish the ambulance carts here, I shall immediately carry out your instructions. In the meantime, I send you a sort of list of the whole thing, and you will be able to judge if the expense or size is too great for the Stafford House Funds; at present the cost of working it is, roughly speaking, seventy Turkish liras a month at the outside.

I have arranged that at Sheylandjik the wounded have soup ready for them, and they have already partaken of it, and enjoyed it much.

On the night of the 9th I received 553 wounded at the station here; on the 10th, 229; on the 11th, 69 very badly wounded. On all these occasions I personally assisted and superintended the matter, and our waggons were of much service. Dr. Lake is now here; he arrived on the night of the 11th. The trains conveying wounded often arrive after 10 p.m., and we have been at the station as late as 1.30 a.m. next day before we could get all the wounded away.

My reasons for having established the local transport service were, that when I came here everyone was loud in complaining of the way in which the sick and wounded were received here on their arrival; that they were left all night in the station, etc. So I set to work to remedy this, and since we have been here no wounded have been left; they have always all been carefully removed. Often have I been down when there was no one on the part of the civil or military authorities to receive them, and our people have carried them to the ambulance waggons. I must say that, stimulated perhaps by the example of others, the authorities seem to be working out of their lethargy now, and to be becoming alive to the fact that badly wounded men cannot walk, and require somewhat tender removal.

(Signed) J. E. D. Hayes.

Transport List or Notes.—Rasgrad: One man permanent and three occasional bearers; one man to travel with train to see after soup, etc. Shumla Road: One man. Varna: One chaousb, seven drivers, four bearers, one vitalis piperus, thirteen horses, six pair-horse waggons, one single-horse waggon, twenty-two mattresses, twelve stretchers. On the Railway Line: Eight stretchers, eighty carriage cushions, thirty-five mattresses.

Note.—Five pair-horse waggons take two persons each; one waggon, one man full length or three sitting; one waggon, six men sitting. The waggons have sometimes to make four trips per station to hospital.

(Signed) J. E. D. Hayes.

No. 10.—Cullen's Section, Varna.

Varna, le 16 Septembre, 1877.

J'ai l'honneur de vous remettre ci-joint copie du tableau que j'ai addressé au Comité Central du Croissant Rouge à Constantinople, comprenant la statistique du mouvement médical de cet hôpital du 21 Août époque, à laquelle nous avons commencé de recevoir des blessés jusqu'au 31 Août, vieux style.

Il resulte de ce tableau, que durant ce temps nous avons soigné 49 blessés juste le nombre des lits que l'hospital peut disposer.

De ces 49 blessés, 1 a guéri, 3 sont morts, 11 devra rester encore sous traitment, et 34 étaient susceptibles d'être evacués.

(Signé) D. Konvaros.

(C.) *Copy of a Telegram received from Mr. Cullen.*

Philippopolis, September 18, 1877.

Sketchley went on to Bazardjik with stores and medicines for Temple Bey and Dr. Moore. Large numbers of wounded are walking the whole of the way between Arimia, Sophia, and Bazardjik, in bad condition. No transport service. Temple Bey urgently solicits the presence of our transport service, and supplies are badly provided for.

(D.) *Copy of a Telegram sent by Dr. Neylan.*

Philippopolis, September 17, 1877.

One hundred and fifty wounded arrived here last night.

Barker will leave with some to-morrow. I go with him for a few days, being ill. Minassian temporarily in charge. Manvury and Wood have hospitals. Total of wounded here at present, 850; all going well.

(E.) *Copy of a Telegram received from Dr. Neylan.*

Philippopolis, September 16, 1877.

Stores received. Gave Wood a hospital. Manovitch going to Plevna. Stoker just brought twenty serious cases, and the Turks 300 more. We can accommodate all the bad cases here. Dragoman wanted. Colley returning invalided. All going well.

(F.) *Telegram from Kennett.*

Kezanlik, September 17, 1877.

Nine hundred fugitives have no food for the last three days. I have distributed all my private money. See Layard. The road from Sophia is one string of Turkish fugitives. Urgent need. Sophia messenger arrived says only one foreign doctor; crowded with wounded; gangrene, and many deaths. Wounded arrive down here in very bad condition.

Bond Moore.

FROM ABROAD.

Lesions of Bone in Hereditary Syphilis.

In the *Gazette des Hôpitaux*, No. 111, we find some notes of an interesting lecture delivered by Prof. Parrot at the Hôpital des Enfants-Assistés, on "Bony Lesions by the aid of which we may diagnose Hereditary Syphilis."

"When young infants," he observes, "are emaciated, whether from the fact of the disease itself or from any other cause, there are certain parts of the bony system on which it is possible, with a little attention, to discern certain indications of syphilis. The first region towards which the physician should at once direct his attention when he suspects in a child the existence of syphilis, and in the absence of all other clinical manifestations, is the inner surface of the tibia. There, in fact, in place of that habitual depression which exists in all healthy subjects of good conformation, is found a true bony tumefaction, in convex relief. Sometimes the swelling exists in a general manner, occupying the whole of the inner surface of the tibia; while in other cases, which are, however, exceptional, in place of this general thickening of bone we meet with small projections or tuberosities, separated from each other by depressions. Another point which should also be carefully examined is the lower part of the humerus. But while the tibia, owing to its superficial position, easily lends itself to investigations, these are less easily conducted on the humerus. This, in fact, especially at its lower end, is covered by numerous muscles and tendons, and the skin is notably thicker at this part; so that all these conditions impede the perception in a very evident manner, especially when not sufficiently habituated to it, of bony lesions, the existence of which it is of importance to verify. However this may be, when, in a child the subject of syphilis, we lay hold of the lower part of the arm, grasping it from before backwards, we find a more or less considerable increase of thickness of the humerus. Nothing, indeed, is more easy than to overlook this lesion, especially when not familiarised with this examination, and not accustomed to these children; but in doubtful cases it is sufficient, in order to convince oneself that the bone is really affected, to first of all grasp the middle of the humerus, and then let the fingers slide down to its lower extremity. We then perceive, on comparing the thickness of the diaphysis of the bone with that of the epiphysis, a pretty notable difference in favour of the latter.

"Another very important sign which you will meet with in a considerable number of cases, but at a somewhat more advanced age, about the seventh, eighth, or twelfth month, is the following:—When the cranial surface is inspected, not only do we perceive that it is very devoid of hair (a circumstance common enough in individuals quite free from syphilis), but we are struck by the presence of prominences disseminated around the bregma and anterior fontanelle: on the two frontals at their obtuse angles, and on the parietals at the angles which border on the bregma, four more or less notable projections are observable—one on each bone. These projections or bumps are rounded, as if small orange-peels had been applied to these parts of the cranium. It is easy, by passing the hand over the cranium, to verify the existence of these prominences when they are not apparent enough to be recognised by simple inspection. Finally, there is another characteristic which should be mentioned, but which is much rarer than those which precede. In certain infants, and especially those which are not older than from a fortnight to two or three months, we observe in the continuity of the limbs one, and sometimes two, fusiform tubercles or true nodosities. At these points the bones seem set in a body of an olivary form. These lesions are especially met with in the femur and at the upper part of the limb, and they are due to fractures in process of consolidation, consisting of a semi-osseous, semi-fibrous callus, as is shown at the autopsy.

"Such are the lesions of the bones that are sometimes met with in infants the subjects of syphilis, and which, when present, are certain indications of the disease. The knowledge of the fact is the more valuable that you may frequently observe them in individuals who exhibit neither on the skin or elsewhere any other sign that might enlighten you on the subject."

Artificial Suckling of Infants.

The Paris Municipal Council, which on various occasions has meddled with things it little understands, has quite recently, in consequence of the great attention of late paid by the public to the immense mortality of young infants, voted a considerable sum in order that experiments may be made on a large scale concerning the artificial feeding of these little beings. It desired the Assistance Publique to conduct such experiments, but that body, somewhat better informed as to the true position of the question, demurred, and refused, at all events, to enter upon such a course unless this was sanctioned by the Academy of Medicine. The Préfet of the Seine accordingly communicated this resolution to the Academy, with a request for its advice upon the subject. This request having been referred to the Committee for the Hygiene of Infants, this body has just made its report thereon through M. Denonvillers. In this he observes that since the Academy has of late more especially occupied itself with the question relating to the hygiene of children, all its efforts have been directed to induce the bringing up of infants by the breast, and especially the maternal breast; and it has received reports which show that in some of the provinces these efforts have been attended with a certain amount of success. Bringing up by hand should not be resorted to except in extreme necessity, accompanied by care and precautions which are difficult to put into force. If it succeed under exceptional circumstances, as when associated with suckling, or when carried on in the midst of families by aid of excellent milk, this will not be the case when it is employed under quite different circumstances, and especially if attempted in large towns and in special establishments, the agglomeration of children in which is in itself a fertile source of disease. For the Committee it seems absolutely certain that the trial at Paris of an establishment for conducting artificial feeding of young infants would produce the most murderous effects on these, and would soon have to be abandoned. It would be far preferable that the sums proposed to be devoted to this object should be expended in rewarding nursing mothers.

When it was proposed to the Academy to agree to the report entirely denouncing the scheme, M. Jules Guérin protested against this, inasmuch as it is admitted that artificial feeding is a necessity with a vast number of infants, and that under its influence a very great proportion die, the reasonable course would be to encourage study and experimentation with

the view of rendering this means of feeding less disastrous in its effects. The subject of artificial feeding has made much progress of late years, and future improvements should be encouraged in place of being arrested by such decisions. Much of the harm attributed to the use of the sucking-bottle is really due to the premature use of solid food. M. Devilliers, while admitting that this distinction between artificial suckling and premature feeding should be borne in mind, maintains that the former, even when exclusively employed, leads to great mortality. Thus, in Normandy, where the practice is very prevalent, and the milk usually of good quality, the deaths of infants reach the high proportion of 35 per cent. as contrasted with the 15 or 16, or even less per cent. under maternal suckling. M. Colin agreed with M. Guérin in thinking that artificial suckling required further investigation, for surely it is not logical to conclude that because in the hands of ignorant and mercenary women it gives rise to such disastrous results, it will have the same effects when properly directed and regulated according to the laws of hygiene and physiology. Surely, in the present state of science and chemistry, a milk might be prepared from the milk of animals, very analogous to, if not identical with, that of women. Experiment has shown, with regard to animals, that artificial suckling, properly conducted, gives rise to the best results; and why should it not be so in the human species? M. Depaul stated that he was entirely of the opinion of the Committee. The Academy could not give its support and approbation to a series of experiments that must lead to a deplorable result. That artificial suckling is bad has been amply demonstrated, and the Academy cannot encourage experiments that would only consign other infants to the tomb. Chemistry is quite unable to render any help in the matter, and has often even led to deplorable errors. M. Blot was of the same opinion, and could not endorse M. Colin's opinion as to young animals thriving under artificial suckling. Having for some time past had to keep young calves for the purpose of animal vaccination, which were suckled artificially, he found them waste away very rapidly. M. Devergie said that the Committee had not stated the case so strongly as it felt, believing, as it did, that these experiments would be not only dangerous, but immoral.

The conclusions of the Committee were adopted by the Academy. M. De Ranse, commenting upon the subject in the *Gazette Médicale* (Nov. 3), observes that the Academy seemed to fear that the adoption of the project would be an encouragement given to artificial suckling to the detriment of natural suckling. But the question was either badly put before it, or ill understood. The object was not to patronise and encourage artificial suckling, and to place it in parallel with maternal suckling, which is so infinitely superior, but to render it less destructive in those instances, unfortunately so numerous, in which recourse to it is obligatory. Even as regards the execution of the experiments, infants nursed by devoted persons, under the inspection of physicians ready to substitute a nurse on the signs of mischief appearing, would certainly be less exposed to the danger of death than if they were consigned to women who made bringing them up an occupation.

Twin Births.

In a paper in the *Journal de la Société de Statistique de Paris* for September, M. Tschouriloff treats of twin births in an ethnic point of view, and states that his investigations with regard to France (in 1861-65), Bavaria, and Italy, all lead him to the same conclusion, viz., that there is almost a constant relation between the frequency of twin births and the development of the stature. The way he seeks to prove it is by comparing in each department of France the number of twin births and that of the exemption from service on account of stature. He finds that in two departments in which the twins varied from 14 to 13 per 1000, there were but 3·93 per cent. of exemptions; while in six departments in which the twin births varied from 8 to 7, the exemptions mounted up to 10·54. With rare exceptions, the principle held good throughout all the departments. In Bavaria the same held good; but it was in Italy that the most striking results were obtained. It is in the South that fewest high statures are found, while in the North (which has been peopled in part by the taller natives of Gaul and Germany) are the largest number; and if stature is to be regarded as an ethnic characteristic, the prevalence of twin births, which corresponds to it, should be so also considered.

GENERAL CORRESPONDENCE.

HOSPITAL MORTALITY.

Letter from Mr. Lawson Tait.

[To the Editor of the Medical Times and Gazette.]

Sir,—A review of my book on this subject appeared in the last number of the *British and Foreign Medico-Chirurgical Review*, of such a character that I find it necessary to make a reply; and as the journal in question has ceased to appear, I am obliged to trespass on your courtesy for the publication of what I have to say in answer.

When I undertook the compilation of the material for my book, I knew that I had a difficult and, perhaps, thankless task before me. I knew that I must certainly so far interfere with vested interests, that I should lay myself open to rough treatment if I allowed any errors to be discovered in my work. I knew, also, that such an amount of material could not be gathered and arranged without error, and therefore I was quite prepared to receive much adverse criticism. I was not, however, prepared to find it possible that my critics should manufacture blunders for me, and then find fault with me for making them; or that they should construct sentences of their own out of fragments of mine, so as to put both the subject and its treatment in a wholly false light. This, however, in my opinion, is what has been done by my critic in the *British and Foreign Medico-Chirurgical Review*.

The first sentence to which I take exception, as containing a distinct misrepresentation, is as follows:—"Sir James Simpson followed a plan of investigation at any rate calculated to lead to some definite results. By limiting himself to one set of cases only, he was able to draw comparisons between hospital and private practice, which were certainly of some value." This sentence seems to me to mean that as I have not followed Simpson's plan, my results are of no value. But if anyone will glance at my book, he will find that I follow Simpson's plan of collecting and contrasting computations—which alone was Simpson's plan; that I do it on a much larger scale than Simpson did it; that I avoided what all Simpson's critics, including myself, saw was Simpson's error; and finally, that I come by this and other methods to the same conclusions as Simpson did. A little further on in the article I complain of, I find that my words are made to convey a meaning which they do not possess, by the unfair process of taking extracts from my sentences, and placing the quotation in inverted commas after a few words by the reviewer. Thus:—

Review.	*Original.*
Mr. Tait found that this part of the subject had been so thoroughly done by Sir James Simpson that "he felt that any further investigation of the subject must be prefaced by research in another direction."	His papers were placed in my hands by his son, but I found so little that had not been used by him that I felt that any further investigation of the subject must be prefaced by research in another direction.
The more he thought on the difficult subject of discovering something which should be more than a repetition of Sir James Simpson's work, "the more he became satisfied that the first step was to establish the facts of a total hospital mortality for a definite and somewhat extended period."	The more I thought this difficult subject (statistics of amputations) over, the more I became satisfied that the first step was to establish the facts of a total hospital mortality for a definite and somewhat extended period.

As a further illustration of the misrepresentations to which I have been subjected by the writer of this review, the following sentences will serve:—

"The average number of patients to each bed is calculated by dividing the average number of full beds into the yearly number of patients. Thus, let us say, a hospital of a hundred beds has on an average only ten full, and receives one hundred patients per annum. Mr. Tait would put the patients per bed as ten. Another hospital of one hundred beds might have every bed full all the year round, and receive a thousand patients, and Mr. Tait would still call the average per bed ten, and would say that one hospital was as active as the other."

I never have said any such thing, and the illustration given by my reviewer, together with the reasoning following

it, seem to me to show an unfairness in his criticism which is not usual in such journals as the late *British and Foreign Medico-Chirurgical Review*. He apparently does not understand the difference between the *total work done* and *activity*. If five men could mow a five-acre field in a day, and another twenty men could mow another field of twenty acres in the same time, the activity of each set of men would be equal, as would also be that of each of the men. But the total work would not be the same for the two sets of men. But if the set of five men could mow six acres instead of five, whilst the twenty men could not do more than their twenty acres, both total work and activity would be increased. If there were only five acres to be mown by the first set, then the five more active men would finish their work in less than the day. There would be then a greater *activity*.

The reviewer does not seem able to understand the difference between the number of beds which any particular hospital states in the columns of Churchill's "Medical Directory" that it possesses, and the numbers which it has actually in use. "We must say that such gross blunders about a hospital (St. Bartholomew's), of which the prospectus and the printed report can be obtained by anyone, have rather shaken our faith in the accuracy of the rest of the table." The gross blunders consist in having stated that the number of beds in this hospital is 710. But I do not state this. What I do say is that the hospital has only 301·49 beds in average occupation, *exclusive of ophthalmic beds*, though in the "Directory" the number is given as 710. The reviewer has not read the context, which is necessary to understand the tables.

Again, he says, "The hospital held up as the type of all that is bad is University College Hospital." This is not true, neither is the statement that the amputation mortality of St. Bartholomew's is 1 in 3·7, while that in University College is 1 in 4·3. The correct statement is that in Bartholomew's the mortality is 1 in 4·36, and in University 1 in 4·68. The difference is so fractional, and the number of cases given for University College Hospital is so small, that the reviewer is not entitled to say that "the pupil and master are at such utter variance, it is evident further investigation is necessary before either of their conclusions can be considered reliable."

Finally, to review a book it is necessary to learn what its object is. At page 7, I surely stated the object of my book with sufficient explicitness in the following words:—"In an inquiry into hospital mortality it must be distinctly borne in mind that there are three steps in the process which, although interdependent, must be kept distinct. The first is to ascertain what hospital mortality really is. . . . The main object of this essay is with the first of these steps." And yet my reviewer finds fault "that there is not one word in the book, or one figure of this vast mass of calculations, which can really help us to guess at the cause of this variation (in the mortality of different hospitals)." I made not the slightest pretensions to offer any explanation. All I wanted to do in this book is to demonstrate the fact that there are variations *which ought to be explained*.

I am, &c.,

Birmingham. LAWSON TAIT.

THE OXFORD CORONER AND THE RADCLIFFE INFIRMARY.

LETTER FROM MR. HUSSEY.

THE following letter, a copy of which has been forwarded to us by Mr. Hussey, addressed to the Chairman of the Radcliffe Infirmary, was laid before the Committee of that institution at their meeting on Wednesday last:—

St. Aldate's, 27th October, 1877.

My dear Sir,—In the Oxford *Chronicle* of to-day, in a report of remarks made by you—"on behalf of the Committee of Management"—at the late Quarterly Court, I see that you refer to the case of the death of a patient under chloroform, adding that, "in such cases it has been the custom in this Infirmary to hold an inquest, as it is in all the London hospitals."

Of the present custom in the hospitals of London I am unable to speak, but I believe it is not the custom to hold inquests in such cases in private practice.

At the Infirmary I never heard that there had been more than one such case: that was in 1871. In that case the patient died before any surgical operation was begun. In the late case, the death happened, as I understood, after the operation was ended. Information was given to me. I referred th informant to the registrar of deaths; and I heard no more of it.

It seems to me that you cannot be aware of the change which has taken place in the need for inquests under the operation of the late Amended Act for the Registration of Deaths.

In this case, I heard afterwards that there were ten medical doctors present. Surely there was medical evidence enough to justify the registrar in registering the death, and to satisfy any reasonable person that an inquest was not wanted to make the cause of death clear. No application for an inquest was made to me by the friends of the deceased, nor by the officers of the Infirmary. In all the cases at the Infirmary in which I have held an inquest, information has been given to the summoning officer by one of the resident officers of the Infirmary. This has long been the established practice. None was given in this case; and I never knew, till I saw the newspaper last night, that the question of an inquest had been before the Committee.

If I had known it, I should have felt it a duty to the public to attend the Committee, and explain why I did not think an inquest necessary. I am, &c., E. L. HUSSEY.

To the Rev. John Slatter,
Chairman of the Committee of Management.

REPORTS OF SOCIETIES.

THE PATHOLOGICAL SOCIETY.

TUESDAY, NOVEMBER 6.

CHARLES MURCHISON, M.D., LL.D., F.R.S., President, in the Chair.

ANEURISM OF THE ARCH OF THE AORTA OPENING EXTERNALLY.

DR. PEACOCK exhibited this specimen. A man of forty-six was admitted into St. Thomas's Hospital on December 4, 1871, with a large pulsating tumour in the front of the chest, which had existed for seven months. He was kept continually in bed, on a plain nutritious diet, with a small quantity of wine and a mixture containing perchloride of iron. Under this treatment the tumour subsided, so as to be felt merely as a hard knot in the second intercartilaginous space, immediately to the left of the sternum. The patient left St. Thomas's Hospital in May, 1874, and was afterwards an inmate of the Victoria-park Hospital and Guy's Hospital in succession. He was readmitted to St. Thomas's in June, 1876, when he proved to have altered much for the worse. The tumour was much larger, and the integuments over it were thin. Soon after his admission, livid patches appeared on the most prominent parts of the swelling, followed by excoriation; and in a short time an opening formed, from which there were repeating oozings of blood. The patient died on October 4, 1876, exhausted. Post-mortem an aneurism was found occupying the whole of the arch of the aorta from near the origin of the vessel to the point where the left subclavian is given off. The tumour thus formed lay behind the manubrium, which was considerably absorbed. The sternal end of the left clavicle, and the end of the first rib, were also destroyed. From this sac a second aneurism opened, which lay in front of the upper part of the sternum. This was not bounded by any distinct sac, and had only the skin covering it in front; and in this there was an opening about the size of a shilling, partly closed by a clot. The case was interesting (1) on account of the extreme infrequency with which aortic aneurisms opened externally; and (2) from the fact that the opening was the result, not of sloughing, but apparently of ulceration of the integuments from without inwards. A somewhat similar case had recently occurred at St. Thomas's Hospital, where, in an aortic aneurism advancing through the back, a reddening appeared of the skin, and ulceration threatened; the patient, however, died before perforation. Of seventy-four cases of aortic aneurism, collected by Dr. Peacock, there was external opening in two only. It was important to observe that death was not due to hæmorrhage, but to exhaustion.

ABDOMINAL ANEURISM.

Dr. IRVINE showed two specimens of abdominal aneurism. The first was a specimen of aneurism of the cœliac axis. The patient, aged forty-nine, was admitted into Charing-cross Hospital in December, 1876, suffering from inflammation about the

left knee. His illness dated only fourteen days back. There was no history of syphilis, but the patient had gonorrhœa at the age of twenty. During his stay in hospital he developed pyæmic symptoms; and lung-mischief set in towards the end. He had also, during the last seven days, pain in the abdomen, which was examined as carefully as tenderness would permit, but nothing was found. At this time there was a considerable amount of albumen, with mere traces of pus, in the urine. The day before his death, on January 10, 1877, a movable tumour could be felt in the right hypochondriac and lumbar regions, but no pulsation was found. Post-mortem, an aneurism twice the size of an orange was found springing from the cœliac axis. This lay in the middle line, and contained but very little friable clot. Its walls consisted of fibrinous laminæ, an eighth of an inch thick, which were fragile, and could be easily separated from one another. The aneurism was embedded in fat, as were most of the tissues and organs of the abdomen. Among this fat, pus was found burrowing in all directions, and was evidently due to large concretions of curious shape, which projected into the pelvis of the left kidney, and some of which had perforated the organ. The aneurism compressed the right renal vein and the inferior cava above, so that for the distance of about an inch its calibre barely admitted a quill. The liver and spleen were lardaceous. A large, firm clot was found in the right hypochondrium. Dr. Irvine thought that in this case the renal concretions were the source of all the mischief. It seemed likely that the diffuse suppuration consequent on their existence had affected the walls of the arteries, especially of the cœliac axis; and that this vessel, when deprived of its normal support, and of that of the tissues about, had given way in such a manner that a traumatic aneurism resulted. It also seemed likely that the firm fat about had for a time prevented rapid extension, and that a fibrinous lamellar wall had been formed. The movable tumour felt the day before death was the firm clot found post-mortem. Dr. Irvine also showed a specimen of aneurism of the abdominal aorta. The symptoms in this case came on suddenly. The patient, forty-two years of age, was a commissionaire, who had served twenty years in the army. A month before his admission into Charing-cross Hospital, in November, 1876, he had charge of a house during its decoration; he began to suffer from pains in the head and abdomen, and was sent to hospital as suffering from lead-poisoning. There were, however, distinct physical signs of an aneurism in the epigastric region: marked tumour with expansile pulsation, slight thrill, and loud systolic murmur, while the heart's sounds were pure. There was also a systolic murmur in the back opposite the ends of the last two ribs. The man passed a considerable quantity of albumen, and complained frequently of violent pains in the head occurring paroxysmally, but continuing for long periods, the pains being such that it was suggested that he had possibly a cerebral aneurism with consequent meningitis. He at times suffered from violent vomiting, and frequently from nausea. He was also delirious at fitful intervals. He died suddenly on January 17, 1877, and post-mortem a large aneurism was found involving the abdominal aorta from its origin to below the orifices of the renal arteries. It was divisible into two portions—one growing to the right (a true aneurism), and reaching from the liver to the top of the pelvis; the second, a vast mass, separated from the other by a furrow, in which was lying the inferior cava, filled up the whole left side of the abdominal cavity. The latter portion was traumatic, and contained firm clot, which occupied its greater part. It consisted, indeed, of clot kept in place by the posterior peritoneal tissues, which it had carried in front of it. The clot surrounded the left kidney, and completely embedded the left renal vein and artery. The aneurism adhered to the vertebræ, which were partly eroded. The vena cava was stretched, and contained laminated clots. The left femoral artery was almost obliterated by extension of disease downwards. The brain was fairly healthy. It seemed clear in this case that rupture of the true aneurism had been followed by a slow escape of blood into the retro-peritoneal tissues, and by the formation of a large traumatic aneurism. As in the last case, there was pressure on the vena cava, and on one or other of the renal veins; and as the kidneys in the latter case were quite healthy beyond congestion, probably the albuminuria in both—with, in the one, headache, delirium, etc.—was due to direct interference with the venous circulation.

The President said that there were two points of great clinical interest in these cases—namely, the complete absence of lumbar pain in both, and the absence of murmur over the tumour in the first.

Surgeon-Major Robinson asked whether the second patient was a soldier, and had been in India.

Dr. Dowse asked whether there was pulsation at the xiphoid cartilage, or evidence of cardiac dilatation.

Dr. Irvine replied. The two important clinical points mentioned by the President were present. The tumour felt in the first case, just before death, proved to be a blood-clot; there was neither pulsation nor murmur over it. The second patient had been a soldier for twenty years, and had served in India. Neither before nor after death was there evidence of cardiac enlargement. The abdominal aorta proved to be quite healthy in the first case, excepting a small patch of atheroma just beyond the aneurism.

Intra-Pericardial Aortic Aneurism following Cure of Popliteal Aneurism.

Mr. Wagstaffe exhibited this specimen, as well as the specimen of popliteal aneurism cured by operation. Last year Mr. Wagstaffe treated the subject, a man, for popliteal aneurism by applying Esmarch's bandage to the limb (excepting the region of the aneurism) for one hour, and a tourniquet to the artery above for the next five hours. No pulsation remained, but for the next twenty-four hours a slight flow was permitted through the vessel. The patient speedily recovered. Two months later, in November, 1876, he suffered from sciatica of the same limb, apparently quite unconnected with the aneurism. In January, 1877, the man suddenly dropped down dead in the street. Post-mortem, the pericardium contained a pint of blood-clot. At the root of the aorta, opposite the right anterior semilunar valve, was found an aneurism as large as an ordinary thimble. It bulged into the pericardium, and opened into that cavity by means of a hole not larger than the point of a pin. The other viscera were healthy, including the large arteries; but the aorta was peculiarly mottled, and presented soft atheroma in the arch. The popliteal aneurism was cut across, and showed a clot, firm externally, but soft internally, and not laminated. This popliteal aneurism was probably the first exhibited after cure by treatment with Esmarch's bandage. Intra-pericardial hæmorrhage from aneurism was comparatively rare. The size of the opening in recorded cases was remarkably small, yet death in thirty-four out of thirty-five cases was sudden. The base of the aorta might probably be regarded as a likely seat of aneurism, considering its connexions and structure.

Dr. Frederick Taylor said that the question of the mode of death in these cases of intra-pericardial hæmorrhage was very important. He himself remembered two cases in which patients with this lesion survived for days, and were examined physically.

Dr. Crisp said that rupture into the pericardium was one of the most common terminations of aortic aneurism. One question in connexion with Mr. Wagstaffe's case was of much interest. What might be the effect upon such an aneurism at the root of the aorta of the application of Esmarch's bandage to the leg?

Mr. Butlin asked whether any microscopical examination had been made of the solid popliteal aneurism. Such a large clot as this specimen presented was generally believed to be liable to produce inflammation, and even suppuration.

Dr. Goodhart said he believed that the occurrence or not of sudden death in intra-pericardial hæmorrhage depended on the amount of previous inflammation of the parts. The adhesions would cause slow leakage, and corresponding slowness of symptoms. The amount of clot in the sac of the aneurism would also affect the symptoms in a similar manner.

Dr. Irvine said that he had shown two somewhat similar cases last session; in one of them the aneurism was not larger than a pea. Both patients had survived rupture for some time; the second patient lived ten hours after the first symptoms.

Mr. Wagstaffe replied that a microscopical examination of the healed popliteal aneurism had shown that the greater part of the thrombus was organised; the central portion, however, was soft and contained no vessels.

Imperforate Anus.

Dr. Crisp showed a specimen of imperforate anus from a child which survived its birth fifty-six hours. The gut projected at the usual seat of the anus, but the case was mistaken by the midwife and purgatives were given. Surgical advice was sought too late to save life.

Miliary Tuberculosis in an Infant.

Dr. Crisp also showed this specimen. An infant of three months was found dead in the morning, after having suffered from cough and been "delicate" all its life, without other special symptoms. Post-mortem the only organs specially diseased were the lungs. These were everywhere studded with tubercles, light yellowish, as large as a pin's head—amounting, say, to 3000 in number. At the root of the lungs one bronchial gland was as big as a marble, and was soft and caseous. This gland was probably the seat of infection. The mother of the child had died of pulmonary phthisis one month previously, and her family were consumptive; a sister was suffering now from phthisis; the father was healthy. Dr. Crisp added that he had reported a very similar case before, in which the spleen was tuberculous, but in which there was no hereditary tubercular predisposition.

Dr. Day exhibited, in connexion with this specimen, drawings of the microscopical appearances of the lungs in a case of acute tuberculosis in a child of two years and a half; and of a case of catarrhal pneumonia with tuberculosis.

Dr. Douglas Powell said that two years ago he had exhibited a specimen of lung disease from an infant of three months, which had died of hæmorrhage from a pulmonary aneurism in a cavity, and miliary tuberculosis. He had also seen another case of seven months. This case of Dr. Crisp's furnished strong evidence of the heredity of tuberculosis.

Perforation of Diverticulum in the Ileum.

Mr. Alban Doran showed this specimen, which was taken from the body of a boy of four years, who died under the care of Mr. Johnson, of Bedford. The boy complained after a hearty dinner, which included peas, of abdominal pain, and vomited; and a dose of castor-oil neither moved the bowels nor relieved the symptoms, which, on the contrary, were aggravated. Opium was then administered, but there was no improvement; and death occurred on the fourth day, after stercoraceous vomiting. Post-mortem the peritoneal cavity was found to contain flatus, fæces, and ingesta. In the small bowel, at a point which was not quite accurately determined, a contraction was found; and at the same point there was a diverticulum from the bowel. This diverticulum was close to the mesenteric border of the gut, and was composed of all the coats of the intestine, and the narrowing of the bowel was just below it. The diverticulum contained a half-digested pea, and the wall was inflamed and perforated. The nature of the case was therefore evident. The diverticulum was probably an example of the usual embryonic diverticulum at the point of junction of the vitelline duct with the intestine.

The President said that many cases of a somewhat similar nature were on record. He had seen a gall-stone thus impacted in a diverticulum; also typhoid ulceration of a diverticulum.

Single Cyst of the Testicle.

Mr. Doran also showed this specimen, which was removed by operation from a gentleman of thirty-six years, by Mr. Hutchinson. The patient was of strumous appearance, had never had syphilis, and had received a slight injury to the testicle twelve months previously. More than once a hydrocele in connexion with the diseased organ was relieved by tapping, but the testicle itself did not diminish in size. Mr. Hutchinson performed castration with success. On examination, the testicle proved to be occupied mainly by a cyst, single, full of chocolate-coloured fluid, and with irregular walls. On the walls there were some smaller cysts of similar structure; and from the walls there could be floated out many filaments, which proved to be seminiferous tubules with granular and cellular contents. But the deeper layers of the cyst-masses were found to consist of soft material, composed entirely of round cells. The specimen was probably, therefore, an adeno-sarcoma. Adeno-sarcomata were comparatively common near the mamma, but had not been often found near the testis. It presented none of the characters of ordinary "cystic disease" of the testis.

Congenital Occlusion of the Small Intestine.

Mr. Davies-Colley showed this specimen, taken from the body of a child of four days. At birth the child was believed to be quite healthy, and was said to have passed a sufficient and natural motion. On the second day it vomited, and had no movement of the bowels, and it was then brought to Guy's Hospital. When seen, the belly was much swollen, and occasional coils of intestine made themselves visible through the walls. The anus was small, and a watery fluid passed from it: a catheter could be passed in but a few inches. Operation was resolved upon, and a small opening was made between the right anterior superior iliac spine and the umbilicus: a small bit of distended gut was hooked up, stitched to the edge of the wound, and opened, and a quantity of meconium was let out. Relief followed; but on the third day the symptoms returned and the child died. Post-mortem it was found that the small intestine was dilated and thickened until a few inches above the cæcum. It then became greatly contracted, and continued so to the valve, appearing as a mere band. On being opened above and below, there proved to be complete occlusion, the lumen ending in two *culs-de-sac*, which overlapped each other. The opening had been made two inches above the upper end of the occlusion. There was acute peritonitis. Mr. Davies-Colley said that this was the first case exhibited here of such occlusion. The diagnosis was difficult, and the account of the passage of a meconium-motion perhaps incorrect. The situation of the opening for relief proved the value of the method of operating on the right side of the abdomen.

Mr. Wagstaffe inquired what the probable pathology of the case was.

Mr. Davies-Colley replied that the pathology of the case was obscure. It had, however, occurred to him that the situation of the occlusion might be the same as the situation of junction of the vitelline duct.

False Membrane from the Larynx in Typhoid Fever.

Dr. Greenfield showed this specimen, which was taken from the body of a child of five years, a patient with enteric fever under the care of Dr. Murchison at St. Thomas's Hospital. After being in the wards for fifteen days with the ordinary symptoms of enteric fever, the child died of laryngeal complication. Post-mortem, typhoid ulceration was found in the lower three inches of the ileum, with swelling and congestion of Peyer's patches, and swelling of the mesenteric glands. The larynx and upper part of the trachea presented a false membrane, and a muco-purulent fluid. On the soft palate and epiglottis there were also similar changes, and a pellicle covered the upper part of the pharynx, and the openings of the Eustachian tubes. The bronchi contained mucopus, and there was broncho-pneumonia. The case was unquestionably one of enteric fever, and the question was, What was the relation between the enteric fever and the diphtheritic exudation? Was it (1) a co-existing diphtheria?—for epidemics of enteric fever and diphtheria went together; or (2) was the intestinal change diphtheritic?—for swelling of the glands in the lower part of the ileum was frequently seen in diphtheria, with small superficial ulceration. In the present case there could be no question that the intestinal disase was that of true enteric fever.

The President said that the clinical history of the case was simple. The child was under his care with enteric fever, and had reached the sixteenth or seventeenth day of the disease. The symptoms were not extraordinary until about three days before death, when laryngeal complication supervened. No membrane was seen on the fauces during life, but only redness and swelling. A laryngoscopic examination could not be made. There was never regurgitation of fluids through the nose. With respect to the relation between enteric fever and diphtheria, laryngeal complication was not uncommon in enteric fever. Louis had recorded it in many cases, and he had himself often seen it. He did not consider the disease true diphtheria, but one of the fresh inflammations seen in enteric fever, scarlatina, and typhus. Such laryngeal inflammation in fever had been observed long before true diphtheria was recognised. In the present case there was no question about the enteric fever. Another child of the same family was under treatment with symptoms of abortive enteric fever; a second member of the family died of enteric fever at the end of three weeks; and the child's symptoms were characteristic.

Dr. Felix Semon said that he had seen such cases in Germany. The laryngeal disease differed from ordinary diphtheria in beginning in the larynx, and passing upwards.

Mr. Knowsley Thornton asked at what period of enteric fever this complication usually appeared.

The President replied that it appeared at a late stage.

Dr. Clifford Allbutt, of Leeds, said that there was a fourfold connexion between enteric fever and diphtheria. Epidemics of the two diseases occurred together; the combination appeared in many cases of one epidemic, and not in those of

others. The two diseases were traceable to similar causes; and they affected the same neighbourhoods.

Cancer of the Rectum.

Mr. H. Cripps showed two specimens of this disease. The first was from a man who had long suffered from the symptoms of cancer of the rectum, but who died suddenly. Post-mortem, a cancerous deposit was found in the *cul-de-sac* between the rectum and bladder, and a large cancerous mass between the rectum and the sacrum, the latter being partly absorbed. There was secondary deposit in the liver. The second specimen was removed by operation from a gentleman who had suffered from irritation in the rectum for two years, and from greatly aggravated symptoms for twelve months. A cancerous mass was felt on the posterior wall of the rectum, about two inches from the anus; and this, along with the whole of the posterior wall corresponding, was removed by operation. The gentleman was now at business in the City, and suffered only from occasional incontinence of fæces. Microscopically, the growth consisted of characteristic scirrhus.

OBITUARY.

MR. JAMES FLOWER.

The Royal College of Surgeons of England has just lost a valuable assistant well known to scientific members of the medical profession as the able Articulator, under his well-known namesake Professor W. H. Flower, in the Museum of the College. Mr. James Flower was born in 1800, and, at the age of fifteen, enlisted as a soldier in the 18th Hussars, and with that regiment formed part of the English army which occupied France after the battle of Waterloo. When the regiment was reduced in 1821 he left the service, and began to cultivate a taste for natural history, and soon after found employment for many years in the museum which the Zoological Society were then forming at their house in Bruton-street. He afterwards took up the work of articulating skeletons, at the same time going into the business of a licensed victualler at the "Canterbury Arms," now known as the Canterbury Hall. His business as an articulator soon increased to such an extent, principally through the patronage of Professor Owen, that he converted his skittle-alley into a large workroom; and it was here that some of his principal labours were carried on, such as articulating the stupendous megatherium and many of the large skeletons in the Hunterian Museum. The trustees of the national collection had such confidence in him that they entrusted the celebrated Nineveh ivories to him to restore. Here also he made for his Majesty the King of Siam a remarkable work of art. The King being desirous of receiving some general knowledge of anatomy, would have lost caste had he touched a dead human subject: Mr. James Flower therefore executed for him, we believe in sycamore or some other soft wood, a most perfect skeleton of an adult man, which met with the commendation of all who saw it. The late Marquis of Westminster employed him to articulate his celebrated racehorse Touchstone, now preserved at Eaton Hall. Subsequently he articulated Orlando, which was presented to the Museum by her Majesty. Amongst his other patrons were the Earl of Enniskillen, Professors T. Bell, Busk, South, Owen, Flower, Mr. Yarrell, etc. Having been permanently appointed Articulator to the Royal College of Surgeons, he had spacious workrooms and assistants provided for him. It was here that his numerous mechanical arrangements were invented, by which the various surfaces of the bones can be examined separately, without interfering with the remainder of the skeleton. Professor Flower has rendered full justice to his earnest labours, by constantly holding them up for example in his annual reports; and on one occasion the Council "testified their sense of the zeal and skill of Mr. James Flower in devising and executing so many of these improvements," by a special vote of approbation, accompanied with a gratuity. During the past year his health became much impaired, and finally he died from cancer on Tuesday, the 30th ult., in the seventy-seventh year of his age. He received the greatest professional skill and kindness from Sir James Paget, Mr. Howard Marsh, Professor Flower, and other gentlemen who fully appreciated his value. By the last-named gentleman and the Council of the College his loss is greatly regretted.

MEDICAL NEWS.

Royal College of Surgeons of England.—The following gentlemen passed their Primary Examinations in Anatomy and Physiology at a meeting of the Board of Examiners on the 6th inst., and when eligible will be admitted to the Pass Examination, viz.:—

Anderson, John, student of the Edinburgh School.
Bull, Edwin G., of the Edinburgh School.
Dixon, Craig, of the Edinburgh School.
Fehrsen, Frederick J., of the Aberdeen School.
Ford, Richard W., of St. George's Hospital.
Fowler, Charles H., of St. Bartholomew's Hospital.
Giles, William B., of University College Hospital.
Holland, Edward W., of the Bristol School.
Hornibrook, William A., of the Middlesex Hospital.
Hughes, Thomas M., of the Charing-cross Hospital.
Parker, Robert L., of the Edinburgh School.
Powell, Henry A., of University College Hospital.
Sarkies, Sarkies Carapiet, of Calcutta and St. Thomas's Hospitals.
Steuart, William, of the Edinburgh School.
Swabey, L. William, of St. George's Hospital.
Swindells, John A., of the Liverpool School.

The following gentlemen passed on the 7th inst., viz.:—

Bagley, Samuel, student of the Manchester School.
Bernays, Augustus C., of the Heidelberg School.
Biss, Cecil Y., of St. Bartholomew's Hospital.
Chaffey, Wayland C., of St. Bartholomew's Hospital.
Damant, Arthur J., of St. Bartholomew's Hospital.
Johnston, Edward C., of the Birmingham School.
Mennell, Zebulon, of St. Thomas's Hospital.
Oswald, Robert J. W., of the Charing-cross Hospital.
Price, Edward M., of University College Hospital.
Simpson, Robert P., of the Edinburgh School.
Swale, Harold, of St. Thomas's Hospital.
Wright, George F. C., of University College Hospital.

Of the forty candidates examined, twelve having failed to acquit themselves to the satisfaction of the Board of Examiners, were referred to their Anatomical and Physiological studies for three months. Amongst the visitors present at this examination were Drs. George Bennett, F.R.C.S., of the University of Sydney; Edwin Powell, Professor of Clinical Surgery, University of Chicago; Mr. W. E. Cant, F.R.C.S., of the Bristol School.

The following were the questions on Anatomy and Physiology submitted to the candidates at the Primary Examination on the 2nd inst., when they were required to answer at least four (including one of the first two) out of the six questions, viz.:—1. Upon what evidence is our knowledge of the functions of the anterior and posterior roots of the spinal nerves based? 2. Describe the structure of the mucous membrane of the stomach, and the composition and uses of the gastric juice. 3. Describe the sterno-clavicular and acromio-clavicular joints, enumerating the parts in relation with them. 4. Trace the obturator nerve from its origin to its distribution, and mention any varieties occasionally met with. 5. Describe the relations of the flexor longus pollicis muscle in the forearm, and also the dissection necessary to expose that part of it. 6. Describe the origin, course, distribution, and anastomoses of the arteries and veins of the thyroid body.

Apothecaries' Hall.—The following gentlemen passed their examination in the Science and Practice of Medicine, and received certificates to practise, on Thursday, November 1:—

La Page, Clement, Nantwich, Cheshire.
Peacock, Henry George, Melton, Suffolk.

The following gentlemen also on the same day passed their Primary Professional Examination:—

Allinson, Henry Calthrop, King's College Hospital.
Craddock, Frederick Hurst, St. Bartholomew's Hospital.

APPOINTMENT.

*** The Editor will thank gentlemen to forward to the Publishing-office, as early as possible, information as to any new Appointments that take place.

Lawton, Herbert Alfred, L.R.C.P. Lond., M.R.C.S.E.—Medical Officer of Health to the Poole Urban Sanitary Authority for three years; Medical Officer of Health to the Poole Port Sanitary Authority for one year; and Medical Officer to the Borough of Poole Fever Hospital.

NAVAL, MILITARY, &c., APPOINTMENTS.

India Office.—Her Majesty has been pleased to approve of the following admissions to her Majesty's Indian Medical Service. To be Surgeons dated March 31, 1877:—Bengal: William Owen, Walter Gillies, David Morton Jack, Walter Conroy, George Jerome Kellie, John Gatcha

Hancock, Dharmadas Basu, Alexander William Mackenzie, Jeremiah Mullane, M.D., Douglas Mullen, M.D., Robert James Taaffe, Ernest Laurie Robinson, James Alexander Nells, William Beatty Smith, Aylmer Martin Crofts, James Crofts, M.D., William Coates, M.D., Joseph Blood. Madras: Thomas King Rogers, Henry Augustus Fitzroy Nailer, Donald Elcum, George Charles Bouton, Nityananda Chatterjie. Bombay: William Keith Hatch, Hormasji Dadabhoi Masani, Kanoba Ranchoddas Kirtikar, Behary Lall Dutt.

BIRTHS.

FOSTER.—On October 24, at Grosvenor House, Edgbaston, the wife of Balthazar Foster, M.D., F.R.C.P., of a daughter.

GIBBON.—On November 1, at Derby-road, Northend, Portsmouth, the wife of Surgeon-Major E. A. Gibbon, L.K.Q.C.P. Ire., of a son.

TAYLOR.—On November 1, at Kingsclere, the wife of Herbert Taylor, M.D., of a daughter.

MARRIAGES.

BOYD—VAN SOMEREN.—On October 8, at St. Andrew's Kirk, Madras, Sydney Boyd, Esq., of Rangoon, fourth son of Alexander Boyd, Esq., of 76, Bedford-gardens, Kensington, to Helen Lechmere, fourth daughter of W. J. Van Someren, M.D., Deputy Surgeon-General, Indian Medical Service.

CLEGHORN—MOSSOP.—On September 8, at Picton, New Zealand, George Cleghorn, M.R.C.S., of Blenheim, to Harriett Louisa, eldest daughter of Mr. Charles Mossop, of 46, Cannon-street, solicitor.

MACCALL—TOLMÉ.—On November 5, William Neil Maccall, M.D., of Manchester, to Louisa Frances, only surviving daughter of the late Thomas Hurry Tolmé, of 1, Fen-court, Fenchurch-street, and Linden-gardens, W.

PEACEY—MARRIOTT.—On November 1, at Christ Church, Forest-hill, William Peacey, M.B., of Lewisham, to Caroline Constance, daughter of T. J. Marriott, Esq., of Perry-hill, Catford.

SIMPSON—SWINBORNE.—On November 1, at the Independent Chapel, Coggeshall, Thomas Simpson, M.R.C.S. Eng., of Coggeshall, to Emma, youngest daughter of Thomas Chalk Swinborne, of Mount-park, Coggeshall.

URQUHART—CAIRD.—On October 31, at Genoch, Wigtonshire, Andrew J. Urquhart, M.B., of Kirkcudbright, to Helen Crokat, daughter of Alex. McNeil-Caird, Esq.

WILES—SIVEWRIGHT.—On November 1, at Christ Church, Trinity, Edinburgh, Julius Wiles, M.R.C.S. Eng., Surgeon-Major Rifle Brigade, to Maria, daughter of the late C. K. Sivewright, Esq.

DEATHS.

DUNN, ROBERT, F.R.C.S. Eng., at 31, Norfolk-street, Strand, W.C., on November 4, aged 78.

KERSHAW, ROBERT, M.R.C.S., Secretary of the London Hospital Medical College, at 4, Alexandra-villas, Finsbury-park, on November 5.

LINDLEY, JOHN, M.R.C.S. Eng., at Strand-terrace, Derby, on November 3.

VON LINHART, WENZEL, M.D., Professor of Surgery at Würzburg University, etc., at Würzburg, on October 22, aged 56.

VACANCIES.

In the following list the nature of the office vacant, the qualifications required in the Candidate, the person to whom application should be made and the day of election (as far as known) are stated in succession.

EAST SUSSEX, HASTINGS, AND ST. LEONARDS INFIRMARY.—Third Assistant-Surgeon. Candidates for the office must be Fellows or Members of the Royal College of Surgeons of London, Dublin, or Edinburgh. Applications, with testimonials, to the Secretary, endorsed "Application for Assistant-Surgeon," on or before November 10.

LIVERPOOL ROYAL INFIRMARY.—Resident Medical Officer. Candidates must be unmarried. No person is eligible who is not on the Medical Register of Great Britain, and who does not possess at least one medical and one surgical diploma, licence, or degree recognised by the Medical Council. Applications, with testimonials, to the Chairman of the Committee, on or before November 20.

MIDDLESEX COUNTY LUNATIC ASYLUM, COLNEY HATCH.—Assistant Medical Officer in the Female Department. Candidates must be registered, single, and not less than twenty-five years of age. Applications, on a printed form, which may be obtained of the Medical Superintendent of the Female Department, at the Asylum, with not more than three testimonials of recent date, to John S. Skaife, Clerk to the Committee of Visitors, on or before November 10.

WESTON-SUPER-MARE HOSPITAL AND DISPENSARY.—House-Surgeon. Candidates must be unmarried, and hold a registered medical and surgical qualification. Applications, with qualifications and testimonials, to the Secretary, on or before November 19.

UNION AND PAROCHIAL MEDICAL SERVICE.

*** The area of each district is stated in acres. The population is computed according to the census of 1871.

RESIGNATIONS.

Bakewell Union.—The Matlock District is vacant; area 8673; population 5377; salary £20 per annum.

Mere Union.—The First District is vacant; area 19,008; population 4548; salary £105 per annum.

Tavistock Union.—The Tavistock District is vacant; area 11,660; population 7781; salary £55 per annum. Also the Workhouse, salary £35 per annum.

APPOINTMENTS.

Brixworth Union.—Edward B. S. Perkins, L.S.A., to the Sixth District.

Burton-upon-Trent Union.—Clement Palmer, M.R.C.S. Eng., L.R.C.P. Edin., to the Barton-under-Needwood District.

Chorlton Union.—Richard Fullerton, M.B., L.S. Dub., Assistant Medical Officer at the Workhouse.

Eastry Union.—Walter Dixon, M.B., C.M. Edin., to the Eythorne District.

Manchester Township.—Charles F. Diggle, M.R.C.S. Eng., L.S.A., as Assistant Medical Officer at the Workhouse Hospital.

Thame Union.—Timothy W. Lee, M.R.C.S. Eng., L.S.A., to the Thame District.

LIQUOR ARSENICALIS IN PRICKLY HEAT.—A "frequent contributor" to our contemporary the *Indian Medical Gazette* states that he has obtained most excellent results frem the internal administration of liquor arsenicalis in prickly heat. He gives the remedy in the ordinary doses and with the usual precautions. As not a few persons in England suffer much in hot weather from an affection much resembling prickly heat, the remedy is deserving of trial.

DUQESNEL'S MEDICINAL PENCILS.—These are made in the following manner:—Take equal parts of guttapercha, and the medicinal subtance (such as alum, tannin, etc.), and having heated the former to about 100° C., in an iron or copper morter, mix the two thoroughly together, and then roll the mixture into cylinders by means of glass or metal plates. The pencils thus formed, when brought into contact with the mucous membranes, leave upon these a portion of the medicinal principles which they contain.—*Union Méd.*, November 3.

THE NEW MEDICAL DEPUTIES.—The last Chamber comprised thirty-nine medical Deputies, only one of whom belonged to the Right. Of these thirty-nine, five only have not been re-elected, one of these being the notorious Naquet, whose absence is very opportune at this crisis. Two new members have been elected—viz., M. David, Republican, and Baron Larrey, the only medical Bonapartist, as M. Bourgeois, of Venice, is the only Legitimist, of the present Assembly. In the alphabetical list furnished by the *Progrès Médical* we observe the names of MM. Paul Bert, Cornil, Laussedat, and Roussel. In the present Chamber the medical Deputies are therefore thirty-six in number.

RECOVERY AFTER POISONING WITH TEN GRAINS OF MORPHIA.—Dr. Dobrachotow relates the case of a lady of weakly frame, twenty-five years of age, who, on account of cardialgia, took on the evening of May 10 the whole of a mixture consisting of ten grains of acetate of morphia, and five drachms of bitter-almond water. At the end of five hours violent vomiting set in, the skin was pale, cold, and dry, the lips and nails were blue, the pupils contracted to the size of a pin's head, and the gaze unintelligent. Answers were only to be obtained rarely, and with trouble. The pulse varied from 28 to 32, and was small but regular; the respiration, from 4 to 6, was whistling and superficial. In spite of the stimuli employed, the pulse fourteen hours after the poisoning had decreased to 12, and the respirations, with râles, to 2. The pupils first dilated after the administration of one-tenth of a grain of sulphate of atropia subcutaneously, and the same quantity by the mouth, besides sixty drops of tincture of belladonna. After a prolonged sleep, the patient awoke on the morning of May 12 in a state of great debility, but otherwise in a good condition. From May 13 to 16 she suddenly forgot several times a day what had happened the day before, or referred it to ten or fifteen years back, and *vice versâ*. Since then she has completely recovered.—*Petersburg Med. Woch.*, October 20.

COMPOSITION AND QUALITY OF THE METROPOLITAN WATERS IN OCTOBER.—The following are the returns (by Dr. Meymott Tidy) of the Society of Medical Officers of Health:—

Names of Water Companies.	Total Solid Matter per Gallon.	Oxygen required by Organic Matter, etc.	Nitrogen: As Nitrates, etc.	Ammonia.		Hardness. (Clarke's Scale).	
				Saline.	Organic.	Before Boiling.	After Boiling.
Thames Water Companies.	Grs.	Grs.	Grs.	Grs.	Grs.	Degs.	Degs.
Grand Junction .	18·90	0·045	0·090	0·000	0·007	12·6	3·3
West Middlesex .	19·00	0·043	0·090	0·000	0·008	13·7	3·3
Southwark and Vauxhall . .	19·50	0·058	0·097	0·002	0·010	13·7	3·7
Chelsea . .	18·10	0·054	0·165	0·000	0·009	13·2	3·7
Lambeth . .	20·40	0·047	0·135	0·000	0·009	14·8	3·3
Other Companies.							
Kent . . .	26·10	0·010	0·285	0·000	0·004	20·0	5·1
New River . .	17·40	0·018	0·109	0·000	0·007	12·6	2·8
East London .	19·60	0·040	0·099	0·000	0·007	14·3	3·3

Note.—The amount of oxygen required to oxidise the organic matter, nitrites, etc., is determined by a standard solution of permanganate of potash acting for three hours; and in the case of the metropolitan waters the quantity of organic matter is about eight times the amount of oxygen required by it.

The water was found to be clear and nearly colourless in all cases but the following, when it was very slightly turbid—namely, in that of the Lambeth, Southwark and Vauxhall, and the Grand Junction Companies.

THE PARIS ACCLIMATATION SOCIETY.—M. Albert Geoffroy St. Hilaire has just concluded, on the part of this Society, an agreement with the Municipality of Marseilles, whereby the Jardin des Plantes of that city shall be transformed into a succursal of the Paris Jardin d'Acclimatation. The Paris Society alrcady possesses a similar very fine succursal on the island of Hyères. These two succursals are intended to serve as places of transition for plants from hot climates, which it is desired to acclimatise in France. At Marseilles, as well as at Hyères, these will thus find a special climate intermediary between their own original climates and the climate of Paris.—*Révue Scientifique*, October 20.

THE climate of Swatow is one of the healthiest and most delightful in the world. The summer months are not very hot; the maximum of the last six months (July 29 and 30) was 88°, and on the nights following these days the mercury fell to 79° and 81°. It is always so here; the days are hot, but there is enough fall at night to make the air pleasantly cool, yet not enough to produce chills. Even in the hottest weather there is daily a refreshing sea-breeze which gives bloom to the cheeks and vigour to the frames of the most feeble. I have seen delicate children brought here almost dying, who have got well and strong in a short time; and delicate adults who could hardly exist at home, or in other parts of China, quickly gain strength in this genial climate.—*Dr. Jamieson, in the Chinese Customs Gazette.*

POOR-LAW MEDICAL OFFICERS' ASSOCIATION.—At the meeting of the Council of the Poor-Law Medical Officers' Association, on Tuesday last, the following resolution was agreed to:—"That this Council has seen with much satisfaction the action of the Local Government Board in directing their Inspector, Mr. Long, to attend a meeting of the West Bromwich Board of Guardians for the purpose of urging upon them the reconsideration of the case of Mr. Downes, who, it will be remembered, was refused superannuation allowance by this Board after thirty-nine years' continuous service, without any complaint ever having been made against him, and he having reached the advanced age of seventy-six. The Council also begs to express its regret that this generous procedure on the part of the central authority should fail of success."

THE NEW SUPPLEMENTARY CHAIRS AT THE PARIS FACULTY.—The greatest agitation prevails in the professorial world of Paris with regard to the somewhat high-handed appointment of the new Professors without consulting the Faculty. This body has not only sent in a strong protest, but has determined to contest the right of the Minister to make the appointment, carrying the matter before the Council of State if necessary. The *Union Médicale* reminds the Faculty of its determined resistance to the re-establishment of the *concours*, and its refusal a few years since of several new chairs, which M. Waddington, then Minister, offered it, and considers its present opposition somewhat inconsistent with its former procedures. The *professeurs-agrégés* have also sent in their protest against the appointments, on the ground that two of the six chairs are given to persons not *agrégés;* and, although they do not deny that it is not a legal necessity to fill chairs by *agrégés*, they urge that not doing so is to injure vested interests by disappointing legitimate expectations.

CRYSTALLISED EGGS.—We do not remember to have met with "crystallised eggs"—at least, not to our knowledge—but perhaps some of our readers may have. At any rate, the *Druggists' Advertiser*, New York, in speaking of the immense egg traffic of America, tells us, in the following quotation, together with some old things that are unquestionably true, some new things:—"The perishable nature of eggs has naturally detracted from their value as a standard article of diet. The peculiar excellence of eggs depends on their freshness. But lately the process of crystallising has been resorted to, and by this process the natural egg is converted into a vitreous substance of a delicate amber tint, in which form it is reduced seven-eighths in bulk compared with barrelled eggs, and retains its properties for years unimpaired in any climate. In this form, eggs may be transported without injury, either to the equator or to the poles, and at any time can be restored to their original condition by simply adding the water which has been artificially taken away. The chief egg desiccating companies are in St. Louis and New York. No salts or other extraneous matters are introduced in the process of crystallising, the product being simply a consolidated mixture of the yolk and albumen. Immense quantities of eggs are prepared in the spring of the year by liming. Thus treated, they are good for every purpose except boiling. It is a common fraud for some dealers to palm off eggs so treated as fresh, so that imposition is easily practised. In the desiccating process, however, the difference becomes apparent, as from four to five more limed eggs are required to make a pound of eggs crystallised than when fresh are used, and eggs in the least tainted will not crystallise at all."

NOTES, QUERIES, AND REPLIES.

He that questioneth much shall learn much.—Bacon.

Aristarchus.—It would, no doubt, be desirable that Major Bolton, or some other authority, should be armed with the same power of proceeding against the water companies when they supply water insufficiently filtered and containing organic matter, as the Metropolitan Board of Works is over the gas companies, as shown in the recent case of the Commercial Gas Company. The Metropolitan Board called upon the Gas Company to show cause why a distress warrant for £400 should not be issued against them for having, on eight separate days, supplied gas of a less purity than allowed by the Act of the Company. The impurity was proved by the gas examiner of the Board. Various technical objections were raised on behalf of the defence, but they were overruled, and the distress was issued for the amount of penalties incurred.

Athletic.—The virtues of coca during muscular exercise have been exemplified, with the best results, in Canada, by the La Crosse Club of Toronto, after a trial of a prolonged character. Most of the best players of Canada belong to this club. For a period of eighteen months the playing members have accustomed themselves to secure a drachm, or a drachm and a half, of the Chilian leaves, and to chew them at intervals previously to and during a match. On one occasion especially, when the club had to meet men well trained to outdoor exercise, it was observed, during an interval for rest, that while the members of the club, most of whom were engaged in sedentary employment, were as elastic and apparently as free from fatigue as at the commencement of the match, their opponents were quite exhausted. A sensation of heat and dryness of the throat was experienced soon after commencing the coca-chewing, but that yielded at once to a gargle of water, and no ill effects were subsequently experienced.

A. A. L.—St. Thomas's Hospital has an income of £42,000 a year.

Cosmo.—The result of the recent French elections shows that there will be thirty-six medical men in the present Chamber of Deputies, against thirty-nine in the last.

Canine.—The Dogs Act, now in force, more or less, was passed in 1872.

Chemicus.—The prizes for the model for the Liebig monument, to be be erected in Munich, are, for that adjudicated the best 2000, the next best 1500 marken—£100 and £75. They are to be sent to Berlin—"An den Kastellan der Königlichen Akademie der Künste"—between June 1 and 15 next.

An Abstainer.—The Chief Constable of Manchester in a recent report showed that during the last year the arrests in that town for drunkenness on Saturdays numbered 2869; and on Thursdays, when they were fewest, 759. Of the intervening days the numbers varied, increasing and decreasing with tolerable regularity. It is noteworthy that during the recent trade dispute at Bolton the apprehensions for drunkenness decreased by 30 per cent.

Neptune.—It is stated that more than two-thirds of the mortality at known ages occurs in the merchant navy when under thirty years of age. The Parliamentary paper on scurvy, 1871, showed how health can be preserved on the longest voyages by the supply of potatoes preserved in molasses. One case is mentioned in which a British crew, soon after leaving Aden for Callao, became subject to this malady, and the captain persuaded each man to eat daily a raw potato which had been preserved in molasses. Fermentation having taken place in the molasses, the taste is said to have been that of chesnuts. The result was that the disease was completely eliminated, and the ship arrived at Callao with the crew in perfect health.

A Matron.—The total daily supply of milk for London, is estimated to be 70,000 gallons.

Theorist.—"When Bishop Berkeley said 'There was no matter'—
And proved it—'twas no matter what he said;
They say his system 'tis in vain to batter,
Too subtle for the airiest human head;
And yet, who can believe it?"

Mr. John Birkett.—At a meeting of the Council of the Royal College of Surgeons on the 7th inst., this gentleman, who now occupies the President's chair, was unanimously re-elected a member of the Court of Examiners, his term of office having expired. Mr. Birkett, who is the Government Inspector of Provincial Medical Schools, is also a prize essayist, having carried off the Jacksonian Prize in 1848 for his work on "Diseases of the Mammary Glands, Male and Female, and Treatment thereof."

Weather Statistics.

The sixth annual report of the Meteorological Office of the Dominion of Canada, published at Toronto, is issued. It gives full meteorological statistics for the whole dominion, and an account of the way in which the work is carried on in the central office.

COMMUNICATIONS have been received from—

Mr. W. E. Poole, London; Dr. William Squire, London; Dr. Thomas Barlow, London; Mr. Teevan, London; Dr. Alexander Yule, Sussex; Dr. Bruce, London; Mr. John Chatto, London; Mr. Lawson Tait, Birmingham; Mr. T. M. Stone, London; Mr. B. R. Wheatley, London; Dr. J. Marion Sims, Paris; Dr. Ross, Manchester; Dr. Sutherland, London; Mr. Lownes, Liverpool; Dr. Chevers, London; The Secretary of the Apothecaries' Hall, London; Dr. J. W. Moore, Dublin; Mr. Griffith, London; Professor Virchow, Berlin; Dr. Monaghan, Accrington; Dr. C. M. Tidy, London; The Secretary of the Harveian Society; Dr. J. W. Barnes, London; Mr E. L. Hussey, Oxford; Mr. W. Robertson, Royal Aquarium, Westminster; Mr. Balmanno Squire, London.

BOOKS AND PAMPHLETS RECEIVED—

Richard Hughes, L.R.C.P. Edin., The London School of Homœopathy: a Lecture—A. B. Shepherd, M.A., M.D., F.R.C.P., Gulstonian Lectures on the Natural History of Pulmonary Consumption—Surgeon-General T. Longmore, C.B., F.R.C.S., Gunshot Injuries—Broadmoor Criminal Lunatic Asylum Annual Report for the Year 1876—John Smith and Co.'s Physicians' and Surgeons' Visiting List for 1878—John M. Woodworth, M.D., The Safety of Ships and of those who Travel in them; The General Subject of Quarantine, with particular reference to Cholera and Yellow Fever—Dr. M'Call Anderson, Lectures on Clinical Medicine.

PERIODICALS AND NEWSPAPERS RECEIVED—

Lancet—British Medical Journal—Medical Press and Circular—Berliner Klinische Wochenschrift—Centralblatt für Chirurgie—Gazette des Hôpitaux—Gazette Médicale—Gazette Hebdomadaire—Le Progrès Médical—Bulletin de l'Académie de Médecine—Pharmaceutical Journal—Wiener Medizinische Wochenschrift—Medical Examiner—The Louisville Medical News—Boston Medical and Surgical Journal—Nature—Philadelphia Medical Times—Iron—Cincinnati Clinic—Brief—New York Druggists' Advertiser—Edinburgh Medical Journal—Obstetrical Journal of Great Britain and Ireland—La Province Médicale—Archives Générales de Médecine—Bicycling Times—Gazeta Medica da Bahia—Guy's Hospital Gazette—Monthly Letter of the English Anti-Tobacco Society—Union Médicale et Scientifique du Nord-Est—Analyst—Journal of Anatomy and Physiology—Richmond and Louisville Medical Journal.

APPOINTMENTS FOR THE WEEK.

November 10. *Saturday* (*this day*).

Operations at St. Bartholomew's, 1½ p.m.; King's College, 2 p.m.; Royal Free, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.

12. *Monday*.

Operations at the Metropolitan Free, 2 p.m.; St. Mark's Hospital for Diseases of the Rectum, 2 p.m.; St. Peter's Hospital for Stone, 3 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.

Medical Society of London, 8½ p.m. Dr. Drysdale, "On Pigmentary Syphilitic Affections in the Female." With cases.

13. *Tuesday*.

Operations at Guy's, 1½ p.m.; Westminster, 2 p.m.; National Orthopædic, Great Portland-street, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; West London, 3 p.m.

Royal Medical and Chirurgical Society, 8½ p.m. Mr. Barwell, "On a Large Aneurism of Aorta, Innominata, &c., treated by Double Distal Ligature." Mr. Morrant Baker, "On Removal by Operation of a Hairy Mole occupying half the Forehead."

14. *Wednesday*.

Operations at University College, 2 p.m.; St. Mary's, 1¼ p.m.; Middlesex. 1 p.m.; London, 2 p.m.; St. Bartholomew's, 1½ p.m.; Great Northern, 2 p.m.; Samaritan, 2½ p.m.; King's College (by Mr. Wood), 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.

Epidemiological Society, 8½ p.m. Inaugural Address by the President (Surgeon-General John Murray).

15. *Thursday*.

Operations at St. George's, 1 p.m.; Central London Ophthalmic, 1 p.m.; Royal Orthopædic, 2 p.m.; University College, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; Hospital for Diseases of the Throat, 2 p.m.; Hospital for Women, 2 p.m.; Charing-cross, 2 p.m.; St. Thomas's (ophthalmic operations), 4 p.m.

Harveian Society, 8 p.m. Dr. Broadbent, "On a Case of Acute Dementia in a Child; Recovery." Mr. Osman Vincent, "On a New Treatment of Lumbar Abscess."

16. *Friday*.

At the Royal Observatory, Greenwich, the mean reading of the barometer last week was 29·88 in. The lowest reading was 29·44 in. on Monday evening, and the highest 30·24 in. on Thursday afternoon.

* The figures for the English and Scottish towns are the numbers enumerated in April, 1871, raised to the middle of 1877 by the addition of six years and a quarter's increase, calculated on the rate which prevailed between 1861 and 1871. The population of Dublin is taken as stationary at the number enumerated in April, 1871.

ORIGINAL LECTURES.

A CLINICAL LECTURE

ON PROGRESSIVE CHOROIDITIS IN CONNEXION WITH ACQUIRED SYPHILIS.

By JONATHAN HUTCHINSON, F.R.C.S.,
Senior Surgeon to the London Hospital, and Surgeon to the Moorfields Ophthalmic Hospital.

Gentlemen,—The family history of Mrs. P. is that she married at twenty, and had an infant born dead about a year later. Her next lived nine months, was puny, and died. Then followed several healthy children. I put direct questions to her, and she told me that she was not aware that her husband or her children had ever had any indications of venereal disease. She showed me, however, some large, irregular, pigmented scars on her own shoulders, which were left by serpiginous ulcers five years ago. About these I had no doubt that they were syphilitic. Thus, we may take it as probable that she has never had primary symptoms, but, at the same time, as certain that she has in some way become tainted.

Now as to her eye-symptoms. In both eyes there are remains of very extensive choroiditis. It is seventeen years since her left began to fail. It became dull. It has for three years past been practically blind. She can just, at the extreme periphery, see large objects, but cannot count fingers. In this eye the disorganisation is very extensive, and the disc is waxy. There are a few slender iritic adhesions.

The right eye began to suffer for the first time, so far as she is aware, three or four years ago. She then came under Mr. Tay's care, at the London Hospital. It has steadily deteriorated ever since the first beginning of the attack; probably it had begun to fail some time before she noticed it, but it is certain that there was an interval of some ten years at least between the disease in the two eyes, or at any rate before she became aware that her right was materially affected. I must state, as regards other nerve-symptoms, that she has never had any kind of fit, convulsion, or paralysis. She is often giddy, "so that the room goes round." She also suffers from "a very nasty pain across the head." She is fairly healthy-looking, but pale.

There are some peculiarities in the eyes in this case, to which I must now advert. In the left eye there are not merely separate patches of absorption and exposure of sclerotic, but extensive diffuse thinning of choroid and pigmentation of retina, also numerous white lines and grey-white streaks and flame-shaped patches, as if from the organisation of new material. The disc, as I have said, is waxy, and the retinal vessels are very much diminished. In the other eye the conditions are comparatively trifling, but a patch near the yellow spot has caused much interference with sight. The patches in this eye are mainly near the middle of the fundus. The disc is of good colour.

With this case fresh in our minds, in which one eye failed ten years before the other, let me now ask your attention to one which is in some respects very remarkable. A gentleman was one morning led into my room by his wife, a lady apparently twenty years his junior. From the helpless way in which he was led in I supposed him almost blind, and was much surprised when he assured me that he sometimes regained his sight sufficiently "to read the newspaper." He was florid, stout, and apparently in excellent health. Although he did his best to be candid, he was not in some matters a good witness, for his memory for dates was but imperfect. His right eye diverged somewhat, and I found that it was really almost blind; at any rate, he could not count fingers with it. He was very anxious that I should believe that a slight blow on this eye received in the dark more than twenty years ago was the cause of his failure of sight. He admitted, however, that for some months after the accident he could see perfectly, and that then it was the other eye which first failed, so I could not attach much importance to this. He said that his failed sight was an old matter, and that he had not come to me about that, but rather about a general nervousness which had crept over him during the past twelve months. After I had sent his wife out of the room, he said at once, "You are on the right tack, doctor; I have been married two years, and have been getting nervous ever since." He added that he was now accustomed to spend twelve hours of the day in bed, and that an act of intercourse left him weak for six or seven days after. He had become a little uncertain on his legs, and could not go upstairs easily, as he felt afraid of falling. There had, however, been no very definite symptoms, and his feet were neither numb nor cold. He had not experienced stabbing pains in his limbs. His sight had during the last year got a little worse, and he was now obliged to depend upon his wife's reading to him, whereas in former years he had read "acres and acres." His sight, he said, varied much, being tolerable on some days, and almost lost on others. He just managed $\frac{20}{70}$, and read with low glasses (No. 6). "It is curious," he remarked, "that I can see little things better than big ones; and often after making a bargain, having examined the sample carefully, I run over a chair because I cannot see it." This expression clearly pointed to integrity of the yellow spot, and disorganisation of the rest of the fundus. He had central vision only, and could see only those objects which he carefully looked at. I have not yet told you that his age was forty-eight, and that he dated the first failure of sight back five-and-twenty years. So far as he could remember, his first symptom was that he ran against things at night, and had a mist before him. The condition increased steadily, so that in a year or two he was almost blind. The right eye was the one first to suffer, but the left soon followed. During the time the sight was failing he was in good health, and had no brain-symptoms whatever. He was treated throughout by a very distinguished physician and surgeon in the West of England, and also had the advantage of Mr. Bowman's advice on one occasion. Between the years 1854 and 1858 he was, as far as he can remember, almost blind. He could not read in the least, and used to grope his way about by feeling. Rather suddenly in the latter year he began to improve, and he attributes this improvement to his having one night got tipsy. It was a thing that he was not used to, and to his astonishment next morning he found that he could see persons in the street. After this he had some relapses, and the improvement was very irregular; it was, however, ultimately so considerable that in a year's time he could see to read. "Rum, with orange-juice," was, he asserts, his best remedy. Here, however, comes a fallacy in therapeutics; for his memory is very treacherous, and he admits that he is not sure that it was not about this time that he consulted Mr. T., who told him he had taken plenty of tonics and had better now try alteratives, and, in fact gave him a course of mercury. "No one," he says, "ever did me so much good as Mr. T." To shorten our story, the man, who had been more than two years nearly blind, regained sight in the left eye sufficiently to read easily; and from 1858 to 1875 (the date of my notes) he read his newspaper regularly, and conducted successfully a large business, which required sharp sight for small objects. His right eye, we must note, never improved at all; so that there was a definite want of symmetry, which removed the case to a distance from tobacco-amaurosis, and the more usual forms of neuritis. He had, moreover, never smoked, and no cerebral symptoms of any kind had ever been present.

At this stage of my investigation of the case, I used the ophthalmoscope, and found a state of diffuse disorganisation from choroido-retinitis, greater, almost, than I had ever before seen. In the right eye it involved every part of the fundus, the stroma of the choroid and the epithelial layer being absorbed, and the sclerotic showing through everywhere. Accumulations of pigment in minute dots, in specks, and in fine lines, like bone corpuscles, were everywhere seen. The disc was waxy, and its edges ill-defined, and the retinal vessels reduced to mere threads. In the left were similar conditions, with the difference that at the yellow spot was a small, irregular patch of choroid and retina still intact. In this also, the atrophy in other parts near the middle of the fundus was not so far advanced, and ill-defined roundish clouds of grey-white deposit might be recognised in the choroid. In both eyes there was posterior polar cataract—a central opacity from which thick lines branched like spokes round the middle of a wheel.

The choroido-retinal changes resembled those of retinitis pigmentosa in the abundance of minute pigment accumulations in the retina, and in the waxy disc and diminished central vessels, but it differed from it in the absorption of the choroid and the vary various forms and sizes of pigment masses, some of which were of considerable size. There was, moreover, no evidence of zonular arrangement, the pigment being irregularly scattered over the whole fundus. Having found these conditions, I felt certain that the case must be one of syphilis, and reverted to my inquiries on this head. "Have you really never had a chancre?" "Oh yes! I once had one, a very, very little one; it was nothing—only a matter of a few days." "But had you also a very little rash on the skin after it, and a very

slight sore throat?" "I had no rash whatever; but, now I remember, I had a sore throat." "Are you sure that your sore throat was from the disease?" "Yes, for Dr. —— said so, and gave me a wash and a brush to paint it." I relate this colloquy *ipsissimis verbis*, for it was absolutely all that I could get as to syphilis. He did not appear ever to have had a single reminder of any kind. He knew that Dr. —— gave him iodide of potassium, but he could not remember to have had a single spot on his skin. It was within two or three years of this occurrence that his sight first began to fail. Although the quantity of evidence was but small, yet its quality was good, and I have no doubt that he had syphilis, and that the choroiditis followed it. He spoke clearly as to the sore throat and the iodide of potassium; and I may add that he did not show any indications of inherited taint.

Thus, then, we have before us a case in which, within a few years of a very mild attack of syphilis, subacute choroiditis sets in, affects both eyes, and in the course of a year reduces the patient almost to blindness. After this, very possibly under specific treatment, one eye improves, and ability to read is regained, and for nearly twenty years things remain without change. Then, in connexion with sexual loss of tone, increased difficulty in sight is experienced. Finally, we may say that the changes in the choroid closely simulate those of retinitis pigmentosa, and that secondary cataracts, such as occur in the latter, are in process of formation.

The case, so far as the choroidal changes go, is precisely similar to what occurs in the worst forms of inherited syphilis. It is, unfortunately, not very uncommon, as I have elsewhere stated at length, for young adults, who have previously recovered from keratitis, to lose sight almost wholly by chronic choroiditis with diffuse atrophy, pigment accumulation in the retina, and secondary cataract. In acquired syphilis it is more rare. Before we leave the case, let me beg you to take note upon what a fragile fragment of evidence the proof of our diagnosis rests. Had this gentleman chosen to deny the history of his "very little chancre," which occurred a quarter of a century ago, it would have been impossible to confute him; for, excepting the choroiditis, he had suffered nothing whatever in the shape of tertiary symptoms. He might easily have forgotten the chancre, or might have been so convinced that it was "nothing" as to have not thought it worth while to admit it. If a denial had once escaped his lips, it would never have been withdrawn, and we should have been left to grope, if not in hopeless error, at any rate in doubt and uncertainty. Let us keep this fact in mind in other cases of diffuse choroiditis in which specific history is denied. Without giving you time to forget it, I will relate to you yet a third case, and with it I must conclude the lecture.

I show you here portraits of the two eyes of a man named H., who was under care at Moorfields in 1873. In both the choroid is very extensively disorganised, but in the left the patches are larger than in the right. It will be seen from the portrait that the greater part of the choroid at the back of the eye was more or less diseased. There are very large tracts from which the pigment epithelium has been removed, and on which the stroma is so far altered that the network of large choroidal vessels has, in many parts, a greyish-white, instead of a bright red colour, while the capillary network is in these parts probably quite destroyed. Besides these large atrophic areas, there are numerous round patches showing various degrees of change, and in most cases a good deal of pigment accumulation. The disc and retinal vessels healthy. The yellow-spot region is involved. In the portrait of the other eye, which had only lately failed, the most striking feature is the presence of very numerous, rather ill-defined yellowish patches, many of them more or less pigmented in the centre; they vary much in size and shape, and some have become confluent. They differ much less from the colour of the surrounding choroid than do the atrophic patches in the other eye, and the smallest of them might easily be overlooked: the pigment at their centres is brownish and uniform, not in isolated coal-black dots. These patches are, no doubt, recent inflammatory deposits in the choroid. At the lower right hand part of the portrait are, however, some patches of older date, more abruptly defined, and showing dots and rings of coal-black pigment. The newest deposits are in the more central parts of the fundus—a fact which accounts for the recent failure of sight in this eye. The disc and retinal vessels are healthy. It is the disseminate or patchy form rather than the diffuse, but the conditions are mixed, and there is extensive diffuse thinning in some parts. In the left, near the yellow spot, there are traces of the remains of blood-clot. Now, H., who was thirty-nine years of age, and a married man, although he admitted occasional exposure to risk before marriage, denied that he had ever contracted any form of venereal disease. He showed no signs of inherited taint; nor could I make out any history of secondary or tertiary symptoms. He had been married sixteen years, but his wife had never been pregnant. His left eye had, he said, been defective for four years before admission, and was getting worse; in the right he had not noticed any symptoms until a week or two before his admission. He appeared to be in good health. Probably the date of the beginning of the disease was more remote than he thought; for as regards the right eye the changes were quite certainly of old standing. Now, although the history of syphilis is in this case absent, yet the changes are so closely similar to what were present in the two preceding, and in many others which I shall have to mention, that I cannot help believing that he must have suffered from that disease.

ORIGINAL COMMUNICATIONS.

REMARKS ON

TWO CASES OF WRITER'S CRAMP.

By W. R. GOWERS, M.D.,

Assistant-Physician to University College Hospital and to the National Hospital for the Paralysed and Epileptic.

MANY cases are supposed to be instances of writer's cramp which are merely examples of general or local weakness, revealed by the act of writing, but recognisable in all other actions in due proportion—*i.e.*, in proportion as they involve delicate co-ordination and are demonstrative in character. In the following two cases the spasmodic element was so conspicuous, the difficulty was so extreme in the act of writing, and was limited so nearly to that act, that there can be no question as to the applicability to them of the term "writer's cramp." They illustrate points of some importance in the etiology, symptoms, and treatment of the affection.

Case 1.—*Writer's Cramp after much Writing—Inutility of Treatment—Ultimate Complete Recovery on Rest.*

A clerk, aged thirty-four, who had had two epileptic fits in youth, began to notice difficulty in writing, a year before he came under observation. He had written during ten hours a day for the preceding twenty years. At first the difficulty was felt only after he had been writing for some time. Two months after he first noticed the difficulty in writing, he found that other delicate operations were not well performed with the right hand; had to leave off shaving himself, for instance. He never noticed any pain or discomfort in the arm. When seen, writing with the right hand had become almost impossible. He grasped a pen well, but on commencing to write the firmness of the grasp increased, and the thumb gradually became more and more flexed, the tip rising higher and higher on the pen, until, after forming a few letters, he had to stop to readjust the thumb. He had had some electrical treatment at the suggestion of a physician whom he consulted, but on inquiry it appeared to have been faradisation. He had also practised rhythmical movements. The voltaic current from the spine to the muscles was ordered, and was carefully applied for six weeks. Not the slightest improvement resulted—indeed, the patient was of opinion that he was rather worse than better for the applications; they were therefore discontinued, and the patient was strongly advised to learn to write with his left hand, that he might give his right hand a long and complete rest. He did so, and in a few weeks, being a persevering man, was able to write sufficiently well with the left hand to resume his occupation as a clerk. He took internally small doses of bromide and quinine. Three months after beginning to use the left hand, his handwriting with the right showed a very distinct improvement; the thumb remained extended for a longer time. Four months later he could write a few words without the least difficulty. A year after first being seen he could write well; the difficulty in using the hand for other purposes had disappeared, and his use of the left hand was not in the least interfered with. He was then allowed gradually to resume the use of his right hand in writing. After a few months he did the whole of his writing with it, and experienced no inconvenience, his handwriting being as good as ever. In reply to a recent inquiry he states that he

still writes entirely with his right hand, and experiences no difficulty in its use, although he has now used it exclusively for two years.

Case 2.—Writer's Cramp after a moderate amount of Writing—Recovery under Rhythmical Movements—Relapse and Persistence in spite of all Measures—Ultimate Change in Electrical Irritability of Muscle and Nerve.

The patient, who was a clerk in a public office, first found a difficulty in writing in the early part of 1872. His previous health had been good, but he was thin, and somewhat excitable in manner. An uncle had been epileptic, and subsequently to the patient coming under observation a brother died with characteristic symptoms of general paralysis of the insane. During the year preceding the failure of writing power, a family lawsuit had occasioned the patient much anxiety. The amount of writing he had done was not excessive. The first manifestation of his affection was that after writing for a little time his hand would begin to shake, and would suddenly jerk off the paper. This increased, until in three months writing was scarcely possible. He then gave up work and went to a gymnastic establishment at Brussels, where he remained for six months, going through a course of special treatment. At the end of that time he was, as he thought, well; he could write as freely as ever. He came back to England, and again had to suffer severe anxiety on account of the illness of his wife; and during this trouble, before his return to work, his handwriting again failed, and in a week was as bad as ever. He was first seen a month after the relapse. On taking up a pencil and attempting to write, all the muscles of the fingers which were in use seemed to pass at once into a state of spasm. As soon as the first movement of flexion was made, the flexor muscles contracted energetically, and the extensors, to keep the fingers in their place, had to be strongly contracted also. The *appearance* was as if the contraction of the extensors was voluntary, to counteract the excessive action of the flexors. The opposition was not, however, well balanced, and some tremor resulted. By partly supinating the wrist, so that he could fix it on the table, he could write a little better; and the same result was obtained by locking the two outer fingers of the right hand with those of the left, and thus giving a very firm support close to the writing-fingers and thumb. Even then, however, the fingers were cramped, and writing was difficult and awkward. The character of the writing was unaffected by the passage of the constant current through the muscles. As far as was ascertained by examination and questioning, no other movement of the hand was interfered with. He was a good pianist, and could play the piano without the slightest difficulty. No separate movement of the hand or fingers was interfered with. The electric contractility of the muscles was not noted.

The treatment advised was a daily application of the voltaic current, at first alone, afterwards in combination with rhythmical movements, in the method found useful by my friend Dr. Poore, and he was ordered to practise occasionally regular movements of the wrist and fingers. This treatment was very thoroughly carried out. When seen he was writing a little with his right hand, fingers locked; but after a short time, there being no improvement, he was ordered to rest the hand entirely, and learn to write with his left hand. This he did very readily, having acquired in a few weeks sufficient facility to do his official writing with that hand. At first, when writing with his left hand, the fingers of the right hand moved in alternate flexion and extension synchronously with the movements of those of the left. The treatment was carried on assiduously for several weeks after he ceased entirely to write with his right hand, but without the slightest improvement; and after it had been tried for two months the treatment was discontinued.

The patient was not seen again for four years. He had continued during that time to write with his left hand, and he did so with perfect facility, so that he had been in the habit of writing thirty letters a-day, of moderate length, without fatigue. He had never experienced the slightest tendency to cramp in the use of the hand. During the whole of the four years he had not written at all with his right hand: nevertheless the difficulty remained unchanged. Although he had used the hand for every other purpose except writing, including shaving and playing daily on the piano, he was conscious of no difficulty in any other operation, with the exception of scratching out with a penknife, in which the position of the fingers is almost the same as in writing. When he tried to write, the spasm was exactly the same as at first. The thumb became at once strongly flexed; the flexor tendons in front of the wrist were felt to become extremely tense, and gradually the position of the wrist changed—it became more and more extended, the fingers and thumb being held very tightly on the pen. As the wrist became over-extended, the tightness of the flexor tendons was less obvious, partly, perhaps, from the effect of the changed angle of the wrist. When the wrist had become over-extended, he brought it back into its former position, and made a few more letters, but the same spasmodic strife between flexors and extensors returned, the wrist gradually became over-extended, and he had to leave off.

The nutrition of the hand and arm appeared to be the same as of the other, but there was a marked change in the electrical irritability of the muscles compared with those of the other side. The flexors of the wrist and fingers, the muscles of the thumb and little finger, all presented a very marked diminution in their irritability to faradisation on the affected side. A slighter diminution was recognisable in the extensors and interossei. In the flexor muscles the contractility to the voltaic current was altered in the same manner as the faradic contractility, but in a slighter degree. The nerve-trunks, median and ulnar, presented the same diminution in faradic irritability as did the muscles. No change in irritability could be found in the biceps muscle; there was a slight change in the sensitiveness. Faradisation of the muscles was felt less acutely than on the other side, and the same change was noted to the faradic sensitiveness of the skin away from the muscles: a current applied to the tips of the fingers, which could just be felt distinctly on the left, was unfelt on the right side. No diminution of sensibility could be detected by the ordinary tests. The power of the muscles was not measured.

These cases present the characteristic spasmodic element in the disease, and in each case the difficulty was limited to the act of writing, and to certain acts involving a similar co-ordination of the same muscles which are employed in writing. The explanation of such cases which seems to me the most satisfactory is that which is adopted by Dr. Reynolds, in his article in the "System of Medicine," and which refers them to a morbid state of the centres involved in the act of writing. No doubt a primary local disease may sometimes be followed by a condition analogous to writer's cramp, but it does not follow that the influence of the local disease has been solely local.

On the view that writer's cramp is essentially a central affection, the change in the irritability in Case 2, and which, as Dr. Poore has pointed out, is very common in writer's cramp, may be interpreted as an example of the change of nutrition which results from long-continued functional disturbance. Every functional disturbance of the nervous system has, no doubt, an organic basis. The fact that a long-continued functional affection, such as writer's cramp, is attended with an obvious alteration in electrical irritability is thus a demonstration of the underlying or attendant molecular change. Electric irritability is a test of nutrition. A change in irritability, even if slight, means a change in nutrition, although perhaps not one that would be obvious on ordinary histological examination. There is reason to believe that depression of irritability in nerves is attended by molecular changes such as in extreme degree is revealed to the microscope by the segmentation of the myelin of acute degeneration. This depression is commonly preceded by exaltation of irritability. In some other cases of functional disturbance a similar increase of irritability may be found—a condition probably indicative of irritative changes. Such a condition of exalted irritability is found, for instance, in chorea.(a) In the absence of any evidence of primary local disease of nerve, the change in nutrition is, according to current views, to be ascribed to a corresponding change in the nutrition of the nerve-cells of the spinal cord, secondary to the irritative influence of the primary morbid process, wherever that may be situated. It is thus comparable to the similar change in irritability which follows an irritating lesion in some regions of the cerebral hemisphere, causing hemiplegia.

The pathology of writer's cramp as a disease of nerve-centre receives an interesting physiological illustration in some of the facts observed by Romanes in the nervous action of the Medusæ. He found that portions of the apparently homogeneous tissue

(a) *British Medical Journal*, August 25, 1877, page 251.

of a jelly-fish are paths of nervous action, and that if the nerve-force were hindered by an incision from traversing its usual path, repeated stimulation would sometimes, when continued for a little time, open up a new path. That is to say, tissue not functionally, but "potentially" nervous might be rendered functionally active by the breaking upon it, at a given point, of waves of nerve-force. This may be taken as an illustration of the way in which new combinations of nerve-action are physiologically possible. A morbid proneness to permit a similar development of new tracks of action, of new associations of action of connected and often-excited cells, and even of abnormal action within the cells themselves, is probably one element in the pathology of writer's cramp. The morbid condition which thus permits the over-action is indeed best conceived, as Dr. Ringer has suggested, as a diminished resistance to action. There is long-continued and frequent stimulation of nerve-elements which have a proneness to suffer the nutritive degradation by which their "resistive force" is lessened, and the stimulation which should result in balanced muscular contraction causes an unbalanced cramp.

The influence of predisposition to neurotic affections on the occurrence of writer's cramp was exemplified in each of these cases—in the one, in the patient's own history, he having suffered from epileptic fits; in the other, in the family history, an uncle having been an epileptic, and a brother a general paralytic. A similar predisposition may often be seen in cases of this affection. Of still greater interest, however, is the degree of the exciting cause, in these two cases, in relation to their subsequent course. The patient who recovered had written ten hours a day for twenty years; while the other, who did not recover, had done only a very moderate daily amount of writing. *Cæteris paribus*, the amount of predisposition varies inversely as the exciting cause of a disease: the less the excitant needed, the greater must be the predisposition; and here, as in many other (although not in all) instances, the degree of the predisposition, rather than the degree of the exciting cause, has to be our guide in a prognosis as to ultimate recovery.

Lastly, these cases illustrate a point of treatment which is, I think, of great importance—that the sufferer should learn to write with his left hand. Whatever may be the value of various methods of treatment, there can be no question that the most important element in each method is rest; and the first case suggests that sometimes rest may be more effectual alone than when combined with adjuvant methods of treatment. But the only way in which rest can be secured, in a large number of cases, is by the patient learning to write with his left hand; for many, if not most, of the sufferers from writer's cramp are those who gain their living by writing. The cessation of writing means often insufficient food, and (what is worse still) the mental distress which, as Case 2 shows, has so powerful an influence on the occurrence of the affection. A man of average industry and perseverance can learn, in the course of a few weeks, to write legibly with his left hand, and in the course of a few months he can write sufficiently fast to resume the duty of a clerk. The writing is upright or its slope reversed, but the style is not ungraceful. Thus rest, absolute, from writing and similar actions, can be given to the right hand; and thus, as in Case 1, recovery may be permitted, or, as in Case 2, if recovery does not take place, the patient is enabled for a time at least (it may be a long time, as in this case) to earn his living.

But to this the objection may be raised that the sufferer will acquire writer's cramp in his left hand, and that his last state, with a bilateral affection, will be worse than his first. I do not think, however, that the latter statement would be justified by facts. A patient who is unable to write on account of writer's cramp in both hands is in no worse condition than one who is unable to write because he has writer's cramp in one hand, and has not learned to write with the other, provided that other movements than writing are not interfered with by the spasm. Of course, if a spasm began in the act of writing, and then spread to other movements of the left hand as well as the right, the consequence of the use of the left hand for writing would be serious; but I believe the chance of such a result to be so small as not to be worth consideration. It is remarkable how limited the cramp may remain. This is shown by Case 2, in which other movements involving delicate co-ordination, and frequently performed, such as playing on the piano, are not interfered with. I know a gentleman who has been for years the subject of writer's cramp; he has stopped his writing, and, although equally unable to draw with a hard pencil, remains able to (and does constantly) paint with a camel's hair brush.

But I think that the danger of an affection of the left hand has been exaggerated. No doubt it sometimes occurs, but I have not myself, out of a good many cases of writer's cramp and allied affections, met with any instance in which the left hand has become affected when used; and Case 2 shows that even where the conditions seem most favourable for such an extension, so many years may pass without its development that it is now hardly probable that it will occur at all. For in this case there was not only a most powerful predisposition, but the bilateral association of the centres and the morbid excitability of the affected centre were strikingly illustrated by the movements of the right hand synchronous with those of the left during the patient's early efforts to write with his left hand. And yet the patient has been able to earn his living for several years by the use of his left hand, and even to fulfil a specified term of work. A case in which common associated movements occurred when the left hand was used, and in which it was employed for writing without detriment, is recorded by Dr. Poore.

ON CHINESE HÆMATOZOA. (a)

By PATRICK MANSON, M.D.,
of Amoy.

(*Continued from p.* 515.)

Filaria Sanguinolenta.

I EMPLOY this name on the authority of Dr. Lewis, who adopts it from Schneider. The latter applied it to a filaria found embedded in the walls of the stomach of dogs, the description of which, Dr. Lewis says, applies very closely to the animal found by him in the œsophagus, thoracic aorta, and neighbouring parts of the pariah dogs of Calcutta. Dr. Lewis's description nearly corresponds with what I have observed in Amoy, and I have no doubt the parasites are identical. In the following notes I will confine my remarks strictly to what I have myself observed.

Some idea of the extent of its prevalence may be formed from the fact, that of thirteen dogs slaughtered for the purpose of procuring specimens of this parasite, nine contained the living animal in different stages of development, or showed traces of its former presence. So that I think I may safely say that all dogs who have attained any considerable age are or have been its host, though the degrees of infection and accompanying lesions vary from that of the most trivial description to those of the utmost gravity.

As to its presence being recognised during life, Dr. Lewis has always found it associated with free embryo filariæ in the blood, such as I have described as belonging to *Filaria immitis*, and he looks upon these embryos as the progeny of *Filaria sanguinolenta*. He is quite aware of the possibility of his being mistaken, but he thinks it very unlikely, as in several instances in which Filaria sanguinolenta and embryo filariæ were present together, he pursued his search into all the principal bloodvessels for other forms of mature filariæ, such as might have given birth to the free embryos, but without finding any. Still, I think he is in error, and for the following reasons:—Embryo filariæ are found in the blood where there may be no aortic tumours; among the thirteen dogs just referred to, there were seven which, although containing Filariæ sanguinolentæ or exhibiting traces of their presence, yet had no free embryos of any sort in the blood—at least, I did not find them; whereas, when Filaria immitis was present in the heart, free embryos were found in all but two cases. The two exceptions almost amount to a proof in themselves, for in one case unimpregnated female Filariæ immites were found without any male worm, and in the other a solitary male, while aortic sanguinolenta tumours were present, and breeding sanguinolenta females were found in the œsophagus. There are other reasons, which will appear by-and-by, why we should not consider the free embryos often associated with it as the progeny of Filaria sanguinolenta. I conclude, therefore, that beyond perhaps difficulty in swallowing, produced by the mechanical action of a filaria tumour in the œsophagus, there is no reliable symptom by which Filaria sanguinolenta can be detected during life. If the fæces were carefully searched,

(a) From the *Customs Gazette*.

and perhaps the urine also, eggs might be found, and constitute certain evidence. Again, as to the habitat of Filaria sanguinolenta, I have found specimens embedded in characteristic tumours in the walls of the thoracic aorta, in the walls of the œsophagus, in the loose cellular tissue in front of the latter, and in the pleura; never elsewhere. The lesions it produces are very characteristic. On opening the thorax of an affected animal, and drawing the heart and left lung over towards the right side, the straight part of the thoracic aorta may be seen to be studded with small tumours ranging in size from a small pea to a bean, and the anterior and lateral surfaces of the œsophagus bulged out by tumours perhaps as large as a walnut; and where several of these are in juxtaposition, a large lobulated tumour may conceal the œsophagus altogether. To the touch these tumours are hard, though at points there may be a feeling of deep fluctuation. If the aorta is excised and split open, its inner surface is found, at the points corresponding to the tumours on the outside, to be more or less deeply sacculated, the inner coat roughened, and the outer coats thickened. In the latter, worms at different stages of development (I have not found them very large in this situation) may be found, or perhaps the sacculation and external bulging may only be evidence that a worm had once been there, but has disappeared. When the worm has reached a certain stage in its development, a minute orifice can be seen on the inner surface of the tumour, communicating with the cavity containing the animal. Through this hole a purulent-looking fluid can be expressed; this, on microscopic examination, is found to be loaded with characteristic ova, and cells resembling those of ordinary pus. The tumours in the œsophagus occupy the muscular wall, and generally are much larger than those of the aorta. On the inner surface of the œsophagus a small hole is, as a rule, to be seen, perhaps several, communicating with the cavity of the tumour, and through this the purulent egg-laden fluid can be easily expressed; sometimes, and by no means rarely, part of the mature filaria protrudes through this hole and hangs loose in the channel. I have found, connected with the œsophagus, mature tumours embedded as I have just described in the muscular walls, similar tumours cretified and enclosing fragments of a long dead filaria, small pedunculated tumours of filarian origin projecting into the channel, and long tunnels burrowing between the coats, in some part of which a parasite can be found. In addition to these, the more frequent situations, the animal may be found in large or small glandular-looking lumps in the areolar tissue of the posterior mediastinum, or encysted between the costal and pulmonary pleuræ. In all these situations I have found them, and all in the same dog. When small, the parasite is found alone, closely invested by the peculiar tissue it seems to create around itself, lying as it were in a tunnel; but when mature, it is found loose in a large tumour, in company with one or more (eighteen I found in one instance), all encapsuled in a common and perhaps cretified cyst, and floating in a purulent fluid.

The mature female worm measures from three to four inches in length, by about one-sixteenth of an inch in breadth; the male is shorter by an inch or more, and can be distinguished from the female by the simple incurvation at the tip of his tail. The colour in both sexes is a dark pinkish-red. Rolled between the fingers, the body is found to be firm and hard, and when stretched yields, but does not rupture readily. The Filaria sanguinolenta exhibits similar movements to the Filaria immitis, but they are more active.

The coverings of the mature Filaria sanguinolenta are two—the integument, a delicate transversely-striped membrane; and the fibro-muscular, consisting, as in Filaria immitis, of strong coarse longitudinal fibres.

The alimentary canal extends the whole length of the body. The mouth is placed at the very extremity of the head, and is easily distinguished from that of Filaria immitis by its six well-marked lips. These lead to a narrow pharynx, which expands into a straight and capacious œsophagus, about one-third of an inch in length, which terminates in the intestine by a valvular arrangement similar to that in Filaria immitis. From this point the alimentary canal passes, in company with the uterine or spermatic tubes, in a tortuous course towards the anus, before reaching which it expands considerably, to contract again as it opens finally on the surface of the body, some little distance from the extremity of the tail. The walls of the alimentary canal are muscular, and are kept apart in places by a dark granular material, the food of the animal.

The reproductive organs of the female resemble, in their arrangement, very closely those of Filaria immitis. The vagina opens near the junction of the œsophagus and intestine, and after a short convoluted course divides into the two uterine tubes. These expand, and running backwards and twisting round the alimentary canal at intervals, near the caudal extremity gradually taper down to fine ovarian tubules. The latter do not expand again, as in Filaria immitis, but preserve the same calibre throughout their whole length, winding round the alimentary canal and each other in a very intricate pattern. I have shown that the Filaria immitis is viviparous; the Filaria sanguinolenta, on the contrary, is oviparous. I have not studied the various stages in the development of the ovum, but, as observed in the purulent-looking fluid I have described as exuding from the mature filaria tumour, it is seen to be of a cylindrical form, the ends of the cylinder being rounded off. It measures about $\frac{1}{750}$th of an inch by $\frac{1}{1500}$th. The embryo is visible in most eggs, doubled up in the interior, and if a little pressure is applied to the covering slide, the shell can be burst and the animalcule expressed. As thus observed, the embryo measures about $\frac{1}{200}$th of an inch in length, and resembles in form that of Filaria immitis, though rather more truncated at the caudal extremity and exhibiting no movement.

As to the reproductive organs of the male, if the under surface of the tail is examined, two rows of papillæ are seen on each side of the orifice of the sheath of the spicules and the anus, four in front of them, arranged in two lines parallel to the long axis of the body, and two behind placed obliquely. Viewed laterally, these papillæ are seen to have long pedicles. At the very extremity of the under surface of the tail is a clear space shaped like a rose-leaf, and in the centre of this are two more, but very minute, papillæ. The penis is represented by two spicules, one very long attached farther up the body than the other, the shorter. In the specimens I have examined, the spicules were retracted, but the delicate outline of a sheath could be traced to a common opening in front of the anus, through which they are, I suppose, protruded. The tendons of a retractor muscle can be seen attached to the deep end of each spicule. I could not make out the connexion of the vas deferens with the spicules and papillæ, but doubtless it exists. Traced upwards, a point is reached where the vas deferens contracts very abruptly and the testicle begins; this extends to near the junction of the intestine and œsophagus, where the tube becomes doubled on itself, very much as in Filaria immitis; only the doubling is much longer, extending backwards for nearly half the length of the testicle, and when carelessly viewed giving rise to the idea that the testicle, like the uterus, is double. The spermatic fluid I have not examined.

The mode by which Filaria sanguinolenta obtains access to the tissues is made sufficiently clear by an examination of the tissues it attacks. From its being found in and near the œsophagus, we are justified in inferring that the embryo is swallowed, that it attaches itself to the walls of this tube, pierces them, and buries itself in the muscular coat, where a fibrous covering is formed around it; or perhaps its journey is continued a very little farther, and it enters the walls of the thoracic aorta, or the posterior mediastinum. From all of these situations I have extracted specimens, varying in length from a few lines (in the immature animal) to upwards of three inches (in the pregnant female). Small worms are most frequently found in aortic tumours, and on this account I incline to think either that they do not often attain maturity there, or that they leave it for the more favourable situation of the œsophagus. Immature worms are single, and lie closely invested in their tunnels; the mature are always in company, sometimes in considerable numbers, and float loose in a fluid enclosed in a cyst. I infer from this diversity of arrangement at these two stages in the animal's history, that when the sexual organs have arrived at a certain point of development, the parasite resumes its perambulations, seeking out one of the opposite sex. In this way many are brought together, as, where once a track is formed, others, on coming across it, are likely to follow it. I have seen an œsophagus dissected in various directions by long tunnels, at the end of which I found a parasite. When the sexes come together the female becomes impregnated, a small aperture is formed in the cyst leading to the channel of the œsophagus or aorta, and through this ova are poured into the alimentary canal or circulation; the female, more certainly to accomplish this, sometimes protruding her tail through the hole.

Is there any connexion between Filaria immitis and Filaria sanguinolenta? Considering that both are very frequently found in the same dog, and intimately connected with the circulation, some might be tempted to suggest that they are of the same species, in different stages of development. But a glance at the physical characters of each is sufficient to establish the impossibility of this. I give below, arranged in the

form of a table for the sake of the contrast, the principal points of difference.

	Filaria immitis.	Filaria sanguinolenta.
	Viviparous; active embryo $\frac{1}{100}$″ in length.	Oviparous; motionless embryo $\frac{1}{200}$″ in length.
Length . . .	Never under six inches	Never over four inches.
Colour . . .	Milky white	Reddish pink.
Mouth. . . .	Simple	Six-lipped.
Male	Corkscrew-like tail; spermatic tube tapers gradually to testicle	Tail, a simple incurvation; vas deferens ends abruptly by a constriction.
Female . . .	Uterus contracted abruptly to form ovarian tubes, which again expand to gradually taper to short terminal tubules	Uterus gradually tapers down to ovarian tubules, which are long, and do not again expand.
Habitat. . .	Venous system	Arterial system and alimentary canal.

I believe there are three serious morbid conditions produced by Filaria sanguinolenta:—

1. Stricture of the œsophagus, more or less complete. This most frequently occurs when several large tumours are formed, especially when they are grouped together near the cardiac end of the tube, the most frequent locality. Regurgitation of food and slow starvation will be the consequence, unless the tumours diminish in size by the escape of their contents or death of the filariæ.

2. Pleurisy. This is not uncommon in dogs here, and I think is often caused by the bursting into the pleura of a tumour which does not find vent for its contents by opening in the usual way into the œsophagus or aorta. I have found very distinct evidence of this occurrence in one instance. In it, worms were found crawling about amongst recent adhesions in the serous cavity.

3. Paralysis of the hind legs. This is also common here, and is, I believe, caused by plugging of the capillaries of the spinal cord by ova escaping into the aorta. The brain is not affected, as the filaria tumours are seldom, if ever, situated on the cardiac side of the arteries proceeding to the head. Other affections are doubtless produced by the ova in the intestine, kidneys, and other viscera, but I have no knowledge of them or information to offer on this very interesting and important point.

(*To be continued.*)

Guttapercha Tissue.—Dr. Chamberlain gives an account in the *New York Medical Record*, September 29, of a guttapercha tissue, which is rolled out as thin as fine French writing-paper, being almost transparent, with a satiny lustre. It is far cheaper than oiled silk, perfectly pliable, and slightly elastic. It is unaffected by the heat of the body, but softens at a somewhat higher heat. It is insoluble in water, but soluble in ether, chloroform, and alcohol. It is especially suited for wounds or lesions of the hands, forming a neat, light, clean, impervious dressing, allowing the hands to be put into water. Adhesion of cut surfaces and resolution of infiltrated deposits take place very quickly and kindly. If a broad patch of the skin is to be shielded from the air—*e.g.*, a scalded surface or a patch of eczema—a piece of the tissue somewhat larger is laid on the surface, and sealed in position by tracing the margin with a camel's-hair pencil dipped in chloroform, precisely as a covering-glass to a microscope-slide is adjusted.

New Member of the General Medical Council.—Glasgow has received another compliment from the Crown. Professor Lister's removal to London necessitated the resignation of his appointment as one of the Crown representatives on the General Medical Council; and the *London Gazette* informs us that "her Majesty has been pleased to appoint Dr. Andrew Fergus, President of the Faculty of Physicians and Surgeons of Glasgow, to be for five years a member for Scotland of the General Council of Medical Education and Registration in the United Kingdom, in the place of Joseph Lister, Esq., resigned." The appointment appears to be in every way a good one. Dr. Fergus holds a well-known and eminent position in Glasgow, and he is, we have understood, in what we should call here general practice. If so, it is certainly not a subject for regret, to say the least; for the general practitioners—the vast bulk of the profession—may justly demand to be much more strongly represented in the Council than they have hitherto been.

REPORTS OF HOSPITAL PRACTICE IN MEDICINE AND SURGERY.

HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET.

CASES OF HEART DISEASE—THE RELATION OF PYREXIA AND SPLENIC EMBOLISM.

Case 1.—*Mitral Disease—Pyrexia of Hectic Type—Splenic Embolism and Enlargement—Cerebral Apoplexy.*

(Under the care of Dr. GEE.)

Mary Ann B., aged ten years and a half, was admitted, under Dr. Gee, on December 6, 1875. Both parents were dead (the father from heart disease); and the history given of the child was very imperfect. She was stated to have had St. Vitus's dance twice, but it was not known how long before admission. During the ten weeks that the friend who brought her had had charge of her, the child had been short-breathed, had had pain in her "left side," in her calves, ankles, and wrists, but no swelling or redness of the joints had been noticed.

On Admission.—The child walked upstairs, but looked very pale and feeble; there was no cyanosis. Heart: Visible impulse in second and third left spaces close to the sternum; also in fifth space external to nipple, where it feels heaving; no thrill; cardiac dulness for half an inch in second space close to sternum; right limit at right edge of sternum; left limit at one finger's breadth to left of left nipple; there was a high-pitched apex-systolic murmur conducted into the axilla; there was no fulness of jugulars; the pulse was full, hard, and regular, under 100; respiration quiet; breath-sounds natural; no anasarca; nothing abnormal detected in abdomen. For three days the child had diarrhœa, and a trace of albumen in the urine. The temperature ranged from 98° in the morning to 101° and 102° in the evening, and it was difficult to account for this pyrexia. There was no evidence of any alteration in the heart-sounds; the chest was fairly resonant; the abdomen was a little full, but no rose spots could be seen; the tongue was covered with a thin dryish white fur.

December 13.—It is noted there is no wandering; the bowels are now confined, the tongue is slightly furred, moist; pulse only 96. There is a little resistance in the left hypochondrium (? splenic); no tenderness there; no rose spots; and the child's aspect is positively not typhoidal. (For temperature *vide* end of case).

29th.—The child had some pain in the right foot. There was a little puffiness on the dorsum, just in front of the ankle.

January 3.—Yesterday and to-day the child has complained of pain in the belly. The pain is localised to the splenic region. Now the spleen extends three fingers' breadth below the margin of the thorax in the left nipple line, and is very tender on palpation; the edge is distinct. There is relative dulness in the axilla from the fifth rib downwards, and in the back from the angle of the scapula downwards (? splenic). There is no definite change in heart-signs, except a suspicion that the murmur at the apex is softer than it was. The child has no cough. There is a very little rhonchus at the left base, but it clears up when she takes a deep breath. She has had no vomiting and no rigor. Her tongue is nearly clean. She looks very sallow. The puffiness, redness, and tenderness of the dorsum of the right foot continue.

6th.—The tenderness in the splenic region is much less.

7th.—There are some ill-defined "swellings" to be felt on the surface of the spleen—two at least. The blood examined under the microscope seemed natural except for a great number of minute sparkling white molecules, the number of which certainly seemed diminished by the addition of ether.

11th.—There has been no pain in the left hypochondrium for one week until this morning. The spleen is not so easily felt; and there is no visible swelling, which there was before. The pyrexia continues. She has been taking ext. ergotæ liq. ℳx. ter die.

29th.—The lungs were examined again and again, with a view to the possibility of tuberculosis. It was thought that at the right apex there was some high-pitched prolonged expiration; but there were no adventitious sounds. There was some dulness at both posterior bases, regarded as hepatic and splenic. The spleen extends three fingers' breadth below the thoracic margin; the anterior edge comes as far forwards as the left nipple line. There is no tenderness. The child has had occasional vomiting.

February 7.—Great pain yesterday afternoon; made the child scream out. Referred it to her belly (left side and in the middle), but said it was different from the old pain. (? some local peritonitis). She places her hand over splenic region, and to the right of and below the navel, as the spots where she now has pain. Cannot bear to be touched; looks pale and feeble; has vomited several times. No difference in heart-signs, except that the second sound at left base is very accentuated; and that the apex-murmur is now well heard at the left back. The murmur is purely systolic; there is no suspicion of presystolic murmur. Pulse 132, regular, of fair volume.

8th.—The excessive tenderness below the navel has gone; there is only tenderness now in the old place over the spleen.

20th.—Complained in the morning of headache, and in the course of the day vomited two or three times some yellow stuff. At 12.45 p.m., when seen by Mr. Cant, the House-Surgeon, the child was sitting propped up; looked excessively pale—collapsed, in fact; took no notice of anything; when asked, said she had a bad pain in her head; was placed in horizontal position, and soon afterwards became unconscious; then the left forearm became rigidly flexed, whilst the right arm worked round in a horizontal circle on the bed, there being no flexion either of right wrist or elbow. After a few minutes the right forearm became rigidly flexed as well as the left; the pupils closely contracted; insensibility of the conjunctivæ. The face was not drawn at this time, and the limbs remained extended. Subsequently the child came to, and called for a basin; then, according to the nurse's statement, became convulsed in mouth, arms, and legs; at 2 a.m. had rattles in the throat, and at 3 a.m. died.

Post-mortem Examination, twenty-four hours after Death.—Rigor mortis slight. Head: There was a little loose clot in the superior longitudinal and other sinuses. A little blood in the meshes of pia mater covering right hemisphere; much more abundant on the right lateral aspect. Over the island of Reil there was a thickness of half an inch of coagulated blood. In removing the brain a clot the size of a walnut burst through a rough fissure on the side of the right tempero-sphenoidal lobe. It is possible that from this source the blood inside the pia mater had escaped, though no direct connexion could be traced. The blood was especially alongside the branches of the middle cerebral. That vessel and a great many of its branches were carefully traced, but no rupture, nor aneurism, nor atheroma, nor thrombus was discovered. The laceration of the temporo-sphenoidal lobe was the only one found on the exterior of the brain. On opening up the ventricles there was a clot found in each, and extending into the third and fourth ventricles. The corpora striata and optic thalami seemed natural. There was a small laceration external and posterior to the right optic thalamus. The rest of the brain was natural, and nothing could be detected wrong with the vessels. Thorax: The heart was not so big as had been expected; it weighed only four ounces. The pericardium was adherent to the left costal pleura at one spot, accounting for the apex-beat being felt distinctly external to the left nipple-line. There were old adhesions of the two layers of pericardium, but they were not very firm. The left ventricle was of about natural thickness. There was contraction of the mitral orifice, with some small vegetations. Also there were some vegetations on the endocardium of the left auricle. No ulceration. Lungs: No apoplexies; a little œdema. In the middle of the right upper lobe there was a small group (about six) of racemose fibrous tubercles; none elsewhere. No consolidation. Glands round right bronchus showed old caseous change. Left lung œdematous, but no consolidation and no tubercle. Glands round left bronchus natural. Abdomen: The dulness at the left posterior base was due mainly to the spleen, which extended quite up to the spinal column; but a little of it was due to the left lobe of the liver, which extended across above the spleen. Spleen greatly enlarged; weighed eleven ounces and a half; very flabby and soft, but not diffluent; not so soft as a pyæmic spleen; it was of a chocolate-brown colour. The Malpighian bodies were white and round, bigger and plainer than usual. There were four infarcts in the spleen, two at the hinder end and two in front; each of them the size of a Spanish chesnut. To the most anterior one there was an adhesion of the great omentum, which probably corresponded with the attack of local peritonitis that the child had. These infarcts were of a dirty brown colour; the one last referred to was the most recent. Liver large and flabby. Kidneys enlarged; eight ounces and a half together; capsule stripped easily; there was some general cloudiness; two large infarcts in each. Intestines and genital organs natural.

Case 2.—Mitral Disease—Ulcerative Endocarditis—Cerebral Embolisms—Splenic Embolisms—Pyrexia.

(Under the care of Dr. CHEADLE.)

Annie I., aged eight, was admitted May 25, 1877. Father had suffered from acute rheumatism. This child three years before was stated to have had St. Vitus's dance. After one month she got whooping-cough, then the St. Vitus's dance went away. The whooping-cough lasted two months, and was followed by rheumatic fever, which disabled her for four months. Never right since. Has continued pale and has not made flesh. She had been under observation as an out-patient for nine months, with mitral regurgitation. There was nothing special about her except marked anæmia, and once or twice syncopal attacks, until five weeks before admission. She then suddenly began to vomit, and complained of pain in the forehead. Vomiting continued for twenty-four hours, on and off, and she had also pains "all over." Then for two days the mother said she became blind, and was convulsed in arms, legs, and eyelids. When brought to the out-patient room the child was pyrexial, but no change in her physical signs could be made out. The mother refused to leave the child in then. A few days afterwards she had another fit, and subsequently was delirious and semi-maniacal. When examined in the out-patient room there was no physical sign to account for the child's pyrexia, with the exception of some tenderness below the left margin of the thorax. And although the edge of the spleen could not be felt, t was considered possible, in the light of the first case, that the fever might possibly be due to splenic embolism, and splenitis set up thereby. The fits, which had passed off without leaving any paralysis, and the delirium, were considered possibly to have been due to temporary blocks in some of the small cortical vessels.

The patient was admitted on May 25. The following report is abstracted from the notes of Dr. Garlick, Registrar:—"The child has considerable dyspnœa; requires to be propped up in bed; leans on to left side; alæ nasi, however, do not work; respirations 60; pulse 132, regular, full, not very compressible; face chlorotic; has vomited several times; tongue moist, with patches of fur. Cardiac region bulged; apex-beat sixth space, outside nipple; impulse heaving, but not strongly so;

has a long systolic apex-murmur; sounds at base muffled; posterior bases of chest resonant; a few coarse râles; abdomen distended; liver and spleen not palpable; no œdema of feet or any other part; temperature 104·2."

26th.—Morning temperature 103·2°, evening 104·6°; pulse 148; respirations 64. Bowels moved six times; urine faintly acid, no deposit, a trace of albumen. At 5 p.m. some tremor was noticed in the back of the left hand, the right arm became rigidly extended, and there was internal strabismus of the right eye. At 7 p.m. there was some twitching of the right side of the face and the right arm, whilst the left side was not moved; this lasted ten minutes. At 8.30 there was again convulsion of the right side of the face and the right arm, the left side remaining unmoved; the legs were not noticed. There was no change to be detected in the fundus of either eye when examined ophthalmoscopically. At 10 p.m. it was found that the left side of the body and the left side of the face were paralysed.

27th.—Morning temperature 103·6°, evening temperature 104°; pulse 144; respirations 56; pulse 168. Bowels moved ten times; motions green and offensive, passed in the bed twice during the night. Urine also passed in the bed, in fair quantity, as far as can be judged. Now perfectly conscious; rather irritable; constantly begging for drink and ice; lips and tongue dry; the latter covered with thin brown fur: exceedingly pale; the left hemiplegia continues—the lower part of the face, and, to a slight extent, the left orbicularis palpebrarum, and the left arm and leg; sensation natural; tongue deviates to the left; no strabismus; pupils equal (dilated by atropine); sees and hears equally on the two sides; speech natural; swallows well now; said sometimes to choke a little. Chest: A good deal of rhonchal fremitus; left side does not expand so much as right. Abdomen full; no tenderness; *tâche cérébrale* appears after a short time.

28th.—Morning, temperature 104·4°, pulse 142; respirations 68; evening, temperature 105·2°, pulse 156, respirations 64. Bowels moved four times. Had a restless night; is sensible, but not so sharp as she was yesterday; left hemiplegia continues; speech is a little thick; extreme thirst.

29th.—Morning, temperature 103°, pulse 152, respirations 64; evening, temperature 104·8°. Bowels moved twice. Speech still thick; takes little notice, but answers rationally; hemiplegia as before; the left eyelid does not close completely; sometimes eyeballs not parallel; still the abdomen is full, but the spleen is not felt; edge of liver just below thoracic margin. There is a little œdema of the left foot.

30th.—Morning, temperature 104·6°, pulse 152, respirations 60; evening, temperature 105·4°; speech indistinct; swallows badly; coughs when liquids are taken. Pulse continues full, regular, and incompressible. The heart's impulse is noted today as low as the seventh space, and two inches outside the nipple line, but is felt best in the fifth and sixth spaces. There is also impulse at the epigastrium. There is no murmur except the apex-systolic one, but the second sound at the base is weak and muffled. There is now venous pulsation in the neck, and slight cyanosis with the pallor. The œdema has disappeared from the left foot. The abdomen is resonant in the flanks. There is a trace of albumen in the urine.

31st.—Morning, temperature 104·2°, pulse 136, respirations 68. Extreme pallor; profuse sweating; abdomen distended. Became unconscious at 2 p.m., and died shortly afterwards.

Post-mortem, twenty-four hours after Death.—Head: The right middle cerebral at its point of division blocked by a pale and adherent firm thrombus. No changes discovered in the other vessels. Brain generally very pale. No softening or hæmorrhage to be found. Left lung adherent; adhesions old; some congestion at the base. Right lung adherent; a little tough consolidation of the anterior portion of the middle lobe (? old). No apoplexies or other changes. Heart: Both layers of pericardium adherent; weighs twelve ounces and a quarter; right side almost healthy. Left side—auricle dilated and hypertrophied. Above the anterior division of the mitral valve there is an irregular area the size of a shilling on the auricular endocardium. In parts it is ulcerated with sharp-cut edges; in other parts there are small adherent polypoid masses. The area has a shaggy, worm-eaten appearance. There are also two small swollen areas situated at the junctions of the two divisions of the mitral. One area has ulcerated a little in the centre. The mitral valve is thickened and shortened; the edges present small polypoid masses; there is no ulceration. Loosely attached in the auriculo-ventricular aperture there is a firm pale clot the size of a hazel-nut. On section there is softening in its centre. Mitral orifice measures three inches and an eighth. Left ventricle is hypertrophied and dilated. No ulceration of endocardium. The aortic valves nearly healthy. Liver natural; weighs twenty-four ounces. Kidneys weigh together six ounces; a small red infarction on the surface of one. Spleen weighs three ounces and three-quarters: the lower two-thirds of the organ consist of a thin-walled sac, full of dark red grumous fluid. Within this cavity there is a piece of splenic tissue remaining, the size of a chesnut; this contains softening infarctions. In the upper third of the organ there is a small yellow infarct. The splenic artery, where it enters the spleen, is blocked by pale adherent thrombus.

Notes.

In vol. v. of the *Clinical Society's Transactions* there is a paper by Dr. Andrew on a case of wide daily range of temperature in rheumatism with disease of heart and infarctions of spleen. The main facts are the following:—A boy, aged sixteen, who had had rheumatic fever two years before, and again three weeks before admission to Victoria-park Hospital, was admitted with signs of mitral disease and enlargement of spleen. The spleen enlarged during the first three weeks of his stay in the hospital, and then diminished. There was no excess of white corpuseles in the blood. He had marked dyspnœa, unattended by sufficient physical signs of lungs or pleuræ to account for it. There was extreme anæmia, muscular weakness, and drowsiness. There was pyrexia of the hectic type, and when the spleen was at its largest the diurnal range of temperature was widest—viz., from 98·8° in the morning to 105° in the evening. There were no rigors.

At the post-mortem there were large, soft, reddish-brown vegetations on the free edge of, and auricular surface of, the mitral valve. The spleen was enlarged, and presented infarcts in various stages. There were some infarcts in the kidneys. The lungs presented nothing abnormal except slight congestion posteriorly.

It was with the foregoing paper in view that Dr. Gee was led to associate the pyrexia of Case 1 with splenic embolism, and enlargement consequent thereupon. Although at first there was a little diarrhœa, there were no rose-red spots to justify a suspicion of typhoid. With respect to the other common cause of persistent pyrexia, although it is true that some very slight evidence of tubercle was found post-mortem in the right lung and the right bronchial glands, yet this was obviously of old date; it was, in fact, cicatricial.

In Case 1, the endocarditis, although probably progressive, was not ulcerative in character, and the pyrexia could not be attributed to it *per se*. The varying enlargement of the spleen, which was at times visible as well as palpable, and apparently on one occasion sufficiently irritating to set up some local peritonitis, appeared to be the cause of the pyrexia, in the absence of anything else which could satisfactorily explain it. Other points of interest in this case are:—1. The enlargement of the spleen backwards and upwards as well as downwards. In children the spleen often extends right back to the spinal column, and posterior splenic dulness may be easily mistaken for pleuritic effusion. 2. The anatomical peculiarity of the left lobe of the liver extending across and above the spleen. 3. The adhesion of the pericardium to the costal pleura, thereby bringing the heart's apex forwards to the chest-wall, and leading to the suspicion of an amount of hypertrophy which not exist. 4. The distinctly systolic character of the murmur, along with a moderate degree of mitral regurgitation. The source of the cerebral hæmorrhage remained a mystery. No aneurism and no disease of vessel could be made out.

In Case 2 the endocarditis was of the ulcerative form; and to this fact the pyrexia might possibly be referred by some, but it is a question whether, even in ulcerative endocarditis, the pyrexia is not due to the discharge of emboli into the blood-stream and the inflammatory disturbances set up by these emboli in the organs wherein they lodge. In a clinical leeture by Dr. Cayley, published in this journal November 10, the term "infecting endocarditis" is suggested, because in the case which forms the text of Dr. Cayley's lectures there were symptoms of ulcerative endocarditis without ulceration, and because "one of the most prominent results is the infection of the blood with some morbid poison." In the light of Case 1 it seems reasonable to believe that the condition of the spleen was responsible for part of the child's pyrexia in Case 2. On that organ fell the brunt of the patient's troubles; and the severity of the disturbance set up by the embolisms may be measured by the evidence of hæmorrhagic softening of the lower two-thirds of the organ. It is of interest to note that in this case the edge of the spleen could not be felt below the thoracic margin, and the tenderness felt once or twice in the left hypochondrium was the only suggestion of local trouble.

SATURDAY, NOVEMBER 17, 1877.

PROFESSOR VIRCHOW ON THE PENGE CASE.

Some member of the English medical profession, believing that at the present time the state of public opinion amongst us is unfavourable to the formation of a thoroughly unprejudiced judgment on the Penge trial by an English medical man, has furnished Professor Virchow, of Berlin, with the details of the post-mortem examination, and of the opinions expressed on it by the doctors present at the time, and by Drs. Payne and Greenfield and others afterwards, and has begged him to act as a kind of umpire, and declare into which scale he throws the weight of his universally recognised authority. Professor Virchow has responded to the appeal in the article a translation of which is given elsewhere in our pages, though we propose to lay the gist of it here also before our readers.

In the first place, he emphatically declares that our system of post-mortem examination for forensic purposes is faulty in the extreme, and he reiterates the words which we ourselves employed in an article published in this journal of October 6 page 392—that the late trial "shows the utter folly of leaving, such inquiries in the hands of men not specially trained to, and skilled in conducting them," and confirms our further remark that "it is high time the system of medical evidence in criminal cases were reformed."

Passing on to the post-mortem examination of Harriet Staunton's body, he makes two main objections to the forensic value of the medical report on it, and the deductions from the latter—viz., that on the one hand the autopsy was not made with sufficient care and thoroughness, nor the written description (*Protokoll*) of it drawn up with the necessary accuracy; and that, on the other hand (if we understand him rightly), the imagination was allowed too much play in the testimony of those gentlemen who came forward to oppose the plea of the prosecution that death was due to enforced abstinence from food.

Speaking of the first objection, Professor Virchow calls special attention to the discrepancies between the joint report furnished by the committee who made the post-mortem at which Dr. Wilkinson was present, and Dr. Wilkinson's own notes of the latter. The first stated that "adhesions were found" between the arachnoid membrane and the pia mater, "showing the existence of previous inflammation"; and the second, that "there was no trace of meningitis, *no adhesion*, and no effusion."

Professor Virchow's comment here is:—"What must the judges, statesmen, and the public generally think of experts (*Technikern*), who not only cannot state the facts accurately, but who give different descriptions of facts which they observed in common!"

Turning next to the question, whether the so-called "tubercular deposit" in the pia mater (joint report) or arachnoid (Wilkinson) was really tubercular, and, if so, whether it was the true cause of death, Professor Virchow cleverly avoids giving a decided opinion for or against "tubercle," though he rather implies that the latter might have been nothing but Pacchionian corpuscles, or, in his nomenclature, "arachnoidal warts." He expresses himself, however, with great plainness as to the theory that Harriet Staunton died of tubercular meningitis. He says (*loc. cit.*)—"I can only state that neither my own personal experience, my acquaintance with German criminal trials, nor my knowledge of forensic literature, would justify me in concluding that a single deposit of tubercle, even of the diameter of twenty-one millimetres, was the cause of a person's death—least of all if it were situated on the surface of the convexity of the left cerebral hemisphere." He goes on to say that the reports of the autopsy do not allude to any changes in the adjacent parts of the brain, to any fresh inflammatory alteration in the neighbourhood of the deposit, or to the existence of any exudation; and he asserts that "the well-marked congestion of the brain and its membranes," to which reference is made, "must have been described very differently from what they were, especially in a corpse six days old, to be accepted as a proof of general inflammation of the brain and its membranes."

After some caustic observations on the terminology adopted in the reports of the post-mortem, and on the way in which Drs. Payne and Greenfield assumed that Mrs. Staunton's death was due to meningeal tuberculosis, and attempted to explain the symptoms observed during life, and especially the loss of flesh and wasting, on this hypothesis—Professor Virchow refers to his second objection to the medico-legal conduct of this unhappy case, on the ground that the two witnesses just named, in their zeal for their hypothesis of tuberculosis, allowed the *possibility* (the italics are Virchow's) of food having been purposely refused to be thrown completely into the background, or, more accurately speaking, to be quite lost sight of. "The human fancy is only too apt to overlook all the possibilities which actually occur in nature and in the course of human existence. . . . Hence we older men are ever warning the members of future generations not to enter too minutely into all those possibilities which their fancy pictures when they are called on as physicians to give a technical opinion, and not to get outside the question of the cause of death and the circumstances under which death itself took place, and to embrace in their decision the whole series of biological events which led up to it, and which form the proper (judicial) domain of the judge and jury."

We shall give the remainder of the article in Virchow's own words, which can hardly be too often repeated:—"Did Harriet Staunton," he asks, "die of tubercle of the arachnoid? Certainly not, if Dr. Wilkinson's report is correct. Perhaps, if Dr. Longrigg's account is reliable. But are we called on to decide whether the first or second opinion is the right one?

"If Harriet Staunton died of arachnoidal tuberculosis, her wasted condition *may* have been due to the latter. But it is still somewhat difficult even to prove the *possibility* of its

having been so. As a fact, a body-weight of seventy-four pounds is very small, remarkably small indeed for a person of thirty-five years. Dr. Greenfield is quite aware of this, and hence inclines to the view that Harriet Staunton was already mentally diseased and the subject of general paralysis before she became tuberculous. Such a contingency is also possible, but whether it is, cannot be decided by the autopsy, but only by the evidence of witnesses who can testify to the course of events during life; and in default of such evidence (for what is before us is quite insufficient for the purpose) there is always the possibility remaining that the patient was intentionally deprived of food. Yes, even if the existence of mental disease were proved, this possibility would, as this particular case stands, still appear admissible. Hence the medical verdict offered to the court should have been—"Not proven." (*Das ärztliche Urtheil musste demnach in der Gerichtsverhandlung lauten: Non liquet.*) Such is my unprejudiced opinion; may it help in some slight degree to clear up the views which have been expressed (on this case) on the other side of the Channel, and to introduce there also order, certainty, wise reserve, and the knowledge which springs from previous study (*vorbereitete Kenntniss*) into forensic practice."

PARTIAL BALDNESS.

The pathology of Alopecia areata, or Area Celsi, has of late years attracted much attention among dermatologists, and various attempts—not very successful, it must be admitted—have been made to explain the formation of circumscribed smooth, more or less circular, hairless patches on the scalp and other hairy regions of the body. The latest contribution to this question is a lecture by Dr. P. Michelson, of Königsberg (Prussia), in No. 120 of Volkmann's *Sammlung Klin. Vorträge*, in which the author unreservedly rejects the idea of a parasitic origin for Alopecia areata (Gruby, Malassez), and regards the disease as due to arrest of growth in the hair itself, "leading," as Bärensprung puts it, "to a more scanty production of the cellular elements out of which it is developed." The structural alterations in the root of the hair—loss of its bulbar swelling, absence of defined cellular elements in the root-sheath, fibrillary splitting of the shaft in a longitudinal direction, etc.—described by Michelson and others (curiously enough, no allusion is here made to the papers of Duckworth and Bristowe), are not characteristic of Alopecia areata, but are met with in other diseases in which the nutrition of the hair is interfered with. What is it that causes these alterations in the case of Area Celsi? Will the neurotic theory explain them? and "must," as Duhring says ("Diseases of the Skin," 1877), "the fall of the hair be viewed as a state of perverted innervation, and can the suddenness of the attack be only accounted for by regarding the nervous system at fault?" Michelson answers that, in the first place, the symptom of *diminished sensibility* of the affected skin, which is usually regarded as a proof of perverted innervation, is not constant, and he gives the details of some careful observations on a case of his own, in which the sensibility was, on the contrary, *increased*. The headache, which not unfrequently accompanies the development of the affection, he also regards as not improbably due to a chronic inflammatory process in the soft tissues of the head, and he points out that the instances of loss of hair or baldness following injuries of nerves will not bear very close examination, and that this symptom is not mentioned as having occurred in any of the numerous cases in which section of nerves has been performed by modern surgeons. Further, it is not certain that those alterations in the growth of hair and the nutrition of the skin, which have been reported as following gunshot injuries of nerves (Weir-Mitchell, Fischer, and others), and which have been referred to lesions of "trophic" nerves, are really due to the latter, for it has been shown by Kölliker that some at least of these alterations occur if a limb is, as was the case in the above instances, confined for a long period in a close-fitting (plaster of Paris) bandage.

In any case only quite a small percentage of nerve-lesions is followed by alopecia; and to explain the occurrence of such a symptom as the general diffuse baldness, which is sometimes met with, by a neurotic agency, it would be necessary, as Michelson says, "either to accept the hypothesis of a gradual implication of all the 'trophic' nerves of the skin, or else that of a trophic centre in the brain or spinal cord, which becomes the seat of a gradually progressive disease."

The existence of such a centre is absolutely hypothetical, and by no means probable, and the evidence in favour of a lesion of "trophic" nerves is also extremely slight. Hence Michelson concludes, and we think justly, that "the neurotic origin of Alopecia areata is, in the present state of medical science, an unproven hypothesis." He confesses, however, that he is unable to substitute for it a better one, but he agrees with Hutchinson that one element in the causation of the disease is "a lowering of the general nutrition of the body." Another element (purely hypothetical) may possibly be a diminution in the calibre of the bloodvessels, which would explain the remarkable pallor of the affected skin; and, lastly, the *disappearance of the subcutaneous cellular tissue, and thinning of the skin itself*, which is a nearly constant symptom (according to Michelson), may constitute an earlier stage of the same process which ends in loss of hair, though, of course, until we know why the subcutaneous tissue, etc., atrophies, we are no nearer the true explanation of the origin of the disease than we previously were.

It is evident from the foregoing that Alopecia areata is still an unsolved mystery. Whether careful microscopic examinations of sections of the *skin* in the diseased area, which are much needed, will eventually throw any light on its *rationale*, we cannot say, but persons with a love for original investigation may be reminded, in the words of an anonymous English author, with which Dr. Michelson closes his lecture, that "there is no subject that more invites the study of those who would fain leave science more advanced than they found it."

THE GOLDEN-SQUARE HOSPITAL.

It will be remembered by our readers that the award recommended by the Distribution Committee of the Hospital Sunday Fund to be made this year to the Hospital for Diseases of the Throat was withheld by the Council in August, on the ground of an impending investigation into certain charges against the management of that charity. The committee of investigation was appointed at the request of H.R.H. the Prince of Wales, the patron, and consisted of the Duke of Grafton and the Earls of Clarendon and Dunmore, with Sir William Gull, it is said, as an adviser. Since the inquiry, and it may certainly be held as a result of it, H.R.H. the Prince of Wales has withdrawn his patronage from the Hospital, and the Marquis of Bute has resigned the presidency, while shortly or just before it some members of the committee and of the staff of the Hospital sent in their resignations. And it may be added, as a fact of apparently some significance, that Sir William Jenner some time ago resigned the office of consulting physician. All this must, unless explained away, produce a very unfavourable impression on the public with regard to the management of the Hospital, but we have hitherto declined to take any notice of the matter till it should come before us in some authentic shape, by the publication of the report of the Committee of Investigation, or by some action on the part of the Hospital Committee. As yet, however, both parties have, as far as the public are concerned, remained silent. On the 5th inst., however, the Council of the Sunday Hospital Fund, at their meeting, took into consideration a request made by the Committee of the Hospital to be allowed to send a deputation to be heard in explanation of certain charges of mismanage-

ment which had been the subject of inquiry by what we may call the Prince of Wales' Committee. The Council felt bound to go into the matter, as the Distribution Committee, whose award they had temporarily withheld, had virtually ceased to exist, and it therefore rested with themselves to finally decide the matter after considering the official report of the Committee of Inquiry, which was laid before them. This was read, and, after a short discussion, the Council agreed to the following resolution:—"That this Council, having heard read to them the report of the Committee appointed to investigate certain charges made against the management of the Hospital for Diseases of the Throat, and signed by the Duke of Grafton and others, resolve that, in existing circumstances, the award recommended by the Distribution Committee be not sanctioned by the Council." It was ordered that a copy of the resolution should be sent to the Committee of the Hospital, with the information that the Council declined to receive the deputation. We do not know whether the report of the Committee of Inquiry will now be made public by them, or not; but we confess that we hold a strong opinion that it ought to be, in justice to the public who support the Hospital, and in justification of the Committee of Inquiry, and of the Hospital Sunday Fund Council. The results of the investigation have already been very serious, and the prosperity and status of the Hospital cannot but be still more gravely injured if the present silence on the whole matter is maintained. If the Hospital is not to sink deeply in the regard of the public and the profession, the cloud at present hanging over it must be cleared away. Why do not the present Committee of Management, or the present Professional Staff, or both, demand the publication of, or make public, the report of the Committee of Inquiry, and refute the charges made against the management; or show that where, if anywhere, defects or errors were proved, they have been remedied? If neither the Committee of Management nor the Staff care to move in the matter, the public have surely a right to know why the management of a public charity has been so gravely impugned.

THE WEEK.

TOPICS OF THE DAY.

It is not satisfactory to find, from the Thirty-first Annual Report of the Commissioners in Lunacy, that there has been no check to the steady increase of insanity in England and Wales. Ever since the year 1859 there has been a steady and almost uniform rise in the number of insane persons, at the rate of about 1000 a year, and the total has now increased from 36,762 to 66,636. The last year's returns give an increase (considerably above the average) of 1720, and the result is noticeable from the fact that in the preceding year the number had fallen to the lowest ever recorded—viz., to 1123. The most favourable year before 1875 was 1865, when the recorded increase was only 1155; and the highest total was reached in 1869, when it amounted to 2177. The insane, in fact, are fast gaining ground upon the sane; and whereas the general population augments only at the rate of 1½ per cent., that portion of it which is of weak or deficient intellect is found to be increasing at the rate of fully 3 per cent. The class of the community which contributes most largely to insanity is the poorest, which fills the pauper asylums. In 1859 there were 31,782 persons in these latter establishments, and 4980 in private asylums, or, roughly speaking, about six of the poor to one of the rich. On the first day of the present year the figures were respectively 59,039 and 7597, making the proportion nearly eight to one. In only one year (1868) has there been a decrease in either class, and then it amounted only to fourteen in the private houses, counterbalanced by an increase of 1929—or more than 300 above the average—in the pauper lunatics.

Amongst the uneducated classes there are several kinds of wager prevalent, but we are inclined to think the following history unique. At an inquest held at Leicester on the body of a man named Ira Humphries, aged twenty-seven, it was elicited that the deceased, a stone-cutter, was at a house called the "White Swan" in company with others. He made a wager with another man that he would eat a certain quantity of raw meat; some raw beef was fetched from a butcher's, and the deceased ate it, but soon after became very unwell. He was taken to a chemist's for advice, and then returned to the "White Swan," and shortly afterwards was found lying on the floor near a furnace in the back-kitchen, quite dead. It was supposed he was suffocated; there was, however, no evidence to show that death arose from other than natural causes, and a verdict to that effect was returned. Query: Are these wagers relics of the horribly barbarous ages in which our grandfathers lived, or are they developments of the all-improving powers of national education?

The members of the Noxious Vapours Commission, of which Lord Aberdare is the chairman, have recently visited Swansea, and have inspected and taken evidence as to copper and other works. During the past weeks the Commissioners have held sittings in London, and have commenced the consideration of their report.

The Volunteer Sick-Bearers' Association has now commenced its work, with the object of providing for the reserve forces a medical or ambulance department within themselves (without interfering with the combatant strength of the various regiments), by instructing the medical officers and two or more men per company in the most important duties of attending to sick and wounded men in the field. It is intended to instruct those who are willing to attend, in the primary dressing of wounds, the methods of stopping profuse bleeding, and removal of wounded men from the field to ambulances in the rear, thus saving valuable lives, which, without such aid, must necessarily be sacrificed. The first of a series of lectures and drills will be given at the rooms of the Society of Arts, Adelphi, on Friday, November 23, at seven o'clock, and will be followed by three similar lectures on the evenings of November 30 and December 7 and 14, after which it is expected they will be continued at the Albany-street Barracks Riding-school, Regent's-park. None but members of the Volunteer Force are eligible for admission, and all particulars may be obtained of Mr. A. Maclure, jun., 97, Queen Victoria-street, E.C.

A death is reported to have taken place at Lincoln on the 5th inst. from the administration of ether. Miss Steele, daughter of the late Captain Steele, who had resided for some years in the house of Dr. George May Lowe, of Lincoln, was about to undergo an operation for cancer. The ether was administered by Dr. Mitchinson, in the presence of Dr. Lowe and Mr. Septimus Lowe. The result of the post-mortem examination showed hidden organic disease fully sufficient to account for death.

The President of the Local Government Board last week received a deputation from the inhabitants of the parish of Wilmslow, with reference to the scheme of the Rural Sanitary Authority of the Altrincham Union for the sewerage of the district, and the proposal to constitute Wilmslow a local government district.

The spread of education, and consequently of common sense, if sure, is certainly very slow. At a meeting of the York Board of Guardians, held last week, it was stated that an outbreak of scarlet fever had occurred in the Walmgate district owing to the practice of "waking" the dead which prevailed amongst the Irish who inhabited that quarter. In one fatal case a "wake" had been held over the body of a child whose death had resulted from scarlet fever, and, notwithstanding a warning from an official, had been kept up for three or

four days. Fifteen or twenty cases of scarlet fever had followed in the district. If there is no law at present in existence to deal with this indecent and senseless practice, it is certainly time that legislation stepped in for its prevention.

The report of the Sanitary Committee of Guardians of the City of London Union upon the small-pox epidemic of this year is noticeable from the fact that it proves, on the very best testimony, how general vaccination and revaccination have become, in spite of inflammatory efforts on the part of sundry agitators to prevent such a desirable state of things. The Committee on being appointed immediately placed themselves in communication with the six district medical officers, and amongst other precautions it was suggested that house-to-house visitation was most desirable, as a means of ascertaining not only if the vaccination of any children had been omitted, but also what unsuccessful cases were apparent in the adults, and to impress upon the people generally the necessity of re-vaccination. One of these district medical officers, Mr. Alder Smith, states that in the public schools in his district—four in number—he examined 492 boys and girls, and found only six who had no marks, and seven with bad ones requiring revaccination. The very small number of children found unprotected in these schools clearly shows that the people, as a rule, have been well vaccinated, and reflects credit on the satisfactory manner in which the public officers of the City of London Union have carried out their duties in this respect. This is corroborated by the return recently issued by the Metropolitan Asylums Board, which shows that from October, 1876, to September, 1877, only ninety patients were admitted to the small-pox hospitals from the City of London Union.

Sunday last in Dublin was devoted to the annual collection for the local hospitals. Earnest appeals were made in all the Protestant and Dissenting places of worship in the city and county on behalf of these charities. The churches were in general well filled, considering the weather, which was very inclement. The result of the appeal has not yet reached us. In the Jewish Synagogue the collection was made on the previous day, and £27 was subscribed. As in the three previous years, the Roman Catholics declined to join the scheme, and consequently the hospitals which are under their management do not participate in the result of the collection.

The Medical Officer of Health for Bradford, Mr. Butterfield, in his last report made several suggestions in reference to the treatment of persons afflicted with scarlet fever, pointing out the necessity of taking ample precautions to prevent the spread of the disease. It appears that recently numerous cases of scarlet fever have occurred in the town, and it is of importance that the utmost care should be exercised to prevent the occurrence of an epidemic of this disease. The town, however, is provided with an establishment which is set apart specially for the treatment of fevers of all descriptions, and as it will therefore be possible to isolate the earlier cases, the medical officer, if properly supported, should have no difficulty in dealing with the threatened outbreak.

At the annual meeting of the Royal Albert Hospital, recently held at Devonport, Mr. Tremayne, M.P., said that no one could dispassionately examine the evidence which public returns supplied, without coming to the conclusion that the Contagious Diseases Acts were beneficial, and ought to be extended to all populous places. The great difficulty they laboured under was that, although they could stamp out disease in their own districts, the Acts could not prevent the importation of disease from outside the area of their operations. Admiral Willes, C.B., said he should be glad to see these Acts universally applied; but Mr. Tremayne, in reply, observed that he did not go so far as that, but only to places where there were large aggregations of people; and he hoped the animosity against them in some quarters would be removed. The opinion of a large meeting in these views was unanimous, several other influential speakers bearing testimony to the excellent results from this Act of the Legislature.

An unfortunate sectarian difficulty would seem to have arisen in connexion with the nursing arrangements of the Glasgow Royal Infirmary. A charge has been made of undue preference and partiality being shown in the appointment of nurses of the Roman Catholic persuasion to the nursing staff of the Infirmary. At first this charge was met with an authoritative denial, which it was thought would be sufficient to allay the apprehensions of the West of Scotland Protestant Association; but subsequently, for the satisfaction of the public, it was determined to institute a thorough investigation, and the result has now been circulated. The report of the House Committee, to whom the task was confided, would appear to rebut any charge of undue preference in the selection of Roman Catholic nurses; and it is to be hoped, for the welfare of a large and very useful institution, that these religious differences, which are by no means of an important nature to the physical well-being of the sick in the Infirmary, will now be definitely set at rest.

Our readers will not have failed to notice the recent trial at the Northampton Assizes, in which a gross charge was brought against a surgeon; fortunately the testimony of several eminent medical witnesses, who all came forward to give their evidence gratuitously, succeeded in saving the reputation of an innocent man. But the moral of this case, which we would strongly impress upon all medical men and dentists, is, never to administer an anæsthetic without the presence of assistants or witnesses. If this rule had been adhered to, the charge to which we allude could never have been made, or, bearing in mind the valuable evidence given by Dr. B. W. Richardson at the trial, if made could instantly have been rebutted.

Dr. William Wright, for many years Resident Medical Officer of the General Dispensary, Pontefract, was last week found dead in his sitting-room at that institution. The unfortunate gentleman had been attending his patients as usual during the day, and had shown no symptoms of being indisposed.

PRECAUTIONS AGAINST HYDROPHOBIA AND MAD DOGS IN FRANCE.

M. Proust, a candidate for the vacancy in the Section of Hygiene in the Académie de Médecine, read before that body on the 6th inst. a paper—"Results of the Official Inquiry Concerning the Cases of Hydrophobia observed in France from 1850 to 1876." He terminates his memoir with the following conclusions:—1. Cauterisation being up to the present time the sole prophylactic known, it would be of interest to obtain a statistical account, not only of the caustics employed, but also of the manner in which they were applied, and the exact time which had elapsed between the rabid inoculation and the cauterisation. 2. The contagious transmission often taking place by means of little pet dogs, whose sickness at first gives rise to no distrust, an instruction having for its object the making generally known the early symptoms of the disease, would prove of great efficacy against this form of the contagion. The dog is not only dangerous when, according to the happy expression of Professor Bouley, it has lost its reason, and is only dominated by the ferocious dispositions which the disease has engendered. It is more perfidious while the sentiment of affection is still vivid, and, with its slaver already in a virulent condition, it dangerously caresses more than usual individuals with whom it is familiar. The opinion so prevalent that rabid dogs always and necessarily manifest a horror of water, is absolutely false. So untrue is it, that they have been known to traverse rivers in order to attack flocks of sheep which they have seen from the opposite bank. 3. The provisions of the sanitary police should be always rigorously applied in winter as in summer, and that alike against suspected dogs and those actually rabid. The

measures employed should be: the obligatory wearing of an official collar, the seizure and slaughtering of all stray dogs and of dogs unprovided with collars, the slaughtering of rabid dogs, and the slaughtering or sequestration for eight months of all suspected dogs. Notice should also be given that in case of accidents or death being caused by rabid dogs, their proprietors may, by the French law, be prosecuted, independently of their liability to civil action for damages.

THE EFFECTS OF FARADISATION IN HYDROPHOBIA.

In a note, communicated by M. Bouley, read at the Académie des Sciences, at its meeting on October 29, M. Mennesson relates the case of a young veterinary surgeon who contracted hydrophobia at an autopsy that he had the imprudence to conduct while having some excoriations on his hands, which came in contact with the saliva contained in the buccal cavity. About three months after this inoculation symptoms of hydrophobia manifested themselves with fearful intensity; but the point of interest in the case is the palliative effect that was produced by faradisation. This was practised by applying one of the poles to the nape of the neck, and the other to the sole of one of the feet. Immediate relief ensued, a remarkable calm succeeding to the excessive excitement, the patient being able to converse and drink water without the spasms occurring which its sight or contact had hitherto induced. The action of the current causing great pain, it was, at the request of the patient, interrupted, and the convulsions at once returned, as fearful as ever. The patient's sufferings lasted for two days, only temporarily relieved whenever the application was made, and he then suddenly expired. The relief in this case was so decided that it forms an encouragement for future trials of faradisation in the region of the bulb.

As this case was only presented, and not observed or reported, by Professor Bouley, we may freely remark that the report is so imperfect and wanting in scientific accuracy that the case is curious rather than anything else. It would have been important had we been informed how soon after death the autopsy of the dog was made, for it would be very instructive to know how long after death the saliva of a rabid animal retains its specifically poisonous quality. The form of faradisation used appears to have been the "general faradisation" so largely employed by Drs. Beard and Rockwell, of New York; and we may remark that in the second edition of their large work on Electricity, published in 1873, they suggest a trial of electricity in the treatment of hydrophobia; but they, naturally, suggest *central galvanisation*, rather than faradisation. We need hardly add that faradisation tetanises the muscles.

RABIES AND HYDROPHOBIA.

We are informed that the Scientific Grants Committee of the British Medical Association, at a meeting held on Wednesday, appointed a Committee consisting of Mr. Callender, Dr. Burdon-Sanderson, Dr. T. Lauder Brunton, and Mr. Ernest Hart, to organise an investigation into the causation, pathology, and treatment of rabies and hydrophobia; and the Committee of Council of the Association have granted the sum of £100 towards the expenses of the inquiry. It is understood that the inquiry will be divided into various heads. Under the first, an investigation will be made into the locality and order of succession in time of the registered deaths from hydrophobia in this country during the last few years; and this will form the basis of an attempt to trace the history of various local epidemics with the aid of such medical men, medical officers of health, and veterinary surgeons as may be found to be in possession of facts relating to such epidemics. The pathology of rabies will be investigated by the aid of a microscopic and chemical research to be carried on by eminent pathologists and physiologists; and, for this purpose, post-mortem specimens will be requested from those whose duty it becomes to make the necropsy of fatal cases of hydrophobia and rabies. Special directions will be issued as to the best means of preserving for microscopic examination those parts of the nervous system and the salivary organs of which the examination is most likely to afford the necessary information. The tabulation and investigation of any methods of treatment which have seemed to afford a hopeful prospect, and the investigation of the action of remedies to which efficacy has been attributed, will form the subject of the third part of the inquiry. The investigation is one which appears to be urgently called for; and the assistance and co-operation will be invoked, not only of specially skilled experts in histological and chemical investigations, but of those members of the profession generally who have had recently, or who may have during the progress of the inquiry, cases either of rabies in the dog or of hydrophobia in man.

THE ADMISSION OF VISITORS TO FEVER HOSPITALS.

Mr. Hopkins Walters, M.R.C.S., has recently reported a case to the Local Government Board which affords a sad illustration of the evils which arise from carelessness in admitting visitors to patients in fever hospitals. In July last a domestic servant named Rosa Ball was admitted into the fever hospital at Stockwell, suffering from scarlet fever. After her admission she was attacked with small-pox. During her illness she got a fellow-patient to write to her father in the country, informing him of the fact. He went to the hospital, and was admitted to see his daughter without being told of the nature of the disease from which she was suffering. After leaving he went home, and almost immediately fell sick of small-pox. His wife was first attacked, and then six other persons, four of the cases terminating fatally. Mr. Walters is of opinion that there was great neglect of duty somewhere, especially with regard to Mr. Ball having been admitted without, in the first instance, being informed that his daughter was ill with small-pox; and also because proper and necessary precautions were not taken whilst he was in the hospital with a view to prevent him from catching the disease. It would be wrong in all cases to refuse to admit the nearest friends of patients in fever and small-pox hospitals, but the dangers connected therewith should be clearly pointed out, and, as far as possible, precautions taken to prevent the spread of contagion.

AMERICAN AMENITIES.

Charges of plagiarism are not unknown among ourselves, but in this, as in so many other things, our American cousins certainly beat us hollow. In the *St. Louis Clinical Record* the following recently appeared under the heading of "Honours to an American":—"Several of our contemporaries are giving great prominence to Dr. Sayre's very flattering reception in England. It seems that Dr. Sayre went to England to advertise his (*sic*) method of treating spinal curvature. He intends to publish a book describing his (?) processes, and expects a large sale under an English copyright. This would be all very well—in fact, just as it should be—if Dr. Sayre had ever invented anything, which he never did, so far as we are informed. 'Dr. Sayre's hip-joint splint' was invented by Dr. Davis. 'Dr. Sayre's plaster-of-Paris jacket' was invented and first applied by Dr. Bryan, of Lexington, Kentucky. 'Dr. Sayre's method of self-suspension in rotary-lateral spinal curvature' was invented by Dr. Benj. Lee, of Philadelphia. 'Dr. Sayre's Lectures on Orthopædic Surgery' were by Dr. Louis Bauer, formerly of Brooklyn, New York, now of St. Louis. As a plagiarist and 'father of other men's ideas,' Dr. Sayre is without a rival. We are glad to see that our English cousins delight to honour such representative Americans (Heaven save the mark!) as P. T. Barnum and L. A. Sayre. *Vive le humbug!*"

The charges made against Dr. Sayre are so wholesale and gross, that we should not notice them had they not been quoted by so respectable a journal as the *Philadelphia Medical Times*, with the remark that, "if true, they ought to be generally known, and, if not true, ought to subject the editor of the *Record* to damages for libel"; and not even then, had they not been partially noticed by one of our English contemporaries, and been deemed worthy of a reply by Dr. Sayre himself. In the following number of the *Philadelphia Medical Times*, that of October 27, Dr. Sayre declares that each and every one of the charges "is wholly and absolutely false," and he refutes them *seriatim*. In answer to the first, he refers to the *Transactions of the American Medical Association* for 1860, pages 505 to 508, and to his "Orthopædic Surgery and Diseases of the Joints," and points out that the specifications of Dr. Davis's splint, which was patented, show that it is entirely different from his own, which was given to the profession. Secondly, he refers to his own works in proof that he has done full justice to Dr. Bryan. Thirdly, he remarks that in his work on Spinal Curvature, just published in England, he has noticed that "the late Professor Mitchell, of Philadelphia, used to treat cases of lateral curvature by suspending them under the arms, and causing them to suspend themselves by the hands," and that Dr. Benjamin Lee "was the first person who caused his patients to practise *self-suspension*," etc. And fourthly, he remarks that his book on Orthopædic Surgery was published from stenographic notes of his lectures, taken at the time of delivery, and that "most of the lectures were upon cases presented at the time in the lecture-room, and which Dr. Bauer could never have seen, as he at the time lived in St. Louis." If Dr. Sayre's friends in England think that any answer to the charges made against him was needed, they will certainly deem his refutation complete and satisfactory.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

At the meeting of the Council of the Royal College of Surgeons, on the 8th inst., several important questions were taken into consideration. The report of the Committee on the dental diploma or licence of the College was adopted, with the important amendment that lecturers on dental anatomy and physiology may be members of the College only, or licentiates in dental surgery only. It will be remembered that in commenting on this subject, some time ago, we insisted that the College could not cast such a slight on the value of their own dental licence as to declare that its possessors are unfit to be lecturers and teachers in the subjects examined in by candidates for it. Mr. Simon's proposals, that the rule that only Fellows of the College shall be eligible as examiners in anatomy and physiology, shall be rescinded, and that further it is desirable to appoint separate examiners for each of the two subjects, were referred to a committee, who are to consider the matters and report to the Council. The first proposal, which, we believe, is grounded on the fact that the majority of the lecturers on physiology in London schools are physicians, appears to involve a principle and to be rather for consideration by the Council than by a committee. And as to the second, we should fear that an examiner who devotes himself only or mainly to physiology would be likely to expect too wide or too deep a knowledge of the subject from the average student. Though physiology is one of the foundations of medical science, no large knowledge of it can be well asked for from the great majority of candidates—the candidates for the minimum qualification to practise. We shall not be surprised, however, to hear that both proposals are held over for the consideration of the Committee of Reference and the examiners of the Conjoint Scheme. The representatives of the College on the Committee of Reference are appointed, as will be found stated elsewhere in our columns. At an extraordinary meeting of the Council, Mr. John Birkett, the President, was re-elected on the Court of Examiners.

REPORT ON THE HEALTH OF THE POLICE FOR THE YEAR 1876.

The report of the Chief Surgeon on the health of the Metropolitan Police Force for the year 1876 calls, as its author admits, for little comment. The rate of sickness, as measured by the daily loss to the service, is exactly the same as last year, the number of cases being slightly greater, but their average duration somewhat less. The year was marked by no peculiar hardship of service, or peculiarity of weather, or epidemic disease, as the outbreak of small-pox, which commenced in London in the latter months of 1876, only contributed three cases, and any further effects from this epidemic will be shown in the records for the succeeding year. The practical inferences to be gathered from this and previous reports are—that under the present system (which is confessedly not one of the strictest medical supervision) the daily average loss from sickness is a little over 3 per cent., and cannot be reduced below that rate; that the nature of the cases of sickness is, as a general rule, not severe, the duration being short, and the death-rate low (about 5 per cent.); and that the rates of men who receive pensions on account of sickness or physical infirmity is, as nearly as possible, 2 per cent. per annum. The principal causes of unfitness amongst the men invalided were rheumatism, rheumatic gout, and sciatica; age, long service, and debility; and phthisis, and disease of the lungs.

THE UNIVERSITY OF LONDON.

A requisition, addressed to the Chairman of Convocation of the University of London, to summon an extraordinary meeting of Convocation, has, we believe, received a certain number of signatures among the graduates. The subject proposed to be brought before the House is the desirability of obtaining a new Charter, which shall include radical changes in the constitution of the Senate, as well as other important reforms. We have not previously taken any notice of this requisition, as we believe its appearance highly inopportune in the present aspect of affairs in the University of London; and, in referring to it now, we would strongly urge the promoters of the requisition to refrain from further action in the matter during the approaching crisis. The ordinary meeting of Convocation is held early in January, and on that occasion the Annual Committee will present their report on the conference with Senate, and the whole subject under discussion will be regularly re-opened.

THE COMMITTEE OF REFERENCE OF THE CONJOINT SCHEME.

Half of the number of medical authorities concerned in the formation of the Conjoint Examining Board for England have elected their representatives on the Committee of Reference. Sir James Paget and Mr. Simon have been appointed representatives of the Royal College of Surgeons. Mr. Bradford and Dr. Corfe have been elected by the Society of Apothecaries; and Dr. G. H. Philipson and Dr. G. Y. Heath have been chosen to represent the University of Durham. The representatives of the Royal College of Physicians have not yet been appointed, nor have we heard who will be sent to the Committee of reference by the Universities of Oxford and of Cambridge.

The Berlin Hospitals in 1876.—The eleven hospital establishments received, during 1876, 30,217 patients, of whom 23,260 were discharged cured or improved, and 4110 died, giving a mortality of 13·5 per cent., 2857 patients remaining in the hospitals at the end of the year. The Charité, by far the largest establishment, received 13,705, of whom 1263, or 9·2 per cent., died; and the University Clinical Hospital received 1015, with a mortality of 14·4 per cent. In the Augusta Hospital, with 911 patients, the mortality rose to 18·5 per cent.; in the Lazarus Hospital, with 914, it rose to 23·6 per cent.; and in the General Town Hospital, with 4134, to 24·3 per cent.—*Deutsche Med. Woch.*, October 27.

THE SENATE AND CONVOCATION OF THE UNIVERSITY OF LONDON.

On Wednesday, the 14th inst., the deputation appointed by the Annual Committee of the University of London, to present a memorial on the subject of the differences between the two bodies, waited on the Senate at its ordinary meeting. The deputation consisted of Mr. Abbot, B.A., Dr. Curnow, Dr. Hilton Fagge, Dr. Tilbury Fox, Mr. McDowall, B.A., B.Sc., and Dr. Pye-Smith; and Dr. Tilbury Fox was spokesman. The following are the words of the memorandum laid before the Senate:—

"In pursuance of a resolution passed at an extraordinary meeting of Convocation, held on July 27, 1877, the Annual Committee of Convocation beg to submit to the Senate the following resolution, passed at the same meeting:—

"Resolved—'That this House regrets that the Senate has, by adopting a permissive Act of Parliament (Act 39 and 40 Vic., cap. 41), without reference to or consultation with Convocation, materially altered the constitution of the University, and has thus practically superseded the privileges of Convocation.'

"In proposing this resolution the following points were urged:—

"1. That the question submitted for discussion was not that of the admission of woman to the degrees of the University, but one affecting the privileges of Convocation only.

"2. That the Senate was legally justified in adopting the Act in accordance with the opinion of the law officers of the Crown; but,

"3. That, having regard to the permissive character of the Act, and the circumstances under which it was adopted, the Senate ought not to have exercised the powers conferred upon it by that Act.

"It was contended—

"That by the terms and intentions of the Charter, no fundamental change should be made in the constitution of the University without the joint action of the Senate and Convocation, and that the proper mode of effecting such change should be by obtaining power by means of a new or supplemental Charter asked for by the Senate and approved by Convocation.

"That a fundamental change would be effected in the constitution of the University by the adoption of the Act. That the opinion of the law officers of the Crown to the contrary was based upon the assumption that there was a 'slip' in the proviso of Section 1; whereas, in fact, women admitted to degrees in the University under the Act would not be excluded from, but would enjoy, the full privileges of graduates, including admission to Convocation. This contention was supported by the opinions of Mr. Farrer Herschell and Mr. Montague Cookson.

"That, by giving effect to the Act, the Senate would be dealing with one Faculty of the University in an exceptional manner, and would do in the medical what it could not do in other Faculties without application for a new Charter, which would require the consent of Convocation.

"That the Act being a purely permissive one, and applying to a number of other licensing bodies, there was the less necessity for the Senate to take so important a step as its adoption without consultation with Convocation.

"Lastly, that the action of the Senate was felt to be the more imperious to the privileges of Convocation, because it speedily followed the passing of the resolution contained in Minute XI. of the meeting of Convocation on May 8, 1877, which was as follows:—

"'That this House is of opinion that it is inadvisable for this University to admit women to the degrees in medicine before it shall have considered the general question of their admission to the degrees of all Faculties.'"

Our readers are already acquainted with the opinion of Mr. Farrer Herschell, Q.C., referred to above, as it was published at some length in the *Medical Times and Gazette* for August 4. Mr. Montague Cookson, Q.C., gives his opinion under three heads—First, that under Russell Gurney's Act, if it be adopted by the University of London, the word "graduate," as used in the Charter, has received a statutory extension, so as to include females on whom medical degrees have been conferred. Secondly, that members of Convocation are entitled to take part in the government, management, or proceedings of the University. And, thirdly, that the proviso contained in Russell Gurney's Act, and which has been alluded to above, does not neutralise the operation of the Act in the Charter, so far as relates to the right of women admitted to medical degrees to be regarded as members of Convocation, and to exercise all the privileges which, in the case of male members, that position involves. Before stating his opinion on the third and last head, Mr. Cookson says: "The words (of the proviso) are—'No person who but for this Act would not have been entitled to be registered shall, *by reason of such registration*, be entitled to take any part,' etc. Now, any woman holding a medical degree within Section 15 who may take part as a member of Convocation in the proceedings of the University, will do so, not by reason of being registered under the Medical Act, but by virtue of Sections 15 and 21 of the Charter, which confer this power upon her as holding the very degree which constitutes Convocation-membership; and all the proviso says is that registration shall not confer the title. It does not say, 'the degree shall not, anything to the contrary in the Charter notwithstanding.' To this it may be objected that if this be so the proviso is wholly inoperative, for that in none of the Universities or corporations to which it was intended to apply was there any connexion at the date of the passing of the Act, between registration under the Medical Act and the right to take part in the proceedings of the University or Corporation. Assuming this to be the fact, there is nothing unreasonable or absurd in supposing that such a connexion might be created thereafter, for it might well be that actual practice in medicine (which involves registration as a medical practitioner) might be made a qualification for the management of a medical Corporation, such as the College of Physicians, or the College of Surgeons. It is true that if a statute is manifestly intended to be remedial it must be so construed as to give the most complete remedy which the phraseology will permit; but this is not a remedial statute, but an enabling statute, which, *primâ facie*, is to be liberally construed; the proviso on the contrary being a disabling proviso, and therefore not to be enlarged beyond what the words necessarily import. There being nothing ambiguous or absurd in the Act, it is, in my opinion, to be construed according to its ordinary grammatical construction, without reference to any supposed motives which dictate the proviso, and without changing the words 'by reason of such refutation' into the words 'by reason of such grant of qualification,' or any other words not of equivalent meaning."

To this memorial the Chancellor returned a reply, which had previously been approved of by the Senate. The Senate, Earl Granville said, had agreed to receive the deputation from Convocation, and trusted that the conference might have the best results. The subject of the difference between the Senate and Convocation was the question of the admission of women to degrees in medicine. On more than one occasion Convocation had approved of the admission of women to all Faculties, and had recommended that a new charter should be obtained by which such admission might be secured. Convocation had disapproved only of the admission of women to degrees in medicine alone. The Senate, on the other hand, had passed a resolution to admit women to degrees in medicine under Russell Gurney's Act. In this difficulty the course which the Senate proposed to follow was that the University should proceed with a resolution passed by the Senate last summer—to apply for a supplemental Charter which should admit women to degrees in all Faculties. The Senate trusted that this proposal would meet the wishes of Convocation, and that Convocation would co-operate with the Senate in carrying the proposal into effect.

Having received this reply, or a reply of which this is the substance, the deputation withdrew, and will report the proposal of the Senate at a meeting of the Annual Committee this (Friday) evening.

In the present state of relations between the Senate and Convocation of the University of London, we would, as far as possible, refrain from strong comment upon the foregoing reply. But we must say that we miss in it two points to which we expected that reference would have been made. First, the Senate has carefully remained silent on the question of the right of Convocation, and has adroitly returned to the old ground of the admission of women to the University. There is not a single word of regret that the Senate should have forgotten or disregarded the constitution of the University, and set at nought the expressed wish of Convocation in a matter vitally affecting its interests. And, secondly, the reply of the Chancellor contains no definite promise for the future. The Senate asks the co-operation of Convocation in carrying

out a measure which may satisfy both bodies, but it does not undertake that it shall cease to proceed under Russell Gurney's Act. The future is all uncertainty. The Senate itself is divided on the women's question. Convocation is equally unsettled on the same subject. And, as we notice in another column, there is at this moment a strong feeling among many of the graduates, that when the University sets about modifying its Charter, it should have a new and not a supplemental one; and that this new Charter should effect radical changes in the constitution of the Senate itself. It is, to say the least, extremely improbable that all the difficulties will be cleared away to the satisfaction of the Senate. But, as long as these difficulties are not settled, the Senate has it in its power to proceed, if it see fit, to carry out its standing resolution to adopt Russell Gurney's Act. From previous experience we must not be surprised if the Senate should do so in the event of serious opposition to their alternative proposal. The deputation from Convocation should have insisted upon receiving a distinct promise from the Chancellor that the old difficulties should be swept away before new ground was taken up. When the Senate had renounced Russell Gurney's Act, and had thus conciliated Convocation, it could have proposed the application for a supplemental Charter with an easy conscience and with the assurance of the earnest co-operation of Convocation. As it is, we fear that Convocation will not be able to meet the Senate in its proposal with that consciousness of being treated with consideration and justice which is indispensable for successful co-operation.

RECENT ROYAL WARRANTS FOR MEDICAL OFFICERS OF THE AUXILIARY FORCES.

From Royal Warrants published in this month's Army List, nearly affecting the profession, it would appear that officers now holding appointments as assistant-surgeons and acting assistant-surgeons in the Auxiliary Forces, will in future be styled surgeons and acting surgeons respectively.

The relative rank of surgeons in the Yeomanry, Cavalry, and Volunteers is determined by the same rule as that which governs the relative rank of surgeons of the Regular Forces, except that acting surgeons will always rank as lieutenants, irrespective of their length of service.

Surgeons of Yeomanry, Cavalry, and Volunteers, appointed before October 1, 1877, under previous regulations, will continue to hold the relative rank of major.

A medical officer of Militia, who has not elected to be placed on the departmental list, under the Royal Warrant of July 12, 1876, will remain in the same position in regard to pay and personal allowances, whenever his services may be required, as that which he occupied before the date of the Warrant, and he will not be promoted beyond the rank of surgeon.

In the event of both medical officers in a militia regiment being qualified for the rank of surgeon-major on the departmental list, they may be promoted to that rank; but the junior will be borne as supernumerary in the regiment until absorbed.

Militia medical officers on the departmental list will carry on their duties under the Director-General, Army Medical Department, to whom they will make all communications, and from whom they will receive instructions, through the principal medical officer of the district in which they are serving.

They will be eligible for duty in, and for charge of, both dieted and non-dieted station hospitals.

Medical officers of the Militia on the departmental list will, when in receipt of full pay, be liable to perform any medical duties that may be required of them at the places where their respective regiments are stationed, without additional remuneration. Claims made by them for duties in respect of which payment is allowed by regulation will accordingly be accompanied by certificates showing that they were not in receipt of full pay during the periods for which such claims are respectively made.

When the head-quarters of Militia regiments to which medical officers of the Militia on the departmental list are attached are not at the head-quarters of brigade depôts, they will attend the permanent staff of the regiment, receiving the allowance granted to Militia medical officers for the necessary expenses of medicines under former regulations.

When the regiments to which they are attached are assembled for training, mobilisation, or for summer manœuvres, they will accompany their regiments, and, when their regiments are trained at a brigade depôt, or at a station where there is a military hospital, they will draw whatever instruments, medicines, etc., may be required from the Army Medical Department, submitting their requisitions through the principal medical officer of the district to which their corps belongs.

When the regiment to which a Militia medical officer is attached is not at the head-quarters of a brigade depôt, and when an Army medical officer is not available, he will examine recruits enlisted for it, receiving 2s. 6d. for each recruit examined by him, up to and not exceeding £1 a day.

A Militia medical officer will be eligible to examine recruits for the Army, receiving the usual allowance for each recruit finally approved by a medical officer of the Regular Army.

When serving on full pay and allowances they will not receive any remuneration for examining recruits either for the Army or Militia.

Exchanges between medical officers attached to Militia regiments, and transfers from one regiment to another, will be permitted, if recommended by the Director-General, Army Medical Department.

When Militia recruits called out for preliminary drill are stationed at the head-quarters of a brigade-depôt, or when an Army medical officer is available, the services of the Militia surgeon will not, as a rule, be required.

If Militia recruits are called out for preliminary drill where the services of an Army medical officer are not available, the Militia surgeon will be required to take charge of them.

When a Militia regiment is trained at the head-quarters of a brigade-depôt, or when there is a station hospital, the sick will be treated in the military hospital.

When a Militia regiment is trained away from the head-quarters of a brigade-depôt, a non-dieted hospital under the charge of the surgeon of the regiment will be opened for the treatment of the sick, except under special circumstances, when reference will be made to the Director-General of the Army Medical Department.

The usual stoppage returns for militiamen who are treated in hospital will be forwarded by the medical officer in charge.

Militia recruits passed by an Army medical officer will not be rejected by a Militia medical officer. Should the latter consider a recruit ineligible, the case will be referred to the principal medical officer of the district.

When the adjutant of a Militia regiment proceeds to out-stations periodically for the enrolment of recruits, he will, if there is no Army medical officer available for the duty, or no private medical practitioner qualified to pass the recruits at the several out-stations, be accompanied by the medical officer of the regiment, who, if on the departmental list, will receive his regimental pay for each day he is actually absent from head-quarters, together with travelling expenses and personal allowance.

A Militia medical officer on the departmental list will for the future receive allowances at departmental rates, according to his relative rank as previously laid down.

All future appointments of medical officers to Volunteer corps will be to the rank of surgeon, which will be the only substantive rank of medical officer in the force.

When more than one medical officer is allowed to a corps, or to the staff of an administrative regiment, only one such officer (a surgeon) will in future have substantive rank. The other officer, or officers, as the case may be, will have the rank of acting surgeon only.

Corps that are not entitled to a medical officer of substantive rank will, on the occurrence of a vacancy, be allowed a medical officer with the rank of acting surgeon.

A Royal Warrant has also been issued, in which it is stated that it has been deemed expedient to extend the regulations under which certain payments are authorised to be made to civilian medical practitioners engaged to take charge of troops, and authority is accordingly given to the Secretary of State for War to vary such payments from time to time as he may consider necessary.

We have considered it advisable to publish the clauses of these several Royal Warrants *in extenso*, as they will no doubt be interesting to many of our readers, whose interests they will materially affect. We believe we are correct in stating that the present is the first occasion on which any provision has been made for recognising the status of medical officers of Volunteer regiments.

VIRCHOW ON THE PENGE CASE.

(*Concluded from page* 524.)

THE course of the proceedings in the Penge Case has been such that the real controversy turned on the question whether meningeal tuberculosis was present; and, if present, whether this was the cause of death. What say the experts on this point? In the protocol we find it stated, "There were some small patches of rough millet-seed-like deposit in the meshes of the pia mater, *probably tubercular*." Dr. Wilkinson says, "The brain and membranes were healthy, with the exception of a small recent patch of tubercular deposit upon the arachnoid membrane, on the upper part of the left hemisphere, about the size of a fourpenny-piece."

The only fourpenny-piece I possess measures twenty-one millimetres in diameter. This is not inconsiderable, and in Germany scarcely anyone would call such a tubercular deposit a small one. But what are we to think of a method of note-taking (protocolling) where one eye-witness mentions a single such deposit, giving at the same time the situation in which it was found, while the others (eye-witnesses) describe "some," that is, several!

Doubts arose during the trial, as to whether this change, which was not further described or examined, and which in the Notes was entered as "probably tubercular," really was tubercle, or whether it was not simply Pacchionian bodies, or, as I would suggest, arachnoideal growths. The experts, however, unanimously and decisively declared that these questionable bodies were tubercular, and English critics accepted this view. Indeed, Drs. Greenfield and Payne, chiefly on the strength of these statements, conclude that death resulted from meningeal tuberculosis, or from tubercular meningitis. But this is certainly assuming that the original statement of "some" such deposits is the correct one. I do not venture to decide whether the single deposit, which was only subsequently described by Dr. Wilkinson, would suffice for them: I can only say, for my own part, that neither as the result of personal experience, nor of my acquaintance with German criminal proceedings, nor, finally, from any knowledge of the literature of the subject, should I consider myself justified in attributing a fatal significance to a deposit of tubercle, even though it were twenty-one millimetres in diameter, and least of all when situated on the surface of the convexity of the left cerebral hemisphere. Whether it were in the meshes of the pia mater, or situated on the arachnoid, in neither case could it have any considerable thickness. And, concerning any change of the surrounding brain-substance or of any exudation, or indeed of any recent inflammatory change of neighbouring parts, not only is no mention made, but the contrary is definitely protested. The "well-marked" congestion of the brain and its membranes would have to be described in quite another manner than it is, in order to be able to deduce, more especially six days after death, the signs of a general inflammation of the brain and its membranes. The statements in the protocol concerning the membranes of the brain are indeed such that we lose all confidence in the anatomical skill of those who drew it up. Their arachnoid "or fibrous (and serous) membranes enclosing the brain," and the pia mater distinct from these, "or internal membrane of the brain itself," sufficiently indicate that these gentlemen did not arrive at any clear ideas concerning these membranes. A few of our elder brethren would find it rather difficult to steer clear through the confusion of ideas concerning the arachnoid and pia mater, but, as a rule, we can make out from their protocols what they really mean. But in the Penge Case this is indeed difficult. It is difficult to come to an understanding with a man who first of all calls the arachnoid a fibrous membrane, and who then, in order to soothe his scientific conscience, immediately adds that it is also a serous membrane. One easily comes to the conclusion that he is not exactly the man to find those fine sub-miliary tubercules (granulations) which frequently lie hidden within the pia mater at the bottom of the sulci.

I may just take this opportunity of stating that some years ago, in a short essay on "Hæmatoma of the Dura Mater," I discussed, historically, the question of the arachnoid and pia mater and the identity of the two membranes, and also endeavoured to establish the tautology of the double appellation. (*Würzburger Verhandlungen*, 1857, Bd. vii., page 134). If one could decide to abolish completely the term—parietal layer of the arachnoid—which for pathological teaching is not only superfluous, but even prejudicial, there would be nothing to prevent our uniting the visceral layer with the pia mater, and then it would suffice to speak of the superficial and deep processes of these membranes. *Arachnitis superficialis* and *Arachnitis profunda* would convey all one could wish to express.

Now, according to Dr. Wilkinson's statement, there really was no arachnitis profunda in the Penge Case, and Harriet Staunton could not reasonably have died from a single deposit of tubercle, even if it had been situated *in*, and not, as he asserts, *on* the arachnoid. On the other hand, according to the Notes, a chronic arachnitis profunda, and also a multiple tuberculosis, were undoubtedly proved. According to this, as the *Lancet* has it, Harriet Staunton may have suffered from general progressive paralysis, and, as Dr. Greenfield believes, may finally have died from meningeal tuberculosis. This is possible; but can it be substantiated, and in such a manner as to warrant a definite medical opinion being given? Should any medical expert with a good conscience venture to express any opinion at all on a basis of such conflicting statements as these? I think not. At the trial, Dr. Longrigg states, "There were *old adhesions* between the internal and external membranes, with a deposit of tubercular substance in the lining membranes." It is impossible to reconcile this foregoing statement with that of Dr. Wilkinson. Now, can we accept the bare statement of this witness, that the (as stated by himself) single deposit of tubercle in the arachnoid was recent? With equal assurance he tells us that the *tubercular deposit* in the apex of the left lung was inactive; and yet in the Notes it is stated, "a small patch about one and a half to two inches square contained tubercular deposit (grey and hepatised)."

Here another extraordinary definition of size occurs. A patch of one and a half to two square (surely he means cubic) inches should not be described as small; and if the within-contained mass were recognised as grey and hepatised, no one in Germany would venture offhand to describe this hepatisation as inactive. At every point we see that these medical witnesses have not learnt terminology. They speak a medical language, partly of their own invention, partly from hearsay, and their listeners may make out of it whatever seems to them to be right.

The opinion of Dr. Greenfield in his first communication to the *British Medical Journal*, page 496, was very much to the point; he says:—

"The incomplete and imperfect manner in which the facts are recorded, makes it almost impossible to form any decided opinion as to their true nature, based upon the description given. Thus, in the description of the small millet-seed-like bodies in the membranes of the brain, no mention is made either of their position with regard to the upper and under surface, or of their relation to the vessels—points which are of great importance in deciding upon the nature of such bodies in doubtful cases, where no other tests can be applied."

But in his second communication, in the *Lancet*, Dr. Greenfield, as Dr. Payne had before him, throws off his cautious tone. Not only does he accept the meningeal tuberculosis as certain, but infers from it the symptoms, death, and especially also the emaciation. Hence *the possibility* that there may have been deprivation of food is forced quite into the background, or, more strictly speaking, is entirely set aside.

And, to my thinking, herein lies the second chief objection which may be taken to these proceedings. All novices in medico-legal post-mortem examinations take a delight in conjuring up from the post-mortem evidence, whenever it is possible to do so, the whole circumstances of the death, and sometimes also the (connexion of) events—even to details—of the latter part of life. In this "Wissenschaft des Scharfsinns" (science of acumen), as Caspar loved to call it, nothing affords so great a pleasure as the complete reproducing of the facts of a case from isolated (phenomena) appearances (found) in the dead body. How often we experience this among our young medical jurists! With what pleasure do they allow their imaginations to wander, in order to think out the various possibilities to their minutest points, and then with their scientific facts before them to adopt a choice between them! But human imagination only too easily falls short of the possibilities which nature and human life actually realise. This or that manifestation, in spite of all our care, is overlooked, or wrongly

interpreted, and acumen loses itself in wrong or uncertain paths. Hence, let us elders ever strive to warn the workers of the rising generation, in cases where the technical opinion of the medical man is demanded, not to minutely detail all those possibilities which are present to the imagination, nor to drag in the whole combination of biological science, when judging of the causes or the mode of death, which after all is properly the domain of the judge and of the jury.

Did Harriet Staunton die of arachnoideal tuberculosis? Certainly not, if the report of Dr. Wilkinson is correct. Possibly, if the statements of Dr. Longrigg are right. Are we, however, called upon to decide whether the former or the latter is in the right?

If Harriet Staunton did die of arachnoideal tuberculosis, her emaciation might be due to tuberculosis. But it is somewhat difficult to prove even this *possibility;* a weight of seventy-four pounds is, in truth, very little—remarkably little—for a person thirty-five years of age. Dr. Greenfield is himself quite sensible of this, and hence he is inclined to admit the assumption that the woman was already suffering from mental disease and general paralysis before she became tubercular. This is also possible, but it cannot be demonstrated by an autopsy. It can only be ascertained from witnesses who are able to report what took place during life. In the absence of such depositions—for those they had were altogether insufficient—the possibility of her having been starved remains uncontradicted. And even if mental disease had been proved, as the case now stands, this possibility would still be admissible. Medical opinion, therefore, at the trial ought to have been: *Non liquet.*

Such is my candid opinion. May it in a small degree assist in reconciling opinions across the Channel, and in bringing about the introduction into forensic practice of special knowledge, method, trustworthiness, and a wise reserve.

FROM ABROAD.

Prognosis and Treatment of Diphtheria.

Dr. Lewis Smith, Clinical Professor of Diseases of Children at Bellevue Medical College, observes (*American Journal of Medical Science*, October) that the endemic persistence of this disease in some localities, as New York, and its frequent epidemic outbreaks in country villages and towns, have aroused great attention as to its nature and treatment. No disease also, he adds, stands more in need of all the light which science and experience can throw upon it, not only on account of the divergence of views which prevail respecting it, but because of the frequency with which the prognosis is belied. This uncertainty of prognosis, he believes, depends much upon the fact that diphtheria terminates fatally in several distinct ways, so that while the patient may seem safe with respect to the more manifest and common conditions of danger, a fatal result may still occur from some unseen and unsuspected cause.

Death may result from (1) diphtheritic blood-poisoning; probably also from (2) septic poisoning, produced by absorption from the under surface of decomposing pseudo-membrane—especially when this is extensive, deeply embedded, and attended by an offensive effluvium. Cervical cellulitis and adenitis, which may cause very considerable swelling of the neck, appear to be often, if not usually, due to septic absorption from the lower surface, the inflammation extending from the absorbents to the glands and connective tissue. Considerable swelling of the neck, therefore, seldom occurs in diphtheria or scarlatina without manifest symptoms of toxæmia, and is to be regarded as a sign of its presence. (3) Obstructive laryngitis; (4) uræmia; (5) sudden failure of the heart's action, either from the anæmia and general feebleness, from granulo-fatty degeneration of the muscular fibres of the heart, which is liable to occur in all infectious diseases of a malignant type; or from ante-mortem heart-clots. (6) Suddenly developed passive congestion and œdema of the lungs, probably due to feebleness of the heart's action, or to paralysis of the respiratory muscles. Death may occur from this cause during what seems to be convalescence. The physician is less likely to err who bears in mind the possibility of these various terminations; and Dr. Smith believes that the condition of the urine is too infrequently and too superficially examined, seeing that it often contains a large quantity of albumen.

"Among the symptoms which render the prognosis unfavourable are repugnance to food, vomiting, pallor, with progressive weakness, and emaciation from the blood-poisoning; a large amount of albumen, with casts in the urine, showing uræmia, to which the vomiting is sometimes, but not always, attributable; a free discharge from the nostrils, or occlusion of them by inflammatory thickening and exudation, showing that a considerable portion of the Schneiderian membrane is involved; hæmorrhage from the mouth or nostrils; and obstructed respiration. One, at least, of these has been present in most of the fatal cases which have fallen under my observation."

It is remarkable, Dr. Smith observes, that concerning a disease which has been so long under widespread and able observation, such wide discrepancy of opinion as to treatment prevails. This has arisen in part by the different views taken of the nature of the disease, but still more is due to the unreliability of the statistics of treatment, owing to the very varying types the disease presents even in the same epidemic, so that while some cases resist all measures, others scarcely require treatment at all. He believes that the germ-theory of diphtheria has done immense harm by concentrating attention so much on local and general antiseptic treatment, which, as far as his experience goes, proves of little use; and he is of opinion that the fact of the treatise in Ziemssen's Cyclopædia, which propagates this doctrine, having been published before Sanné's more useful book, has led to great mischief. Experience has, however, brought on a reaction, and practitioners are beginning to learn that constitutional treatment is of as paramount importance in diphtheria as it is in scarlatina. As the result of his own large experience, he lays down the following propositions:—1. In ordinary cases the poisonous principle of diphtheria enters the blood through the lungs, and after an incubation, varying from a few hours to seven or eight days, gives rise to the symptoms of the disease. 2. Facts do not justify the belief that the system can be protected by antiseptic or preservative medicines given internally. 3. There is no known antidote for diphtheria, in the sense in which quinia is an antidote for malarial disease. 4. Diphtheria, like erysipelas, has no fixed duration. It may cease in two or three days, or continue for as many weeks, the specific poison acting more intensely at the commencement than at a later period; so that diphtheritic inflammation—as laryngitis, *e.g.*—is more severe and dangerous at an early period than when the disease has continued a few days. 5. The indication of treatment is to sustain the patient by most nutritious diet, tonics, and stimulants, employing other measures as adjuvants as the indications arise, the same rules of treatment being for the most part appropriate as are applicable in scarlatina. Local treatment should be unirritating and designed to prevent putrefactive changes and septic poisoning. Irritants which produce pain lasting more than a few minutes, or which increase the area or degree of redness, are hurtful, and increase the extent and thickness of the pseudo-membranes.

The most nutritious and easily digested food should be given, the preservation of the patient's inclination for food being of vital importance. Beef-tea, or the expressed juice of meat, milk, with farinaceous substances, etc., should be given every two or three hours, or to the full extent without disturbing digestion. Failure of appetite and refusal of food are justly regarded as most unfavourable signs. In malignant diphtheria or scarlatina patients are allowed sometimes to slumber too long without nutriment. It is the slumber of toxæmia, and should be interrupted by feeding at stated times. *Stimuli*, as observed by Sanné, are indicated in proportion to the gravity of the case; and while mild cases do well without alcohol, this is required in all cases of a severe type, and should be given in large and frequent doses, wherever pallor or loss of appetite, or of strength and flesh, indicates danger. Of *tonics*, none answer the purpose better than cinchona and quinia. Concerning the doses of the latter, the greatest difference of opinion prevails, according as its antipyretic or its tonic effects are sought to be obtained. But high febrile action calling for antipyretic doses of three, five, or more grains are seldom observed after the first forty-eight hours, while at a subsequent period the tonic dose of two grains every two or four hours will be found sufficient. Great difference of practice also prevails with respect to iron, some using it exclusively in large doses, while others employ moderate doses as an adjuvant to vegetable tonics. The formula which Dr. Smith prefers, say

for a child five years old, is the following :—℞. Quiniæ sulph. ʒss., elixir adjuvantis or elixir taraxaci co. ʒij. Give one teaspoonful every two to four hours, and one teaspoonful of the following hourly between—℞. Tinct. ferri chlor. ʒij., pot. chlor. ʒij., syrup ʒiv. The tonic effect of the iron is not impaired by the chlorate of potass, which is added on account of its action on the inflamed surface. The citrate of iron and ammonia alone, or combined with carbonate of ammonia, may be given in two-grain doses, in syrup, instead of the above, when the inflammation of the fauces has considerably abated or is moderate. As the disease begins to abate, the intervals between the doses may be lengthened, but the tonic should not be entirely discontinued until the patient is far advanced in recovery, on account of the dangerous sequelæ which originate in an impoverished condition of the blood.

The object in *local treatment* should be to reduce the inflammation of the mucous surfaces, and destroy the diphtheritic poison and contagious properties in the pseudo-membrane, and to destroy the septic poison, and prevent its absorption should any form. Forcible removal of the pseudo-membrane, irritating applications, the use of a sponge or other rough instrument for making the applications, should be avoided as likely to do harm. These should be made with a large camel's hair pencil, or (better for most of the mixtures employed) with the atomiser. The hand atomiser, like Delano's, which is cheap and of simple construction, is very useful, but the constant spray of the steam atomiser is more effectual, and is preferable in some cases. Dr. Smith employs the following mixture :—1. Salicylic acid ʒss., glycerine ʒij., lime-water ʒviij. 2. Carbolic acid gtt. xxxij., glycerine ʒij., lime-water ʒvj. 3. Carbolic acid gtt. xxxij., chlorate of potash ʒiij., glycerine ʒiij., water ʒv. Half a dozen or a dozen compressions of the bulb of the hand atomiser cover the surface of the throat more effectually with the liquid than can be done by several applications of the brush, and it is usually not dreaded by the patient. Diminution in size of the pseudo-membrane under the use of the spray is a favourable sign; but if it do not diminish, its presence can do little harm if properly disinfected. In many cases the spray suffices for local treatment, but this mixture (carbolic acid gtt. viij., liq. ferri subsulph. ʒij.-ʒiij., glycerine ʒj.), applied by a large camel's hair pencil, is also very effectual, converting the pseudo-membrane into an inert mass, and putting a stop to all movements of the bacteria which swarm in it. It may be used two or three times a day between the spraying, or oftener without this. *Pseudo-membranous laryngitis*, the most formidable symptom of diphtheria, is best treated by the spray. Of twenty-five cases treated by Dr. Smith, seven recovered by inhalation of spray, and two by tracheotomy. When the *Schneiderian membrane* is especially affected, being more sensitive than the fauces, it requires a milder treatment. The best consists in injecting into the nostrils, by means of a small syringe, every third or fourth hour, one or two teaspoonfuls of a mixture formed of carbolic acid gtt. xxiv., glycerine ʒij., and water ʒvj., using it of the temperature of the body, the head being thrown back, and the eyes covered with a cloth.

Benjamin Barrow, F.R.C.S., Justice of the Peace and Alderman of the Borough of Ryde, has been elected, for the fourth time in succession, Mayor of that town.

Natural Science Teaching at Cambridge.—The Vice-Chancellor of the University of Cambridge, Dr. Atkinson, on resigning his office on November 3, spoke of the progress of scientific teaching in the University. The efficiency of the University as a school of natural science has been greatly promoted, Dr. Atkinson stated, during the past year by the erection of the new buildings for the department of comparative anatomy and physiology. Although the whole building is not yet completed, many of the rooms are already in use, and the accommodation which is thus provided for both teachers and students will be of the greatest advantage. In connexion with this subject, Dr. Atkinson referred to Professor Clerk Maxwell's announcement that the Chancellor of the University, his Grace the Duke of Devonshire, has now completely equipped the Cavendish Laboratory with all the apparatus and instruments which the Professor considers that a first-class institution of this kind ought to possess. This munificence, continued so steadily and ungrudgingly for a number of years, is but one of the many proofs which the Chancellor is constantly giving of his unwearied care and concern for the welfare of the University.

PROVINCIAL CORRESPONDENCE.

IRELAND.

Dublin, Nov. 7.

The Opening of the Session 1877-78 (*continued*): House of Industry Hospitals; Meath Hospital and County Dublin Infirmary; Catholic University School of Medicine; Mater Misericordiæ Hospital.

Since I last wrote to you on the subject of the opening of the present session, introductory addresses have been delivered in such other of our Schools and Hospitals as still cling to this mode of inaugurating each succeeding period of medical study.

On Thursday, November 1, the clinical session of the Richmond, Whitworth, and Hardwicke (House of Industry) Hospitals was opened by Dr. Robert D. Lyons. His address partook of the nature of practical advice to the students, and dealt principally with the plan of conducting the clinical work in the hospitals during the ensuing session, together with a description of the system of case-taking which would be pursued.

The 127th session of the Meath Hospital and County Dublin Infirmary was inaugurated on Monday, the 5th inst., by Dr. Arthur Wynne Foot, Senior Physician to the Institution. Having offered a few words of welcome and encouragement to the students—of welcome to the new arrivals, of encouragement to all,—Dr. Foot spoke of Dr. Graves's system of clinical teaching, first practised in the Meath Hospital. In introducing this, the leading theme of his address, he said :—"The indispensable necessity and the vital importance of hospital attendance are due to the fact that it is in such a place alone, where every form of illness and injury is collected, you can acquire that familiarity with the ways of the sick, and with the management of disease, which are the attributes and the essential qualifications for a medical life. Elsewhere you may *hear* about diseases, or may read about them; but it is here you can *see* them, and you will soon find out how much more lasting and vivid are your impressions of disease when formed from attentive observation of the originals than when they are grounded on what are at the best but hearsay descriptions, or paper copies. What the laboratory is to the chemist, the field to the botanist, the studio to the artist, the gymnasium to the athlete, the hospital is to the student of medicine or surgery.

"Here you can see at work that enemy with whom you will have to fight a life-long battle. The name of Death, synonymous with terror and mystery, is enough to make the bravest pale. If you would have the power to preserve your self-possession and composure when engaged with him in some hurricane of trial, when a distracted mother screams to you to save her child or her husband from his tiger-spring, mixing threats and entreaties, commands and prayers, in a wild tempest of grief and horror—life and your reputation both at stake—do not neglect the only place where you can acquire practical experience of his power, where you can learn the subtle turns and twists of the grim assailant—his sudden, treacherous springs, his stealthy, insidious approaches,—where you can learn to recognise him in his disguises, for, pirate-like, he hides his pale ensign often under the rosy mantle of a damask cheek, and, like a basilisk, looks out through the glittering eyes of his intended prey!" He continued—

"The dominant genius of Graves established here the great and true principle of teaching by *action*. The essential feature of this system is the allowing any pupil so inclined, and who is sufficiently advanced, to undertake the care of patients in the hospital under the direction and superintendence of the attending physician. Such working or "practising pupils," as he loved to call them, have the opportunity of finding out by their own powers what is the matter with the patient, and of suggesting treatment, and have the privilege of carrying out in detail the management of the case while the patient remains in hospital. Nothing can be better adapted than this method of clinical teaching for the instruction of a beginner, or for the improvement of a more advanced student."

Speaking of his hearers' prospects in life, the lecturer observed—"There are two reasons why it is especially unlikely for medical men to amass great fortunes—one is that so large a portion of their time and skill is lavished upon those who are *unable* to repay them; the other is the generosity, often almost romantic, which is so characteristic a quality of the medical

mind." But, "by patient perseverance in well-doing you will not fail to attain the position Providence has thought best for you. There are numerous spheres of action for a medical life, all of which, whether humble or lofty, duty faithfully done, with singleness of purpose, can illuminate with a divine light, the reflection, however dim, of an eternal sun. In many a quiet country churchyard in this land the grass grows green over the ashes of medical men whose good and useful deeds were unknown much beyond their dispensary districts; for often it happens that 'the world knows nothing of its greatest men.' They lie at rest from laborious duties which were oftener repaid with the blessings of those who were ready to perish, or the song of joy from the widow's heart, than with any form of pecuniary recompense. The active benevolence of such men's lives speaks from their quiet graves, to those who have an ear to hear it, the same language as the marble statues of the more famous heroes of a larger stage of duty. The light radiating from the faithful life of the humblest practitioner contributes to the lustre of the medical firmament, just as the minor constellations of the sky support the zenith stars of the first and second magnitude in forming the glittering beauty of the starry heavens."

These few paragraphs, I can assure you, do but scant justice to Dr. Foot's masterly and most classical address.

On the afternoon of Monday, the 5th inst., Dr. John A. Byrne, Dean of the Medical Faculty in the Catholic University of Ireland, delivered the inaugural address in that Faculty in the Lecture Theatre of the School of Medicine and Surgery, Cecilia-street.

The last "introductory" I shall notice is that delivered at the Mater Misericordiæ Hospital, on Tuesday, the 6th inst., by Mr. Patrick J. Hayes, one of the surgeons to that institution. In the course of a singularly able address he spoke at length on the vexed question of "Vivisection."

After alluding with expressions of horror and indignation to the report of certain practices in some continental schools of veterinary surgery, and stating his conviction that "British Medicine did not deserve the slight lately put upon it—an indignity as uncalled for as it is harmful," the lecturer went on to say:—"I have been intimately associated with teachers of physiology during a period extending over twenty years, and although, both as student and teacher, I have assisted at experiments and observations upon living animals, I have never seen more suffering inflicted than would be caused by a small wound, or the instantaneous division of a nerve-fibre. The assertion that callousness and inhumanity are generated in the minds of students who witness such investigations does not merit serious notice. By alluding to it I only seek an opportunity for expressing my belief in the emotional and clap-trap nature of the charge. Happily, the sons of medicine ever have been—and, I feel assured, ever shall be—recognised by characteristics directly antagonistic to the sentiments of heartlessness or cruelty. I am no advocate for, but rather am I opposed to, the repetition of like experiments time after time; nor do I argue that warm-blooded—and, consequently, sensitive—animals should be subjected to fear or pain, merely (to quote the words of Professor Huxley) for the purpose of impressing some scientific truth upon the minds of students." Mr. Hayes then proceeded to mention modern instances of the value of experimentation on animals—as the discovery by Wolfe, of Glasgow, that conjunctiva will bear transplantation from the eye of the rabbit to the human eye, and so cases of otherwise incurable symblepharon can be successfully treated; and the sub-periosteal treatment of diseased bones, introduced into practice by Ollier, of Lyons. In further illustration of this he said:—"The late Professor Bennett, of Edinburgh, having subjected rabbits to poisonous doses of strychnine, found he could arrest spasms and overcome the effects of the drug by means of the administration of hydrate of chloral, and thus he proved its antidotal power. The peculiar influence which curare exerts upon the nervous system of any animal, when inserted beneath the skin, induced a Prussian physician recently to employ this poison in a case of presumed hydrophobia, the result being that the patient made a most satisfactory recovery. Additional evidence of a favourable nature, it is to be hoped, may soon be forthcoming, so that at long last a reliable remedy may have been found for at least one terrible and hitherto incurable disease. Need I recall to the memory of my hearers the amount of light shed over the modern pathology of tuberculosis through the inoculations of inflammatory products practised upon the lower animals by Villemin, Burdon-Sanderson, Fox, and others; or refer to the experiments, and consequent discoveries, made by Cohnheim, Stricker, Purser, and several other distinguished observers, with regard to the part played by leucocytes in the various degrees and stages of inflammation?" The lecturer concluded with a few words to those who, lately pupils, are now professional men; and charged them to complete the promise of their youth, and in age—well, in age they would respond to the sentiment of the poet—

> "'For age is opportunity, no less
> Than youth itself, though in another dress;
> And as the evening twilight fades away,
> The sky is filled with stars invisible by day.'"

GENERAL CORRESPONDENCE.

PHILANTHROPY IN WAR.

Letter from Mr. R. H. A. Schofield.

[To the Editor of the Medical Times and Gazette.]

Sir,—I am, of course, ignorant of the source of the information embodied in the article on philanthropy in war which appeared in the *Medical Times and Gazette* of October 20, but as I have served under the National Aid Society, both in the Belgrade Hospital, and more recently in Bulgaria, I am in a position to correct one or two errors as to matters of fact which occur in the article. The facts as to the Servian war are briefly these:—The National Aid Society, early in August, 1876, sent out a number of surgeons, six or seven of whom worked on the Servian side, and the remainder on the Turkish. This, it should be remembered, was only three or four weeks after the beginning of the campaign, and full three months before its close.

Later on, the Society sent out four more surgeons to work in the Belgrade Hospital. Whether it is a fair representation of these facts to say "The Society sent out a few surgeons *just before the war came to a close*," your readers will doubtless judge for themselves.

Again, it is quite a misrepresentation to say that "many wounded would have had to die had it not been for the personal generosity of Dr. Attwood," for when I left the hospital in December, 1876, there were only about sixty wounded remaining, the majority of whom were rapidly recovering. There were, of course, some severer cases, hopeless from the first, and these died just as inevitably in the hospital as they would have done out of it.

A few lines lower down these words occur: "The Servian war came to a close, and we ask, what has the Society done since? Nothing, to the best of our knowledge." In reply to this, I may be excused for stating in a few words what the Society has done since. In the first place, it maintained two surgeons at Belgrade all through the winter, and four or five on the Turkish side at Nisch and Sophia.

Soon after the opening of the present campaign a steamer, the *Belle of Dunkerque*, was freighted with every appliance, both medical and surgical, for the treatment of sick and wounded, not to mention several thousand blankets, large stores of preserved provisions, and a dozen large hospital marquees for field work, each capable of sheltering forty wounded men. With the steamer five surgeons were sent out, and all were hard at work in Roumelia, Bulgaria, and Armenia before the end of July, rendering surgical assistance in the first lines, where it is always most valuable.

Subsequently four more surgeons have been sent out to Turkey; and still more recently several surgeons of the Society have gone with stores to Bucharest.

Further, the steamer *Belle of Dunkerque* has been employed on several occasions to transport wounded both from Varna and Soukhoum Kaleh to Constantinople.

Your readers will see from the above bare outline of facts that the Society has not been idle, and that the assistance given has been not only on a large scale, but rendered just where it was most needed. I am, &c.,

R. H. A. Schofield.

St. Bartholomew's Hospital, October 31.

[Our readers "will doubtless judge for themselves" whether Mr. Schofield's account of the work of the "National Aid Society" really at all betters entire case. The gist of our charge against the Society is its entire want of organisation; and if Mr. Schofield will take the trouble to read rather

more carefully what we said, he will comprehend that, and will see also that the sentence quoted by him, in which we say that, so far as our knowledge goes, the Society has done nothing since the Servian war, has special reference to the state of unpreparedness and entire want of organisation in which the outbreak of the Russo-Turkish war found the Society. Our readers will also "judge for themselves" whether what we said about the Belgrade Hospital is a "misrepresentation." Mr. Schofield admits that when the Society gave up the hospital in December, 1876, there were "about sixty wounded remaining in it." Dr. Attwood has stated that when the Society discontinued its operations, on December 1, the hospital contained above ninety cases. Dr. Attwood determined to stay and carry on the hospital, and he was joined by two other members of the staff, Dr. Wattie and Mr. Hume. That their services were really needed was recognised in the end by the Society itself, for it continued its allowance of £1 a day to Dr. Attwood and his collcagues for three months, and gave a contribution of £100 towards the £700 that the hospital cost in the six months during which Dr. Attwood continued it.—Ed. *Med. Times and Gaz.*]

REPORTS OF SOCIETIES.

CLINICAL SOCIETY OF LONDON.

Friday, November 9.

George W. Callender, F.R.C.S., F.R.S., President, in the Chair.

A Case of Urethral Calculi.

Mr. Bellamy exhibited two calculi, removed from a sac communicating with the urethra in front of the scrotum. The patient, who was about forty years old, had, when he was aged eleven years, two other small calculi removed from the same part. The two calculi exhibited had been noticed and had steadily increased in size for the last eleven years, until they formed a tumour the size of a pigeon's egg. This was simply inconvenient for its size, but gave rise to no obstruction to the passage of urine nor to any other symptom. The man had passed no gravel; nor could a calculus be detected by the sound in either the bladder or urethra. The calculi were removed by a simply longitudinal incision into the sac, which was found to communicate with the urethra by a small opening, through which a small probe passed. The wound healed perfectly, and no urethral fistula remained. The calculi together weighed exactly an ounce; were curiously facetted together, their opposed surfaces being highly polished; and, when placed together, they measured 1·7 inches in length, 1·2 inches in breadth, and 1·5 inches in depth. The external surfaces were irregularly mammillated, and exhibited, on section, successive layers of phosphatic deposit. No nucleus was visible at the time of section. Mr. Bellamy thought the calculi were originally in contact, and that the fresh deposits of calcareous matter had only been added to their outer surfaces, whilst their opposing surfaces became polished from friction.

Urethral Calculus.

Mr. Sydney Jones showed a specimen of large urethral calculus, which he had removed by excision from a man, aged sixty. He had been sent into St. Thomas's Haspital for difficulty of micturition, and was supposed to have stricture; but, on passing an instrument, this impinged upon a calculus lodged just behind the bulbous part of the urethra. It might be felt in the perineum; and the forefinger being placed on the rectum, and the thumb on the perineum, the foreign body could be moved to and fro, and made to grate on a metallic instrument in the urethra. A catheter might be passed over the calculus into the bladder. The calculus was about the size of a small chesnut. Each time a catheter was passed there was a rigor, the temperature rising considerably, once to 106·3°, and falling again to normal on the subsequent day. On October 3, Mr. Sydney Jones cut down upon the calculus and the perineum, and easily removed it. The wound was closed by two deep and two superficial sutures, and a No. 8 catheter, with drainage-tube attached, was passed into the bladder. At 7 p.m. there was a rigor, and the temperature rose to 104°. On the next day, the temperature was normal, and remained so. Two sutures were removed three days after the operation, and the remaining two on the fifth day. One catheter was removed on October 9, six days after the operation. On October 10 and 11 he passed water in a good stream without difficulty or pain; none escaped by the wound, which was not quite healed towards the front part. Except on one doubtful occasion referred to by the patient—viz., on October 15—no urine passed by the wound after the operation. He was allowed to get up a fortnight after removal of his calculus, and left the hospital a few days afterwards quite well. Mr. C. Stewart, who examined the calculus, which weighed 153 grains, reported that its nucleus was oxalate of lime, around which was fusible calculus with mixed phosphates; the rectum showed dark lines, for the most part made up of oxalate of lime.

Mr. Heath said he had exhibited such another specimen as Mr. Bellamy's before the Pathological Society. This calculus was lying in the urethra, and seemed connected with a former lithotomy. It was easily extracted. Mr. Bellamy's case was remarkable for the small size of the opening into the urethra. How had the stone grown? Could it have been a phlebolite?

Mr. Teevan thought the great value of Mr. Bellamy's case rested on the fact that no fistula was left after operating. A small stone, however, might easily be removed subcutaneously without leaving any fistula. If an attempt was made to push the stone back into the bladder, it was best to use a soft bougie, which would mould itself to the surface of the stone.

Mr. Barwell remarked that a similar calculus had already been removed from Mr. Bellamy's patient. This second stone had probably been formed in some adventitious cavity outside the urethra.

Mr. Bellamy could give no idea as to the mode in which the stone was formed.

Mr. Sydney Jones thought they might form in cysts of mucous membrane connected with the urethra. At all events, this might be so with the uric acid stones.

Unilateral (Gunshot) Injury to the Spinal Cord.

Dr. Gowers brought forward this case. The patient, who had been in University College Hospital, under the care of Mr. Heath, had fired a pistol into his mouth, and died sixty hours afterwards. The bullet had passed through the body of the second cervical vertebra, and had lodged between the arches of the atlas and axis on the right side. It had not penetrated the dura mater, but had driven a spiculum of bone into the membrane, and had bruised the cord between the second and third cervical nerves, the bruise being confined to the antero-lateral column, the anterior and posterior cornua, and the central part of the grey matter on the right side. All these parts contained many extravasations. The left half of the cord, both grey and white matter, was intact; and the right posterior column was simply swollen, apparently from œdema, there being only a few very minute extravasations in it. The symptoms during life were: Paralysis of the right arm and leg, complete always in the arm, and at first in the leg; after the first twenty-four hours, there was slight power of moving the leg. There was hyperæsthesia, or rather hyperalgesia, on the paralysed side, below the part supplied by branches from the cervical plexus; in the latter, sensation was normal. On the opposite side there was no motor weakness; but there was complete, or almost complete, loss of sensibility to pain, and very little change in tactile sensibility. The reflex action was diminished, almost abolished, in the paralysed leg; it was excessive in the opposite leg, in which sensibility to pain was diminished. Temperature on the side of motor paralysis was uniformly higher (one or two degrees) than on the other side; and on the paralysed side there was a peculiar change in the irritability of the muscles and nerves, that of the muscles being a little less, that of the nerves being a little greater, than on the other side. The change was the same to each form of electricity. In commenting upon these symptoms, Dr. Gowers observed that the cross sensory and motor paralysis was in accord, although not completely, with the view now generally accepted. The slight recovery of power in the leg might be explained by supposing that some fibres of the antero-lateral column recovered functional power; but, considering how easily the motor impulse was arrested by a slight injury, he thought this explanation

improbable, and that the recovery of power afforded support to Vulpian's opinion that the motor path, although crossing chiefly at the decussation of the pyramids, also crossed to a less extent lower down the cord, and that this subsidiary decussation for the leg had escaped, so that, when the shock of the injury was over, there was some return of power over the leg. He pointed out that the slight change in tactile sensibility in the analgesic limbs afforded support to the view that tactile and common sensation traversed different paths in the cord; and the undamaged state of the posterior columns was interesting in connexion with the assertion of Schiff, that they conducted tactile impressions. The increased sensitiveness of the paralysed leg, so common in these cases, but associated as it was here with diminished reflex action, could not be ascribed, as it had been, to the withdrawal of an inhibitory influence on the grey matter of the lumbar enlargement. The contrast in this respect between the two legs, in both sensibility and reflex action, seemed significant. In health, reflex action in the legs was restrained by a higher centre, probably in man the optic thalamus. The lesion of the right half of the cord, which divided the sensory path from the left leg, interrupted also this inhibitory influence. Hence it would seem that these two paths corresponded. Might not the opposite condition of the right leg be due to the intensification of the influence of the left optic thalamus? This would account for both the diminished reflex action and the hyperæsthesia, since the thalamus was a sensory centre. Its over-action might be due to the accumulation of the obstructor nerve-force in its fellow, acting upon it by means of the commissural fibres. The difference in irritability of nerve and muscle must be interpreted as an abnormal state of the paralysed limbs, and was, although unusual in character, probably due to an irritative influence exerted by the lesion on the grey matter of the lumbar enlargement, and thence on the motor nerves. The persistence of sensibility in the branches of the cervical plexus showed how high up in the cord these fibres decussated.

Dr. Althaus said the paper presented few openings for discussion, the case had been so excellently reported. He was sorry there was no reference made to the sense of temperature. Was there any priapism? It would be interesting to know with what portion of the spinal cord this phenomenon was connected. He agreed as to the electric phenomena.

Dr. Broadbent also spoke of the excellence of the paper. He thought that the case rather tended to confirm Schiff's theory of the use of the posterior columns of the cord as conductors of tactile impressions. The phenomena of locomotor ataxy did not, however, confirm this. Wherever, indeed, the lesions might be, the patient could often localise the point of contact. The increase of reflex action on the injured side tended to corroborate his own speculations as to the structure and action of certain parts of the nervous system. He thought the same cells received both sensory and reflex impulses. If the upward course of the former was arrested, the latter would be more strongly marked than before. He thought the anæsthesia of hysteria due to diminished blood-supply from irritation of the vaso-motor system, yet tactile sensibility remained. Here there was vaso-motor paralysis, and, consequently, hyperæsthesia.

Dr. Buzzard asked what was the condition of the muscular sense when power partially returned to the leg.

Dr. Althaus thought the inhibitory centres were situated rather in the corpora quadrigemina than in the optic thalami.

Dr. Gowers, in reply, said the case was admittedly imperfect. The difficulties were great; the patient could not speak English, and sank rapidly. He could hardly go into the evidence of the optic thalami being the inhibitory centres, and he quite agreed as to the difficulties of Schiff's theory of the function of the posterior columns of the cord. There was no priapism.

Left Hemiplegia and Hemianæsthesia associated with Loss of Speech.

Dr. Broadbent communicated, for Dr. J. Burnley Walker, a case of left hemiplegia and hemianæsthesia with general diminution of motor power and of sensation, associated with loss of speech, peculiar voice and articulation, and ataxy of the upper extremities, due probably to embolism of the basilar artery; recovery. He said that the patient was a woman, aged twenty-six, who, four days after the birth of a child, was greatly excited by her husband coming home drunk. A severe rigor came on, and a few hours later, while she was sitting up to take food, she fell back in a swoon. When seen by Dr. Walker she was perfectly unconscious, though she swallowed liquids; her pulse was 48, and scarcely perceptible; the pupils were equal; the face was drawn a little to the right. After the free administration of brandy, she could be roused, and it was seen that the legs, limbs, face, and tongue on the left side were paralysed. Sensation was also greatly diminished on this side, and there was decided impairment of both motor power and of sensibility on the right half of the body as well. As the prostration was recovered from, she was found to be absolutely speechless, and the expression of her face, her laugh, and features were almost idiotic. She gradually gained power, but for a long time had had no proper control over the movements of her limbs. She could not take hold of an object, or guide a spoon to her mouth. She spoke for the first time eleven weeks after the attack, and then in a peculiar loud voice and with uncouth articulation. When seen by Dr. Broadbent about three months after the attack, she could answer simple questions, but in a peculiar loud whining voice. She said she could not walk, but did so with the aid of a single finger; the movements of her hands were vague. Her mental condition appeared to be childish, and she smiled idiotically. Further improvement took place, and now (October, 1877) she could walk and carry her child, and attend to her house; but she still fumbled long over buttons and pins, and had only just become able to dress herself. She could not now control a knife so as to cut bread. She conversed fairly well, but not in a natural voice. Dr. Broadbent said the case was interesting, as throwing light on reported examples of aphasia with left hemiplegia, or with lesion in the posterior part of the brain. Had the patient died during the eleven weeks in which she was speechless, the case might have been considered one of this class; but the mental condition, the peculiar phonation and articulation, and the mode in which speech was recovered, showed that the derangement of the cerebral operations and the injury to the cerebral mechanism were altogether different from those which were seen in aphasia. The time and mode of the attack pointed to embolism of a cerebral artery as the cause of the symptoms, but these were not such as could be accounted for by blocking up of any one branch of the carotid, or of this vessel itself, or of the posterior cerebral or superior cerebellar, or both. The general impairment of motor power and of sensibility, in addition to the left hemiplegia and the motor ataxy, pointed to the conclusion that the basilar artery was the one plugged, the left branch getting more blood than the right, either by a larger post-communicating artery or by a less perfect occlusion. This would account also for the effect on the heart.

Peculiar Phonation as well as Articulation associated with Paralysis.

Dr. Broadbent brought to the Society brief notes of four cases in which, as in that of Dr. Walker, these peculiarities had existed. Case 1 was that of a girl, aged twenty, who, seven months after the birth of an illegitimate child, was seized, after an emotional shock, with pain in the head, vomiting, and delirium; after which, she was completely paralysed on the left side, partially on the right, then speech was said to have been lost; it was probably rather unintelligible. As she recovered, the voice was altered and impaired, and the articulation was indistinct and almost monosyllabic. Case 2 was that of a woman, aged twenty-seven, who, during an attack of small-pox, five weeks after the birth of a child, had a fit, after which she could not move a limb or speak a word for some weeks. When she had so far recovered as to be able to walk and feed herself, her intonation was loud and unnatural, and articulation imperfect, attended with effort, and monosyllabic. Case 3 was that of a schoolmaster who, a year after contracting syphilis, became suddenly hemiplegic on the left side. Twelve months later he gradually lost his speech, and for six months could not speak at all, deglutition, moreover, being affected. He regained speech, and some power in the left limbs, but the voice was squeaky and unnatural, and articulation peculiar and attended with great effort. In Case 4 there was cross paralysis of the left limbs and right face, attended with affection of the voice and articulation. The feature common to these cases and that of Dr. Walker was that, except in the last (which was reported as helping to identify the seat of the lesion and to locate it in the pons), there was for a time speechlessness, which might have been taken for aphasia, whereas the subsequent history showed

that the damage to the mechanism of speech had occurred at a quite different point.

Dr. ALTHAUS thought the case well illustrated the localisation of function in the brain. There were now two camps—one for localisation, the other against; he rather sided with the former. Dr. Broadbent's case illustrated the fallacies of Brown-Séquard's school; had death occurred early it would undoubtedly have been considered a case of complete aphasia, but it was now proved not to be so.

Dr. BROADBENT had encountered several of these cases, and was desirous of putting them on record. This has been briefly done above.

MEDICAL NEWS.

UNIVERSITY OF LONDON.—The following is a list of the candidates who have passed the recent Second M.B. Examination:—

First Division.—Albert Boyce Barrow, King's College; Peter Horrocks, Guy's Hospital; Boyd Burnett Joll, University College; Herbert Urmson Smith, St. Thomas's Hospital; Charters James Symonds, Guy's Hospital; Nestor Isidore Charles Tirard, King's College.

Second Division.—Judson Sykes Bury, University College; Charles Henry Cattle, Leeds School of Medicine; Paul Morgan Chapman, University College; William Edward Collins, St. George's Hospital; Edward Marriott Cooke, King's College; George Michael James Giles, St. Mary's Hospital; Francis Goodchild, St. George's Hospital; William Gristock, University College; George Hawson Keyworth, Guy's Hospital; John Mortimer, University College; Samuel Thomson Plumbe, St. Bartholomew's Hospital; James Ryley, University College; Herbert Richard Octavius Sankey, University College; Arthur Robert Wyatt Sedgefield, King's College; Edward Arthur Snell, King's College; Leader Henry Stevenson, Guy's Hospital.

ROYAL COLLEGE OF PHYSICIANS AND SURGEONS, EDINBURGH.—DOUBLE QUALIFICATION.—The following gentlemen passed their First Professional Examination during the recent sittings of the examiners:—

Black, Patrick Francis, County Meath.
Crofts, William, Cork.
Drinkwnter, Thomas William, Carlow.
Hannay, John, Dudley.
Lyon, John, Liverpool.
Macfarlane, Edward Parlane, Islay.
MacLoughlin, Thomas James, County Meath.
Mahony, Percy George, Preston.
Mossman, Robert Arthur, Lincolnshire.
Murdoch, Ivon Lewis, Pitsligo.
Purcell, John, Cork.
Rankin, Walter Lorrain, Govan.
Smyth, James, County Limerick.
Steele, John Currie, Johnstone.
Stumbels, Samuel, Philips, Kilmallock.
Taylor, David, Down.
Whiteley, Richard Hanser, Wakefield.
Williamson, Albert Vaughan, Middlesborough.

And the following gentlemen passed their Final Examination, and were admitted L.R.C.P. Edin. and L.R.C.S. Edin.:—

Andrianaly, Madagascar.
Blunden, Abraham, Kilkenny.
Coward, Frank Augustus, Cape of Good Hope.
Culliman, John Richard, County Wexford.
Doyle, Edward Alexander, Lancashire.
Eastwood, Lewis, Halifax.
Fergusson, Reginald Archfield, New Granada, S. America.
Ford, Edwin Moses, Mausfield, Notts.
Gill, John, Leadhills.
Goggin, George Taylor, County Clare.
Gunn, Alexander, Caithness-shire.
Holdsworth, Samuel Rayner, Wakefield.
Kennedy, Samuel, County Down.
Lawless, Edmond James, Malta.
Loveless, Walter King, Stockbridge, Hants.
M'Kee, William Alexander, Crumlin.
M'Mann, John Alexander, Sligo.
Marsh, Edwin Addison, London.
Miller, Alfred Henry, Portsmouth.
Moody, Joseph Woods, Newry.
Muir, James Claudius Pollock, Luton, Beds.
Norman, Arthur Harry, Colchester.
Redpath, Robert Knox Wighton, Edinburgh.
Rentoul, Robert Reid, County Antrim.
Scriven, John Swain, Weymouth.
Smellie, Thomas Stewart Traill, Fergus, Ontario.
Spencer, Henry Ebenezer, Leicestershire.
Warden, David Brown, Ayrshire.
Whiteley, Edward Arthur, Wakefield.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—The following gentlemen, having undergone the necessary examinations for the diploma, were admitted Members of the College at a meeting of the Court of Examiners on the 13th inst., viz.:

Bellwood, John, L.R.C.P. Edin., Addiscombe, student of University College.
Bernays, Augustus Charles, M.D. Heidelb., St. Louis, Missouri, U.S., of Heidelberg and Berlin.
Bottrell, Jas. Francis Henry, L.S.A., Hereford, student of the Westminster Hospital and King's College.
Crallan, George Edward James, Hayward's Heath, of St. Bartholomew's Hospital.
Cross, Horatio Robt. Odo, L.R.C.P. Edin., Craven-street, Strand, of King's College.
Dickinson, George Dixon, Darlington, of the Edinburgh School.
Elam, William Henry, Mirfield, near Huddersfield, of the Leeds School.
Flint, Horace, M.B. Edin., Canterbury, of University College.
Fort, Thomas, L.R.C.P. Edin., Oldham, of St. Thomas's Hospital.
Goode, Charles Fox, L.S.A., Haverfordwest, of St. Mary's Hospital.
Greasley, Joseph, L.R.C.P. & S. Edin., Melton Mowbray, of the Edinburgh School.
Hollingworth, John, Sheffield, of the Sheffield School.
Lane, William Arbuthnot, Woolwich, of the Sheffield School.
Orlebar, Hotham George, M.B. Aber., St. Leonards-on-Sea, of St. Thomas's Hospital.
Palm, William Stuart, M.B. Edin., Rotterdam, of the Edinburgh School.
Prickett, Marmaduke, Bridlington, Yorkshire, of St. Bartholomew's Hospital.
Steventon, Walter Thos., L.S.A., Snaith, Yorkshire, of University College.
Thomas, William, Ucheldrefgoed, Anglesey, of the Liverpool and Dublin Schools.
Tuchmann, Maro, M.D. Würzburg, Haverstock-hill, of Berlin.
Underwood, Arthur Swayne, Bedford-square, of King's College.
Whitehead, Hayward Reader, Harrow, of the Charing-cross Hospital.
Wilkinson, Arthur Thomas, L.S.A., Didsbury, of the Manchester School.

The following gentlemen were admitted Members on the 14th inst., viz.:—

Beard, Spencer Francis, L.S.A., Hayward's Heath, student of the Sheffield School.
Claremont, Claude Clarke, Camden Town, of University College.
Davidson, Alexander Deas, L.S.A., Erith, Kent, of St. Thomas's Hospital.
Gabb, Jas. Percy Alwyne, Bewdley, Worcestershire, of University College.
Goss, Samuel, Sidmouth, Devon, of St. George's Hospital.
Greasley, John, L.S.A., Canterbury, of the London Hospital.
Greenwood, Arthur, L.S.A., Chipping Norton, of Charing-cross Hospital.
Hornsby, George Harcourt, L.S.A., Bromsgrove, Worcestershire, of the Birmingham School.
Hunt, Robert, Preston, Lancashire, of the Manchester School.
Lighton, Henry Alfred Hamilton, Ross, Hereford, of St. George's Hospital.
Manby, Herbert Lynsey, East Rudham, Norfolk, of Guy's Hospital.
Newmarch, Bernard James, South Eaton-place, of King's College Hospital.
Paulley, Job Nathaniel Legge, Weymouth, of St. Bartholomew's Hospital.
Richards, Thomas, L.S.A., Salisbury, of Guy's Hospital.
Thomas, Hugh William, L.S.A., Beaumaris, of the Birmingham School.
Taylor, Frank, L.S.A., Bristol, of the Bristol School.
Taylor, Richard Stanley, Derby, of Guy's Hospital.
Walker, Charles Edward, Darlington, of the Edinburgh School.

Six gentlemen were approved in Surgery, and when qualified in Medicine will be admitted Members of the College; and fourteen candidates having failed to acquit themselves to the satisfaction of the Court of Examiners, were referred to their professional studies for six months. The examination was brought to a close on Thursday; the list of successful candidates will be published next week.

The following were the questions on Surgical Anatomy, and the Principles and Practice of Surgery, submitted to the candidates on the 9th inst., when they were required to answer at least four (including one of the first two) out of the six questions:—1. Describe the position and relations of the prostate, and the effects produced by its enlargement. 2. Enumerate in order the parts which would be divided in amputation of the thumb at the carpo-metacarpal articulation. 3. What are the pathological changes which occur in whitlow? Describe the complications which may arise in severe cases. 4. Describe the structure of a varicose vein; and the causes and consequences of that condition as affecting the lower limb. 5. What are the diagnostic symptoms and the treatment of acute glaucoma? 6. What are the early symptoms of inflammation of the hip-joint? Describe the appropriate treatment. The following were the questions on the Principles and Practice of Medicine submitted the following day, viz.:—1. Describe the symptoms of, and the pathological conditions giving rise to, hemiplegia, with the general principles of treatment in the different stages. 2. Describe a case of acute bronchitis in the adult, giving the causes, course, physical signs, and treatment, with two different prescriptions written out in full. 3. What are the different effects of opium, belladonna, hyoscyamus, cannabis indica, chloral, and stramonium? What are the chief indications and counter-indications for their employment?

ROYAL COLLEGE OF SURGEONS, EDINBURGH.—The following gentlemen passed their First Examinations during the October sederunt:—

Caird, John Hay, Fort George.
Lang, James, Renfrewshire.
Rankine, John, Stirling.

And the following gentlemen passed their Final Examination, and were admitted Licentiates of the College:—

Beresford, Francis J., Leicestershire.
Burns, Walter, Ayr.
Hewson, Robert William, Salisbury.
Innes, John Caithness, Marykirk.
Mann, James, Nairn.

APOTHECARIES' HALL.—The following gentlemen passed their examination in the Science and Practice of Medicine, and received certificates to practise, on Thursday, November 8:—

Craddock, Frederick Hurst, St. Luke's Hospital.
Hammond, Alexander Billing, Queen-street, Finsbury.
Hepburn, Alfred, Upper Bedford-place.
Johnson, Christopher John Byron, Whitwick, Leicestershire.
Ling, Maurice Edward, Saxmundham.
Murray, Charles Herbert, 122, Kensington-road.

The following gentlemen also on the same day passed their Primary Professional Examination:—

Betts, Edward George, Middlesex Hospital.
Sutcliffe, Joseph, St. Thomas's Hospital.

APPOINTMENTS.

*** The Editor will thank gentlemen to forward to the Publishing-office, as early as possible, information as to any new Appointments that take place.

COATES, STANLEY BERESFORD, L.R.C.P., L.R.C.S. Edin.—Medical Officer to the No. 4 Dispensary District, Belfast, *vice* — Mark, resigned.

LUDWIG, Dr. GUSTAVUS, of Darmstadt.—Resident Medical Officer to the German Hospital, Dalston.

MANN, H. W., M.B. and C.M.—Resident Assistant-Physician to the Sterling District Lunatic Asylum, Larbert, N.B.

SEMPLE, C. E. ARMAND, M.B., M.R.C.P. Lond.—Fourth Physician to the North-Eastern Hospital for Children, Hackney-road, E.

NAVAL, MILITARY, &c., APPOINTMENTS.

WAR OFFICE.—MEDICAL DEPARTMENT: Surgeon-Major William Menzies Calder retires upon temporary half-pay. SCOTS GUARDS: Surgeon Thomas John Peatfield, from half-pay Medical Department, to be Surgeon, *vice* E. W. Cottle, resigned. The Secretary of State for War has appointed Alfred Sharpe, M.D., L.R.C.S. Edin., to be Visiting Surgeon for Woolwich, *vice* Dr. Stuart, resigned; and Alexander Forsyth, M.D., to be Visiting Surgeon; and Hubert Wilson, South Sturton, M.R.C.S, Eng., to be Assistant Visiting Surgeon for Greenwich under the Contagious Diseases Acts, 1866 to 1869. In accordance with the provisions of her Majesty's Order in Council of February 4, 1875, Inspector-General of Hospitals and Fleets Sir William Richard Edwin Smart, K.C.B., M.D., has this day been placed on the retired list from November 13.

BIRTHS.

EASTES.—On November 10, at 69, Connaught-street, Hyde-park-square, the wife of George Eastes, M.B., of a son.

MADGE.—On November 11, at 4, Upper Wimpole-street, the wife of Henry M. Madge, M.D., of a daughter.

MAHON.—On November 2, at Aspley Guise, Woburn, Beds, the wife of D. Mahon, M.R.C.S. Eng., of a daughter.

RICE.—On November 12, at 34, Cadogan-place, S.W., the wife of M. W. Rice, M.D., of a son.

WALL.—On November 14, at 46, Norfolk-terrace, Bayswater, the wife of A. Wall, L.R.C.P. Edin., of a daughter.

WALKER.—On November 6, at The Grove, Portland, the wife of George E. Walker, L.R.C.P., of a son.

WYLIE.—On November 5, at Skipton, Yorkshire, the wife of William Wylie, M.D., L.R.C.P.E., of a daughter.

MARRIAGES.

PARSONS—DEAKINS.—On November 7, at the parish church, St. Matthew's, Bayswater, Charles William Nicholas Parsons, M.R.C.S. Eng., of West Haddon, to Laura, fifth daughter of Francis Henry Deakins, late of The Hill, Herefordshire.

DEATHS.

GLYN, HENRY ARTHUR, M.B., of the Borough Hospital, Birkenhead, and 69, Gloucester-street, Belgrave-road, S.W., on November 11, aged 23.

HUDSON, LOUISA, wife of W. T. Hudson, F.R.C.S., at 45, Cumming-street, N., on November 10.

TAYLOR, THEODORE THOMAS, M.R.C.S., L.S.A., of Cirencester, at his father's residence, Cricklade, on November 4, aged 34.

VACANCIES.

In the following list the nature of the office vacant, the qualifications required in the Candidate, the person to whom application should be made and the day of election (as far as known) are stated in succession.

LIVERPOOL ROYAL INFIRMARY.—Resident Medical Officer. Candidates must be unmarried. No person is eligible who is not on the Medical Register of Great Britain, and who does not possess at least one medical and one surgical diploma, licence, or degree recognised by the Medical Council. Applications, with testimonials, to the Chairman of the Committee, on or before November 20.

QUEEN'S HOSPITAL, BIRMINGHAM.—Resident Physician and Resident Surgeon. Candidates for these appointments must be registered practitioners. Testimonials, with certificates of registration, to the Secretary, on or before December 1.

ST. PETER'S HOSPITAL, 54, BERNERS-STREET, W.—House-Surgeon, duly qualified. Applications to the Secretary, at the Hospital, on or before November 20.

WESTON-SUPER-MARE HOSPITAL AND DISPENSARY.—House-Surgeon. Candidates must be unmarried, and hold a registered medical and surgical qualification. Applications, with qualifications and testimonials, to the Secretary, on or before November 19.

UNION AND PAROCHIAL MEDICAL SERVICE.

*** The area of each district is stated in acres. The population computed according to the census of 1871.

RESIGNATIONS.

Bangor and Beaumaris Union.—The Second Anglesey District is vacant area 19,616; population 5201; salary £75 per annum.

Tenterden Union.—Mr. A. R. Paterson has resigned the Biddenden District; area 7201; population 1419; salary £49 per annum. Also the High Halden District; area 3729; population 689; salary £15 15s. per annum.

Thetford Union.—Mr. Charles Morgan has resigned the Hopton District area 5222; population 1242; salary £27 17s. per annum. Also the Hepworth District; area 4520; population 1318; salary £28 4s. per annum.

APPOINTMENTS.

Brentford Union.—Henry R. C. Litchfield, L.R.C.P. Lond., M.R.C.S., the Ninth District.

Erpingham Union.—Robert McKelvie, M.D. Edin., L.R.C.S. Edin., the Cromer District.

Keynsham Union.—Nathaniel Crisp, M.R.C.S. Eng., L.S.A., to the Keynsham District.

Runcorn Union.—Wm. H. Carruthers, M.D., M.B., M.R.C.S., to the Halton District.

St. German's Union.—John B. Kerswill, L.R.C.P. Edin., M.R.C.S. Eng., to the First District.

Sedgefield Union.—Thomas Thompson, L.R.C.P. Edin., L.R.C.S. Edin., to the Bishopton and Sedgefield Districts, and the Workhouse.

Sleaford Union.—George K. Barton, M.D. Aber., F.R.C.S. Eng., to the Leadenham District.

West Bromwich Union.—Henry L. Browne, M.R.C.S. Eng., L.R.C.P. Edin., to the South-West District of the Parish of West Bromwich.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.—This Society will meet to-day (Friday, November 16) at 7.30 p.m. The report of the Council will be read on the following subjects:—"The Registration of Epidemic Infectious Diseases" "The Proposed Metropolitan Building Bill." Professor D. T. Ansted, F.R.S., F.G.S., will read a paper "On Rivers, and their Relation to Public Health."

QUININE FOR HYPODERMIC USE.—Dr. Morris has found the following formula for a solution of quinine to act satisfactorily:—Bromide of quinia is dissolved in alcohol, a grain to a minim, and then diluted with water as desired. It acts promptly, and leaves no scar, and the alcohol prevents the formation of fungi. It is usually readily absorbed, and has a peculiar quieting effect on the nervous system.—*New York Med. Record*, October 6.

CHLORAL IN MIGRAINE.—Dr. Couyba states that he has found chloral of great utility when given at the very commencement of an attack of migraine, it being, however, of no use if given at a later period. He prescribes three grammes in 100 of mint-water and fifty of syrup, giving a tablespoonful every half-hour until sleep is induced. If, on awaking, the migraine is still found persisting, the chloral is again given in the same manner; and it is rare to find that it continues after the second awakening.—*Rév. Méd.*, October 29.

A FRENCH "STUDENTS' NUMBER."—The *Progrès Médical* of November 3 is almost devoted to a *Numéro des Etudiants*, which, if less full of information than our own well-known productions of that character, contains a great deal of matter of great interest to all concerned with medical education in France. After an elaborate description of the circumstances attending the different *concours*, it gives a detailed account of the teaching at the Paris Faculty and of the Enseignement Libre and full lists of the medical officers, hours of attendance, etc., of the different hospitals. The medical societies are also described. The other French medical faculties and medical schools are detailed at considerable length. The number is sold separately for half a franc.

ACTION OF PILOCARPIN ON THE EYE.—M. Galezowski, in a communication to the Société de Biologie, narrated the results of the trials he had made on the eye with pilocarpin, the active principle of jaborandi. These show it to be possessed of powerful myotic powers. One drop of a mixture consisting of ten parts of water and one-fifth of a part of pilocarpin, instilled into an eye the subject of paralytic mydriasis, gives rise to such a contraction of the pupil that at the end of half an hour this measures scarcely a millimetre in diameter, the contraction continuing for from five to eight hours. This result has been verified upon a great number of patients, so that it may be now stated that pilocarpin possesses myotic powers as active as those of eserine, while it does not excite irritation like that substance, the prolonged employment of which may give rise to peri-orbital pains, intense conjunctivitis, and great nausea. M. Galippe observed that the experiments which he and M. Bochefontaine had made were attended by precisely the same results as those described by M. Galezowsky.—*Gaz. des Hôp.*, November 6.

ORIGINAL LECTURES.

ABSTRACT OF A CLINICAL LECTURE

ON THE TREATMENT OF COMPOUND FRACTURES.(a)

By PROFESSOR RICHARD VOLKMANN.

GENTLEMEN,—It is particularly gratifying to me to be able to place before you to-day the results which, during the past four years and a half, I have obtained in my cases of compound fracture of the extremities treated by the antiseptic method. Their chief feature can be summed up in a very few words. During the time I have mentioned, seventy-five such injuries, occurring in seventy-three patients, have been subjected to conservative treatment. A small proportion of these—eight altogether—had to be subjected to secondary amputation. But neither of those who were treated throughout on conservative principles, nor of those where the conservative treatment failed, and where secondary amputation had to be undertaken, did one single patient die; *they one and all recovered!*

As I am not the inventor of the "antiseptic method" of treating wounds—the greatest advance which surgery as a science has ever made,—you will not consider it boasting if I venture to call this a very remarkable result; indeed, as compared with our former experience, it is quite an unheard-of result. For the mortality of such injuries, until the antiseptic method was discovered, was a very high one, no matter what treatment was adopted. Compound fractures, that is, fractures with an open wound, until within a very few years past, were among the most dangerous injuries. Acute septicæmia and pyæmia, especially in hospitals, carried off a very large number of these patients. The losses were large, especially in French and German hospitals; while in England, where more attention was paid to cleanliness and ventilation, the results were somewhat better. Nevertheless, the mortality even in English hospitals was very considerable; and what was so bad and so striking in the situation was this—that in any given case one could never give any guarantee as to the result. In the simplest case of compound fracture, even where only a sharp fragment of one extremity of the broken bone had made a small, clean-cut wound in the soft parts, and where there was no splintering of the bone and no contusion of the soft parts, a surgeon, however experienced he might be, could not prophesy whether the patient's life would be saved, however carefully he were watched, and notwithstanding the fact that he (the surgeon in charge) had had ample experience in the treatment of similar cases. We have no sufficiently large statistical compilations from which we can gather how large a mortality there has been in Germany—and, after all, it is this which interests us chiefly,—nor how large the mortality actually now is in places where the various antiseptic dressings and precautions are not in use. Many surgeons at the head of large hospitals are quite unacquainted with their own results. They would be shocked if the actual figures lay before them. Some, indeed, cannot bring themselves to publish their unfavourable figures. It is not everyone who has the courage of my friend, Professor von Nussbaum, who, in order to adduce an instance of another—and at one time still more fatal—injury (than that to which I have just alluded), which now *per se* has also become free from danger, has not hesitated to put in print that of sixty-four thigh amputations performed in military and civil practice combined, during the sixteen years immediately preceding the introduction of antiseptics, he had only saved seven cases. After Nussbaum's admission, it is very easy for me to acknowledge that my own results were very little better. But now, since the introduction of the antiseptic method of treating wounds, I get more successful cases in a single year than I had previously done during the whole of my surgical career.

Adequate statistics of mortality after compound fractures not treated on the antiseptic plan are only to be had for gunshot fractures. I will just give you a few figures taken from the well-known tables collected by Billroth. In one respect, certainly, they do not quite correspond to our present requirements, since they include *primary* amputations; these latter do not, of course, come into consideration while giving the results of treatment for fractures. According to Billroth, of 2021 gunshot fractures of the thigh, no matter how they were treated, 1229 died; and under similar circumstances, of 1699 gunshot fractures of the leg, 401 died. This gives a mortality of 60·8 per cent. for the thigh, and 23·6 per cent. for the leg.

Unless one or other among you happen to have seen a little paper, which I published some years ago in Von Langenbeck's *Archives for Clinical Surgery* on "comparative statistics of mortality in military and civil injuries," you will at once reproach me that these figures, derived from a series of murderous wars, can have no weight in the estimation of the results of civil practice, because the mortality during a war is necessarily so very large. "Of those struck by the enemy's bullets on the field, many died, who at home would have been saved, partly because they were deprived of regular and sufficient nursing, and partly because they were subjected to all kinds of pestilences, especially to those dangerous and fatal wound complications which so often prevail in military field-hospitals." You will then further add that gunshot fractures never ought to be compared with compound fractures occurring in civil practice—at least, with such as are treated conservatively. The extensive splintering of bone produced by modern firearms, with which nothing in civil practice is comparable, sufficiently explains the high mortality.

Formerly I used to entertain similar rambling views upon the special mortality of the wounded in war. "When, in 1866, I first entered the field-hospital at Trautenau, and undertook the charge of about 1000 severely wounded men, among whom were the enormous number of 451 cases of compound fractures of long bones, and when, during the third week, I began to see the enormous mortality set in, I felt much as other surgeons did, who for the first time were called on to practise surgery 'en gros' (wholesale). I was quite stunned by the brute force of such figures. The effect of this immense single dose on my brain was quite other than that produced by repeated small doses, out of which my views on the danger of analogous injuries occurring in civil practice had been built up. It never occurred to me to doubt that the unfavourableness of the surroundings, and the especial severity of gunshot injuries in war time, should demand a relatively higher sacrifice."

However, on my return home, when I compared my newly-gained material with the cases—few, it is true—of compound fracture which I had treated in civil practice, I found to my astonishment that my home results, expressed in percentage, were much more unfavourable.

In Trautenau, of 109 compound fractures of the thigh, 51 died; and of 104 fractures of the legs, 25 died. In round numbers, then, of the former about one-half, and of the latter about a quarter.

A retrospect of the note-books of my surgical wards in Halle showed that of eleven compound fractures of the femur six, and of sixty-four compound fractures of the leg twenty-six (!) died. The difference, especially in the leg cases, was very considerable, and it was not in our favour; and I should have expected exactly the contrary, because I know that of the sixty-four cases treated in this hospital a considerable number of them were compound in consequence of simple puncture of the soft parts by some sharp fragment of bone.

But researches and inquiries, which I undertook with my then pupil Dr. C. Fränckel, soon convinced me that the figures were equally bad whenever sufficiently large statistics of civil practice were available. Thus, of 885 compound fractures of the leg, taken at random from English and German hospitals, treated either by amputation or conservatively, 339 ended fatally. This gives a mortality of 38½ per cent. for civil practice, as against a mean mortality in war of 23·6 per cent. The results of civil practice, therefore, are less favourable by 15 per cent.

I must here remark that the value of these figures (38·5 per cent.), as the mortality after compound fracture of the leg in civil practice, is considerably augmented by the fact that the results of individual hospitals, especially in Germany, about which we have any statistics at all, coincide in a remarkable way. Those who have occupied themselves with statistics are aware how widely the figures, the means of which we utilise for statistical purposes, differ at their extremes. One surgeon has had unusually good results, another extraordinarily bad ones. Here, however, the differences are scarcely worth mentioning; they fluctuate within a minimum of something less than 4 per cent.—in surgical statistics, an almost unheard-of conformity. Baum, in Göttingen, lost 38 per cent.; Billroth, in Zürich, 38·7; Breslau Hospital, 40·5; Halle, 40·6; Bonn, 41·8 per cent.; and if I add that Rose, in Zürich, obtained almost the identical results, and that Lücke's Report of the Bern Hospital showed a mortality of something over 38 per cent. for *all* compound fractures (not those only of the leg), secondary amputations being included, as is the case with the

(a) *Sammlung Klinischer Vorträger.* Leipzig. Nos. 117 and 118.

above given figures, then we may fairly conclude that the percentage of 38·5, as the mortality after compound fracture of the leg in civil practice, is not far from the truth; and, further, that the different methods of treatment adopted in the different hospitals referred to—having this only in common, that they were *not* antiseptic—had little or no influence on the ultimate result.

I have gone somewhat more into detail concerning these figures and statistics than I at first intended; but I was anxious to give you a correct idea of what the antiseptic method really is capable of, by contrasting it with the treatment and results of earlier times.

Coming now to a consideration of the cases themselves, we find among the seventy-three patients that the injury was due to direct violence forty-eight times; and the bones were more or less splintered at the seat of fracture twenty times. In a large number of instances the injuries were due to steam machinery; and it sometimes required the most serious consideration whether we should even venture to try conservative treatment at all. The table(b) shows a variety of cases, and includes one where the skin was loosened from the knee to the malleoli.

The fractures were divided as follows:—

8	fractures of the	arm.
20	„	„ forearm.
1	„	„ thigh.
3	„	„ patella.
43	„	„ leg.
Total . . .	75	fractures in 73 patients.

Secondary, or more properly speaking intermediate, amputations were performed on eight patients—

2	with injury of the	arm.
1	„	„ forearm.
4	„	„ thigh.
1	„	„ leg.

Total . . . 8 amputations in 75 fractures = 10·6 per cent.

Excisions were performed in seven cases—

1 shoulder-joint.
4 elbow-joints.
2 ankle-joints.

Total . . . 7 excisions in 75 fractures (two primary and five secondary) = 6·6 per cent.

The larger joints in these seventy-five cases were opened twenty-one times, viz.—

Shoulder-joint	1	time.
Elbow-joint	6	times.
Wrist	3	„
Knee	4	„
Ankle	6	„
Total	21	times = 28 per cent. of the total cases.

Thus in twenty-one cases of accurately diagnosed injury to joints, secondary amputation was performed three times only; there were, however, seven excisions; while eleven patients (somewhat more than the half) were treated conservatively throughout. Of these eleven patients, one was discharged with an anchylosed joint—a patient with fractured patella, who was admitted thirteen days after his accident with a suppurating joint. The remaining ten patients were discharged with a freely movable joint—"an extraordinarily favourable result, of which surgery of the pre-antiseptic era can offer no analogues."

In one point only is my material somewhat defective—it is as regards compound fractures of the thigh. I have only a single case. During the period of four years and a half there was only one case of fracture of the thigh, compound from the "coming through" of the broken bone. All the other cases in which the femur was broken or splintered were due to railway or machinery accidents; and in these the limb was either entirely or almost severed from the body, and the soft parts so injured that primary amputation of the limb or exarticulation at the hip was the only resort.

But the defective experience in this matter was somewhat atoned for, and complemented, by seventeen "wedge-osteotomies" of the femur, which I performed during the same period. In no one of these cases, treated antiseptically, did any accidental wound-complications, abscesses, or phlegmonous processes occur. The incisions healed almost without any inflammatory reaction, and this notwithstanding the operations were of a serious nature—for nine times the wedge-shaped piece of bone was removed from just below the hip, seven times from below the knee-joint, and only once from the middle of the shaft. The bone was exposed by an incision from three to six inches long, the periosteum was detached all round, and then a wedge-shaped piece of bone, larger or smaller according to circumstances, was removed with a chisel. Sixteen out of these seventeen patients recovered without the slightest disturbance; the seventeenth, a bleeder, died within the first twenty-four hours, of primary hæmorrhage. During this period, too, I had three severe false-joint excisions of the femur in cases of ununited fractures, which healed in a most typical manner under the antiseptic treatment. Thus, in addition to the single case of compound fracture, we have these twenty cases of surgical injury to the femur. Concerning the influence which age exerts, contrary to what obtains in other methods of treatment, with the antiseptic method, age seems to make but little difference, provided there have not been much loss of blood. Old patients cannot bear the effects of septic fever so well as younger ones, and this, under the old method of treatment, was always a source of danger.

And now for the technical part of the antiseptic process. *The first dressing decides the fate of the patient and the course and issue of the wound.* All counter-incisions must now be made and drainage-tubes put in; loose splinters of bone must be removed, and the fractured extremities put into position; any little sharp projections may be rasped away; and the wound then must be completely disinfected. If this is done thoroughly and with care, the knife need never be taken into the hand again, however long the healing may require; nor will any further drainage-tubes be required, though possibly some small bits of necrosed bone may require removal; but this should only be done when all danger to the patient is past and over. Here is ample ground for doing the first dressing with the very greatest care, and with the most pedantic minuteness. We must not hesitate to bestow half an hour, or even three-quarters of an hour if so much be necessary.

I do not generally undertake this first dressing in the ward itself, but in a special operating theatre. The floor is asphalted, and provided with a drain and waste-pipe, which allow a very free use of water and carbolic acid; we are well provided also with irrigators and douches, disinfected sponges, and a plentiful supply of linen, bandages, and instruments. The patient is generally chloroformed, and then a thorough cleansing of the injured part and of the limb with soap and water, scrubbing-brush, and razor (if needs be), etc., can be conveniently carried out. In all cases the wound is enlarged sufficiently to admit the finger freely, or to allow of the seat of fracture being seen when the soft parts are retracted. The finger having been introduced, is made to cleanse (with a stream of carbolised water) the wound and all recesses opening out of it: every trace of coagulum is to be carefully washed away. If there are any deep pouches they must be incised, and preferably so at the extremity of the *cul-de-sac*, in order to thoroughly drain them. Especially, too, in any places where the skin is separated from its subcutaneous attachments, must incisions be made here and there, as circumstances seem to require, in order to let out any blood, whether liquid or partially coagulated, which may have collected, and drainage-tubes must also be introduced. Any muscular shreds which may have been too severely bruised may be at once removed with scissors.

If the wound is situated so as not to offer a free and easy outlet for the secretions, a counter-opening at some convenient place must be made, and a drainage-tube inserted.

All loose splinters must be carefully removed; such larger ones, however, as are firmly adherent to the periosteum may be left, care being taken not to loosen their periosteal attachments. If there are sharp projecting ends, round them off with the bone-forceps. Be careful that there are no portions of muscles between the broken ends of the bone, as they prevent union; indeed, they are the most frequent cause of protracted consolidation, and of "ununited" fractures (pseudarthroses).

Having got thus far, the wound may once again be well washed out with carbolised water, and the remaining part of the dressing must be carried out under the carbolic spray.

First of all, the wound itself and its surroundings are covered with a thick handkerchief-like pad of carbolic gauze. I prefer this to the "protective silk" for the first few days; for the fifty to a hundred layers of gauze which are thus lying on the wound readily absorb both any blood and wound secretions

(b) Our space prevents us giving this table in full. It may be consulted in the original (*op. cit.*).

which may flow out. Then upon this comes Lister's dressing proper, which I need not here further describe.

I generally change this first dressing on the following day, or on the day but one after at latest, in order to see whether all is going on properly, and whether the drainage-tubes are *in situ* and acting properly. Subsequent dressings are done every second, or third, or fourth day, according to circumstances; so soon as there is no further secretion from the wounds, after freely squeezing the limb, I remove the drainage-tubes. This is generally done about the third or fourth day.

The antiseptic dressing must be continued until the coagula, filling up the wounds, have become organised, or until their place is taken by granulation tissue. Sometimes the long-continued contact of carbolic dressings gives rise to a dermatitis. In such cases the skin may be gently rubbed with some antiseptic oil or ointment—such as boracic ointment—which will protect the skin, and still be antiseptic. In cases where the carbolic treatment disagrees radically, a constant irrigation with a solution of salicylic acid in water, as proposed by Thiersch, may be carried out.

In the foregoing lecture I have endeavoured, gentlemen, to make you acquainted with a method of treating wounds which entirely neutralises the danger of even the severest injuries, and which, in addition to this advantage, is free from pain. It insures cleanliness, does away with foul smells, protects the bed-linen, and paralyses the great evils which the overcrowding of hospitals would otherwise bring along with it. The dressing requires changing but seldom, and thus in large hospitals the work is considerably lessened.

The question of costliness is only an apparent disadvantage, because the shortened residence in hospital which these patients require more than makes up for the first outlay, which, no doubt, is rather large.

ORIGINAL COMMUNICATIONS.

ON CHINESE HÆMATOZOA.(a)

By PATRICK MANSON, M.D.,
of Amoy.

(*Continued from p.* 540.)

Filaria Sanguinis Hominis.

The extent and importance of the part played by nematode worms in human pathology is becoming year by year more recognised. I have elsewhere pointed out the probable connexion of a filaria worm with chyluria and elephantoid disease. The intestinal oxyuris and lumbricus are well known, as are also the Strongylus gigas, the Guinea worm, and the Trichina spiralis. The hæmaturia of the Cape, Egypt, and the Brazils is now acknowledged as depending on a similar parasitic cause, and I doubt not that, in time, many strange and at present unaccountable diseases of ex-European countries will be found to have a similar pathology; and I have described a peculiar and very prevalent form of stricture of the œsophagus I meet with in Amoy. Would not such a tumour in man, as I have shown is produced by Filaria sanguinolenta in the dog, account for all the symptoms of œsophageal obstruction that I therein described? Could such lesions as this filaria produces in the aorta of the dog give rise to aneurism were they to occur in man? The great frequency of aortic aneurism among Europeans in China, and the prevalence of filaria aortic disease in dogs in the same country, is a significant coincidence. Another of our domestic animals, besides the dog, is well known to be affected by a penetrating filaria in China; the worm in the eye of the horse, which most medical men in China have, I suppose, been called on to extract, is another member of the genus. Seeing, then, that both the dog and the horse, man's most frequent companions, suffer from the presence of filariæ, is it improbable that man himself should be the victim of a similar intruder?

These are some of the conjectures which this study in what I might term comparative pathology has thrust on me; and I cannot but regret that native prejudice forbids their being put to the test of post-mortem dissection.

Since what precedes was written, I have met with the Filaria sanguinis hominis in the human blood no less than fifteen times.

With the practice I had acquired in the detection of hæmatozoa in the blood of the dog, I commenced some time ago the systematic examination of human blood. To help me in the work, which is excessively tedious and laborious, I familiarised two Chinese assistants with the appearance of the canine hæmatozoon, and showed them how to manipulate for the detection of similar organisms in man. No selection is made of cases, but the first patient or healthy person who presents, and is willing to have his finger pricked, is examined; six slides of blood, at least, being carefully searched. In this way we have got over 190 cases, with the rather unexpected result of finding hæmatozoa in fifteen instances, or in about 8 per cent. To prevent mistakes or imposition, when the parasite is found by my assistants, I take care to verify the observation for myself from a fresh specimen of blood, which I see drawn. I failed to find hæmatozoa in four instances in which they were reported; but I believe my assistants' observations were correct: they were confirmed by the persons who supplied the blood. Their horror at the snake-like animal they had given birth to was conclusive. As my re-examination was made some days after the first detection of the parasites, it is likely that these had disappeared temporarily. This has happened in several instances I have myself closely watched.

The Filaria sanguinis hominis resembles very closely in general appearance and movements the canine hæmatozoon previously described. Accurate measurements are difficult to make, on account of the restlessness of the animal when alive, and the contraction which its body undergoes when fixed in desiccated blood. The short time when the blood is thickening, previous to thorough inspissation, is the most favourable for examining the animal; then its movements are languid, and admit of the details being studied. From a number of observations, I conclude that it measures slightly less than $\frac{1}{3000}$th of an inch in breadth, by about $\frac{1}{90}$th of an inch in length, or thereabouts; on the whole its dimensions are rather under those of the canine variety. There are two or three points in which distinct and characteristic differences can be made out in the two species, when seen through a high power. The canine variety appears to be naked and structureless; the human, on the contrary, is provided with a very delicate non-contractile integument, within which the body of the animal is incessantly shortened and elongated. This, I believe, is the explanation of the appearance of a lash of extreme tenuity at the head and tail being sometimes visible, and sometimes not, and the occasional thickening of the extremity of the tail. The lash is the collapsed integument from which the head or tail has been withdrawn, and into which they are again projected. It seems to have no elasticity or spring, but follows like a limp string the movements of the body of the animal. Unlike the canine hæmatozoon, in many specimens of the human variety, though not in all, there is about the centre of the body an elongated yellow patch, the structure of which with the microscopic power at my command I cannot make out. I believe it appertains to an alimentary canal. On close examination with a high power, distinct movements as of a mouth can be made out at the extremity of the head. They resemble the breathing movements of a fish's mouth. The aperture, if aperture exists, is not simple, but, I think, is provided with several lips.

In a future report I hope to give details of all the cases I have examined for hæmatozoa; at present I will confine myself to short notes of the cases only in which they were found.

Case 1. *Hæmatozoa and Elephantiasis Scroti.*—Angkhi, male, aged fifty-eight, from Changchiu, Liauho-sia, cake baker, in comfortable circumstances. Father died long ago, he does not know of what disease; mother died from fever and dysentery; two brothers are alive and well, one brother died from fever and dysentery. He states that when twenty-eight years of age, in the spring of the year, he had an attack of what he calls ague, accompanied by inflammation of the scrotum; the fever lasted for but one day, but it was two months before the scrotum recovered its original size; before doing so it desquamated. Since that time he has had attacks of fever every year from four to eight times, each attack being accompanied by inflammation of the scrotum. Two years ago the scrotum did not, as formerly, recover after the fever, but remained swollen, and has grown steadily ever since. Formerly he was strong and stout, but for the last ten years he has lost flesh. He never had chyluria. His scrotum presents the usual appearance of elephantiasis. I suppose it to weigh about eight pounds. On its under surface there is a solitary vesicle about the size of a split pea, and near this a bunch of dilated lymphatics: pricking these places gives vent to a drachm or two of coagulable milky lymph. Blood from his finger or scrotum contained numerous specimens of Filaria sanguinis hominis; nearly every slide contained one or two.

(a) From the *Customs Gazette.*

On the second day of his stay in hospital, filariæ could easily be found, though they had manifestly diminished in number. On the third day, though thirty slides were examined, not one specimen could be obtained, and during the five subsequent days, though frequent examinations were made, there was no reappearance of filariæ. I was anxious to keep this man under observation for some time before operating on his scrotum, but the frequent examination of his blood seems to have alarmed his friends, and he was in consequence removed from the hospital unrelieved.

Case 2. *Hæmatozoa without Concomitant Disease.*—Sin-to, male, aged twenty-one; born in Tintai; came to Amoy about five years ago, and became a pupil in the English Presbyterian Mission School. Does not remember to have suffered from any particular disease, except an attack of jaundice about four years ago, succeeding a smart fever (calls it ague) of one day's duration. His urine continued dark for about a month. He says he has been short-sighted ever since the jaundice. Never had abscess, boils, enlarged glands, or anything resembling elephantiasis, lymph-scrotum, or chyluria, but has always been strong and healthy. Being at the hospital one day (not as a patient) he saw a student examining the blood of a sick man. Out of curiosity he submitted his own for examination. In six slides three filariæ were found in full activity. A week afterwards I found them in nearly every slide. A fortnight afterwards I searched six full slides very carefully, but could fine none.

Case 3. *Hæmatozoa and Lymph-Scrotum.*—Siah, male, aged forty-five, a field labourer, lives in Lamoa, Choanchia. This man is intellectually very dull, and his memory appears to be very imperfect, so that a reliable account of his early history is difficult to obtain. One fact he dwells on with great obstinacy, perpetually recurring to it during his examination—viz., that for twelve years he has suffered from feelings of discomfort and pain in his bowels, grinding of his teeth at night, and frequent seminal discharges. When sixteen years of age, and again at twenty-eight, he had attacks of fever. Three years ago he had frequent fits of what he calls ague, the fever never continuing for more than one day at a time, but recurring every week or two. But before this occurred he noticed that his scrotum was itchy and covered with vesicles, which, when broken, would exude fluid in great abundance for seven or eight days. The scrotum and inguinal glands gradually enlarged, but it was not until they had attained considerable size that he became liable to fever. Last year he had a course of quinine at the hospital; since then he has had only one attack of fever, four months ago, and of three days' duration, and his scrotum he says has diminished very much. During the attack of fever, he says that the scrotum was not affected, but that the glands were inflamed. The scrotum is not very large, but it is a characteristic "lymph-scrotum." The left inguinal glands are slightly swollen; the right inguinal and right upper femoral glands are very much enlarged, feel soft and doughy to the touch, and are evidently varicose. During a residence of about a week in hospital, this man's blood was daily examined, and on no occasion were filariæ absent, varying in number from two to five in six slides.

Case 4. *Hæmatozoa without Concomitant Disease.*—Kim, a large-footed married woman, aged thirty-three, from Changchiu; came to hospital for ulcerated cornea and pannus of five years' duration. Her general health is good, though she has leucorrhœa, and at times aguish feelings. She is liable to swelling (œdema ?) of the arms and legs. She has enlarged inguinal glands on the left side; these appeared about the time she came to hospital; they were painless, and have been considerably diminished by rubbing them. She says she is dyspeptic and at times breathless; has never had chyluria. Filariæ are abundant in this woman's blood. Fourteen specimens were seen in six slides; they were found daily for a week.

Case 5. *Hæmatozoa, Fever, Enlarged Glands (and Chyluria ?).*—Sia, male, aged twenty-two, native of Hooihoah; farm servant and coolie. His father has elephantiasis of the leg, and enlarged glands. When seven years of age he remembers to have had an attack of fever and inflammation of the glands. For the last four or five years has had frequent attacks of a fever like quotidian ague, each attack lasting for three or four days, and being accompanied by swelling of the inguinal glands. At present these glands are but slightly enlarged; the skin of the scrotum, however, is *perhaps* slightly hypertrophied. He says that when he has fever his feet become red and swollen. In the fifth month of last year he once passed chylous urine: this is his statement. On examining his blood six slides were found to contain three hæmatozoa.

Case 6. *Hæmatozoa and Elephantiasis Scroti.*—Tso, male, aged fifty, native of Hooihoah; has been a chair coolie in Amoy for twelve years. For the last fifteen or twenty years has been subject every fortnight or three weeks to attacks of shivering heat, and sweating, each attack lasting only for two or three hours, and followed by lassitude and anorexia, incapacitating him for work for the day. These attacks are preceded and accompanied by aching about the right knee, and swelling of the inguinal glands, especially on the right side. No swelling at these times of the scrotum. Otherwise is quite well. Never had chyluria. The right inguinal glands are enlarged, and the skin of the scrotum slightly but distinctly hypertrophied. Filariæ were found in every second or third slide of blood. A week after the first examination, filariæ were again detected, but after another week in seven slides none could be found; that morning he had had one of his usual feverish attacks.

Case 7. *Hæmatozoa, Fever, and Anasarca.*—Liengoo, male, aged thirty-four, native of and resident in Amoy; formerly a preacher and teacher, at present unemployed. Until he was twenty-nine years old never had any serious illness; that year he noticed a swelling of his legs. At thirty he had general dropsy for a month. At thirty-one had severe fever, accompanied by delirium, and when the fever left him he was dropsical and had a yellow complexion. After this attack he suffered from fever every month. He says he could tell the approach of the fever by observing that his body swelled, while his urine became scanty. Fever was not preceded by rigor; when the fever subsided, urine increased in quantity and the dropsy disappeared. These attacks always occurred at the end of the Chinese month, and would last from three days to a week at a time. During his thirty-second year, though his body was slightly dropsical, he had no fever. In the ninth month of his thirty-third year, he was weak and breathless; during the eleventh month his body again swelled, and he had attacks of fever more violent than before. Two months ago he had a very severe attack, accompanied by high delirium. I saw him at this time; he lay quite insensible in high fever, and his body was very much swollen; bedsores had formed over his sacrum. Under treatment by quinine, digitalis, and nitre he recovered, the fever and dropsy subsiding and the sores healing. During the whole time he has been subject to these attacks, his appetite, even during the fever, has continued good. His friends say he is liable to maniacal attacks; his style of conversation and manner are certainly peculiar. Heart and urine normal. Skin is yellow, flabby, and coarse-grained. Scrotum and inguinal glands partake of the general dropsy, but appear otherwise to be healthy. His blood contains filariæ in great abundance.

Case 8. *Hæmatozoa; no Concomitant Disease.*—Kim, female, aged twenty-three; Amoy; unmarried. Three years ago had a fever, supposed to be typhoid. Previous to this she was suspected of being phthisical, but since the fever, cough and all other symptoms of lung disease have disappeared. Has never had chyluria or any affection of the lymphatic glands or integuments, and is apparently in good health. This girl is the sister of the principal assistant in the Chinese hospital. Out of curiosity she got her brother to examine her blood, and in the first slide inspected three filariæ were found. The girl was shown the worms, and was so much alarmed by their appearance that she refused for a long time to allow any further examination. A few days ago I was allowed to examine her blood, and, although seven slides were carefully searched, no filariæ could be found. The specimens yielded by the previous examination I myself saw, so that there can be no doubt of the truth of her brother's statement. It may be worth while to mention that the day before the last inspection she suffered from slight feverishness.

Case 9. *Hæmatozoa and Lymph-Scrotum.*—Toon, male, aged sixty; native of Lamoa, Toa Rhæ; a chair coolie; has lived in Amoy for eleven years. Between twenty and twenty-five he became subject to attacks of fever and inflammation of the scrotum, coming on at irregular intervals of from a month to a year. These attacks have recurred more or less frequently ever since; sometimes, however, he has been free from them for a year or two. This year the fever is much less severe, but it comes more frequently than formerly, the intervals between the attacks being only from four to six days. The fever resembles an ague very closely in its distinct division into cold, hot, and sweating stages; but, unlike an ague, there is no regularity to be observed in the time of its accession, sometimes coming on at night, sometimes during the day, and not recurring at regular quotidian, tertian, or quartan intervals. Each attack lasts about five hours, and is accompanied by slight swelling of the scrotum. Never had abscess of scrotum, or chyluria. Two nights previous to examination he had one

of the usual fever fits. The scrotum is considerably enlarged, and varicose lymphatics on its surface yield a milky lymph on being pricked. His blood contains abundance of hæmatozoa; one slide had as many as five specimens in full activity.

Case 10. *Hæmatozoa in a Leper.*—Nin, male, aged twenty-six; Lamcheng; shopkeeper; a leper for two years. I have no extended notes of this case, nor did I see hæmatozoa in his blood myself, though I searched many slides. My assistant, however, says that in the first slide he examined he found one, and his statement is confirmed by others.

Case 11. *Hæmatozoa with Debility.*—Beng, male, aged twenty-two; Petsuia; a student in the Chinese Hospital. As in the foregoing case, only one worm was found, which I did not see. Many slides were subsequently examined. This lad suffers from debility, and though young has very bad teeth, bad complexion; has at times feverish attacks accompanied by feelings of languor. Has no swollen glands, or any appearance of elephantiasis, and has never passed chylous urine.

Case 12. *Hæmatozoa, Enlarged Inguinal Glands, Thickened Scrotum, Leprosy, and Fistula in Ano.*—Boo Kiong, male, aged thirty-eight; Chinpo; farm servant; came to the hospital to be operated on for fistula in ano. Over his right malar bone is a patch of thickened skin, two inches in diameter, of a reddish colour and insensible to the touch (? leprosy). A near relation is leprous. No similar spots on any other part of the body. Was twice working in the Straits Settlements, five years at a time, and while there had ague; occasionally now has aguish feelings, and two years ago had an attack of fever, during which his scrotum became swollen and inflamed. At present the scrotum is slightly thickened, and on both sides the inguinal glands are enlarged. My assistant found two filariæ in six slides. Next day I failed to find any, although a similar number of slides were examined.

Case 13. *Hæmatozoa without Concomitant Disease.*—Sin, male, aged 27; Oahai; shopkeeper; in good health. When sixteen years of age had an attack of ague during eleven days; has been much troubled with lumbrici, otherwise quite well. Inguinal glands readily enlarge when he has any irritation about his feet or legs, never otherwise. Is not subject or feverish attacks, never had chyluria; scrotum and glands normal. An assistant found one hæmatozoon in four slides; he examined twelve more, and I seven, but not another specimen could be found.

Case 14. *Hæmatozoa; no Concomitant Disease.*—An, male, aged twenty-eight; from Oahai; a cooper. Had ague when sixteen or seventeen years of age for four or five days. Three years ago had an eruption on his legs and face. He describes the spots as being red, slightly itchy, and each about the size of a cash; it kept out for about a month. With these exceptions, has always had excellent health. Never had chyluria or enlargement of scrotum, legs, or glands. In six slides examined by an assistant, thirteen filariæ were counted. Next day the same assistant searched seventeen slides in order to show me a specimen, but without success. I pricked the lobule of the ear, and from blood thus obtained placed a full drop between two slides; in this I found one solitary specimen.

Case 15. *Hæmatozoa; Enlarged Glands and Abscess.*—Leng, male, aged thirty; Lamoa; a cobbler. Came to hospital on account of an abscess over the insertion of the right deltoid. I regret I cannot give this man's early history. His inguinal glands were enormously swollen and varicose—so much so that he was attempting to disperse the swelling on one side by the application of a native plaster. The scrotum was not affected. There were no hæmatozoa in the first six slides examined, but the conviction I entertained on account of the characteristic appearance of the inguinal glands was justified two days afterwards, when on opening the abscess many filariæ were found in the blood from the wound.

(*To be continued.*)

NORMAL OVARIOTOMY: BATTEY'S OPERATION—OOPHOROTOMY.

By J. MARION SIMS, M.D.

The criticism in your issue of October 27, on "normal ovariotomy," so called, is both just and temperate. From a letter recently received from Dr. Battey, I learn that he has now performed this operation twelve times, with two deaths. I have performed it seven times, with one death.

The success of the operation so far is not what we expected; but we hope for better results hereafter. As I am at an early day to bring this subject formally and fully before the profession, I shall here confine my remarks to the name by which we should recognise this operation.

Dr. Robert Battey, of Rome, in Georgia, U.S.A., based this operation on the theory of bringing about change of life by extirpating the ovaries, and thereby arresting the menstrual molimen. The name he gave his operation—normal ovariotomy—has been much and justly criticised in my own country. Two or three years ago, Dr. Battey asked me to give his operation a name, as the profession objected so much to the one he had chosen for it. He called it "normal ovariotomy," because he supposed he was extirpating a normal ovary—an ovary in a normal state, and of normal size. But all the ovaries that Battey and myself have removed by his operation were found to be in an abnormal or diseased condition. There was a radical organic change of structure in each and every one we have examined—a change easily seen by the eye without the aid of the microscope. Hence the term "normal ovariotomy" is incorrect, inappropriate, and we should get rid of it.

This operation, like many others that have led to great results, has a little history of its own, which is by no means uninteresting.

Some years ago, Dr. Battey saw a young lady, aged twenty-one, die from the effects of an unrelieved menstrual molimen. Then he asked himself the question, "Would it not be possible to cure such cases by bringing about an artificial menopause by the extirpation of the ovaries?" A few years after this he saw another young lady, aged thirty, in a like suffering condition, who, after prolonged and fruitless efforts on his part, was about to pass away, worn out with epileptiform convulsions, vicarious hæmorrhages, pelvic hæmatoceles, and pelvic inflammations and abscesses. The case was evidently absolutely hopeless under the ordinary methods of treatment. Death was imminent; and Battey proposed, as a *dernier ressort*, the extirpation of the ovaries. The patient gladly accepted his proposition. Battey, living in a little country town, had no great masters in medicine to stand by him; so he wrote to many of the leading obstetricians and gynæcologists of the country, stating his views, and asking their advice on his proposed operation. But he received no encouragement whatever from any of them. He explained all this to his long-suffering patient. But she was not at all discouraged, and begged Dr. Battey to perform the operation. He operated on her in August, 1872, removing both ovaries by abdominal incision. Fortunately his patient recovered. Her recovery was tedious. But the cure was perfect, and remains so to this day. Her epilepsy, hæmatoceles, pelvic cellulitis, abscesses, and vicarious hæmorrhages,—all disappeared with the disappearance of the menstrual molimen; and she is now a useful member of society. If we except the heroic operations of Ephraim McDowell, in the backwoods of Kentucky, in 1809, for the removal of ovarian tumours, I do not think the annals of medicine can produce an example of higher moral fortitude than that shown by Battey, when he, assuming all the responsibility, which was of the gravest character, dared to perform this hazardous operation, not only without the approval, but against the advice, of his brethren, and that, too, in an obscure little country town, on a lady in the higher walks of life.

We may do heroic and untried operations in large hospitals in great cities, and, if the result is unfortunate, the responsibility is divided with our *confrères*, and in the whirl of life it is remembered by a few, but soon forgotten by the many. But in a little village of two or three thousand inhabitants, such rashness, as it would be called, might damage a man's reputation seriously even if attended with success, and would surely ruin it if unsuccessful.

I would like to see this operation recognised by the profession as "Battey's operation." I think he is entitled to that honour. He was the first to grasp, in its widest range, the influence and effects upon the general system of what he calls an "unrelieved menstrual molimen." He was the first to suggest a method of cure. He was the first to carry out his own suggestion, and to perform an operation for the cure of a disease that had never been cured before. He performed the operation on his own responsibility, without the co-operative aid of a single member of the profession. He has demonstrated the correctness of the principles upon which it was based, and proved its success in practice. He has established a precedent that may now be followed with safety, and opened up a new field of observation that promises results as grand as those now achieved by ovariotomy. He has raised sorrowing women from a perfect slough of despond; from indescribable suffering; from epileptic convulsions; from repeated pelvic inflammations, hæmatoceles, and abscesses; from vicarious and alarming hæmorrhages; from threatened insanity; and

in some instances from impending and certain death: and restored them to health, to friends, to usefulness, and therefore to happiness.

We have precedents enough for naming diseases and operations for those who have been the first to discover and describe the one, or to originate and perform the other. I may name Bright's disease, Addison's disease, Colles' fracture, the Hunterian operation, Syme's operation, Pirogoff's operation, Graefe's operation, etc. The moment they are named, we recognise each operation, and the manner of executing it in its manifest details. Let us honour Battey by calling this "Battey's operation."

It would be easy enough to give it a classical name to distinguish it from ovariotomy. We should continue to apply the term "ovariotomy" to the removal of ovarian tumours, properly speaking; and we might coin the term "oophorotomy" to designate Battey's operation, but for myself I prefer to designate it as Battey's operation. He has won the honour, and let him wear it. The difficulty already encountered in finding a name sufficiently distinctive and characteristic of this operation justifies us in calling it Battey's operation.

I appeal to my professional brethren in the Old World to join in honouring the profession in the New World by affixing the name of Battey to the operation, which he so ingeniously worked out, and has so heroically and successfully established.

Paris, 2, Rue d'Albe.

REPORTS OF HOSPITAL PRACTICE IN MEDICINE AND SURGERY.

NEWCASTLE-ON-TYNE INFIRMARY.

CASE OF INTRATHORACIC TUMOUR INVOLVING THE ROOT AND LOWER LOBE OF THE RIGHT LUNG — PERICARDITIS — DEATH — SECONDARY NODULES IN THE LIVER.

(Under the care of Dr. BYROM BRAMWELL.)

W. M., aged sixty-six, a sailor, single, was admitted on November 4, 1875, complaining of cough, shortness of breath, and great debility.

Previous History.—He enjoyed excellent health until eight months ago, when his present illness commenced. It was brought on, he thinks, by exposure to cold and wet. He has never spat any blood. The family history is good.

Condition on Admission.—He has an unhealthy, sallow look, and is considerably emaciated. The feet and legs are œdematous. Lungs: There is marked dulness over the right chest below the level of the second rib. From the third rib downwards the dulness is absolute. Posteriorly there is absolute dulness below the inferior angle of the scapula. The left side is normal. On auscultation over the dull area the vocal resonance is found to be diminished, and faint bronchial breathing is heard. The measurements of the two sides of the chest at the level of the fourth rib are equal—viz., seventeen inches and three-quarters. Cough is frequent; expectoration scanty and frothy. There is great dyspnœa on exertion. Heart: The area of cardiac dulness is considerably increased, and is continuous with the dull area over the right chest. The apex-beat is felt between the six and seventh ribs, two inches below the nipple. A soft systolic murmur is heard at the base and over the course of the great vessels. The aortic second sound is somewhat accentuated. The heart-sounds (free from murmur) are heard very distinctly between the right border of the sternum and the right nipple. Over the same part of the dull area indistinct pulsation can be felt. The radial pulse is 84, somewhat visible and jerking; the artery feels rigid. The right pupil is fixed, much smaller than the left, and irregular. The temperature is normal. The blood and other organs are normal.

Diagnosis.—After some hesitation the case was diagnosed to be an intrathoracic tumour, pleurisy being excluded by the presence of bronchial breathing. In this, as in the two cases reported by me in the *British Medical Journal* of January 6 and March 3, there were observed some of the signs of thoracic aneurism, notably the accentuated second aortic sound, the deep pulsation at the third and fourth right interspaces, and the clearness of the heart-sounds at the same spot. The subsequent progress of the case confirmed the diagnosis, and is seen in the following notes:—

November 24.—The dulness is gradually becoming more and more extensive; the general condition of the patient is worse.

December 20.—The dulness has now reached the superior border of the second right rib; posteriorly it mounts as high as the middle of the scapula. Occasional friction-sounds are now heard over the right base; the right side of the face is œdematous; the veins running over the front of the chest and up the right side of the neck are prominent; some enlarged glands can be felt above the right clavicle. The shortness of breath is worse. He now complains of difficulty in swallowing. The aortic systolic murmur is not now heard. Over the dull parts of the right chest, coarse crepitation is occasionally heard both with expiration and inspiration.

23rd.—He coughed up a considerable quantity of thick purulent-looking fluid.

26th.—He died.

Autopsy, twenty-seven hours after Death.—The left lung was adherent; it weighed one pound one ounce, and was healthy. The right lung was adherent throughout; the upper lobe was much congested, and in its lower parts consolidated; the lower lobe was consolidated throughout, and when cut into was found to contain in its centre a large brain-like mass of new growth. The tumour had apparently originated at the root of the lung, and thence made its way along the course of the larger bronchi. The bronchi of the right lung were greatly compressed. The tumour had invaded the pericardium. The sac of the pericardium contained several ounces of thick purulent fluid. Between the base of the right lung and the diaphragm there was a small collection of thick pus. The tumour was of a pinkish-white colour, and on microscopical examination was found to be composed of small round and angular cells; its central portion was softened. No communication could be traced with the bronchi, nor could the source of the purulent expectoration of December 23 be made out. The heart was somewhat enlarged; its valves were healthy. The aortic arch was atheromatous and dilated. The liver weighed three pounds four ounces; there were several large deposits of new growths on its upper surface, which was firmly adherent to the diaphragm. There was no apparent continuity between the new growth in the lung and that in the liver, although they were in close proximity and were the only deposits in the body. There was nothing of importance in the other organs.

Remarks.—The post-mortem showed the cause for the accentuated second aortic sound—viz., the dilated and atheromatous arch. It is somewhat remarkable that no pericardial friction-murmur was ever heard, and that notwithstanding frequent auscultation. I can hardly presume that it was entirely absent, for the effusion was by no means great, and the opposed surfaces of the pericardium were thickly coated with shaggy lymph. Dr. Sibson's elaborate statistics(a) show that, with rare exceptions, pericardial friction is audible throughout the period of effusion. "In six cases out of forty-three," he says, "the friction disappeared and reappeared during the decline of the effusion."(b)

LONDON HOSPITAL.

CASE OF CEREBRAL SYPHILIS—CHOROIDO-RETINITIS—DISEASE OF LEFT ANTERIOR CEREBRAL AND LEFT MIDDLE CEREBRAL—THROMBOSIS—SOFTENING OF LEFT FRONTAL LOBE, LEFT CORPUS STRIATUM, AND LEFT OPTIC THALAMUS—RIGHT HEMIPLEGIA, HEMIANÆSTHESIA, AND HEMISPASM.

(Under the care of Dr. RAMSKILL.)

[Reported by Mr. B. W. WALKER, House-Physician.]

WM. B., aged twenty-three, a cigar maker, admitted on March 24, 1877. The patient seemed very intelligent, and stated that until two years ago he had enjoyed good health continuously, with the exception of an attack of "gastric fever" and "small-pox" when quite a child. Since twelve years of age he had frequent watery discharge from the right ear; this continued to the time of admission. About two years previous to admission he had a single hard sore on the penis, which did not discharge, and which was covered with a hard "scale." Three weeks later he had "buboes" in each groin. These were hard, but after a time suppurated. For these symptoms he went to a doctor, who administered powders. He took them regularly for a month, and then found that his mouth watered a great deal. He was then supposed to be cured of his complaint. Rather more than three months before admission, he noticed that his hair fell off in large quantities; and a month later a

(a) Russell Reynolds, vol. iv., pages 318-327.
(b) *Ibid.*, page 383.

rash appeared all over his body, accompanied by sore throat and severe headache. These last symptoms existed on admission.

When admitted (March 24, 1877), the patient's condition was as follows:—A well-made man and well nourished, with a dry skin, powdery, and of a yellowish tinge. Upon the lower part of trunk were some patches, scaly and copper-coloured, fairly symmetrical; none on extremities. Complete loss of all hair of face and scalp. The soft palate presented the appearance of symmetrical congestion, with some loss of substance. The larynx was greatly congested. The heart, lungs, liver, and spleen presented no abnormal physical signs. Eyes presented marked double optic neuritis. The ophthalmoscopic appearances were described as follows:—Veins large and tortuous, even to the periphery; arteries, where visible, normal. The discs much swollen, and margins very indistinct. Special appearances of right eye: A whitish material to inner side of disc, extending beyond the distance of the disc's diameter, entirely obscuring the fundus; no hæmorrhages. Special appearances of the left eye: A large well-marked hæmorrhage above the disc, besides several small streaky ones in other parts of fundus. Above the disc, at some distance from the disc (about three diameters), was to be easily seen a perfectly white streak, tapering at both ends, with an artery distinctly running through the axis of it. The vessel is lost entirely between this and the disc. His sight was sufficiently good to allow him to read the newspaper easily. Deaf to some extent with both ears; no appreciable difference; watery discharge from ears. General condition: Very quiet and melancholy, and when pain was less severe he used to sleep heavily; cleanly in habits; appetite good; bowels regular.

April 19.—The patient has been taking iodide of potassium in doses gradually increased from five grains to thirty-five grains three times a day. To-day a rash is observed over forehead and cheeks only, papular and confluent. The dose of iodide of potassium was reduced to ten grains three times daily. By this time the pain in the head was far less severe, but this he attributed to the ice-bag he was allowed to apply to the head.

May 13.—The patient has been noticed to answer questions in a strange, stupid manner for some days lately. Has an exceedingly dull, stupid appearance. The appetite has failed of late, and he has been much troubled with vomiting at odd times. He says he has no pain at all.

14th.—It was discovered this morning that there is complete loss of power in the right arm (which remains helplessly at his side), and also of the right leg. When pricked with a pin (through the skin), he maintains that he cannot feel anything, and certainly he shows no sign of doing so. There is apparently loss of sensation in the affected side. Tickling the sole of the right foot causes no movements whatever. There is no affection of speech; he speaks slowly, but well. There is no obvious facial paralysis, though when he laughs the mouth is more drawn to the left side, and when he screws up his eyes the left is the more tightly shut. The tongue protruded points to the right. The uvula is long and inclines decidedly to the left. No appreciable difference in the hearing of the two sides, though both are defective. From all that can be ascertained, the above symptoms came on gradually. He took to his bed of his own accord yesterday, as he did not feel well and had some difficulty in standing, he said; and last night he took off his shirt, but did this feebly, and without any energy. On the same afternoon the patient was seized with a "sort of fit." The nurse found him unconscious. The right arm and leg were "working" backwards and forwards, and his eyes moved rapidly from side to side; his face was not in motion, and was unaltered in expression. This attack lasted about fifteen minutes.

15th.—When seen this morning he could not be got to speak at all, nor could he be made to put out his tongue, and, to all appearance, he did not understand what was spoken. He showed no sign or movement when a pin was thrust into the right arm, but when this was done to the left he simply moved the arm a little.

17th.—There is some ptosis of the right eye; vomits occasionally; apparently is free from pain.

18th.—A second fit, similar to the one mentioned above, lasting five minutes. Refuses food, or rather is too unconscious to take it; is accordingly fed through the nose, and castor oil also given on account of obstinate constipation. Passes water involuntarily for the first time.

27th.—For the last nine days the patient has remained in the same unconscious condition, lying on his back with his head turned to the left (if moved to the right it rolls back again immediately to its former position); his breathing is quiet, and pulse normal. He has been fed regularly three times a day on milk, beef-tea, and eggs, by means of the tube passed through the nose; castor oil given also as required. All motions and urine passed under him. His face and scalp much spotted over with yellow purulent crusts; these particularly large over the cheeks and bridge of nose. A raw, watering surface is left when these crusts are removed. The odour arising from the patient is most objectionable, in spite of the free use of antiseptics.

28th.—This morning the patient had a third fit of the same nature, and affecting the same parts as the former ones, but not so severe on this occasion. This time was noticed a very slight twitching of the face and mouth. The eyes were not affected. This evening the breathing is rapid, short, and shallow, ceasing entirely (apparently) at intervals of about two to three minutes for ten to fifteen seconds. Immediately after each cessation breathing commences by being particularly slow and shallow, but gradually increases in rapidity as it approaches the next cessation. The breathing is abdominal, the upper part of the chest remaining almost motionless. The alæ nasi "work" and the corners of the mouth are sucked in during each inspiration. Pulse exceedingly feeble and rapid, so much so that it is impossible to count it at times. There is great lividity of the face and general blueness of the skin. Half an hour later the patient died. His temperature had never been above 100°, and generally was normal; pulse normal.

Post-mortem Appearances.—The surface of the brain was much congested. The left hemisphere fell back, so as to appear smaller than the right. In one perivascular canal on the left frontal lobe was a large collection of colourless corpuscles. The anterior cerebral artery of the left side was distended by a large decolorised clot, softened in the centre, but so firmly adherent to the walls of the artery that it could not be detached. The middle cerebral artery of the same side was similarly plugged, but the clot was probably more recent, as it was readily detached. The walls of these vessels were considerably thickened. The left frontal lobe and the left corpus striatum and optic thalamus showed well-marked red softening. Heart normal and contracted. The lungs showed some recent pneumonia and a slight amount of pleurisy. The spleen, kidneys, and testicles were normal. The liver was much decolorised on the under surface, and showed on section arborescent discoloration in the course of the vessels; this was apparently due to decomposition. No nodes were anywhere detected.

Note.—That fertile cause of brain disease—otitis—though present in this case, does not appear to have been responsible for the morbid conditions found. The otitis was on the right side, the cerebral lesions were on the left; and the latter were due not to disease of sinuses or membranes, but to disease of arteries, which had nothing to do with the otitis. Independently of the history of local infection, the copper-coloured patches on the trunk, the extensive alopecia, the cicatrices on the soft palate, and the disease of the choroid, were as conclusive evidence of syphilis as if gummata had been found in the liver and other viscera. There is the strongest probability that the changes found in the cerebral vessels were not of the nature of ordinary atheroma, but of the syphilitic thickening described by Heubner, and that these changes led to thrombosis and softening of the parts of the brain supplied by the diseased vessels. In the choroid there appears to have been evidence of exudation alongside some of the arteries, though whether there was disease of the arteries themselves must remain undecided. The optic neuritis in such cases is generally secondary to the choroiditis. Amongst the clinical features worthy of note are—(1.) The *gradual onset* of the hemiplegia so frequently observed in cases of "block" of vessels, whether from embolism or thrombosis. (2.) The hemianæsthesia, in connexion with the fact that there was softening of the optic thalamus. (3.) The convulsive seizures on two occasions, limited to the right limbs, *plus* the bilateral movements of the eyes. It is noteworthy that post-mortem, besides congestion of the *surface* of the brain, there were some changes observed along one of the perivascular sheaths on the *surface* of the left frontal lobe, and that there was softening of the whole of the left frontal lobe, and some wasting. (4.) The persistent deflection of the head towards the left, noted on the 27th. This was probably a condition allied to the conjugate deviation of the eyes, to which Hughlings-Jackson has directed attention as occurring frequently in grave cerebral lesions. According to the usual rule, "the

patient is looking towards his lesion" (Hughlings-Jackson). It would have been interesting to know if there was any hemiopia, but the patient's mental condition at this period obviously must have prevented such a point being investigated. (5.) The speechlessness, noted first on the 15th, is of interest in connexion with the disease of the left frontal lobe. The somnolent, half-conscious, quasi-intoxicated condition, which appears to have lasted in this case for many days, is, according to Heubner, very common in the course of cerebral syphilis. (6.) The "Cheyne-Stokes" respiration, the rapid feeble pulse, and the lividity, associated with the pneumonia found post-mortem, are of interest, as the "last term" of severe hemiplegic seizures, which do not prove fatal within twenty-four hours after the onset.

SATURDAY, NOVEMBER 24, 1877.

THE LONDON WATER-SUPPLY.

It has been said that nothing is impossible to modern engineering. At all events, modern engineers are fertile in grand schemes, especially as regards the water-supply of great cities We have had schemes for bringing water to London from Wales and from the Lakes. Manchester seems determined on attempting the tapping of the latter district. The latest scheme, however, which has come on the *tapis* is that fathered by Mr. Bramwell and Mr. Easton, both, we believe, having their *forte* rather in mechanical than in civil engineering strictly so called. These two gentlemen made a proposition, a little time back, which, after having been considered by the engineer of the Board of Works, has been accepted by that body. As sanctioned by the Board of Works, this scheme involves, first, the purchase of all existing waterworks in connexion with London, and, secondly, the superaddition of a new scheme for obtaining water from the water-bearing strata around London.

With regard to the former we have not a word to say, and by itself it is a scheme of sufficient magnitude to occupy many years, inasmuch as the various water companies are prepared to resist to the death. That there should be one central authority which could absolutely control our water, supply seems to us to be an unmistakable advantage. The principle of individual exertion has always maintained in this country, but, unfortunately, so has that of tyranny by corporate bodies. London is watered by various companies some supplying water which is notoriously bad, whilst in other districts the supply is altogether unexceptionable. Yet the inhabitant has no power to stop the supply of bad water and take in that which is good; he must submit to what he can get in his district. Take, for instance, the unfortunate dweller in the region occupied by the Southwark and Vauxhall Company: he cannot exchange the filthy stuff supplied to him for the purer supplies of the New River or West Middlesex; he can only submit to be gradually poisoned. Yet the sources of the Southwark and Vauxhall and of the West Middlesex are the same. Against such bodies there is no appeal. It would be well, therefore, that all should be united under one common and responsible management were this practicable.

But why should such discrepancies prevail in the quality of the waters supplied by companies taking their water from the Thames about the same spot? The answer is not hard to find. The one company has large areas for storage and subsidence in proportion to the quantity of water sent out; the other has, comparatively speaking, only a few filter-pits, and the quantity sent out is great. With the one, no water need be taken in at time of flood; in the other case, the only question is the quantity of water which must be supplied, no matter what comes—fish, dirt, or anything else. Here is where a uniform management would infallibly do good; but to that end subsidence beds, with filtering areas (the two being usually combined), would have to be largely extended to supply the present deficiency. New pipes would have to be laid down, and a large sum of money spent. This is just what the Board of Works shrink from facing. No, their plan is to buy up the old works, and supplement them by a brand new scheme, which, with all due respect, is as yet in the region of the wildest hypothesis. Deep wells are to be sunk in the water-bearing strata round London, whence is to be drawn as much as 16,000,000 gallons of water a day. This is to be conveyed to London by a special set of pipes, and in a special set of pipes distributed all over the London district under a high pressure. This supply of pure water is to be devoted to what? The extinction of fires! True, a small quantity may be used for drinking and cooking, but the main object is to be the extinction of fires. To this end hydrants are to be fixed all over the metropolitan area at specified distances. What is to happen to the houses which these do not reach we do not know, but we should think that the greater number of fire insurance offices might at once shut up as far as those houses within the reach of the hydrants are concerned. All this is to cost a mere trifle of £5,500,000, according to estimate; what it would cost in reality we shudder to think. For, in the first place, the notion of being able to obtain such a quantity of water from the chalk is the offspring of pure hypothesis, to which all the facts with which we are cognisant are in conflict. In certain areas round London there is water to be found, but in others there is none; but in all the quantity is distinctly limited, and must vary with the seasons. We cannot calculate on an unvarying, equable, and ample supply. At all events, this we believe to be a fact that the Kent Company, which derives its water from deep wells, had occasion to seek for an increased supply some time ago, but found that, after digging a new well, the quantity was no greater than before. The water-supply of the whole district had been tapped already. Again, some little time ago an artesian well was bored at Meux's Brewery right down to the lower greensand; they never got more than a few gallons, and the well is now closed. Does the Board of Works intend to favour us with a succession of such costly experiments? We look upon the whole scheme, in the meantime, as little better than mere moonshine. True, it may suc-

ceed, but people so heavily taxed and rated as we are ought to have something more than vague hypothesis before being asked to spend millions of money which will only benefit engineers and contractors.

What, then, is to be done? To this, again, as it seems to us, the answer is simple. The Water Companies have, with a few exceptions, grossly misused their great privileges. They deserve no pity at the hands of the public, whom they have so long maltreated. Is their property worth purchasing? Is our present system of taking water for all purposes mainly from the Thames and Lea a justifiable one? These are the two fundamental questions. The former we may pass by, but the latter is within the range of easy experiment. We may admit at once that it is absolutely impossible to keep either river absolutely pure from contamination, but we may well inquire into various questions in connexion with the impurities which we know may be destroyed during the onward flow of a river. The questions are such as these: How much organic matter may disappear during the flow of a stream of water over a given surface, at a given rate, and in a given time? Or, to put it otherwise, How long does it take to destroy all traces of a given quantity of organic matter in a stream of water running at a given rate? Next to this would come, What is the effect of various kinds of bottom material—sand, gravel, chalk, clay, mud, etc.? Again, What is the effect on this organic matter of standing water? Does the organic matter disappear; and if so, at what rate? We know perfectly well that there are already some materials for answering such questions as these, but their proper investigation ought to be undertaken by a reliable and faithful committee. The Board of Works and the Water Companies had far better agree to this than to waste money on obtaining the services of conflicting chemists. Already we hear that So-and-so is retained on this side or on that. Why not unite to have this first and most important matter settled—Can the present water-supply of London be rendered unexceptionable, or, at all events, of fairly satisfactory purity? There need be no difficulty about quantity.

THE ALLEGED OUTBREAK OF RELAPSING FEVER IN BOMBAY.

For many years past the medical men of India have maintained a vigilant watch upon the progress of a disease which, in most of its leading characteristics, very nearly resembles the Relapsing or Famine Fever of Europe. India was long supposed to be equally free from this disease and from true typhus. The earliest history of this disease appears still to demand investigation, but it became generally known to the profession when its destructive appearance in the Central Gaol at Agra in 1860 was described by Dr. Walker. It again prevailed with great virulence in the Agra Gaol in 1864; and, in that and the subsequent year, it appeared in the gaols of Umballa, Futtehghur, Allyghur, Jyepore, Malwa, etc. It was described by the several reporters as true typhus, contagious fever, typhoid fever, yellow typhus, and contagious jaundice fever; but great praise is due to the careful and judicious manner in which Dr. David Boyes Smith reviewed the majority of these reports in the second and third volumes of the *Indian Medical Gazette* in 1867 and 1868, and proved, at least to the conviction of many, that the fever of the Agra and Umballa gaols was nearly identical with the relapsing fever of Ireland, Germany, and America. This disease has occurred extensively and very destructively in the Punjaub, especially in the gaols of that province; and in 1867 Dr. C. A. Gordon, C.B., the Principal Medical Officer, Port Louis, reported that the "relapsing fever, with or without jaundice, but always with more or less hepatic complication, had been introduced into Bourbon by immigrants from India."

To the sanitary legislator, rather than to the pathologist, the relapsing fever of India is distinguished from the disease, as pourtrayed by Murchison, in being attended with great mortality. The fever which appeared at Agra destroyed 406 prisoners in 1860, and 250 in 1864. Consequently, it is not surprising that when, in April last, Mr. Blaney, a medical practitioner and member of the Town Council of Bombay, stated that a fever which then afflicted those resident in the relief camp on the Flats was not the ordinary malarious (marsh remittent) fever, but was "a contagious epidemic disease—a relapsing fever," the Government immediately desired Surgeon-General W. G. Hunter, the Head of the Medical Department, to institute inquiry into the nature of this fever among the immigrants, and into the condition of certain very unwholesome huts which, there was reason to believe, were sources of great danger to the health of the town and island. Accordingly, Dr. Hunter appointed two highly competent medical officers (Surgeons-Major Cook and H. V. Carter) to conduct the inquiry; and, on Dr. Cook's departure to Europe, Surgeon-Major Hewlett, Acting Sanitary Commissioner, was appointed to this duty. We have before us the report of this committee, with Dr. Hunter's own report, as reprinted in the *Indian Medical Gazette* of October 1 last. We cannot regard the committee's report as being by any means an exhaustive inquiry into the vitally important question at issue. They separated at first twenty-four, and subsequently twenty-five, patients, as being fairly representative cases, for observation, and made their report in three weeks; during which it is stated that many of the patients, especially of the second batch, "left before they were really convalescent." It was considered that, of these forty-nine persons, twelve had "fever of the relapsing type," three "intermittents (?)," seven "remittents," twenty-seven "undecided." "Five deaths are known, all amongst the cases too briefly studied to be accurately discriminated." For purposes of discrimination, the committee, we are told, noted—"(1st) common symptoms, (2nd) the natural course of the disease, and (3rd) diagnostic points; and, upon these grounds, they were of opinion that there was then prevalent in Bombay a severe form of fever which presented a decided recurring tendency, and which had also many of the more general characters of "relapsing" fever, so-called. They especially urged that, amongst the few cases it was practicable to examine, in five instances (four of which may be regarded on other grounds as typical) the peculiar organism known as the *Spirillum febris recurrentis* of Cohn (*vide* "Health Reports of the Privy Council," new series, No. III., London, 1874), had been satisfactorily demonstrated by one of themselves to exist in the blood of patients during the febrile paroxysms. They added—"Now, if this last fact be viewed as truly diagnostic, the question of the nature of the more prevalent form of fever here is so far disposed of, that it may be said there is the strongest resemblance between the relapsing fever of Bombay and that of Europe. To advance more than this might be premature, for it is well known to medical men that the remittent variety of malarious fever is capable of assuming many phases; and besides, there is on record abundant evidence of the prevalence in India, in late and bygone times, of fever nearly approaching the relapsing type, but not yet proved to be identical with the European species."

Surgeon-General Hunter entered upon the inquiry with great care and discrimination; and, in May, Dr. Lewis, attached to the Sanitary Department of the Government of India, was with Dr. Hunter's consent, deputed to institute inquiry into the nature of the fever. Measures were adopted for having observations carried on throughout May in two Bombay hospitals; and it was intimated to Dr. Carter that his microscopic observations of the blood should not be restricted to examples of supposed relapsing fever, but should embrace all

cases of malarial fevers (intermittent or remittent), and also all disorders attended with a high temperature.

Dr. Hunter gives in his report a history of the spirillum from its first discovery in the blood of patients suffering from relapsing fever, by Obermeier, during an epidemic of that disease in 1872. He particularly insists upon the importance, in its bearing upon the present question, of a series of observations which demonstrate the occurrence of the spirillum elsewhere than in the blood of persons suffering from relapsing fever. Cohn, who has shown that these organisms do not belong to *Spirillum*, but to the genus *Spirochæte*, observed them in the mucus of his own mouth, in damaged food, and in marshy water. They have also been found in considerable numbers by Manassein, in the liquid exuding from a fistulous passage communicating with the antrum of Highmore.

Dr. Hunter next announces a fact which must be viewed with great interest by pathologists both in India and in Europe —viz., that when the blood came to be examined microscopically in the Bombay hospitals, these organisms were found "not only in the blood of the subjects of so-called relapsing fever, but also under totally different pathological conditions; for example, in enteric or typhoid fever, in pneumonia, and in remittent fever."

Dr. Hunter then enters into a very full review of the diagnostic evidences afforded by the temperature charts adduced during the course of this inquiry. He shows that there is a constant tendency to remit in relapsing fever, so much so that Cragie, in 1843, regarded and designated it, on this account, as a variety of remittent fever. He infers that the temperature charts of relapsing fever (so called) and of remittents, as prevailing in Bombay, are insufficient for purposes of diagnosis.

True relapsing fever is invariably acknowledged to be a highly contagious disease. Dr. Hunter, however, fully argues out all the evidence upon this point that he has been able to collect, and concludes that he cannot find any proof whatever of the so-called relapsing fever of Bombay being contagious. With regard to mortality, Dr. Hunter's report is founded upon 177 cases, of which 25·9 per cent. proved fatal.

The Surgeon-General then proceeds to argue that the relapsing fever of Europe "is the offspring of destitution, in the sense that typhus is the result of overcrowding," and brings evidence to show that "the destitute condition to which the immigrants into Bombay were said to be reduced was highly exaggerated." So far we are disposed to agree with him; still, seeing that we have always had valid reasons for considering that the normal condition of the labourer throughout the length and breadth of India is one of lifelong semi-starvation, which loss of work or failure of health may convert into actual starvation for the individual and his family, and which a bad season will increase into famine for the masses, we cannot altogether coincide with Dr. Hunter and Mr. Blaney in believing that famine had nothing to do with this fever. It is stated that none of the persons were "deprived of food" at the time of the attack; that when these immigrants left their villages in the preceding October, and came to Bombay in search of work, the scarcity in the Deccan did not amount to famine; and that, from November last, work for the labouring classes has been abundant in Bombay, and, though wages were low, they appear to have been regularly paid.

We are inclined to think that the condition of many in this immigrant camp, and in what the Government pointed out to the commission as "the very unwholesome huts," driven by scarcity in their own district to seek uncertain labour among strangers, upon a low rate of remuneration, may not have been, as regards nutrition and physical power of resisting the incursions of disease, at all higher than that of the prisoners in the Punjaub gaols, who, becoming the subjects of relapsing fever, were, upon the reports of Drs. Dallas and Gray, allowed a more liberal diet, an increase of breathing space, and better clothing.

Dr. Hunter mentions the very interesting fact that Dr Cunningham, in watching the recent famine in the Madras Presidency, found that bowel disorders were common and very fatal, but that fever was practically non-existent.

The Surgeon-General arrives, from the whole of the evidence before him, at the conclusions—"first, that the contagious relapsing fever of Europe has had no existence in Bombay; second, that the fever is of a remittent character, has its origin in malaria, and is, consequently, not contagious."

We do not find it stated that the cases which were investigated were subjected to the quinine test. Doubtless they were; but, as we believe that it is generally found elsewhere that the relapsing fever of India is not at all materially influenced in its course by quinine, it would have been more satisfactory had this point been fully worked out. The profession must, no doubt, fully coincide with Dr. Hunter in thinking that the merit of the discovery of the spirillum (*Spirochæte*) in the blood of persons suffering from fever in Bombay is eminently due to Dr. H. V. Carter. We trust to learn shortly that further observations have been made on this very interesting point elsewhere in India, in cases of enteric and marsh and terai remittent and intermittent fevers, where no suspicion of the coincident existence of true relapsing fever exists.

THE PATHOLOGICAL SOCIETY.

Several specimens of great interest were exhibited at the meeting of the Pathological Society on Tuesday evening, although discussion was not so ready or vigorous as it has been at the two previous meetings this session. The first specimen, which was one of aneurism in the cavity of a hepatic abscess, was exhibited by Dr. Irvine, and was considered unique. The subject of the disease, a soldier who had served in India, after suffering from throbbing pain and fulness in the epigastrium and frequent hæmatemeses, died from a return of the hæmorrhage. It was found post-mortem that a small aneurism in the wall of an abscess of the liver had given way, and that the blood had found its way into the stomach through a perforation in the midst of old adhesions. Dr. Powell brought forward a somewhat analogous specimen, in which a small aneurism was found to be the source of suddenly fatal hæmorrhage from a gastric ulcer. These cases, coupled with the now familiar cases of pulmonary aneurism in phthisical cavities, form a series of remarkable interest to the pathologist; and they also bear, in respect of causation, an important relation to Dr. Irvine's case of aneurism of the abdominal aorta, described in the last report of the Pathological Society (see page 528, November 10).

Dr. Powell mentioned a fact in connexion with the case just referred to, which, while interesting in itself, shows in a striking manner how great the direct practical value of pathological anatomy may be. The patient was suffering from extensive fresh tuberculosis of the lungs, and right pleural effusion; and it was found that the tubercular disease in the right lung was exactly limited below by the surface of the effusion. Dr. Powell said that he believed that pressure on a lung not only exempts it from tuberculosis, but that an effusion of fluid may even cure a pre-existing tuberculosis.

Dr. Cayley exhibited two specimens of hyperostosis in several bones, illustrating the curious connexion between this change and the presence of cancer. Dr. Greenfield then gave a minute description of the histology of a syphilitic growth on one of the cerebral arteries, which had led to thrombosis, and consequent softening of the brain. The important point of the description was that the manner of syphilitic growth seems peculiar in this respect: that the endothelium of the newly formed vessels in its turn proliferates, and obstructs

their lumen by its products. It is probably in this way that the blood-supply of the mass is cut off, and caseation results. The next specimen, which was also shown by Dr. Greenfield, was one of hæmorrhagic pachymeningitis, better known as hæmatoma of the dura mater. Though very frequently seen abroad, and though said to be common in the insane, this lesion had never been brought before the Pathological Society. The pathology of the disease is still unsettled, notwithstanding Virchow's well-known account of it, according to which the hæmorrhage is secondary to the growth of a membrane on the dura mater, which afterwards forms the walls of the blood-cyst. On this occasion both the President and Dr. Greenfield seemed to incline to the older view—that the hæmorrhage was, at any rate in part, the primary lesion.

Dr. Ralfe's case of Chyluria may be said to have been the case of the evening, inasmuch as it provoked a long and very instructive discussion on chylous discharges. The case itself does not appear to differ in any important particular from other cases of chyluria from the West Indies. The important features were connected with the results of the careful chemical investigation of the chylous urine by Dr. Ralfe. It was found that not only serum-albumin, but fibrin and casein, were mixed with the urine; and, further, that the fluid easily passed through ordinary filtering paper. Assuming that the discharge of "chyle" had actually occurred from the kidney (which appeared from several facts to have been the case), there seems to be no reason why this should not have happened without actual rupture of the capillaries, as the ordinary blood-pressure would be sufficient to force such diffusible fluid through intact walls. Dr. Dickinson and Dr. Morison, in the discussion that followed, gave some particulars of the greatest interest of two cases of chyluria at present under their care; and, at the invitation of the President, they agreed to submit specimens of the chylous urine from their patients to investigation by the Chemical Committee of the Society. The subject of chyluria will therefore be re-opened in the course of the session.

At the end of the meeting the President made an announcement respecting an exhibition and discussion of specimens of lymphadenoma and leukæmia, which will be found in another column.

THE WEEK.

TOPICS OF THE DAY.

The Parkes Museum of Hygiene, which is in course of formation at University College, is fast approaching completion, and will soon be available for the purpose of diffusing a practical knowledge of many branches of sanitary science, the aim of the executive committee having been to make the Museum as widely useful as possible for teaching purposes. The Council of the College have devoted an area of 3500 feet for the purposes of display, and contributions of all sorts are arriving almost daily. The India Office, the Museum of Economic Botany at Kew, the South Kensington Museum, the Hygienic Department of the Army at Washington, and the city of Brussels, besides many manufacturing firms and individuals, have already made valuable contributions. The Museum is to be divided into a library and eight classes; the library will be devoted entirely to works on hygiene, reports, pamphlets, etc. Class 1 will be dedicated to local hygiene and sanitary engineering, and will consist mainly of plans, drawings, etc., illustrative of drainage, sewerage, water-supply, burial, and hygiene of crowded districts. Class 2 deals with hygienic architecture, and will be illustrated by plans and drawings properly classified. Class 3 is devoted to the subjects of lighting and warming; Class 4 to clothing; and Class 5 to food. Class 6 deals with personal *régime* and comfort for invalids, including the transport and care of sick and wounded in battle. Class 7 is appropriated to safety and rescue; and Class 8 to the hygiene of the professional and industrial classes.

An application was last week made at the Wandsworth Police-court, under the 27th section of the Sanitary Act, by the inspector of nuisances to the parish of Battersea, for an order to remove to the mortuary, prior to burial, the body of a person who had died from typhus fever. It was stated that the body was at that time lying in a room occupied by several persons. In answer to a question, the inspector said he proposed to have the body buried in two days' time, but the wife wished the interment to be delayed. The magistrate eventually made an order for the removal of the body to the mortuary, and for its interment at the date proposed by the officer.

At Dorchester, recently, Colonel Cox attended a meeting on behalf of the Local Government Board, to inquire into the drainage and water-supply of that town, the Town Council having proposed to borrow a sum of £8000. During the inquiry, it was elicited that new barracks are being erected by the Government at the Dorchester Depôt Centre, and that, to supply them with water, a new elevated reservoir would be required. Towards the expense of this, Government had offered £1250. Colonel Cox called attention to the 17th section of the Public Health Act of 1875, which relates to the flow of foul matter into watercourses and streams, and, while advising that the drainage question should be carefully considered, strongly recommended the increased water-supply.

The Council of the Metropolitan Hospital Sunday Fund have issued their report on the present year's collection, which, however reassuring as regards the increased co-operation of the various religious bodies, cannot be considered satisfactory when the total amount realised is taken into consideration. In fact, the results of the five years' collections, since the movement was introduced in 1873, show that £30,000 is the outside limit attainable by means of this appeal to the public—by no means a large sum when the wealth of the metropolis and the number of places of collection are borne in mind. The Council state that the present year has proved one of gradual but highly satisfactory growth in the number of contributing congregations as compared with former years—thirty additional places being credited to the Church of England, and sixteen to the Congregationalists; whilst nearly all other denominations have maintained steady averages. As a total, the Council are glad to be able to show an average increase of fifty new contributions. They endeavour to account for the falling off in this year's total by the serious financial depression which has so materially depreciated the means of the charitable; and in recapitulating that £22,747 have been distributed to seventy-six hospitals and four institutions, and £2223 to forty-three dispensaries, they explain that nearly all the awards are slightly below those of 1876, in consequence of an increasing number of applications to participate, and a slight decrease in the amount to be administered. The total of each year's collection has been as follows:—1873, £27,700; 1874, £29,936; 1875, £26,396; 1876, £27,042; and 1877, £26,082. The working expenses of this year's Fund, inclusive of all charges, have been 3¼ per cent. of the gross receipts.

Overcrowding is still an evil with which the East-end authorities are almost powerless to grapple. At a recent meeting of the Whitechapel Board of Works, the sanitary inspectors of the district reported that they had paid a midnight visit to various houses in Miller's-court, Fashion-street, Dorset-street, Rose-lane, and Inkhorn-court, situate in the parishes of Whitechapel and Spitalfields. With one exception, the rooms visited were occupied by foreign Jews, the exception being a room tenanted by three Irishwomen and a child. In addition to the overcrowding, many of the rooms

and bedding were in a most filthy condition, and several of the occupants were sleeping on dirty rags, sacking, etc., on the floor. In many instances it was necessary, in order to ascertain the number of persons in such rooms, to turn down the bedding, when children were found huddled together in a most shocking manner; and many of these children looked very sickly. Orders were issued by the Board for the abatement of the overcrowding and the enforcement of sanitary regulations.

The Exeter Town Council have for several years been endeavouring to obtain control of the Water Company's works in that town. The last offer made was to purchase on a basis of a perpetual 7 per cent. on the share capital; but the Company refused this, and it has at length been determined to proceed for Parliamentary powers to compel the Company to sell. The terms the Council offered would have involved the expenditure of £120,000, and it was apprehended that a further outlay of £8000 would have been necessary before a constant supply could be given.

The medals of the Royal Society for the present year have been awarded by the President and Council as follows:—The Copley Medal to Professor James Dwight Dana, for his biological, geological, and mineralogical investigations carried on through half a century, and for the valuable works in which his conclusions and discoveries have been published. A Royal Medal to Mr. Frederick Augustus Abel, C.B., F.R.S., for his physico-chemical researches on gun-cotton and explosive agents. A Royal Medal to Professor Oswald Heer, of Zürich, for his numerous researches and writings on the tertiary plants of Europe and other countries, and for his able generalisations respecting their affinities, and their geological and climatic relations; and the Davy Medal to Robert William Bunsen and Gustav Robert Kirchhoff, for their researches and discoveries in spectrum analysis. This is the first award of the Davy Medal, which, it will be remembered, was founded by the proceeds of the sale of a service of plate, bequeathed for the purpose by Sir Humphry Davy. The medals will be presented at the Society's anniversary meeting on the 30th inst.

A somewhat singular case of death is reported from Devonport. A child, six and a half years old, was taken to Dr. Wilson of that town, the father stating that she had been playing with some beads, and had got one into her ear. A similar accident had occurred to the child about three years before, when Dr. Wilson succeeded in extracting the bead. Upon the present occasion he endeavoured to remove the foreign body, but without success, and after a lengthened operation the child suddenly expired, in the opinion of Dr. Wilson from loss of blood and nervous shock. The post-mortem examination failed to discover the bead, but Mr. Christopher Bulteel, who performed it, suggested that it might have been extracted, and not noticed when it left the ear; he had no doubt that Dr. Wilson acted for the best, but he thought some want of judgment was displayed in continuing the operation so long. The hæmorrhage and shock together were, in his opinion, sufficient to account for death. The jury ultimately returned a verdict in accordance with the medical testimony.

On Saturday last the Duchess of Teck opened a new Infirmary at Hemel Hempstead. This institution was originally founded in the year 1826, by the late Sir John Sebright, Bart. About four years ago it was condemned by the sanitary authority, and the governors determined upon erecting a new building. The present structure will accommodate fifty inpatients, and, including an outlay of £900 for the purchase of three acres of land, will cost £13,000. A distinguished company was assembled to meet the Duchess, and, after a brief religious service conducted by the Bishop of St. Albans, her Royal Highness was conducted through the building, and formally declared the new Infirmary open for the reception of the sick poor of West Hertfordshire.

A serious outbreak of fever is reported to have occurred at Staveley, a village in Derbyshire, and the disease is spreading to such an extent that two schools have already been closed. At Staveley twenty-five families are stricken with fever, which has already proved fatal in many cases. The outbreak is supposed to be traceable to Eckington, and it has also spread to Speedwell and Lowgates, hamlets in the vicinity. The medical officer of health for the district is carrying out a prompt system of isolation, with a view of stamping out the epidemic.

Yellow fever is reported to have appeared again at Jamaica, and is stated to have proved fatal in the cases of Captain H. A. Mackey, R.A., Brigade Major, and a daughter of Major Locock, commanding Royal Engineers, both of whom died of the disease on the 21st ult. The *Army and Navy Gazette*, however, hears that the ships on that part of the West Indies station, and the residents at the naval establishments at Port Royal, continue free from attacks of the fever.

THE SENATE AND CONVOCATION OF THE UNIVERSITY OF LONDON.

The Annual Committee of Convocation of the University of London, at its meeting on the evening of Friday, the 16th, received the reply of the Chancellor to the deputation which waited on the Senate on the previous Wednesday. The reply, which we published last week, was accepted as satisfactory by the Annual Committee, who considered that in giving this answer to the memorial from Convocation the Senate had virtually "abandoned" their resolution to proceed with the admission of women under Russell Gurney's Act. The Committee also expressed itself as willing to co-operate with the Senate in procuring a supplemental charter; and this generous behaviour of the representatives of Convocation cannot but have the best effect in helping to restore a good feeling between the two bodies in the University. The non-medical members of the Committee, and especially Mr. Magnus, expressed their appreciation of the manner in which the medical graduates had commenced and conducted the struggle for the rights and privileges of Convocation. The medical graduates have indeed every reason to congratulate themselves, not only on the successful issue of this long and serious difficulty, but on the position which they have secured for their Faculty in the University by their watchfulness and zeal.

At the same meeting, Dr. Pye-Smith, speaking on the subject of a new Charter, discussed at some length the desirability of extending the functions of the University. At present the University of London is a mere Government machine for examining and granting degrees. Many of its members would be glad to see the University more directly engaged in the encouragement of literature and science. The single effort of the University towards the encouragement of scientific research under its own auspices is the acceptance of the Brown Trust. And, as Dr. Pye-Smith said, the Brown Institution is one of the few places of interest which we are able to show to foreign workers in science. To a prominent member of the medical representatives in the Senate is due the credit of having prevailed upon the University to extend its functions in this direction; and we trust that the Arts and Laws members may not rest until they shall have done as much for the sister Faculties. Dr. Storrar announced in the course of the meeting that, in answer to the requisition to which we referred last week, he had decided not to call an extraordinary meeting of Convocation to discuss the question of a new Charter. Probably Dr. Storrar, like ourselves, believes that the present time is somewhat too critical for opening a subject which will

disturb the whole constitution of the University. It is evident, however, that the University of London is entering upon an era in its history when every member will do well to devote all that he can spare in time and in attention to its interests.

THE COMPULSORY REGISTRATION OF INFECTIOUS DISEASE.

A SHORT time ago, at page 441 of our current volume, we directed attention to the fact that the Corporation of Bolton had obtained from Parliament, during the last session, authority to institute a registration of infectious diseases within their borough; and we gave the provisions of the "Bolton Improvement Act," relating to the subject. We should have reminded our readers that a similar experiment is being made also in the borough of Huddersfield, under provisions contained in the "Huddersfield Waterworks and Improvement Act," 1876. The powers taken under the Bolton Act have a much wider scope than those given by the Huddersfield Act, and in other respects the two Acts differ considerably. In the latter Act (the older one of the two) the compulsory registration is made to apply to "any inmate of any building used for human habitation who is suffering from small-pox, cholera, or any contagious or infectious fever of a dangerous character, and who is without proper lodging or accommodation enabling the case to be properly isolated so as to prevent the spread of the disease or the proper treatment thereof"; while the Bolton Act provides, it will be remembered, for the registration of all cases of "small-pox, cholera, or any contagious or infectious fever," without the addition of the word "of a dangerous character," and without reference to the state of the lodging of the patients;—that is to say, it makes provision for the general registration, within the borough, of the infectious diseases specified. Again, in the Huddersfield Act the responsibility, under penalty, of informing the sanitary authority (the Corporation) of the existence of the disease is thrown on the occupiers or persons having the charge, management, or control of the buildings or rooms in which the disease occurs, or on the patient himself, if able; and the medical man in attendance, if any, is required, also under penalty, "forthwith to fill up, sign, and deliver," to one or other of the persons referred to, a certificate, or declaration, stating, according to a form supplied by the Corporation, the name of the person suffering from the disease, the situation of the building wherein such person is, and the name of the occupier or other person having the charge, management, or control of the building or room; and the certificate states simply that the disease comes within the terms of a named section of the Act under which it is given. But the Bolton Act requires that the certificate shall state, in addition, "the nature" of the disease; and the medical man in attendance, as well as, and in addition to, the head of the family, or the occupier, or the person having the management of a building, is required, under penalty, to give notice to the Corporation. The Huddersfield Act, as well as the Bolton Act, provides that the Corporation shall pay to every medical practitioner making and giving the required certificate a fee of 2s. 6d. for each such certificate.

THE FEVER CARRIAGES OF THE METROPOLIS.

DR. JAMES STEVENSON, Medical Officer of Health for Paddington, has prepared a report for the local Vestry on the arrangements made by the several parochial authorities within the metropolitan area for the removal of persons suffering from infectious diseases to the fever hospitals. The report, which is very exhaustive, and must have involved much labour on the part of Dr. Stevenson, shows that the arrangements for the above purpose are most diverse, and in almost all cases very inadequate. In most parishes the fever carriage is the property of the Board of Guardians, in some of the Vestry, in others of a District Board, whilst in others it forms part of the stock-in-trade of a cab proprietor or of an undertaker. Then as to the custody of the carriage: generally it is entrusted to some official connected with the Board of Guardians, and is kept in grounds adjoining the workhouse; in other instances its custody devolves on some one attached to the Vestry, and it is kept in the parish stone-yard; and in rarer instances it is kept, when not in use, in an ordinary mews or in a common cab-yard. When housed, it frequently stands with other carriages—it may be a brougham, a bread cart, a laundry van, a butcher's cart, or a hearse and mourning coach. In many parishes there is only one fever carriage, which is used indiscriminately for all cases, whether a form of fever or a case of small-pox. Some have two vehicles, one for fever the other for small-pox; whilst three parishes have each three, and one parish (St. Saviour's) has four. As to the form of the carriage, some are of the four-wheeled cab pattern, others are covered vans, and others are of the brougham type of conveyance. In most instances the fever carriage has been built for the purpose, but in some few instances a worn-out cab or brougham is utilised, without any attempt at "conversion" having been made. There is a similar want of uniformity as regards the horsing of the carriages, but the drivers are generally the servants of the Guardians, or of the Vestry or District Board. Dr. Stevenson comes to the conclusion that the existing arrangements are objectionable on the score of economy and on sanitary grounds, and are, moreover, ill adapted to the requirements of the public, and of the persons more immediately concerned. He recommends that neither Local Authorities nor Boards of Guardians should any longer be expected to provide conveyances for the removal of the infectious sick, but that the necessary conveyances, horses, and drivers should be supplied by the managers of hospitals for the reception of patients suffering from infectious diseases; also that a trained and paid nurse be sent with the carriage each time it is used to superintend the removal of patients, and who should be responsible for the charge of the patient whilst under his or her care, riding either inside or outside the vehicle, as circumstances and the condition of the patient may require. As to the carriage, it should be made of hard wood, smooth, painted, and varnished, and of the brougham type. It should be easy, light, and properly ventilated, with doors on both sides, and a door or doors at the back, opening vertically, not horizontally as some do, and with a drop-seat inside to accommodate the nurse or attendant if required. It should be long enough to allow the patient to lie down, and sufficiently wide to admit two trays or frames, with beds covered with some waterproof material. The windows should be of ground glass, except the one in front, through which the nurse should be able to see and communicate with the patient. These recommendations seem to us to be sound, and we shall be glad to hear that they have been adopted by the various local authorities of the metropolitan parishes.

DESTRUCTION OF OBSCENE (SO-CALLED) MEDICAL WORKS.

A GREAT public service has just been performed by the Medical Defence Association in checking the practices of a man named Matthew Allison Orr, who for a considerable time past has been selling copies of works in which advice was given how to prevent the natural result of intercourse of the sexes. This was to be accomplished by the use of an instrument, said to be invented by a "Dr. Bruce," called a preventive "pessary," which was recommended to be introduced into the vagina, and fitted over the os and cervix of the uterus, before sexual intercourse. These instruments were to be obtained through Mr. Orr, as agent for Dr. Bruce, but it is believed that this latter name is a fictitious one assumed by Mr. Orr. Numerous complaints having been made to the Commissioners of Police respecting the nature of the

pamphlets and books sent out by Mr. Orr, they referred the matter to the Council of the Medical Defence Association, and promised the aid of the detective department if the Association would take the initiative in the endeavour to stop the publication of the works complained of. Accordingly, Mr. Pridham, solicitor to the Association, applied to Mr. Paget, at the Wandsworth Police-court, for a warrant to search the house occupied by Mr. Orr at Park-hill, Clapham, which was at once granted, and 1700 copies of a pamphlet on over-population, one hundredweight of a pamphlet entitled "England to the Rescue!" and 750 copies of a book containing instructions as to the use of the preventive pessary, were seized. On the 16th inst. Mr. Orr appeared at the Wandsworth Police-court, in answer to a summons, to show cause why the whole of the above-mentioned works should not be condemned to be destroyed as obscene. Mr. Besley, who defended, said he would not advise his client to appeal against the decision of the magistrate if he ordered the pamphlet on over-population to be destroyed; but he submitted that "England to the Rescue!" was not indecent, whilst the "instructions" were only directions as to the use of an instrument, and were not distributed for gain. The presiding magistrate (Mr. Bridge) overruled Mr. Besley's objections, and made an order in each instance for the destruction of the works.

BROADMOOR CRIMINAL LUNATIC ASYLUM.

The Annual Report on the Broadmoor Criminal Lunatic Asylum for the year 1876 shows that during that period the daily average number of patients resident was 498. The Asylum, when full, is capable of accommodating 413 men and 150 women, and the number of vacancies existing on the last day of the year under notice was 24 in the male and 46 in the female division. The rate of mortality during the year, calculated upon the average number resident, was 4·01 per cent. —a result which has only been once exceeded—viz., in the year 1866. The average rate from the opening of the Asylum down to the end of 1876 was 2·88. Of the deaths which occurred during the year, 12 out of 20 were due to diseases of the respiratory organs, and in the frequency of diseases of this description the year 1876 resembled its predecessor. In the four years preceding 1875 the number of deaths from this class of disease was small, being 5 in 1871, 1 in 1872, 2 in 1873, and 4 in 1874; and in 1875 the number increased to 9. This increase appears to have been due to the greater severity and frequency of winds blowing from the north and east during the last two years. The inmates of the Asylum consist largely of persons in whom the nervous system has undergone deterioration to a greater or less degree, and who are, in consequence, less able to resist sudden and violent variations of temperature, such as occurred frequently during the spring of last year and the year before. With the exception now mentioned, the general health of the inmates throughout the year was satisfactory, and the Asylum was entirely free from zymotic and infectious disorders. It is further satisfactory to find from the Report that, notwithstanding the character of the lunatics confined at Broadmoor, no form of mechanical restraint was used in any part of the Asylum during the year. Since the last report, Dr. Cassidy, the Deputy Superintendent, has resigned, and has been succeeded by Dr. Nicolson, formerly Senior Medical Officer of the Portsmouth Convict Prison.

THE WOMAN DIFFICULTY AND THE PHARMACEUTICAL SOCIETY.

At the last meeting of the Council of the Pharmaceutical Society, held on the 7th inst., the names of two ladies who had passed the Minor Examination, and had applied to be elected Associates of the Society, were submitted to the Council. This again brought up a question which has troubled the Council more than once. At the previous meeting of the Council, a lady who had passed her examination with very great credit had for the second time applied to be elected a Member of the Society, and had been refused; and the two ladies who now wished to be received as Associates had stood highest on the list of successful candidates on the day when they passed their examination. The discussion on the question was a lengthy one, and the Council seem to have been about equally divided in opinion, seven voting for and nine against the election of the ladies, while the President and one other member of the Council did not vote. It is to be observed that tho being refused election into the Pharmaceutical Society does not in any way prevent or directly hinder ladies who have passed the necessary examination from going into business as chemists; but it debars them from using the museum and library of the Society whose examination they have passed, as a matter of right, and it withholds from them the power of calling themselves Associates or Members of the Pharmaceutical Society. This may, we suppose, be a disadvantage to them, for one of the speakers asserted that in some parts of the country the term "Member of the Pharmaceutical Society" carries more weight than the simple designation of "Pharmaceutical Chemist." We think ourselves that the trade of a chemist and druggist is one for which women are admirably, and in some points—as delicacy, and neatness of manipulation—especially well fitted, and we shall be glad to see every help and facility given them in entering into the business as thoroughly well-educated chemists. And we must confess that we do not see why they should not be elected as Associates of the Pharmaceutical Society. It is allowed that there is no legal difficulty in the way, but one of the objections raised to it is, that if ladies are elected as Associates, the Council cannot refuse, should they afterwards pass the Major Examination, to elect them as Members, and then they might be elected on the Council, or even reach the Presidential chair. We will not presume to offer an opinion as to the desirability or the expediency of that; but we suppose that the honour of election on the Council is not the *right* of any Member, but a mark of distinction, to be gained by success or eminence of some kind, which can always be withheld by the majority of Members should they not think anyone fitted for it. The great obstacle to the election of the lady candidates into the Society, on this and the last previous occasion, was, however, the fact that in February, 1873, when the question of the election of three ladies as students or apprentices of the Society was before the Council, it was deferred till the June meeting, in order that the matter might in the meantime be referred to the annual meeting. That meeting decided against the admission of ladies, and it was urged that the Council would now be, at least morally, if not legally, wrong if they decided the question without again taking the opinion of the Society at large. And in the end it was resolved that the question of admitting ladies to all the privileges of the Society (Membership or Associateship) shall be referred to the next annual meeting. We are glad to see that the Society is prospering in every way, and is able to increase the pensions granted by its benevolent fund.

THE GOLDEN-SQUARE HOSPITAL.

We have received for publication, from Dr. W. MacNeill Whistler, Secretary to the Medical Council of the Hospital for Diseases of the Throat, Golden-square, the following extract from the minutes of a meeting of the Medical Council held on November 20, Dr. R. H. Semple in the chair:—

"Having listened to a detailed account of certain operations referred to in the recent charges against the medical administration of this institution, the staff resolved unanimously that these operations were performed with proper skill and care, and that no blame can attach to Dr. Mackenzie's clinical assistant."

ST. THOMAS'S HOSPITAL.

At the adjourned meeting of the Governors of St. Thomas's Hospital, held last week in the Board-room of the Institution, in the course of the proceedings, the chairman, Mr. Samuel Tomkins, the Senior Almoner and temporary Treasurer, pointed out that there would be some difficulty in adopting the resolution that the House Committee should consist of the Treasurer, Almoners, and six members of the Grand Committee, two of whom should have been "physicians or surgeons to the Hospital," as at the present time there were not two such gentlemen on the Grand Committee available. It was accordingly moved, and carried *nem. con.*, that Mr. Simon should be elected to the Grand Committee. Mr. Chambers then proposed that Mr. Alderman Stone should be elected the Treasurer to the Hospital, which was seconded by Mr. Alderman Sydney, the senior alderman present. It was explained that the Court were averse from having a paid treasurer, as such an appointment would not be in harmony with the history of the Hospital. Mr. Alderman Stone was then unanimously elected; and it was further resolved that the Grand Committee should at once prepare the residence for the Treasurer. We can hardly look upon this little episode in the history of St. Thomas's Hospital with satisfaction. There has been far too much of clan feeling and avidity of power displayed, and the result has been, as usual, a partial victory on both sides—in other words, a compromise. The Treasurer has been docked of some of his authority; but the Medical Staff and School authorities have, as a body, been imperfectly and partially recognised. We are not of those who hold that all power should rest with the medical authorities; but they know best the necessities of hospital management, and ought to have due weight in the councils of the managing body. It will be seen that at the very outset the governors had perforce to get over the obvious difficulty indicated already by us—to elect Mr. John Simon to the Grand Committee. More will crop up. Meanwhile, what about a Resident Superintendent? Is there to be such an authority? We hear that the *Treasurer's* house is getting ready.

KING AND QUEEN'S COLLEGE OF PHYSICIANS IN IRELAND.

At a special meeting of the College, held on Monday, November 19, to consider letters from the Registrar of the Board of Trinity College, and from the Registrar of the Board of Governors of Sir P. Dun's Hospital, in reference to the letter of November 3, to the Registrar of the Board of Trinity College, informing him that this College had on Friday, November 2, rescinded the resolutions of February 21, 1868, with reference to the King's Professors being Clinical Physicians to Sir P. Dun's Hospital (see *Medical Times and Gazette*, November 10, 1877, page 522), it was resolved, by fourteen to nine votes—"That this College, after mature consideration of the question, have decided not to rescind the resolution passed by them on February 21, 1868, viz.:—'Resolved, that in future no King's Professor in the School of Physic shall be allowed to hold an appointment as medical officer to any clinical hospital other than that of Sir Patrick Dun. *N.B.*—This rule not to affect existing arrangements.'" In the discussion on the question it was admitted on both sides that the relations of the School of Physic to Sir Patrick Dun's Hospital, under the "School of Physic in Ireland Act," were by no means as satisfactory as they might be, and that the time must sooner or later come when Parliament should be asked to readjust those relations in accordance with the progress of medical science and medical thought.

OBSTETRICAL SOCIETY OF DUBLIN.

The opening meeting of the fortieth annual session of this body was held on Saturday evening, the 17th inst., in the Hall of the College of Physicians, Kildare-street, Dublin. The chair was taken by Dr. Thomas Darby, of Bray, President of the Society. Several distinguished visitors and a large number of members were present. Dr. J. Rutherford Kirkpatrick, Honorary Secretary, read the report of the Council for the past year. Dr. A. V. Macan moved the adoption of the report, and in doing so expressed his regret at the unsatisfactory financial position of the Society. They were beginning the current year with a deficit of £60, which was mainly owing to the fact that out of 130 members forty-eight were defaulters. The motion was seconded by Dr. Henry Kennedy, and carried. The President then delivered an address introductory to the session; after which Dr. McClintock moved a vote of thanks to the President for his address. Dr. More Madden seconded the motion, which was carried unanimously. The ballot for officers of the session 1877-78 was declared to have resulted as follows:—*President:* Thomas Darby, F.R.C.S.I. *Vice-Presidents:* Stephen M. MacSwiney, M.D., and Jno. Rutherford Kirkpatrick, M.B. *Council:* Lombe Atthill, M.D.; John Denham, M.D.; George Johnston, M.D.; George H. Kidd, M.D.; and Alfred H. McClintock, M.D. *Honorary Treasurer:* John Joseph Cranny, M.D. *Honorary Secretary:* William Roe, M.D. Dr. Darby returned thanks for his re-election as President. Dr. McSwiney moved a warm vote of thanks to Dr. Kirkpatrick, the outgoing Secretary, and to Dr. Roe, the outgoing Treasurer, for the manner in which they had discharged their duties. The motion having been seconded by Dr. Atthill, and passed, the outgoing officers expressed their acknowledgments. A vote of thanks to the visitors having been passed unanimously, Dr. Robert McDonnell, F.R.S., President of the Royal College of Surgeons, responded, and the proceedings terminated.

THE CHAIR OF ANATOMY AND PHYSIOLOGY IN QUEEN'S COLLEGE, GALWAY.

Dr. Joseph Patrick Pye has been appointed to this chair, lately vacated by Dr. Cleland, the present Professor of Anatomy in the University of Glasgow. Dr. Pye is a licentiate of the Royal College of Surgeons, Edinburgh, and a gold medallist of the Queen's University in Ireland, in which he graduated as M.D. and M.Ch. in 1871. At first a Demonstrator of Anatomy in Queen's College, Galway, Dr. Pye was lately appointed Professor of Materia Medica and Lecturer on Medical Jurisprudence in the same College. He is also one of the Examiners in Materia Medica and Therapeutics in the Queen's University.

EXHIBITION OF SPECIMENS OF DISEASES OF THE LYMPHATIC SYSTEM.

At the last meeting of the Pathological Society, it was announced by the President that the Council had decided to set apart one or more meetings during the present session for the exhibition of specimens illustrative of Disease of the Lymphatic System, including Leukæmia and Lymphadenoma. The first exhibition is fixed for the second meeting in March.

ILLNESS OF DR. WILLIAM STOKES, D.C.L., F.R.S.

We deeply regret to learn that our illustrious Irish *confrère* is very seriously ill. For many months Dr. Stokes has been declining in health and bodily strength, while the powers of his mind have remained unimpaired and vigorous. Last Saturday, however, a paralytic stroke occurred, which has left him partially paralysed on one side, and placed his life in jeopardy.

The Harveian Lectures will be delivered on the evenings of December 6, 12, and 20, by Dr. Graily Hewitt, "On the Mechanical System of Uterine Pathology." It will be seen that the lecture is unavoidably altered from the 13th (as first announced) to the 12th December.

MORTALITY AMONG THE MEDICAL STAFF.

The following extracts from a Swedish work on Military Medical Care(a) have been kindly forwarded to us, and will be read with interest by most of the profession:—

"It is a general, but mistaken idea, that the military medical man is less exposed to danger than the commanding officer. This error is sufficiently refuted by experience, the mortality among the medical staff in active service being much greater than that among the officers. I have mentioned above what the military staff suffered during the campaign of 1808, and in another place recorded the fact that during the year 1789 no fewer than sixty medical men lay sick at one time at Carlskrona.

"Of 216 medical men on service in the above-mentioned place in 1789-90, 210 sickened, and forty died. During the epidemic of 1808-9, twenty or thirty medical men, most of them in the prime of life, died in the same place. In Scania, where a military corps was collected in 1809, a similar rate of mortality prevailed amongst the medical staff. Besides a number of subordinate officials in service at the hospitals, two physicians-in-chief (Thielke and Sörling) fell victims to the prevailing epidemic. These instances from our own more recent military history may suffice. I subjoin some from the armies of the chief powers of Europe.

"In the War of Liberation (against Napoleon I.) the medical staff of the Prussian army amounted to 2170 individuals. Of these, nine fell in battle, forty were wounded, and 150 died in hospital, most of the latter of typhus. Eighty civilians on hospital service shared the same fate. In the Russian War with Turkey (1828-29), the Russian army lost 300 graduates of medicine and nearly all their surgeons.

"During the Twenty Years' War carried on by the French (under the First Republic and the Empire), one-eighth or one-ninth of the military staff were generally incapacitated by sickness acquired in hospital. One-third of those that were more seriously affected died, and during the prevalence of infectious fevers more than one-half the medical staff sickened, and the mortality among them was twice as great as at other times. Hence a reserve of one-tenth of the effective number was always found at head-quarters to be disposable as substitutes for their deceased colleagues. Between 1792 and 1801 the French army lost more than 2000 medical practitioners, and in every campaign one-fifth of those on service in the hospitals perished. In Egypt, in 1792, eighty-two perished out of 125 army surgeons who attended the army from France. On this occasion the loss of the medical staff was two-thirds of its entire number, whilst that of the other departments of the army was only one-third. In the first three campaigns, the Western Army of the Pyrenees lost in fifteen months above 300 of the medical staff with fever, and in 1794 and 1795 the loss amongst the medical staff of the Eastern Pyrenean Army from dysentery was one-half of the entire number. The same results were observable in the case of the Rhenish army at the siege of Mayence, and subsequently in Italy. Of 130 surgeons who followed the French army to St. Domingo, nearly two-thirds died of yellow fever. The greatest mortality amongst the French medical staff occurred in 1793-1797, when the medical department was in a state of total disorganisation, every measure adopted on the spur of the moment, and the greater part of the military practitioners had never seen, much less treated, a patient. The succeeding years, up to the Prussian campaign in 1807, displayed an improved state of affairs. But in the Peninsular War, in 1808, and still more in 1809, an increased rate of mortality prevailed amongst the medical staff, the hospitals being badly arranged, and proving, from their crowded and filthy condition, centres of infection. The campaign of 1812-14 was so fatal to the French army in general, and particularly to the medical staff, that it is impossible here to exhibit the total extent of the losses incurred by the latter. In 1835, out of twenty-two medical practitioners attacked by cholera in Algiers, only three survived, two of whom were massacred by the enemy. Out of thirty-two army surgeons despatched to Africa in September, 1842, five died within fifteen months, two of them killed by the enemy, and two from the prevailing dysentery. From 1830 to 1837 forty-two military practitioners died in Africa. The Crimean War cost the French army eighty-two military practitioners—a loss greater than that sustained by any one corps in the army; of these forty-six died of typhus. In the Italian campaign, under Field-Marshal Radetzky (1848-49), 800 medical men served in the Austrian army; of these, during the two years' campaign, 150 died of prevailing epidemics, and more than thirty fell in battle or died of their wounds, making one-fifth of the entire corps—a rate of mortality nowhere equalled amongst officers, and seldom amongst rank and file."

(Evidence from Military History as to the Necessity of Medical Care in the Swedish Army. By Dr. P. O. Liljewalch, Physician-in-Chief to the Garrison of Stockholm.)

THE LATE PROFESSOR WUNDERLICH.

With sorrow we have to record the death of the eminent man, whose name, as the Father of Clinical Thermometry, we hold in such high respect in this country. Wunderlich, whose health since 1872 had been a continual source of anxiety to his numerous friends, and who had been prevented by gangrene of the tonsils from occupying his chair at Leipsic during the summer session of the present year, gradually sank in the last few months, and died of cancer of the mesenteric glands and tuberculosis of the lungs on September 25, 1877.

Wunderlich was born (we are indebted to a memoir by Dr. Bahrdt, in the *Berliner Klin. Wochenschrift*, for these details) in 1815, at Sulz, in Würtemburg. His father was a medical man, and his own early desire seems to have been to enter his father's profession. After finishing his education in arts at the gymnasium at Stuttgart in 1833, Wunderlich studied medicine at Tübingen, in company with Griesinger, Roser, and other embryo celebrities, and received his diploma in 1837. He then visited Paris, and attended the lectures of Andral, Dupuytren, Bouillaud, and Broussais, whereby, no doubt, he to some extent laid the foundation of his future success. In 1838 he became house-surgeon to a hospital at Stuttgart, and in the next eighteen months saw a great deal of active practice. In the latter part of 1839 he again visited Paris, and soon afterwards published his first literary effort on "The Nosology of Typhus Fever." In 1840 he visited Vienna, the result of his visit being a work entitled "Vienna and Paris: a Contribution to the History and Critical Appreciation of the Present Condition of Medical Science in Germany and France." From this time Wunderlich's progress was continually upward. In 1843 he was created *Extraordinary* Professor of Medicine at Tübingen, and even before this event he had set on foot his *Archiv für Physiologische Heilkunde* (Journal of Physiological Medicine). In 1846 he was appointed Professor (in his thirty-first year), and simultaneously he began his great work, the "Handbook of Pathology and Therapeutics," which he finished unaided in 1854. Meanwhile, he had succeeded Oppolzer, at Leipsic, in October, 1850, and he held the chair of Clinical Medicine, to which he was then appointed until his death. In 1871 he was made Rector of the University. His monograph on "The Temperature in Disease" appeared in 1868, and was in 1870 translated into English for the Sydenham Society by the late Dr. Bathurst Woodman. Among his other writings may be named two lectures, "On the Diagnosis of Typhus Fever (Fleck-typhus)," and "On Syphilitic Affections of the Brain and Spinal Cord," in Volkmann's *Sammlung Klinischen Vorträge*, the latter of which gives the reader an excellent idea of his style and power as a clinical teacher. It was partly in the latter capacity, and partly in that of a "medical critic of the first rank," that Wunderlich was celebrated. His critical power was not only displayed in his writings, but also at the bedside, where "differential diagnosis" was to the last one of his favourite subjects. The extraordinary progress which thermometry has made in the last ten years (and practically the birth and growth of this branch of medicine are almost comprised within this short period of time) is due in the main to Wunderlich; and perhaps when the history of medicine comes to be written by our successors, and the past is contrasted with the past, and a fairer judgment is pronounced than is possible at present, the merits of Carl August Wunderlich will stand out even more decidedly than they do now, when his body is but just committed to the grave.

We heartily sympathise with Germany in the loss she has sustained, and offer our sincere condolences to the bereaved University of which Wunderlich was so great an ornament. —*Ruhe seiner Asche.*

FROM ABROAD.

Injurious Electrical Treatment.

Dr. Lincoln read an interesting paper before the Boston Society for Medical Observation (*Boston Medical and Surgical Journal*, October 25) upon the "Injury resulting from Electrical Treatment," which contains some cautions, that are the more useful as coming from a proficient in the employment of electricity as a therapeutical agent.

"Electricity," he observes, "does not act alike on all persons. In this it resembles many other nerve-remedies, and even articles of diet, as spirit, tea, coffee, and tobacco, which in certain individuals produce apparently opposite effects from those regarded as normal. The closest and most intelligible analogy of this fact is found in the effect of a cold bath. Most persons are exhilarated; a few seem to be capable of bearing an indefinite amount; while others are chilled or prostrated for days by a single plunge. A sense of exhilaration is, in like manner, a very common attendant upon electrical treatment; but some never feel it, others feel it irregularly, and others cannot bear the least amount without apparent injury. Another point in which bathing resembles electrical treatment is the frequency with which sleep is produced. Sometimes a patient is hardly able to get out of the room for drowsiness; at other times the feeling comes on an hour or two later. It were greatly to be desired that this effect could be so managed as to occur at the right time for sleep; but I am doubtful if this can be accomplished with any certainty. The hypnotic action of electricity, however, is certainly of value. It would be possible to explain all the actions of electricity by the simple word 'stimulation.' I am not aware that there is any evidence that electricity acts like tea and alcohol, by arresting waste, and supplying material for consumption. On the contrary, it seems to me, from clinical observation, that its action rather resembles that of alteratives, which increase elimination, and that, like these, its use protracted beyond a certain point may rapidly run down the system. And this effect may be produced at the same time that each individual application gives a sense of relief or of increased vigour, which, though brief, and soon replaced by lassitude, is so decided while it lasts as to tempt both physician and patient beyond the limits of prudence. It is this result that physicians should be warned against. There is also a temptation to try large doses where small ones do not succeed; and it must be confessed that respectable authority for such practices is not wanting. Although there are few direct warnings in text-books, there is a rule laid down for practical guidance which amounts to the same thing. We are advised, in brief, to give but one or two dozen applications, and then to wait for a month or two, in the expectation that the curative process, once commenced, may go on of itself in the interval. This may be a correct view to take, but I should like to add that the long pause may be simply a necessity in order to enable the constitution to recuperate its forces."

According to Dr. Lincoln's own experience, however, while great benefit may result in many cases from electrical treatment, the instances are few in which it does harm when judiciously applied. He has met with only five such in his own practice, three of these being examples of rheumatic arthritis or muscular pains, one of spinal exhaustion, and one of locomotor ataxia. In some of these, while the local ailments for which it was administered were improved or cured, the patient still was more or less injured by the use of the electricity—"a general exhaustion, or at least an exhaustion of the spinal forces, furnishing the chief element of injury. To this statement an exception is furnished by the first case (rheumatic arthritis), in which an attack of local arthritis supervened during electrical treatment. There are other cases in which the expression 'local irritation' furnishes a more intelligible explanation of the mischief."

With respect to other symptoms of mischief ensuing on the use of electricity, Dr. Lincoln expresses a qualified opinion:

"The group of symptoms which includes giddiness, faintness, nausea or vomiting, disturbance of the circulation or respiration, and excessive drowsiness, is familiar to all electrical practitioners. It is commonly thought, and I have been in the habit of saying, that these efforts are absolutely to be avoided, if possible. And yet I have seen a man, suffering from mental fatigue and insomnia, relieved to a considerable extent for a fortnight after an application to his head of the induced current, which made him very giddy and sick for five or ten minutes. A patient who had aural disease, with tinnitus and epileptiform attacks of dizziness, received by accident at his first visit an overdose of galvanism. He became giddy and faint, and was unable to work next day; but on the day following his tinnitus was gone, and finally yielded to subsequent treatment. From such experiences I am led to doubt whether these symptoms are to be regarded as indications that a given application of the current is absolutely doing harm rather than good. Another effect of too concentrated galvanic currents is the production of superficial eschars, rather slow in healing. It is well to say to those who have had little experience that these may be produced in a few minutes, without any warning pain, in certain patients whose cutaneous perceptions are weakened. It is undeniable that neuralgic affections are occasionally made worse by electricity. This may sometimes be due to the influence of imagination; sometimes it results from the injudicious treatment of nerves while in a state of active congestion; and I suppose it may be caused by a simple excess of electrical stimulation. The latter statement is doubtless true of the muscles."

After quoting Benedikt's cautions with respect to the employment of electricity, and especially the induction of painful currents (which he seems to think somewhat exaggerated), Dr. Lincoln concludes his paper by observing that, "as far as I am able to judge, the harm that may be done by electricity mostly arises from the effects of over-stimulation—that is, exhaustion of the spinal or ganglionic systems."

Gonorrhœal Peritonitis.

In a communication to the *Archives Générales de Médecine* for October and November, entitled, "Peritonitis and Subperitoneal Phlegmon of a Gonorrhœal Origin," Dr. Faucon, after referring to the history of the subject from the time of John Hunter, the author of the first observation, and narrating in great detail a case that has come under his own notice, arrives at the following conclusions:—

1. Peritonitis and subperitoneal phlegmon should be ranked amongst the possible complications of gonorrhœa. 2. These accidents are only distinct effects of the blenorrhagic inflammation, propagated from the urethra to the peritoneum or the subperitoneal cellular tissue by the intermedium of the vas deferens, the vesiculæ seminales, the prostate (perhaps the bladder, ureters, and kidneys), and the cellular "atmosphere" surrounding these organs. 3. Their appearance is, therefore, always preceded by the ordinary blenorrhagic complications, resulting from the preliminary inflammation of the tissues or organs which serve as intermedia (deferentitis, vesiculitis, etc.), so that they are true tertiary accidents of gonorrhœa. 4. Gonorrhœal peritonitis may exhibit various points of origin, so that it has been met with in the pelvic region opposite the recto-vesical *cul-de-sac*, while at other times it arises at the internal orifice of the ingninal canal. 5. It may remain localised at the points where it has arisen, and there undergo a cure; but it may also become generalised, or at least extend to a more or less considerable portion of the abdomen, pass on to suppuration, and terminate fatally. 6. Subperitoneal phlegmon has been observed in the lumbar fossa, at the lower part of the internal iliac region, and of the anterior wall of the abdomen. It may terminate either in resolution or suppuration, but its influence is less mischievous than that of peritonitis. 7. When a subperitoneal abscess has formed, it should be opened as soon as possible. An energetic antiphlogistic treatment, the prolonged application of ice, and preventive *débridement* may arrest the development of the phlegmon, and prevent its passing into suppuration.

"Survival of the Fittest."

Under this title the *Boston Med. and Surg. Journal* makes some remarks as to the duration of the life of existing medical journals, and states that the *American Journal of the Medical Sciences* has now reached the age of fifty years, being the continuation of the *Philadelphia Journal of the Medical and Physical Sciences*, established in 1820. This is universally acknowledged as the leading American journal, and has been conducted by Dr. Hays alone until 1869, when his son was associated with him. We quite agree with the critic, that this journal is second to none in the language, and cheerfully accord to it the first place, for nowhere shall we find more able and more impartial criticism, and nowhere such a repertory of able original articles. Indeed, now that the *British and Foreign Medico-*

Chirurgical Review has terminated its remarkable career, the American journal stands without a rival. The latter journal, which, under Dr. Forbes' masterly guidance, inaugurated a revolution in medical criticism, was commenced as the *British and Foreign Medical Review* in 1836, and was incorporated in 1847 with the *Medico-Chirurgical Review* (whence its compound name of *British and Foreign Medico-Chirurgical Review*), a journal of much older standing, founded by Dr. James Johnson in 1816, and for many years almost solely conducted by him. The *Boston Journal* assumed its present name in 1828, being formed by the fusion of two journals, one of which dated back to 1812. The writer of the article is in error in assigning an early a date to the *Edinburgh Medical Journal*, commencing, as it did, with that title only in 1855, and being a continuation of the *Monthly Journal of Medical Science*, commenced in 1841. He has confounded it with the *Edinburgh Medical and Surgical Journal*, established in 1805, and terminating a career that, without exaggeration, may be designated as famous, in 1854. The *London Medical Gazette*, founded in 1828, was in 1852 incorporated with the *Medical Times*, founded in 1839, constituting the journal which the reader has now before him. The *Lancet* was established in 1823; but the *British Medical Journal*, originally founded by Dr. Hennis Green as the *Provincial Medical and Surgical Journal*, only dates back as far as 1841. The *Dublin Medical Journal*, published first on alternate months in 1832, then as a quarterly, and now as a monthly, has always been a journal of which any country might be proud. Among existing Parisian medical journals, the *Gazette Médicale* dates from 1830, the *Gazette des Hôpitaux* from 1828, and the *Union Médicale* only from 1847. The *Révue Médicale*, formerly a monthly, and now a weekly journal, was first published in 1820; and the *Bulletin de Thérapeutique*, a fortnightly one, in 1837. The best French medical periodical, the *Archives Générales de Médecine*, was commenced in 1823. In Italy the *Annali Universali di Medicina* has been published uninterruptedly from 1816 to the present time. The immense brood of German medical periodicals are of comparatively recent origin; but the celebrated year-books, so indispensable to all working at any subject, date from 1834 (*Schmidt's Jahrbucher*) and from 1841 (*Canstatt's* and now *Virchow's Jahresberichte*).

Medical Benevolent Fund Society of Ireland.—A quarterly meeting of the Belfast branch of the Royal Medical Benevolent Society was held in that town last week, the chair being occupied by Dr. Ferguson. In submitting the financial statement, Dr. Browne, the Honorary Treasurer, said he thought that the students attending the Royal Hospital should be addressed, and the claims of the Society brought before them. It was ultimately moved, seconded, and carried unanimously—"That Dr. Browne be requested to deliver an address to the medical students in attendance at the Royal Hospital, and bring before them the claims of the Royal Medical Benevolent Fund Society of Ireland." It was further arranged that the annual meeting of this branch be held at Belfast on the first Wednesday of February, 1878, at noon.

The Pancreas in Diabetes.—M. Lancereaux laid before the Académie de Médecine some specimens exhibiting extensive lesions of the pancreas in subjects of diabetes, and having related the histories of the cases whence they were derived, and referring to others already on record, went on to say that it was thus evident that, at least in some cases, diabetes is accompanied by great alterations in this organ. In these cases the progress of the disease has been relatively rapid, and has been attended by polyphagia, polydipsia, excessive emaciation, and abundant glycosuria—in fact, by all the characteristics of saccharine diabetes. So also, animals from which the pancreas has been removed become voracious and rapidly emaciated, and die very quickly. There would seem, therefore, to be no doubt that there is a causal relation between these changes in the pancreas and the disease in question. This form of diabetes may be distinguished by the relatively rapid occurrence of emaciation with polyphagy and polydipsia, and by the peculiar character of the alvine evacuations. Its prognosis is most unfavourable; the indication for treatment consists in suppressing alimentary substances that are digested by the pancreatic juice, in favour of those which undergo digestion in the stomach.—*Gaz. des Hôp.*, November 15.

PROVINCIAL CORRESPONDENCE.

MANCHESTER.

November 21.

Meeting of the Manchester Medico-Ethical Society—Discussion on the Attitude of the Profession towards Homœopaths—Annual Meeting of the British Medical Association, 1877—Treasurer's Statement—Suggested Application to Manchester of the Artisans' Dwellings Act.

The last meeting of the Manchester Medico-Ethical Society, held October 23, and, by adjournment, October 31, was enlivened by a debate of more than usual interest. It had been announced that Dr. W. H. Barlow, one of the honorary secretaries, would read a paper on "The Present Attitude of the Homœopaths," and a large number of members assembled, partly from curiosity to hear Dr. Barlow's views on the subject, and partly in expectation that the reading of the paper would be followed by an animated discussion. The paper might, perhaps, have been more correctly entitled "The Present Attitude of the Profession towards the Homœopaths." Dr. Barlow's remarks were very brief and studiously moderate in tone. He expressed an opinion that our relations with homœopathic practitioners stand in need of reconsideration, and he explained, in few words, his reasons for thinking so. It would be impossible, within the limits of this letter, to give anything like a satisfactory outline of the discussion. So large a number of members desired to take part in it, that it was found necessary to adjourn the meeting to the following week, when the debate was resumed. The main points insisted on by the more prominent speakers on the liberal side were:—1. That no one ought to be excluded from professional intercourse simply for the sake of his opinions. 2. That there do undoubtedly exist honest and sincere believers in homœopathy, whose practice is perfectly consistent with their opinions. 3. That it is they, rather than those other members of the homœopathic body who are ready to explain away their views, who ought chiefly to be considered in any movement towards a recognition of homœopathic practitioners; and, 4, that these men have a real grievance which the profession is strong enough generously to redress. These propositions were not allowed to be passed over without expressions of dissent, for old prejudices are not overcome in an hour.

No resolutions were proposed, and therefore none were passed, but the manner in which Dr. Barlow's remarks were received, and the whole character of the subsequent discussion, showed that there is a much more widely-spread sympathy with liberal views on this question than has hitherto been suspected.

The Reception Committee in connexion with the last annual meeting of the British Medical Association has held its final meeting, and the treasurer's balance-sheet has been presented. Many who took an active part in the organisation of the meeting felt that it would have been a great help if they could have had access to a statement of the expenses incurred in the various departments at some of the previous meetings. It may, therefore, be not altogether useless to place on record a few particulars as to the cost of the Manchester meeting. The total cost was, in round numbers, about £1500. Towards this the sum of £1100 was raised by subscription amongst the medical men residing in Manchester and the surrounding district, the subscriptions varying in amount from £1 to £50. Ten of the more wealthy members of the profession guaranteed to increase their subscription to £100 if required, and amongst these ten gentlemen will be shared the privilege of making up the difference between the expenditure and the amount subscribed. The principal expense was incurred in connexion with the garden party, the annual dinner, and other hospitalities, to which it would not be in good taste, however, to make further reference. The annual museum involved an outlay of £180, while the general arrangements cost about £420. The Committee made provision for an attendance of 2000 members, the actual number who registered their names being a little under 1200. The work involved in preparing for so large a meeting is, of course, very considerable, but the Manchester Committee feels itself amply repaid by the success which attended its efforts, and by the general satisfaction with the arrangements to which so many members attending the meeting have been kind enough to give expression.

The Manchester and Salford Sanitary Association instituted

a short time ago a visitation of the cottage dwellings in certain districts of Manchester, and the report of the visitors has been made the occasion of a memorial to the Corporation, urging the necessity of applying to those districts the Artisans' Dwellings Act. In one district, known as Angel Meadow, there were found, amongst other objectionable arrangements, about 700 back-to-back or single-fronted cottages, in which healthy ventilation is, of course, impossible. To this district the Association calls special attention, and an opinion is expressed in the memorial that improved dwellings might be erected, which would produce a fair interest on their cost, without any increase of the present rentals. The Association is to be congratulated on the usefulness of the work to which it has in this instance applied itself, and it is sincerely to be hoped that the Corporation will see its way to granting the prayer of the memorialists.

GENERAL CORRESPONDENCE.

THE TREATMENT OF SPINA BIFIDA.

LETTER FROM DR. J. W. ROSEBRUGH.

[To the Editor of the Medical Times and Gazette.]

SIR,—In your issue of October 13 is a reply by Dr. Morton anent his right to claim priority in treating spina bifida by injections of iodine, and claiming this treatment as his "new method." Dr. Morton says:—"It may be right to inform Dr. Rosebrugh that the first of my cases was treated in 1871, and published in the April of the following year in the *British Medical Journal*." This acknowledgment of Dr. Morton's is in accordance with my information and belief at the time I put the question in your issue of October 6, to "ascertain how far Dr. Morton is entitled to credit as the originator of this procedure," which he still claims as *his* "new method." Perhaps Dr. Morton will be "surprised to know", that this method was practised and recommended in the medical journals several years previous to 1871.

In the year 1867, Dr. J. S. Carodoc, of Brest, in *L'Union Médicale*, highly recommended this procedure for the cure of spina bifida, the only variation, as far as I am aware, being that Dr. Carodoc diluted the iodine in distilled water, while Dr. Morton employed glycerine—now a fashionable vehicle. The plan recommended by Dr. Carodoc was adopted by me in a case under my care, in March, 1868; three years and a half previous to being used by Dr. Morton, according to his own showing, *for the first time*.

The details of the treatment pursued in my case are as follows:—

Case.—A female child, aged three months; spina bifida tumour in lumbar region one inch and a half either way in size; tense, with fluid, and semi-transparent. March 24, 1868: Tumour tapped, and six drachms of a clear colourless fluid withdrawn. The orifice of the puncture covered with collodion. Over the tumour a light compress, and a wide strip of adhesive plaster reaching nearly around the body, covered with an abdominal bandage. The tumour gradually refilled, and by the fourth day was tense again. On the 28th four drachms were withdrawn, and half a drachm of a solution of iodine (one part of the tincture to five parts of distilled water) was slowly injected into the sac, as far away as possible from the centre, while the opening into the spinal column was kept closed by pressure with the finger. After allowing this to remain about three minutes, it was pressed out, and the tumour dressed as before. On April 1 the tumour was again tapped, and three drachms withdrawn; one drachm injected. On the 6th the operation was repeated. On the 11th the fourth operation was performed; two drachms injected. On the 15th, as the walls of the sac were diminishing and becoming indurated, two drachms of a stronger solution (one to three) were injected. On the 21st, the tumour becoming more and more dense and opaque, two drachms (half and half) were injected. On the 25th no fluctuation could be detected; induration appeared to be complete.

The little babe that then was, is now a lovely girl nearly eleven years of age, healthy and well in every respect, a small cicatrix only remaining to remind her friends of the peril that was averted.

In carrying out the treatment as above detailed, I followed the directions laid down by Dr. Carodoc, with the above complete success; and I presume others in Canada and the United States, as well as in Great Britain and on the Continent, have adopted the same method of treatment. But the question I intended to raise is this: When a remedy for the treatment of a certain disease has been a recognised one by the profession for years, has any person the *moral right* to take that remedy, and, by a slight variation in its dilution, use it as had been formerly done, and then proclaim it to the world as a "new method" of treating the same disease?

I am, &c., J. W. ROSEBRUGH.

Hamilton, Canada, October 31.

REPORTS OF SOCIETIES.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

TUESDAY, NOVEMBER 13.

CHARLES WEST, M.D., President, in the Chair.

MR. WOOD exhibited a patient on whom he had operated for Epispadias, with excellent results, completely covering over the groove on the upper part of the penis.

ANEURISM TREATED SUCCESSFULLY BY LIGATURE.

MR. RICHARD BARWELL read a paper giving the particulars of a case in which an aneurism of the aorta, innominate, subclavian, and carotid arteries was treated successfully by ligature of the two last-named vessels. The patient, R. W., aged forty-five, was admitted into Charing-cross Hospital, under the care of Dr. Pollock, on July 24, 1877, with a large aneurism at the right root of the neck. The man had served both in India and the Crimea, and was at the time of admission into hospital a labourer in a foundry (the work requiring strenuous efforts). He had not had syphilis; the family history was remarkably healthy. In November, 1876, he had vomiting and purging after a drinking bout, followed by rheumatoid pains in shoulders and limbs. These disappeared after a time, but not from the right arm. He first noticed a swelling on the neck during March, 1877; his right arm became weaker, and was occasionally numb. The tumour was oval just above the right clavicle; it stretched from beneath the inner margin of the left nearly to the outer margin of the right sterno-mastoid, and upwards to the lower margin of the thyroid cartilage; its projection was considerable, and its strong pulsation characteristically expansile. Dulness prevailed from the inner third of the clavicle over the first intercostal space and second rib, and mingled with the cardiac dulness; over this space pulsation could be felt. The heart was displaced to the left, its apex beating fully half an inch outside the nipple line; strong epigastric pulsation would indicate some cardiac displacement downwards. The veins of the right side of the neck and chest and of the arm were greatly distended. No bruit at the heart or over the tumour could be heard, and there was no perceptible difference between the two radial pulses. Dr. Pollock treated the case with rest, low diet, digitalis, and ice-bags to the tumour, but the aneurism increased. Deligation was then proposed, but the patient, after consideration, declined and left the hospital. However, he returned under the author's care on August 13, desiring to have the operation performed. In the meantime the cervical tumour had much increased, and was more prominent; it measured horizontally between the limits of pulsation by compass four inches and a half, by tape just over six inches; perpendicularly it extended from the clavicle to above the middle of the thyroid cartilage, measuring by compass, three inches, by tape three inches and five-eighths. The thoracic dulness and pulsation reached as far as the middle of the clavicle. The displacement of the heart seemed rather greater; he had a cough, with very little laryngeal sound, and breathing and circulation were much embarrassed. 14th: The operation was performed first on the carotid; a peculiarity of a greatly enlarged superior thyroid simulating prolongation of the sac upwards, necessitating great caution until the source of the abnormal pulsation was revealed, and only just room enough being found to pass a ligature round the common carotid between the aneurism and the bifurcation. The subclavian artery was then reached with remarkably little bleeding, and a ligature passed round it; pressure on the hollow of the needle obliterating the radial pulse. In disengaging the catgut, a vein above the brachial plexus (either the posterior

scapular, or a smaller but distended vein) was ruptured; its deep position, and the filling of the cup-like wound with blood, rendered its ligation difficult and doubtful. Rather than attempt this, the author did not wait to verify the isolation of the artery, but knotted the catgut loosely, stuffed the wound firmly with antiseptic gauze, and let the patient be carried to bed, the radial pulse still beating. The next day he removed the gauze, and traced down the ligature, which included with the artery a nerve of the plexus; this loose ligature was left in place, and a fresh one passed and tied. These operations—carotid and subclavian—were performed antiseptically. No immediate change in the tumour was perceptible. Low milk diet was ordered. The further notes were as follows:—"16th: The breathing and circulation greatly relieved; temperature normal. 23rd: Cervical tumour harder. Transverse measurement by compass, three inches and a quarter; by tape, four inches and three-quarters. Thoracic pulsation barely perceptible. 25th: A very dry diet substituted. 26th: Slight pulsation, probably collateral, in radial. 28th: Patient suffers much from thirst; heart's action excited. Pulse 102; temperature irregular; radial pulsation disappeared. 29th: Tumour measures by compass three inches and three-quarters; by tape, five inches and a quarter. September 3: The hospital No. 3 diet (fairly nutritious), and one pint of beer daily. 5th: Temperature and pulse still high and irregular. Tumour harder; measurement by compass, $3\frac{1}{8}$; tape, $4\frac{1}{2}$ inches. 8th: Compass, $2\frac{3}{4}$; tape, $3\frac{1}{2}$ inches. 9th: Compass, $2\frac{1}{4}$; tape, $2\frac{7}{8}$ inches. 10th: Compass, $2\frac{1}{8}$; tape $2\frac{1}{4}$ inches. On the 9th some arteritis of the vessels on arm; on the same day temperature went down to 96°, and has since been normal. A like attack recurred on September 23. October 21: Since the rapid diminution in size of the tumour commenced, the man has gone on uninterruptedly well. A firm, solid tumour lies behind the sterno-clavicular joint, with pulsation communicated from the aorta; it feels about the size of a cob-nut. No thoracic pulsation. Dulness extends about half an inch outside manubrium sterni. The whole aneurism is consolidated." The author remarked that the aneurism involved, without doubt, the aorta, innominate, subclavian, and carotid, and was not far from bursting. The operation relieved immediately the oppression of circulation and breathing, showing diminution of the thoracic, while the cervical part of the aneurism responded more slowly. He considered the system of diet produced a very coagulating tendency in the blood. The whole of the subclavian was obliterated, as there was still no radial pulse. The practical proof of the theory that aneurism of the innominate might be treated by double distal ligature had not yet been attained (Mr. Heath's well-known case proved to be aortic only). Six such operations had been performed, of which two proved fatal on the sixth day, one on the fifty-fifth, one on the sixty-fifth day; two, receiving no benefit, lived some weeks. The author said this case furnished the practical proof that not only innominate aneurism, but aneurism of that vessel and of aorta, subclavian, and carotid, are amenable to the double distal ligature. Also there might be deduced from it what Mr. Heath's case had already proved, that aneurism of the first part of the aorta might be cured by ligature.

Mr. Macnamara asked how the ligatures were treated; if they were cut off, or how?

Dr. Silver said he could testify to the enormous improvement effected in the patient by the operation. The aneurismal tumour in the neck was very large, quite as large as the fist; but he was not quite satisfied that the carotid was implicated. In this view he was strengthened by the difficulties attending the diagnosis of certain forms of innominate aneurism, of which he recited an example. It was quite possible for the aneurismal tumour to overlie, and almost completely conceal, the undilated carotid. The patient had undoubtedly been greatly benefited, but it was hardly right to say as yet that a complete cure had taken place; there was tumour where there should be no tumour, thrill and impulse where there should be neither. Nevertheless the case was a remarkable one.

Mr. Wood congratulated the author on his success, and corroborated the great value of diet in these cases. In a case of iliac aneurism treated by electricity there was much benefit experienced by its means. He had used no stimulants and no digitalis. The thirst had been quenched with ice, and the food had been milk and soup. He did not think the aneurism quite cured. In Mr. Heath's case there was at first retraction, but afterwards it again increased. Mr. Barwell recommended the carbolised ligature and spray, but with an ordinary ligature the case might have done as well.

Dr. Barclay also confirmed the great value of diet in these cases. He had a similar case to that narrated, where, with a little digitalis and iron and dieting, much good was done. But this patient could lie quietly in bed, and feel perfectly comfortable; few could do that. Most good could be done by rest and full diet, and no stimulants; but few could stand that long—they got upset.

Dr. Althaus asked if there were any disordered-nerve symptoms. In some there had been hemiplegia or disorder of the functions of the arm.

Dr. Powell considered the temperament of the patient a matter of great importance. Some might be kept much longer in bed than others. The malady might not seem greatly improved at the time even of dismissal, but would improve afterwards. Were any sphygmographic tracings taken, or any pressure symptoms observed in this case?

Mr. Barwell, in reply, said that diet did no good here—operation was required; its value, however, was great, and surgeons may have too much neglected it. Aneurisms involving the carotid were not always easily made out; but in this case he thought the carotid was involved. No doubt, too, a tumour was still there; but that was to be expected. At all events, the aneurism seemed cured. There were no nervous symptoms, and no tracings were taken. The ligatures were cut short.

WEST KENT MEDICO-CHIRURGICAL SOCIETY.

Friday, November 2.

W. Johnson Smith, F.R.C.S., President, in the Chair.

Intestinal Obstruction.

Mr. W. W. Wagstaffe related a case of intestinal obstruction, with remarks on tapping the intestine as a means of cure in certain cases, of which the following is a short abstract:—Mr. Wagstaffe said: Just three years ago a medical man, aged twenty-five (in practice in town), came to consult me, as he had had several attacks of colic and temporary intestinal obstruction. On examining his abdomen I found that, although a very spare man, there was some general fulness, and deep down in the right iliac fossa a lump about the size of a large walnut could be felt, slightly movable from side to side, and decidedly tender. On manipulation, decided nausea was produced, with gurgling in the neighbourhood. A year and a half previously (the spring of 1872) he had had "typhus, with abdominal complications and black vomit." What this really meant was difficult to make sure of, but I assumed he had had typhoid fever with probably bowel ulceration. He recovered, and only five months previously to my seeing him had he had any temporary stoppage. After getting wet through one day he was seized with cramp, abdominal distension, sickness, and constipation, but after two days of purgatives and enemata he was relieved. Since this he had had four similar attacks, each lasting two days, but the last two attacks had occurred in the previous three weeks; and since the first attack he had never passed a healthy, solid motion, but always putty-like. The attacks began with abdominal distension, tenesmus, then blood and mucus, then pain and obstruction, with vomiting and sometimes delirium. He had never had rigors or hectic. Here was a case of occasional obstruction, with some discharge of blood, and at the same time a lump of some kind fixed in the neighbourhood of the cæcum. It might be a case of intussusception, or growth pressing on the gut, or glandular mass, perhaps suppurating and producing the same effect; or, as he had had apparently some typhoid ulceration, it might be that the remains of this were contracting, or pressing upon, the gut. It was hardly likely to be impaction of fæces only, but yet that was a possibility; and the symptoms did not resemble those due to a band or twist. Anyhow, one could only give a guarded prognosis, and caution him against errors in diet. But I may remark that he was an Irishman, and, with the best intentions in the world, he did commit errors in diet, and with rather definite consequences. He went away, and, at my advice, took belladonna whenever he anticipated an attack of obstruction, and, by mild purgation, to make sure his bowels were cleared of their contents; notwithstanding which the lump could always be felt in the same place. I saw him two or three times after; the lump was still there, neither larger

nor smaller, nor apparently tender. There was resonance over the tumour; but I do not attach any importance to that sign, as a piece of intestine may so easily overlap a small solid growth that resonance almost always is found. And in this case, although the resonance present was in favour of the tumour being mainly intestinal, yet I thought it unadvisable to put much trust in it. On May 19, 1875, he indulged in a full meal of beefsteak, after which he vomited. He continued to vomit after everything he took, and was in much pain, chiefly in the right iliac region; tenesmus, but no evacuation. For the next three days there seems to have been less pain, no vomiting, but no evacuation; skin became more bronzed; conjunctivæ tinged; tongue foul; and delirium, very marked at night. On the 24th I saw him, and learned that his attacks had been much more frequent since September, one lasting four days. They commenced usually by sweating around the anus, coming on twelve hours before other symptoms; then palpitation, followed shortly by nausea, and faintness; then tenesmus, and dragging pain, beginning apparently in the upper part of the rectum on the right side; then cramps, violent straining, and distension. For the last six months his motions have never been larger than one's little finger. I found him now breathing with some difficulty, complaining of griping pains in the hypogastric and right iliac regions; his abdomen was greatly distended, and there was some tenderness in the left hypochondriac region; skin deeply bronzed; no evacuation for five days; no sickness now; urine passed normally. I passed a long tube up the rectum for fully eighteen inches, and injected a pint and a half of water. A previous insertion of the tube was said to have been followed by blood. On the 26th he was no better: rather worse. Another enema of castor and olive oils failed to do any good. I resolved, before resorting to more serious measures, to relieve the tension of his abdomen, hoping thereby to take off pressure from above the point of obstruction, and possibly by that means allow the fluid contents of the bowel to pass on. The circumference of the abdomen was now thirty-seven inches and a half. His respirations were 35, entirely thoracic; pulse 140; temperature 100·6°. A puncture was now made with a fine trocar in median line of abdomen, rather nearer the ensiform cartilage than the umbilicus—into, in fact, the most prominent coil of intestine. An enormous escape of gas immediately followed, not very offensive in smell; the abdominal walls were relaxed, and the breathing was at once relieved. The circumference of abdomen was diminished by two inches; pulse reduced fourteen beats per minute. Respirations remained about the same in number, but the breathing was at once abdominal. He had a small dose of morphia, and passed a good night, sleeping readily. On May 27 he refilled with gas, and towards evening respiration was again interfered with, and although early in the day it had decreased to twenty-five per minute, it rose again in the evening to thirty-five. The abdomen also again increased in circumference, and slightly exceeded the dimensions of the previous day, measuring now thirty-eight inches. The heart was forced upwards, so that the apex was felt beating between the fourth and fifth ribs, close to the sternum. I therefore thought it advisable to tap him again, and used the same small trocar and canula (No. 1). My first puncture only drew off a little fæcal matter, so I very shortly withdrew the instrument. A second puncture allowed a rather small quantity of gas to escape, and some fæces. This I allowed to go on until only fluid fæces seemed to be escaping. A third puncture produced little more than fæces. A fourth puncture was more successful, and a very large quantity of gas escaped, so that after the operation the abdominal circumference was reduced by two inches, and he felt much relieved. Four hours afterwards he had a good deal of griping pain and loud rumbling in the abdomen, all of which, however, was only preparatory to a complete purging, which began six hours after the last tapping, and lasted for nearly three days, with no special feature worthy of notice. The stools, at first watery, acquired more consistence, and were never bloody. And now, after three days, a complication occurred, which is worthy of record, as it shows what a punctured intestine will bear without serious results following. I have said he was a doctor, and doctors proverbially make bad patients. He was, moreover, an Irish doctor; and on the fourth day after these numerous tappings he was downstairs, and out for a walk nearly an hour, and appeared to be rather proud of the feat. It is hardly surprising, therefore, that, twelve hours after, he had acute pain in the right ilio-lumbar region, tympanitic swelling bulging forward above the right inguinal region, which he did not hesitate to knead, until he had (as he said) dispersed it. His temperature and pulse rose, and he had pain on taking a deep breath, referable to the lower part of the left pleura; I treated him with small doses of morphia, and he rapidly improved. After a week's rest he was up, and although some pain and tympanitic swelling remained in the right inguinal region for a few days, this disappeared after a copious motion; and he went away into the country, full of good resolves respecting diet, in less than a fortnight after his tapping. I saw him from time to time working hard in a harassing practice, with his "thorn in the side" still there—a lump neither larger nor smaller than before, a source of trouble if he departed from the strict rules of diet I had laid down for him. About a year after his tapping he sent for me again, and wanted to be tapped again, as he had indulged in four hot-cross buns on Good Friday, and was, as might have been expected, in trouble; he had had a rigor on the Friday evening, vomiting on the Saturday, the bowels slightly open on Saturday, with some blood and slime. He declared he had vomited two ounces of blood on Sunday. The abdomen was gradually becoming more and more distended; pain was of a crampy character in the right ilio-lumbar region; the vomit was yellowish, and consisted of the contents of the stomach, but was not fæcal. As the abdomen was not fully distended (circumference only thirty-two inches and a half), I ordered him half a grain of the extract of belladonna every four hours; and in twenty-four hours he passed a quantity of wind, followed later on by four copious dark fluid motions. So he was relieved this time, and without the tapping. I need hardly say that now he preferred the belladonna treatment, and feeling that he had a ready means of relief, he kept some belladonna always ready for use, and I think rather frequently took it. Three months went by, and he sent for me again, but I was out of town. It seems he had some pain and threatening of trouble on July 1; was better on the 2nd, and in the evening had to go to a midwifery case, where he fainted, and was thought to be intoxicated. He was brought home; seems to have been in a good deal of pain; took some belladonna and was easier, and went to bed. During the night he was heard to go down to his surgery, and apparently mix himself some medicine. He shortly afterwards became delirious, and died in a state of wild delirium, not complaining of pain. There was no distension of the abdomen then or afterwards; but as I did not hear of his death until some time after, and his relatives were very reluctant to give information about the facts of his death, apparently in fear lest his insurance policy should be forfeited if it should appear that he committed suicide, I am unable to give so satisfactory an account of the pathology of the case as I could wish.

NORTHUMBERLAND & DURHAM MEDICAL SOCIETY.

THURSDAY, NOVEMBER 8.

MR. GEORGE B. MORGAN, President, in the Chair.

PREVALENT DISEASES OF THE DISTRICT.

MR. H. E. ARMSTRONG presented a report of the cases admitted to the Newcastle-on-Tyne Fever Hospital during the month of October, and reported the occurrence of a case of small-pox in Newcastle.

Dr. ADAM WILSON said there were some cases of small-pox at Walker, a village three miles from Newcastle.

PATHOLOGICAL SPECIMENS.

Dr. MURPHY showed a specimen of Anencephalous Fœtus.

Dr. MURPHY also showed an ingenious Instrument which he had invented for the purpose of keeping open the incision after Tracheotomy, while a tube is being introduced or a foreign body removed.

Dr. PAGE showed a specimen of Fracture of the Odontoid Process. The patient had fallen several feet upon the top of his head. Death was instantaneous. The ligaments were unruptured.

Dr. PAGE also showed a large Ovarian Tumour which he had successfully removed antiseptically.

Dr. HEATH, alluding to the use of Antiseptics in Ovariotomy, mentioned his case, published in the *British Medical Journal* of June 30, which was, so far as he knew, the first in which the operation was performed strictly antisepti-

cally. He stated that in late operations he had divided the pedicle into several parts. Each part was ligatured antiseptically; the pedicle was then left in the peritoneal cavity. Dr. Heath also showed a specimen of Ovarian Tumour.

Dr. Heath showed a Common Carotid Artery which had been Ligatured by Antiseptic Catgut. The patient, who was suffering from malignant disease in the parotid region, died eight days after the operation. The ligature had disappeared. The internal and middle coats were undivided. The external coat was constricted. The vessel was filled with a firm clot.

Mr. Fielden showed a Foreign Body which he had removed from the bladder of a female through the dilated urethra. It was two inches long, and an inch and a quarter broad. The urine was retained and passed naturally on the eighth day.

Mr. Fielden showed a specimen of a Tumour of the Kidney weighing four pounds and a half. The tumour was of five months' growth. There was no history of hæmaturia. Dr. Byrom Bramwell had examined the tumour, and stated that it was a small-celled sarcoma. Mr. Fielden also showed photographs of the case.

Mr. Fielden showed a Fatty Tumour from the Axilla.

Dr. Gibson showed a specimen of Hepatic Abscess removed from the body of a Russian sailor, aged twenty-nine. No history could be obtained. There was also a large collection of pus in contact with the spleen. Purulent peritonitis, pericarditis, and pleuritis were found post-mortem.

Exhibition of Patients.

The President showed a patient who had Contraction of the Knee after excision of the joint, and after bony union had apparently been firmly established. The knee was firmly anchylosed at an angle.

Dr. Barron showed a patient who had Six Toes on each foot, and Five Fingers on each hand. There was no hereditary history.

Dr. Heath showed a patient who had Conical Cornea, and stated that the convexity of the cornea had greatly diminished under the use of iodide of potassium.

Dr. Heath also showed a patient, a boy aged six, suffering from Hypertrophy of the Leg, in which the external iliac was ligatured. Before the operation the left leg was two inches and a half longer than the right, and measured at the thickest part of the thigh twelve inches and a quarter, the right being eight inches and a half. Three months after the operation the left leg was only one inch and a half longer than the right, and the measurements of the thigh were twelve inches left, eleven inches right. Since the operation the right limb had been stimulated by the constant current. The hypertrophy was not congenital.

Papers.

The President read notes of a case of Intussusception in an adult, treated by opium, resulting in recovery. The invagination could just be reached per rectum. It felt like the os uteri.

Dr. Embleton reported a case of Pyloric Obstruction with abnormal position of the right end of the transverse colon. The diagnosis was for some time obscure, as no tumour or other apparent cause of obstruction could be detected. At the post-mortem the right end of the transverse colon was found between the diaphragm and the convex surface of the liver.

Clinical Examinations.—At the pass examination for the diploma of Membership of the Royal College of Surgeons, the following very interesting cases were sent from the following hospitals—viz., St. Bartholomew's, Guy's, St. Thomas's, University College, St. Mary's, and St. George's:—Necrosis of phalanx; eczema of face and hands; growth on head (fibroma); united fracture of humerus; hydrocele of tunica vaginalis; bursa in popliteal space; varicocele; bursa of tuber ischii and gout-stones; hydrocele of tunica vaginalis, right; inguinal hernia, left; chronic synovitis of knee; exostosis humeri; united fracture of radius and ulna; sebaceous cysts on back; hydrocele and tumour in thigh; hydrocele of tunica vaginalis; epithelioma linguæ; necrosis of radius; disease of left carpus; hydrocele and chalk-stones; cancer of neck; skin eruption; hydrocele and tumour in thigh; periostitis of lower jaw; mammary gland in the male; glandular enlargement of neck; epithelioma in temporal region; sebaceous tumour in back; inguino-scrotal hernia; chronic abscess in back; disease of antrum; periostitis of tibia; inflammation of carpal end of radius; etc.

LEGAL INTELLIGENCE.

THE FEES OF MEDICAL WITNESSES AT CORONERS' INQUESTS.

In the Court of Queen's Bench, Ireland, the case of the Queen (Jacob) *v.* Finlay, public auditor, was argued before the Lord Chief Justice and the Judges, on November 17 and 19. Counsel for Dr. Jacob—Mr. Purcell, Q.C., and Mr. Furlong, instructed by Mr. Clifford Lloyd. For the Corporation—Mr. Waters, Q.C., instructed by Mr. MacSheehy. For Mr. Finlay—Mr. S. Walker, Q.C., and Mr. David Fitzgerald, instructed by Messrs. V. B. Dillon and Co. For Dr. Egan—Mr. Wm. O'Brien, Q.C., instructed by Mr. Davoren.

Mr. Purcell moved that, notwithstanding the cause shown, the *certiorari* granted in this case might be made absolute. Counsel said he appeared for Dr. Jacob, a ratepayer of the city of Dublin, but in reality the case was substantially brought forward by the Irish Medical Association, in order to obtain the opinion of the Court on the Act of Parliament. The *certiorari* had been granted for the purpose of bringing into court the decision of Mr. Finlay, the public auditor, allowing certain payments made by the Corporation. The question turned upon the construction of certain sections of the Coroners Act, 9 and 10 Vic., c. 37. Plaintiff complained that, contrary to the provisions of the Act of Parliament, a permanent medical witness had been appointed, who was paid by salary, whereas the Act contemplated that the witnesses should be taken from the members of the profession generally, and that they should be paid by fees, a guinea for each attendance. Counsel then read Sections 33, 28, and 29, which provided respectively that the coroner shall, when he thinks the attendance of a medical witness necessary, summon as such witness "any legally qualified medical practitioner being at the time in actual practice at or near the place where the inquest shall be held"; that such witness shall be paid "a sum not exceeding one guinea" for each attendance; and that upon receiving from the coroner a receipt duly signed by the witness, the Grand Jury (in Dublin the Corporation) may present for it, along with such sums as they may deem necessary for the payment of the expenses of coroners, including the payment of medical witnesses. Dr. Jacob had made an affidavit, in which he stated as a matter of fact that at present one and the same medical practitioner (Dr. Egan) is employed to act as medical witness at all inquests by the Coroner for the City of Dublin, without regard to the locality in which the death might have occurred, and that such witness now receives a fixed annual salary of £150, payable quarterly, instead of a fee of one guinea for such inquests. At the audit Dr. Jacob instructed Mr. Lloyd to appear and object to the payments, but Mr. Finlay, notwithstanding, was of opinion that the payment should be passed.

At the conclusion of the arguments, which occupied two days, the Lord Chief Justice, in pronouncing the judgment of the Court, said it did not appear that any corruption of any kind was charged, nor did it appear that the result had been any prejudice whatever to the ratepayers, for it would seem that the ratepayers had rather gained by the arrangement which had been made, and the objection was rather of a technical and legal nature. The Court, upon the whole, were of opinion that it would not be desirable that the *certiorari* should go. The result of their making the order absolute would be that they should disallow the money allowed by the auditor, and thereby deprive Dr. Egan of the money paid to him, when, probably, other proceedings would ensue, by which a larger sum would be found due to Dr. Egan. At the same time, it was right to say that they did not approve in point of law of this arrangement, which appeared to have been made so long ago as the time of Surgeon Porter, and which had been more recently acted upon in the appointment of Dr. White and Dr. Egan as medical witnesses. It occurred to them that they should not sanction or approve of any arrangement which fettered any discretion of the coroner to summon from time to time such medical gentlemen as he might think proper to summon as witnesses. The very term "medical witness" conveyed something that they thought was objectionable. A witness ought not to be a standing witness. Therefore, although no doubt this arrangement had been made with proper intentions on the part of the Corporation and of the coroner, the object being to save expense, yet there appeared to be something objectionable to it. The writ would not be granted, and the parties should abide their own costs, except the auditor, who should be allowed his costs out of the rates.

OBITUARY.

W. HANDSEL GRIFFITHS, Ph.D., etc.

It is our melancholy duty to record this week the early death of a highly esteemed and rising member of the profession, Dr. W. Handsel Griffiths, whose valuable life has fallen a victim to that terrible scourge of modern civilisation, enteric fever. In the enjoyment of his usual good health until within a fortnight or three weeks before his death, Dr. Griffiths succumbed to this treacherous disease on Friday, the 16th inst. He was only thirty-one years of age, and leaves a widow and two children to mourn over their irreparable loss. He died at his residence, 10, Upper Fitzwilliam-street, Dublin; and it will be strange if the attention of the Public Health Committee of the Corporation—the Sanitary Authority of Dublin—will not now be drawn to this, one of the most fashionable streets in Dublin, and at the same time apparently one of the most unwholesome. Not very long ago, Dr. Handsel Griffiths lost a little child of enteric fever in the same house in which he died. Within two doors of Dr. Griffiths' residence, Dr. Henry Eames died of typhus fever four years and a half ago. No doubt the disease was contracted in his hospital, but it is only too probable that residence in a tainted atmosphere increased the receptivity of the system to the fever-poison, and hastened or determined the fatal termination of his illness. Last year a case of malignant enteric fever occurred next door to Dr. Griffiths' house, and rapidly proved fatal; and we have reason to believe that small-pox recently prevailed in some of these same houses. This preventable loss of health, and even of life, is very sad, and calls for a searching investigation at the hands of the local sanitary authorities.

Dr. Griffiths, having studied at Queen's College, Cork, and at the Royal College of Surgeons, Ireland, as well as in London and Edinburgh, took the diplomas of the Colleges of Physicians and Surgeons, Edinburgh, in 1871. He settled in Dublin, and was soon afterwards appointed Assistant-Librarian of the Royal College of Surgeons. He also held the post of Lecturer on Chemistry in the Ledwich School of Medicine, Peter-street, Dublin. Considering his youth, he had done a vast amount of work, and his contributions to medical and scientific literature are both numerous and of a high order of merit. He was author of "A System of Botanical Analysis," a "Synoptical Review of the Preparations of the British Pharmacopœia," "Posological Tables" (which ran to three editions in a short time), "Notes on the Pharmacopœia" (1872), "Notes on Therapeutics," "Lessons on Prescriptions," etc. To the *Proceedings of the Royal Irish Academy* he contributed a paper on "Hæmodromometers," and to the *British and Foreign Medico-Chirurgical Review*, one on "Hæmodynamics." For some years he had ably edited the "Monthly Reports on the Progress of Therapeutics" for the *Edinburgh Medical Journal*.

Apothecaries' Society's Prizes.—The following medical students obtained the prizes given by the Apothecaries' Society during the present year, viz.:—For proficiency in botany—first, A. H. S. Lucas, London Hospital, a gold medal; second, S. H. Henty, University College, a silver medal and books; third, C. P. Lukis, St. Bartholomew's Hospital, a bronze medal and a book. For Materia Medica and Pharmaceutical Chemistry—first, A. K. Morgan, Guy's Hospital, a gold medal; second, James Balls, King's College, London, a silver medal and books.

The Gilbert Blane Medal.—The biennial adjudication of the gold medals founded by Sir Gilbert Blane, Bart., physician-in-ordinary to George III., has just been made in accordance with the terms of his bequest, by the Presidents respectively of the Royal Colleges of Physicians and Surgeons of London, and the Director-General of the Medical Department of the Royal Navy. They have been awarded to Fleet-Surgeon Adam Brunton Messer, M.D. and L.R.C.S. Edin., 1858, for his journal as staff surgeon of H.M.S. *Pearl*, 1875, when on the Australian station; and to Fleet Surgeon Francis William Davis, L.K.Q.C.P. and F.R.C.S. Ire., 1873, for his journal of H.M.S. *Audacious*, the flagship on the China station, 1875. The medal, which is a very handsome one, of the value of ten guineas, has on the obverse an excellent likeness of the donor in bold relief, and on the reverse a wounded sailor falling into the arms of a comrade; the name of the recipient is engraved on the legend.

MEDICAL NEWS.

King and Queen's College of Physicians in Ireland.—At the ordinary Monthly Examination Meetings of the College, held on Tuesday, Wednesday, and Thursday, November 13, 14, and 15, the following candidates were successful. For the Licence to practise Medicine—

Asbury, Alfred.
Brereton, John Thomas.
Corbett, Joseph Edward.
Faulkner, Alexander Samuel.
MacNeece, James Gaussen.
O'Hara, Henry Michael.
Perceval, Montague Wm. Cairns.

For the Licence to practise Midwifery:—

Bland, Archibald R. Hamilton.
Corbett, Joseph Edward.
Faulkner, Alexander Samuel.
O'Hara, Henry Michael.
Perceval, Montague Wm. Cairns.

For the Licence as a Midwife and Nursetender:—

Webb, Helen.

Royal College of Surgeons.—The following gentlemen, having undergone the necessary examinations for the diploma, were admitted members of the College at a meeting of the Court of Examiners on the 15th inst., viz.:—

Brindle, R. Francis, Prescott, near Liverpool, student of the Manchester School.
Chapman, Herbert Frederick, Richmond, Surrey, of St. Bartholomew's Hospital.
Colquhoun, Daniel, L.S.A., Upper Kennington-lane, of the Charing-cross Hospital.
Cressey, George Henry, Tunbridge Wells, of St. Bartholomew's Hospital.
Dingle, William Alfred, L.R.C.P. Lond. and L.S.A., Millbrook, near Southampton, of St. Bartholomew's Hospital.
Duke, George Amos, L.S.A., Cornwall-road, of St. Mary's Hospital.
Flint, Arthur, Highbury-park, of St. Bartholomew's Hospital.
Hammond, Alexander Billing, L.S.A., Queen-street, Finsbury, of Guy's Hospital.
Husband, Walker Edward, York, of St. Bartholomew's Hospital.
Johnstou, Alexander John James, South Kensington, of Guy's Hospital.
Lowe, Howard Griffiths, Birmingham, of the Birmingham School.
Master, George Reginald, Norwich, of St. Bartholomew's Hospital.
Parry, George Hales, L.S.A., Docking, Norfolk, of Guy's Hospital.
Rowe, Bernard Meredith, Wrexham, N. Wales, of St. Bartholomew's Hospital.
Smith, Charles Robert, Wolverhampton, of St. Bartholomew's Hospital.
Teevan, Alfred, Richmond, Surrey, of King's College Hospital.
Trevan, Frederick Adolphus, L.S.A., Port Isaac, Cornwall, of St. Bartholomew's Hospital.
Walsh, William Arthur Stephenson, L.S.A., Worcester, of King's College Hospital.
Willcocks, Frederick, L.S.A., Kensington, of King's College Hospital.

Three gentlemen having passed in Surgery, will be admitted Members of the College when qualified in Medicine; and nine candidates having failed to acquit themselves to the satisfaction of the Court of Examiners, were referred to their professional studies for six months.

The half-yearly Primary Examination for the Fellowship of the College, which was commenced on Friday last, was brought to a close on the 20th inst., when the following gentlemen were reported to have acquitted themselves to the satisfaction of the Board of Examiners, and when eligible will be admitted to the Pass Examination, viz.:—

Castle, Hutton, student of St. Thomas's Hospital.
Cathcart, Charles Walker, L.R.C.P. and L.S.A. Lond., of the Edinburgh School.
Chaffey, Wayland Charles, of St. Bartholomew's Hospital.
Coles, Donald Alexander, of St. Bartholomew's Hospital.
Cronk, Herbert George, of St. Bartholomew's Hospital.
Dunn, Hugh Percy, diploma of Membership dated August 1, 1876, of St. Bartholomew's Hospital.
Heath, William Lenton, July 30, 1877, of St. Bartholomew's Hospital.
Lockwood, Charles Barrett, of St. Bartholomew's Hospital.
Paddle, James Isaac, of University College Hospital.
Perry, Francis Frederick, August 1, 1876, of University College Hospital.
Pollard, Bilton, of University College Hospital.
Sheppard, Charles Edward, July 31, 1877, of St. Thomas's Hospital.
Takaki, Kanehiro, of St. Thomas's Hospital.
White, Richard Watts, of Guy's Hospital.

Thirteen candidates having failed to acquit themselves to the satisfaction of the Board of Examiners, were referred to their studies for six months. Amongst the successful candidates will be seen the name of Mr. Kanehiro Takaki, the first Japanese gentleman who has passed this severe ordeal; he passed, also, the Primary Membership of the College in April last.

The following were the questions on Anatomy and Physiology submitted to the candidates for the Fellowship on this occasion, when they were required to answer the whole of the questions, viz.:—1. State your views on the formation of urea, and the experiments or arguments on which they rest. 2. Describe the development of the intestinal canal. 3. Describe in order the parts seen in dissecting, from the surface to the bones, the region bounded by the superior curved

line of the occipital bone above, and the seventh cervical vertebra below. 4. Describe the ligaments of the ankle-joint and of the tarsus, and their relations.

APOTHECARIES' HALL.—The following gentlemen passed their examination in the Science and Practice of Medicine, and received certificates to practise, on Thursday, November 15:—

Evans, Henry, Barmouth.
Garman, Vincent Cornelius, Kent House, Bow-road.
Harrison, Edmund Meredith, Brackley.
Pemberton, Robert, Richmond-terrace, Clapham-road.

The following gentlemen also on the same day passed their Primary Professional Examination:—

Baldwin, Frederick Benjamin Judge, Guy's Hospital.
Jones, George Henry West, Guy's Hospital.
Maybury, Lysander, St. Thomas's Hospital.
Rhys, Joshua, St. Bartholomew's Hospital.

APPOINTMENTS.

*** The Editor will thank gentlemen to forward to the Publishing-office, as early as possible, information as to any new Appointments that take place.

HARRISON, E. M., L.S.A.—Assistant Medical Officer to the Charing-cross Hospital, *vice* Claremont, whose time has expired.

LEAHY, A. W. D., L.S.A.—Resident Obstetrical Officer to the Charing-cross Hospital, *vice* Hoole, whose time has expired.

PYE, WALTER, M.R.C.S. Eng.—Lecturer on Physiology at St. Mary's Hospital Medical School.

ROWBOTHAM, H. C.—Assistant Surgical Officer to the Charing-cross Hospital, *vice* Leahy.

WHITEHEAD, H. R., M.R.C.S.—Resident Surgical Officer to the Charing-cross Hospital, *vice* Wickers.

WICKERS, H. A., M.R.C.S.—Resident Medical Officer to the Charing-cross Hospital. *vice* Steedman, whose time has expired.

BIRTHS.

BATTERBURY.—On November 19, at Berkhempstead, Herts, the wife of Richard Legg Batterbury, M.B. Lond., of a daughter.

DALTON.—On November 18, at Winsley House, Hartwith, Ripley, Yorks, the wife of Henry Dalton, M.D., C.M., British Guiana Medical Service, of a son.

ELLIOT.—On November 14, at The Lawn, Bodenham, Leominster, the wife of John Elliott, M.R.C.S., of a son.

GODSON.—On November 18, at 8, Upper Brook-street, Grosvenor-square, the wife of Clement Godson, M.D., M.R.C.P. Lond., of a daughter.

SAUNDERS.—On November 18, at Lee-terrace, Lee, the wife of Surgeon W. Egerton Saunders, L.R.C.P. Lond., A.M.D., of a son.

SIMON.—On October 13, at Singapore, Straits Settlements, the wife of M. F. Simon, L.R.C.P. Lond., Colonial Surgeon, of a daughter.

MARRIAGES.

BARRY—HAVART.—On November 15, at St. Peter's Church, Tunbridge Wells, James William Barry, L.R.C.P. Lond., M.R.C.S. Eng., of Ramsgate, to Mary Louisa, only daughter of the late Rev. W. J. Havart, M.A., vicar of St. Ives, Cornwall.

CAMPBELL—CLOUSTON.—On November 15, at 3, Abercromby-place, Edinburgh, J. A. Campbell, M.D., of Garlands, Carlisle, to Janet Ann, only daughter of the late Joseph Clouston, of Nist House, Orkney.

ROBERTS—THOMPSON.—On October 27, at St. James's Church, Baroda, Henry Prescott Roberts, M.D., Surgeon H.M.'s 9th Regiment Bombay N.I., to Ellen Rosalinda, eldest surviving daughter of Col. C. Thompson, Commandant 9th Regiment N.I.

SMITH—SCOTT.—On October 3, at St. George's Church, Penang, James Richardson Logan Smith, eldest son of G. H. Smith, M.D., of 80, Great King-street, Edinburgh, to Lucy Grace, eldest daughter of the Hon. Walter Scott, M.L.C.

DEATHS.

DE MORGAN, EDWARD LINDSEY, M.R.C.S., third son of the late Augustus De Morgan, at Aliwal North, Cape Colony, by a fall from his horse, on October 14, aged 35.

MOORE, ST. AUBYN DANIEL, only son of J. Daniel Moore, M.D., of Lancaster, at 3, Queen-street, Lancaster, on November 17, aged 7.

REID, MATTHEW, M.R.C.P. Edin., L.S.A., at 98, Blue Anchor-road, Bermondsey, S.E., on November 13, aged 29.

VACANCIES.

In the following list the nature of the office vacant, the qualifications required in the Candidate, the person to whom application should be made and the day of election (as far as known) are stated in succession.

LIVERPOOL ROYAL INFIRMARY.—Resident Medical Officer. Candidates must be unmarried. No person is eligible who is not on the Medical Register of Great Britain, and who does not possess at least one medical and one surgical diploma, licence, or degree recognised by the Medical Council. Applications, with testimonials, to the Chairman of the Committee, on or before November 29.

LONDON FEVER HOSPITAL.—Assistant to the Resident Medical Officer. Candidates must be duly qualified. Applications, with testimonials, to the Secretary, on or before November 30.

QUEEN'S HOSPITAL, BIRMINGHAM.—Resident Physician and Resident Surgeon. Candidates for these appointments must be registered practitioners. Testimonials, with certificates of registration, to the Secretary, on or before December 1.

ST. PANCRAS AND NORTHERN DISPENSARY.—Resident Medical Officer. Candidates must be legally qualified to practise medicine and surgery in Great Britain and Ireland. Copies of testimonials to the Honorary Secretary, S. S. Wigg, Esq., 26, Gordon-street, Gordon-square, W.C.

UNION AND PAROCHIAL MEDICAL SERVICE.

*** The area of each district is stated in acres. The population is computed according to the census of 1871.

APPOINTMENTS.

Amersham Union.—James O. McCreery, L.R.C.S. Ire., L.A.H. Dub., to the Missenden District.

Southmolton Union.—Thomas Sanders, F.R.C.S. Eng., L.S.A., to the Fourth District.

Thorne Union.—Thomas S. Pitts, M.R.C.S. Eng., L.R.C.P. Edin., to the Thorne District.

MEDICAL SOCIETY OF THE COLLEGE OF PHYSICIANS IN IRELAND.—The first meeting of this Society for the Session 1877-78 took place in the Hall of the King and Queen's College of Physicians, Kildare-street, Dublin, on the evening of Wednesday, November 14. The President, Dr. Samuel Gordon, occupied the chair, and delivered an opening address. Dr. Hayden subsequently made a valuable communication, consisting of an abstract of 330 cases of phthisis, with observations on symptoms and treatment. A brief discussion ensued, after which the Society adjourned.

SULPHATE OF ATROPIA IN PATHOLOGICAL SWEATING.—M. Royet, in his thesis, furnishes the results of the trials made with this substance by Prof. Vulpian since 1873. These demonstrate the efficacy of atropia in sweating under the most various circumstances—as phthisis, rheumatism, convalescence, prolonged suppuration, hysteria, and the influence of jaborandi. The dose of the sulphate varies from half a milligramme to one and a half, it being very rarely desirable to go beyond this. The most convenient form to administer it is in pills or granules, each containing half a milligramme. In order to act with efficacy, the medicine should be given a few hours prior to the occurrence of sweating. Thus, in the nocturnal sweating of phthisis, the pill should be given at eight or ten o'clock in the evening. At least two hours should elapse between the doses, and, if two or three are required in the twenty-four hours, these should be divided by equal intervals. From two to four days suffice to produce a suppression or notable diminution of the sweats; but, in order that the effect may be durable, the use of the atropia should be prolonged, with some diminution of the dose, for eight or ten days. The author of the thesis agrees with Prof. Vulpian in believing that it is nowise imprudent to suppress sweating in rheumatism.—*Lyon Méd.*, November 18.

GONORRHŒAL RHEUMATISM OF THE HEART.—M. Desnos read a case of this affection to the Paris Hospital Society, observing that although these cases are rare, and usually pass unperceived, yet their true nature and connexion is sometimes brought to light by means of the intervening arthritis. About a month ago the subject of this case came into the hospital with acute bronchitis, the heart being then in a normal condition. Some days after, the patient was seized with pains in the shoulder, which then localised itself in the sterno-clavicular articulation, and it was then discovered that he had gonorrhœa. All of a sudden he was seized with violent palpitation of the heart, and the diagnosis was made of narrowing and insufficiency of the mitral orifice; and œdema and infiltration of the inferior extremities, without albumen in the urine, supervened. At the autopsy a small ulcer was found on the mitral valve, together with a considerable vegetant endocarditis of the aortic valves and the whole of the interior of the heart. M. Fournier observed that this was certainly a case of gonorrhœal endocarditis, although important details were wanting. Was there sweating or fever present? In gonorrhœal rheumatism, in fact, the temperature is never high; and just as sweating is so abundant in ordinary rheumatism, it is absent in the form of the disease consecutive to gonorrhœa. A conclusive circumstance in this case was the seat of the affection, the sterno-clavicular articulation being the joint of predilection in gonnorhœal rheumatism. M. Desnos replied that in his case the temperature curves would not be conclusive owing to the pulmonary complications; but the patient had no sweats, and never before had suffered from rheumatism.—*Gaz. Hebd.*, November 16.

Inebriety in Liverpool.—The recent annual report of Major Grey shows that cases of drunkenness in Liverpool have fallen from 20,551 to 15,763, and the decreaso is sufficiently large to justify the conclusion that inebriety of the more flagrant type is diminishing, although it does not necessarily imply a decreasing prevalence of drinking habits.

A New Adhesive Plaster.—Dr. Martin, after detailing the inconveniences attendant upon the use of adhesive plaster, even of the best makers, and referring to its great importance as a means of making extension in various surgical operations, describes a new form of this plaster, which, after many failures, he has succeeded in perfecting. He has received from numerous surgeons who have tried it the highest praise of its value and its freedom from the objections attaching to the ordinary plaster. It is formed by thoroughly incorporating the best Para caoutchouc and Burgundy pitch, and a small proportion of balsam of tolu. The latter article, besides its agreeable fragrance, renders the plaster unirritating to the skin, and improves it in other respects. These ingredients are combined and spread on a very strongly woven cloth (which has been thoroughly shrunk and deprived of every trace of "dressing" by means of Bennet's [Burnett's ?] antiseptic liq. zinci chlorid.) by very expensive machinery devised for other purposes, but well suited for this new production. The commercial charge of the invention has been consigned to Messrs. Metcalf and Co., of Boston, with the direction to present a specimen to every practitioner who may apply for it, so that he may test it inexpensively, and furnish its inventor with his opinion of its value.—*Boston Med. and Surg. Jour.*, October 11.

The Esquimaux in Paris.—The Paris Anthropological Society has appointed a committee, consisting of Prof. Broca and five other members, for the purpose of examining the party of Esquimaux installed in the Jardin d'Acclimatation, a young Dane of the Greenland Society being also appointed interpreter. These Esquimaux come from Christianshaab, near the bay of Disco, where they lived on the produce of their fishing in wretched earthen huts, scarcely sheltered by some stunted birch-trees. It was here that an *employé* of the Greenland Society proposed to them to exhibit themselves in London and Paris, for which purpose they set off last year, accompanied by their dogs, six white polar bears, ten seals and sea-calves, and their picturesque baggage. They are Christians, having been baptized by the Moravian Brothers. The party consists of Caspar Mikal Okabak, aged thirty-two, and his wife Julia, twenty-three years of age, who is regarded as one of the beauties of Greenland, having with them a little girl four and a half years of age, and another thirteen months old, carried on her mother's back in a sealskin bag. Also two other men of twenty-eight and forty-one years of age. The men are of a copper colour, and their hair, which is black as ebony, falls over their shoulders. In spite of their cordial reception, they frequently regret their independent and wandering life and their long sledge expeditions in the bay of Disco, to which it will not be long before they return.—*Union Méd.*, Nov. 15.

In a former number I drew attention to the danger of using Shanghai ice for the cooling of beverages, except with the precaution of making the cooling mediate. The practice of allowing lumps of ice to dissolve in a fluid intended to be drunk is here always dangerous, and may at any moment prove disastrous. People who adopt it fancy that they escape danger by washing the fragments of ice before they are brought to table—an assumption utterly at variance with common sense,—or hold that the process of freezing, like that of prolonged boiling, destroys all living germs. The pseudo-scientific character of the last-mentioned error makes it all the more difficult to combat. It must suffice to say that the idea that impure water can be frozen into pure ice is absolutely false. I may now, in support of my previously published cautions, refer to an article in the *Practitioner* for September, 1876, page 234, wherein is reported a severe outbreak of intestinal disorder in an hotel at Rye Beach, N.H., which was traced to the use of ice gathered from shallow ponds formed during the winter by the flooding of the meadows, and therefore containing, as a rule, more or less grass and other vegetable matter, and consequently far less transparent than the article commonly supplied in our large cities. I was not particularly surprised, then, to find that the ice in this case was rather impure and opaque, and that it contained numerous foreign substances, varying in size, and apparently of vegetable origin. "Grass and other vegetable matter" are bad enough, but they are a mere joke to the contributions made by clothes- and bucket-washers to our pond water, and therefore to our ice supply.—*Dr. Jamieson, in the Chinese Customs Gazette.*

NOTES, QUERIES, AND REPLIES.

He that questioneth much shall learn much.—*Bacon.*

The Penge Case.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

Sir,—In his comments on the Penge case in your number for November 17, Professor Virchow takes the diameter of the English fourpenny-piece to be twenty-one millimetres. None of the fourpenny-pieces at present current have this measurement; the diameter is almost exactly sixteen millimetres. Judging, therefore, from the size of the only coin in his possession, he has concluded that the supposed tubercular patch was more than half as large again as, according to Dr. Wilkinson, it really was; the areas, omitting decimals, being 346 and 201 square millimetres respectively.

Liverpool, November 20. I am, &c., William Carter.

[This only confirms what we have already said as to making these observations accurately, and of giving exact measurement, instead of rough guesses.—Ed. *Med. Times and Gaz.*]

Hertz.—During the academical year 1876-77, the German authorities have licensed 586 persons to practise as surgeons or physicians, of whom 276 are in Prussia, and 149 in Bavaria. In the same period only nine persons have received licences as dentists, 85 as veterinary surgeons, and 334 as pharmaceutical chemists.

Delta.—The phrases, *Naviget Anticyram* and *Tribus Anticyris caput insanabile*, have reference to the fact that sick persons were in the habit of resorting to the three Anticyræ for the purpose of procuring hellebore, for which the places were famous.

Scrutator.—Yes; the gross revenue of the estates of St. Thomas's Hospital is about £42,000 per annum. The net revenue for the actual purposes of the Charity is about £30,000. The new buildings were constructed to contain 600 beds, and they cost nearly £600,000. The Hospital was founded in the City about the year 1540, and opened for the reception of patients in 1552.

Scavengering in Paris.—The cost, by contract, for removing the refuse, garbage, and mud from the Paris streets is, for the Municipality, 700,000 fr. per annum.

Aqua Pura, India.—The Government of India is adopting measures to improve the supply of drinking-water in various military stations. Analyses of all drinking-water in every station are to be made before and after each monsoon.

Victor.—Statistics, recently published, show that the population of Tasmania on October 31, 1876, was 105,484, of whom 49,851 were females.

The Canine Family.—Naturalists say that the average life of a dog, under the most favourable conditions as to diet and exercise, is from eleven to fourteen years.

West London Hospital.—The corner-stone of the west wing and out-patient department of the West London Hospital, Hammersmith, was laid on Monday. The Hospital was established in 1856, and the east wing and central building were opened in July, 1871. The out-patient department, when finished, will consist of six consulting-rooms, and a sorting-room for the house surgeons, and a large waiting-room for male and female patients. The front part will contain three wards with twenty beds. The sum of £11,000 is required to complete these additions.

Experimenter.—It is stated that a German *savant* has exploded the generally accepted notion, that if an animal, such as a man, is almost completely coated with an impermeable varnish, death would ensue in a very short time. He has experimented upon two healthy men, who allowed their limbs to be covered with impermeable plasters, and the remainder of their bodies with several coats of flexible collodion. At the end of a week no ill effects were experienced, and the physiological results were *nil*. Animals, however, treated in a similar manner to the men, quickly die unless the coating is removed.

Patronage.—No doubt the late Sir Samuel Romilly, with good reason, looked forward to being Lord Chancellor, and, anticipating what was not to be, he wrote out some sketch of what he would do when he became Chancellor. The following lines stand in this sketch, and are those to which you refer:—"Invariably to appoint to offices the men who are most fit to fill them; to do this *in every profession, and in every department of the State.*" Sir Samuel, thus resolving, plainly regarded preferment *as duty*. The thing he had chiefly in view was that the place be well filled, the work well done.

Layton.—Forster's "Life of Goldsmith." "There is only one school," cried Hogarth, "and that is kept by Nature."

A Teetotaler.—As to the magisterial dictum that gin shall either be sold unadulterated, or labelled stating what it really is, it is stated that the Local Government Board are now consulting the Inland Revenue Department, and the whole subject will be discussed with a view to determine whether any legislation is practicable or desirable. The computation is that there are only 4,000,000 of total abstainers in this country, as against 29,000,000 who use intoxicating drinks.

Alleged Insanity.

The protracted inquiry, under a Commission of Lunacy, before Mr. N. Nicolson, the new Lunacy Master, and a jury of twenty, to ascertain whether Mr. Arthur Henry Newell, a surgeon, who had resided at Cornwall-road, Bayswater, and is now an inmate of Northumberland House, Stoke Newington, is at the present time a person of sound or unsound mind, has resulted in the jury finding that at the present period he is of sound mind, and capable of managing his own affairs.

Spoliation Years ago.

The first Enclosure Act was passed in 1710. During the following half-century there was a steady, if not a rapid progress in the passing of similar Acts. Before the accession of George III., 334,974 acres were enclosed. In the next eighty years, 7,000,000 acres of common land were enclosed under the authority of private Acts of Parliament.

"These fenceless fields the sons of wealth divide,
And ev'n the bare-worn common is denied."

COMMUNICATIONS have been received from—

Mr. H. Sewill, London; Dr. A. E. Sansom, London; The Secretary of the Obstetrical Society; The Secretary of the Society of Medical Officers of Health; The Registrar of Apothecaries' Hall; Messrs. J. Allen and Sons, London; Mr. C. J. Cullingworth, Manchester; Dr. Sparks, Mentone; Dr. J. Marion Sims, Paris: Sir Jos. Fayrer, London; Mr. J. R. Forresh, London; Dr. Whistler, London; Messrs. Southall Brothers and Barclay, Birmingham; Mr. Maunder, London; Dr. J. C. Moore, Dublin; Mr. Geo. Brown, London; Mr. Peppercorne, London; Mr. R. Edwards, Bala; Miss Bromley, Bewdley; Dr. Carter, Liverpool; Mr. R. B. Carter, London; Dr. J. Collins Warren, Boston, U.S.A.; Dr. Joseph Rogers, London; Mr. W. E. Poole, London; Mr. John Chatto, London; Dr. Thos. Barlow, London; Dr. J. Mitchell Bruce, London; Mr. Haynes Walton, London; Dr. John Williams, London; Mr. B. R. Wheatley, London; Dr. Norman Chevers, London; Dr. H. Ambrose Lediard, London; Dr. J. Balmanno Squire, London; Mr. W. W. Wagstaffe, London; Dr. F. Churchill, London; Mr. T. M. Stone, London.

BOOKS AND PAMPHLETS RECEIVED—

Richard Herring, "Sound Constitutional Principles" in Theory and Practice—Annual Report on the Three Lunatic Asylums in the Madras Presidency during the Year 1876-77—Christopher Heath, F.R.C.S., A Course of Operative Surgery, part 5—W. T. Gairdner, M.D., Two Lectures: I. Lectures, Books, and Practical Teaching; II. Clinical Instruction.

PERIODICALS AND NEWSPAPERS RECEIVED—

Lancet—British Medical Journal—Medical Press and Circular—Berliner Klinische Wochenschrift—Centralblatt für Chirurgie—Gazette des Hôpitaux—Gazette Médicale—Gazette Hebdomadaire—Le Progrès Médical—Bulletin de l'Académie de Médecine—Pharmaceutical Journal—Wiener Medizinische Wochenschrift—Medical Examiner—The Louisville Medical News—Boston Medical and Surgical Journal—Nature—Philadelphia Medical Times—Iron—Cincinnati Clinic—Bicycling Times—Night and Day—Medical Inquirer—Home Chronicler—Shipwrecked Mariner, January—Proceedings of the Medical Society of the County of Kings—Chicago Medical Journal and Examiner—La Province Médicale.

APPOINTMENTS FOR THE WEEK.

November 24. *Saturday* (*this day*).

Operations at St. Bartholomew's, 1½ p.m.; King's College, 2 p.m.; Royal Free, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.

26. *Monday*.

Operations at the Metropolitan Free, 2 p.m.; St. Mark's Hospital for Diseases of the Rectum, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.

Medical Society of London, 8½ p.m. A Clinical Evening. Cases by Dr. Lichtenberg, Mr. William Adams, Mr. J. Astley Bloxam, and others.

27. *Tuesday*.

Operations at Guy's, 1½ p.m.; Westminster, 2 p.m.; National Orthopædic, Great Portland-street, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; West London, 3 p.m.

Royal Medical and Chirurgical Society, 8½ p.m. Mr. Morrant Baker, "Removal by Operation of a Hairy Mole occupying Half the Forehead." Sir James Paget, "Cases of Branchial Fistulæ in the External Ears."

28. *Wednesday*.

Operations at University College, 2 p.m.; St. Mary's, 1½ p.m.; Middlesex, 1 p.m.; London, 2 p.m.; St. Bartholomew's, 1½ p.m.; Great Northern, 2 p.m.; Samaritan, 2½ p.m.; King's College (by Mr. Wood), 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.; St. Peter's Hospital for Stone, 2 p.m.

29. *Thursday*.

Operations at St. George's, 1 p.m.; Central London Ophthalmic, 1 p.m.; Royal Orthopædic, 2 p.m.; University College, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; Hospital for Diseases of the Throat, 2 p.m.; Hospital for Women, 2 p.m.; Charing-cross, 2 p.m.; St. Thomas's (ophthalmic operations), 4 p.m.

30. *Friday*.

Operations at Central London Ophthalmic, 2 p.m.; Royal London Ophthalmic, 11 a.m.; South London Ophthalmic, 2 p.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. George's (ophthalmic operations), 1½ p.m.; Guy's, 1½ p.m.

VITAL STATISTICS OF LONDON.

Week ending Saturday, November 17, 1877.

BIRTHS.

At the Royal Observatory, Greenwich, the mean reading of the barometer last week was 29·65 in. The lowest reading was 28·55 in. on Sunday night, and the highest 30·27 in. on Friday evening.

* The figures for the English and Scottish towns are the numbers enumerated in April, 1871, raised to the middle of 1877 by the addition of six years and a quarter's increase, calculated on the rate which prevailed between 1861 and 1871. Salford, however, forms an exception to this rule, as the estimate is based upon the rate of increase of inhabited houses within the borough during the six years ending July 1, 1877. The population of Dublin is taken as stationary at the number enumerated in April, 1871.

ORIGINAL LECTURES.

ABSTRACT OF A CLINICAL LECTURE

ON CASES OF INHERITED SYPHILIS.

By HAYNES WALTON, F.R.C.S.,
Surgeon to St. Mary's Hospital.

[Reported by J. PERKINS, late Senior House-Surgeon.]

GENTLEMEN,—The eye is an organ in which the morbid influences of syphilis, as an inherited effect, are frequently and strongly developed. The three cases of this ocular juvenile constitutional poisoning, now in the hospital, and to which your attention has been repeatedly drawn, shall supply us with stock materials for this day's clinical remarks.

In the first place, I shall tell how the bad inheritance is derived, whence, and under what conditions it is received. It comes from the one or the other parent. A father or a mother with a primary sore, or with constitutional syphilis, may beget a child and transmit syphilis to it. After impregnation from a healthy male, the woman may receive syphilis by inoculation from a primary sore, and give it to the child in her womb.

A father may beget a syphilitic child without inoculating the mother directly, although she may be secondarily affected by absorbing syphilitic poison from the diseased fœtus. The fœtus or its membranes may show the strongest marks of syphilitic disease.

In all the cases before us, an ophthalmitis—that is, inflammation of the eyeball proper—has been the affection. It is usual to call such iritis; but I have many times explained why I class them as ophthalmitis.

In No. 1 (the oldest), a girl, aged fifteen, the ocular subjective symptoms on admission were, loss of useful vision of the right eye, so that fingers could not be counted a foot off; impaired vision—that is, loss of acuteness of sight—in the other eye. The objective symptoms were alike in both eyes, but much more marked in the left one—namely, redness of the sclerotica, especially in the ciliary region, partial adhesion of the pupil, haziness of the vitreous body. In the left eye, the retinal vessels were not visible; in the right, only faintly seen. According to the patient's account, she had never been well. She had had several inflammatory attacks in the eyes, and an unusually severe one had induced her to seek advice at the hospital.

In No. 2, also a girl, aged fourteen, the subjective symptoms were loss of sight in the right eye, and only enough sight in the left to enable her to find her way about in the ward. The objective symptoms were hyperæmia of both scleroticæ, interstitial opacity of right cornea to a degree that hid the pupil and nearly all the iris, and general interstitial opacity of the left, yet thin enough to enable it to be seen that the iris was discoloured, and the pupillary margin much adherent.

The history told me that the eyes were bad so long as the patient could remember, that the degree of the symptoms had fluctuated, but in later years only had the vision been very much impaired.

In No. 3, a male, seemingly about eighteen, the subjective symptoms were so nearly like those of No. 2, only less severe, that they need not be described; and the objective ones are, in reduced correspondence, alike. No history could be obtained as the poor fellow was deaf, and which deafness must have been acquired within the last few years, as he has full power of speech, and is no doubt of syphilitic origin. Respecting corneal opacities, you must remember that I have endeavoured to point out the distinctions between surface opacities and those which are interstitial, and that the form of corneal inflammation which produces the latter is frequently but a part of general ophthalmitis, *i.e.*, inflammation of the eyeball in which all of its proper tissues partake.

Now as to the evidence of these eye-affections being syphilitic. No. 1 patient was a first child. No. 2 was the first child that lived; it was preceded by a miscarriage. It is usually the first child, or the earlier children, who get the inherited syphilis, and it is common for a syphilised fœtus to be prematurely expelled from the uterus. Abortion from syphilis is well known. There were two marks of former sores about the corners of the mouth. In No. 3 the state of the ears was a syphilitic concomitant. But all the patients had the notched teeth—Hutchinson's teeth—which are an unmistakable characteristic of inherited syphilis.

The usual concurring symptoms of inherited syphilis in infants and young children are—copper-coloured eruptions, snuffles, aphthæ, and mucous tubercles about the genitals or anus. The eyelashes may be exfoliated and the nails may be unhealthy. The specific cachexia is often present. Added to these there may be psoriasis of the trunk and psoriasis palmaris. When the secondary teeth appear, their insufficient development, especially in length, the peg-like form or the notching of the front and lateral incisors, are rarely absent. This is seen in very varying degrees of intensity.

The concurring symptoms are less marked as years are added, as the person grows older.

The time of appearance of inherited syphilis in the eye is either in infancy or in childhood, and the symptoms of it may be so prolonged as to pass into adult age.

There is no essential difference between the symptoms of inherited syphilitic ophthalmitis and syphilitic ophthalmitis in the adult, as one of the secondary symptoms of syphilis. There are not found on the margin of the pupil the gummata characteristic of the adult affection, but there is plastic exudation which ties down the pupil, and more or less fills it; it may even be sufficient to fall into the anterior chamber and nearly fill it. But I may say that, as a rule, the ocular inflammation of the former is subacute; it begins insidiously, is very apt to linger long, and even with long periods of inactivity or repose. But a month ago a farmer, aged twenty-two, came to me with undoubted inherited syphilitic ophthalmitis. Since childhood he had had yearly occurrences of ocular inflammation. Now, with a little interstitial corneitis, partial adhesion of each pupil, and much cyclitis, he can read "long pica" held close to his eyes in a bright light.

Treatment.—The treatment of this should be the same as that recognised for syphilitic ophthalmitis in the adult, adapted to the early age of the patient—namely, mercurial. In infancy and in early childhood the mercury should be used by the inunction method, and rubbed into the soles of the feet, the axillæ, the groins, and the calves of the legs, from a scruple to half a drachm being employed daily. This agency should be continued according to the effect on the inflammation or the exudation. The general health requires most careful attention, and a healthy wet-nurse should be procured during the ordinary suckling period. When a nurse cannot be procured, the food should be cow's milk, with a proper dilution and sweetening, according to the age of the patient, together with cream, and in sufficient quantities until the ninth month. In patients of the ages of those which are the subjects of the lecture, the internal administration of mercury is to be preferred. The medicine cards of these show that they have been taking mercury and hyoscyamus in this proportion, namely, ℞. Hyd. c. cretâ gr. jss., ext. hyoscy. gr. iij.; ft. pil. bis die sumend. Care was taken that neither salivation nor purging was produced. The former may be checked by giving the pill less often, and the latter by reducing the mercury and increasing the hyoscyamus.

I give no other form of mercury internally when I wish to affect the system through this drug. I have long discontinued combining opium with mercury, because it so interrupts digestion, and otherwise enfeebles the constitution for a time. The results of the treatment here are satisfactory. In No. 1 patient you see that the scleroticæ are clear. With either eye she can read the whole of her diet-card, the large and the small type. She is going home. No. 2: The hyperæmia of both eyes is gone. The corneal opacity of the right cornea is much as it was; that of the left is cleared enough to enable large type to be read. Further improvement will follow if she will attend as an out-patient. She will leave against my advice. No. 3 is, at the end of a month, walking about alone, and makes no blunders.

I have fully satisfied myself that this form of syphilitic inflammation is amenable to treatment years after it appears, and may be stopped. Of course, spoiled tissues cannot be regenerated, nor dense corneal opacities removed.

PROF. BILLROTH'S OVARIOTOMIES.—A few days since, Prof. Billroth performed his hundredth ovariotomy. The first occurred in Zürich in 1865, and the others in Vienna. These were executed partly at Dr. Eder's *Heilanstalt*, and partly at the Vienna Clinic, where a room had been expressly constructed for this purpose. The operations were sometimes very difficult and complicated, but not one of them was left uncompleted. The result is, that recovery took place in two-thirds of the cases. This is, indeed, far behind the results obtained by Spencer Wells, as Billroth took the opportunity of remarking, with admiring appreciation of his English colleague.—*Deutsche Med. Woch.*, October 3.

ORIGINAL COMMUNICATIONS.

ELEPHANTIASIS ARABUM.

By Sir JOSEPH FAYRER, M.D., F.R.S.

I HAVE recently received some interesting medical reports from China; and among them is one by Dr. A. Jamieson on the health of Shanghai(a), containing some remarks on the treatment of elephantiasis of the leg by ligature of the femoral artery, on which I have a few words to say.

Alluding to a fatal case in which death resulted from ligature of the right external iliac artery, performed with the view of ameliorating the condition of a woman suffering from elephantiasis of the leg, he says:—"This case once more raises the question whether ligature of the main vessel in elephantiasis is justifiable in itself. Carnochan of New York first suggested it in 1857, and announced a cure. It has since been practised with varying success by Butcher of Dublin, Richard of the Hôpital Cochin, Fayrer, Bryant, Bochard, Baum, Simon, and others. Up to 1872, twenty-eight cases were recorded, in the majority of which the result was negative, while in a few there was a marked diminution of the hypertrophy, and in one or two cases there would seem to have been actual cure. More recently, Werhner (1875) cites thirty-two cases in which ligature gave variable results. Fayrer, Simon, and Demarquay pronounce decisively against it—the last, I think, on theoretical grounds; the two former in consequence of their failures. . . . The latest investigations are summarised in the *Archives Générales de Médecine*, 1876, vol. ii. page 100. But after carefully perusing this summary, in expectation of light to be thrown on the treatment, my impression is that the propriety of ligature is still an open question, only to be decided by its results."

I have no intention of discussing this subject in its surgical aspects, or in relation to the effect of the occlusion of the main artery of a limb in the treatment of local hypertrophy due to other causes. I refer now to it as connected with the disease elephantiasis, and confess I fail to understand what Dr. Jamieson means when he says that I condemn it (*i.e.*, ligature of the femoral artery) on account of the failures only, while Demarquay does so on theoretical grounds. It appears to me that I do so on both. I have very plainly stated my reasons for thinking that this mode of treatment was not hopeful, though I tried it in deference to the opinion of those whom I deemed worthy of confidence; and I find that I have elsewhere made remarks to that effect, and have recorded the experience of certain cases which may be regarded as crucial ones. I had no hesitation in expressing an opinion in 1863, and have repeated it lately, that in theory and practice the treatment of elephantiasis by ligature of the femoral artery was not expedient.

I remarked—"It is difficult to understand on what physiological principle the temporary privation of blood to the limb, by ligaturing the main artery, can have any effect in permanently removing local symptoms of a constitutional disease. . . That it might temporarily ameliorate it (at great risk) there is no reason to doubt, but would not the same effect be produced by pressure on the limb, and by continuance in the recumbent posture." And such, indeed, has been the result in certain cases, where bandaging and protracted rest have been employed. The improvement, however, was only temporary, and the hypertrophy returned on the person resuming the former mode of life.

I may briefly notice that the cases I refer to were typical examples of elephantiasis, where the local hypertrophy was attended by the usual periodic returns of fever. All occurred in Calcutta.

The first case was that of a Hindoo, aged thirty, male. The femoral artery was ligatured on February 23, 1865, and he died of pyæmia (a disease unhappily very rife at the time) on March 15. The circulation had been completely re-established, and there was some diminution in the size of the leg when he died. This case affords no conclusive information as to the permanent effect of the operation on the disease, but it suggests an objection of another kind, and the question of whether the risk is justifiable.

The second case occurred in 1875—another Hindoo male, similarly affected; the artery was ligatured on June 22, and he had recovered completely from the operation on August 1. But the size of the limb had considerably diminished since the operation; it had already begun to return, and with it the recurrence of elephantoid fever; and on November 18 it was nearly as large as before the operation, as follows:—June 21, fourteen inches; July 6, eleven inches and five-eighths; August 1, twelve inches and a quarter; November 18, thirteen inches and three-quarters; and it was still increasing. The progress of this case, therefore, though it indicated temporary diminution of the hypertrophy, affords no evidence of any permanent improvement.

The third case was also that of a Hindoo male, about the same age as the last—forty-five years,—who had also elephantiasis of the scrotum, which was removed on June 28, 1869, and on October 1 following the left femoral artery was ligatured for elephantiasis of the leg. It was then thirteen inches in circumference just above the ankle. On October 24 the patient had recovered from the operation, and the ankle was ten inches—a reduction of three inches; but very shortly both fever and hypertrophy returned, and when he left the hospital (where he was kept to be under observation) on December 30 it was advancing. I saw him again on April 16 following, and made these notes:—

The patient says he is in better health, and much relieved by the removal of the scrotal tumour, but that his leg is now just as it was before the operation, and that it is growing larger. As a matter of fact, the leg was still somewhat smaller than it was before the operation, but it was gradually returning to the original dimensions. When admitted the ankle was thirteen inches, on December 31 it was ten inches and a quarter, on April 16 it was twelve inches and a half, and, as it was still increasing, there can be little doubt it soon attained—perhaps exceeded—the original proportions; so that I think in this case also the operation failed to confer any benefit. My belief is, that the temporary reduction of the swelling after the operation was due more to rest and bandaging than to the ligature of the artery; and I have good grounds for this belief, for I have frequently observed, in the elephantoid legs of those who have been operated on for the scrotal form of the disease, that, with the necessary rest in bed and general wasting that followed, the leg decreased considerably, but increased again when the recumbent position was no longer preserved.

Elephantiasis of the leg, like that of the scrotum, is but a symptom of the general disease, and, as I have before said, is not, in my opinion, likely to be removed by merely altering the channel through which the blood is supplied to the part affected. But it is different in regard to *removal* of the diseased structure, as in scrotal elephantiasis. Here the removal of the outgrowth is generally followed by disappearance of the periodic recurrence of fever as well; and the explanation, I think, is that which I have given elsewhere, as follows:—"The absence of the periodic fever and its cachexia is probably the result of the removal of what had been an ever-present source of blood-dyscrasia—for such I believe the outgrowth to be so long as it remains; and persons have frequently told me that the great relief they experienced from its removal was not so much due to the absence of the tumour as to the cessation of the periodic fever from which they suffered." It is to be understood that I am speaking only of those hypertrophies that result from the disease elephantiasis, and not of hypertrophies ascribable to other causes. I will not venture to assert that temporary blood-starvation (by ligaturing an artery) of the latter may not be beneficial, but I confess I do not understand why it should be so. Be that as it may, I am of opinion that it is not applicable to elephantiasis.

(a) This report on the subject of Elephantiasis has been published in these columns; see page 470.—ED. *Med. Times and Gaz.*

THE RELATION OF GERMS TO INFECTIOUS AND CONTAGIOUS DISEASES.

By ALEXANDER YULE, M.D., C.M.

IT is said by Dr. Roberts, in his address to the British Medical Association, that bacteria are the essential agents in the production of decomposition, and that without them decomposition cannot take place. He shows that organic liquids, and mixtures of vegetable and animal substances, fragments of meat, etc., when exposed to the atmosphere, have remained for years unchanged—bacteria or germs being excluded. In these experiments is it possible to exclude, entirely, atmospheric air and to admit bacteria alone? and, under these circumstances, will decomposition take place? It may be that, to produce decomposition, besides bacteria it is necessary to have atmospheric air and some organic matter, and that if bacteria are excluded no decomposition can ensue, and like-

wise, if bacteria are admitted without atmospheric air, that the result will be the same. In the remarks that I am about to make, I shall endeavour to show, or rather will construct a theory to show, that the cause of the different zymotic diseases is not due to bacteria, but to a poisonous property acquired by the bacterium, which poison is united with it in a very loose form, and can be dissolved in various liquids; or, that it may remain in the atmosphere in union with a bacterium, or in some other form, provided that ventilation is bad, and the supply of air limited—in which case it will slowly multiply itself. Thus, in sewers that are badly ventilated it might be expected that sewer-gas, in which typhoid-fever poison was present, would be highly dangerous. It is not so. This circumstance would indicate the fact that the poison is, then, in a nascent form, and only by a slow process of oxidation, such as would take place on its admission into dwellings, would it become poisonous; however, when there is good ventilation the poison becomes changed into a harmless compound. It may be presumed that in some cases the fever poison may of itself multiply when in a congenial soil, and that independently of the multiplication of bacteria. It may be that the atmospheric bacterium is the carrier of the poison, and that when absorbed, as by milk, the fever poison becomes dissolved out, milk having a higher affinity for it than the bacterium. It may then grow in an albuminous soil, proliferating rapidly, and producing an infinite amount of poison. In a fluid like milk, with such a subtle poison dissolved in it, the danger would be very great, because the atmosphere could not act on it, and change its poisonous composition. The administration of milk in typhoid fever may seem by this mode of reasoning to be founded on false principles, for it may be said that there is introduced into the blood that which is most favourable to the multiplication of the poison. However, when once the fever has arisen, the system becomes protected against fresh infection, although relapses are not infrequent in typhoid fever; and milk, instead of being a hurtful agent, by this mode of reasoning would be quite the contrary, for its great affinity for the fever poison would supply material for its growth, until the system had ceased to respond to its action. In other cases, the poison-laden bacterium, being inhaled, may multiply to an infinite degree, and in this way set up fever, or be dissolved out by the blood and act as in milk or as a ferment. It cannot be said that decomposition is caused by bacteria chiefly, for bacteria are everywhere; and, of course, when matters are decaying they will be there too, and decomposition cannot take place without them: and thus, wherever the air is, there they will be—at times the carriers of zymotic or other poisons. But, doubtless, they mostly in some way influence the nutrition of the body. Thus, we may expect that, wherever there is change, there bacteria will exist. And change is life; and so, likewise, in decomposition there is change, for death and decomposition tend to new forms of existence. Dr. Roberts, in his address to the British Medical Association, quotes various authorities to show that different forms of bacteria give rise to distinctive kinds of fever. I think, if for the word "bacterium" is substituted "specific poison attached to germs, or otherwise, each poison giving rise to its distinctive train of symptoms," another solution of the question will be afforded. "In 1872, Dr. Obermeier, of Berlin, discovered minute spiral organisms (spirilla) in the blood of patients suffering from relapsing fever. This discovery has been fully confirmed by subsequent observations. The organisms are found during the paroxysms; they disappear at the crisis, and are absent during the apyrexial period." These changes may be coincident with the development of the zymotic poison; and the appearance of these organisms may indicate the appearance of the poison of which they are the bearers. These organisms, it is said, are only modifications of the common bacillus, and have been found also in dirty water; so it may be surmised that according to the peculiar constitution of the patient's blood may the peculiar shape of these organisms have been owing. The air is full of germs; and so, according to Dr. Beale, is every organ of the human body; and bacteria are evidently connected with some of the most ordinary nutritive actions in the human body, of which we are, as yet, unacquainted. Germs we must be always breathing, night and day; and, as the atmosphere receives all emanations from the earth and all that is thereon, it is not surprising that septic and zymotic poisons may at times be breathed, carried by these agents. Changes in the blood itself, doubtless, may generate fever poison; and that breathed forth may be taken up and borne along by a germ or germs, which, multiplying under favourable circumstances their kinds, may give rise to epidemics.

I shall now make a few remarks on Dr. Lister's antiseptic treatment of wounds. Three things at least, according to my theory, are necessary for the production of putrefaction, and these are (1) germs, (2) atmospheric air, and (3) some organic material. By the antiseptic method, germs are excluded; therefore, by this theory, decomposition cannot ensue. As germs or bacteria are abundant outside as well as inside the body, it may be hardly possible to entirely destroy them; and as Dr. Lister's method does not entirely exclude atmospheric air, septic poison may occasionally be formed. By the results of treatment, however, it is shown that septic poison seldom or never forms. It is evident that septic and zymotic poisons are of very unstable composition, for there are so many well-known agents that can render them innocuous, so that what may be a deadly poison will by a slight change become quite harmless; and the difference between varying supplies of atmospheric air or oxygen will determine the poisonous or other nature of the compound. Thus, in the badly ventilated sewer, the amount of air or oxygen is insufficient, where there is nascent fever-poison in sewer gas, to render active the poison; while a slow process of oxidation or other change, when the gases escape from the sewer, gives rise to (in those that inhale it, or otherwise receive it into their system) the symptoms of typhoid fever; while, on the other hand, complete ventilation renders the poison innocuous. In the case of wounds Dr. Lister excludes germs; but it may be supposed that by his process he cannot entirely destroy them, for they form in the blood independent of the atmosphere; so that, after all, the exclusion of the atmosphere has as much to do with the success of the treatment as the destruction of germs. Applying the theory of varying supplies of air or of oxygen to the antiseptic system, it becomes evident that neither organisms sufficiently numerous, nor air in sufficient quantity, reaches the wound to produce a septic poison. It may be that bacteria, under certain circumstances, shrink up and remain dormant and adherent to various materials, and only under certain favouring circumstances do they swell out and develope, and then are conveyed into the atmosphere. This may, in a measure, account for the difficulty in getting rid of erysipelas and pyæmia from surgical wards in hospitals; and, likewise, for the circumstance of these diseases being more prevalent at one time than at another; and, likewise, for their temporary absence sometimes. By the theory advanced, it is supposed that these bacteria contain the septic poison, and that, if multiplying, the poison which they contain would increase in a corresponding degree. Treatment of wounds by free exposure to the atmosphere is said to attain results as successful as those attained by the antiseptic method. The difficulty of successfully carrying out the treatment must at all times be great, and the danger of blood-poisoning by neglect extreme. In a wound bacteria multiply rapidly, and septic poison is continually being formed; and if the supply of air is not at all times very free, the poison will not be neutralised, but at times increased, and poisonous bacteria will fill the air and carry infection elsewhere. No doubt wounds may be treated successfully in this way, but, according to my theory, the difficulty of always insuring a sufficient amount of oxygen or air to render the poison harmless is so great as to be almost impossible.

Fernhurst, Haslemere, Sussex.

ON CHINESE HÆMATOZOA.(a)

By PATRICK MANSON, M.D.,
of Amoy.

(*Concluded from page 565.*)

From the foregoing observations I think the following deductions are justifiable:—

1. That a large ratio of the population of this province, and probably of other parts of China, is infested with the Filaria sanguinis hominis. The exact ratio cannot yet be stated, but, if my observations are a fair guide, one in thirteen is near it.

2. That the Filaria sanguinis hominis may be present in the blood, and yet the host be in good health, and exhibit no other morbid phenomena.

3. That in the same person it may be present at one time and absent at another.

4. That at one time or another it is very generally associated with elephantoid disease, and is almost certainly connected with the cause of such affections.

5. That it is sometimes associated with a diseased condition

(a) From the *Customs Gazette*.

characterised by frequently recurring attacks of fever, accompanied by general anasarca unconnected with heart or kidney disease.

This last deduction I make from Case 7 (Liengoo). I have twice closely watched a similar train of phenomena, once in Formosa and once in Amoy. In both these instances, heart, lungs, and urine were carefully and repeatedly examined, but nothing amiss with them could be detected. In one of the cases the anasarca, though general, was peculiarly distinct in the upper part of the body, suggesting pressure on the superior vena cava; but I could detect no aneurism or tumour of any sort to account for it. In both of these cases there was great prostration, weakness of the lower extremities, and what I thought at the time an unjustifiably strong fear of death. Contrary to my prognosis, both died suddenly. I had come to consider that these were examples of beri-beri. After I became acquainted with Filaria sanguinis hominis, I speculated on the possibility of its having anything to do with them. When Case 7 (Liengoo) presented himself, I made a shot at the diagnosis, and told my assistants he had worms in his blood. I was as much astonished as they were to find on examination that I was correct. This man is again ill with fever and anasarca.

I trust that others at the different ports will take up this inquiry as opportunity presents, and above all avail themselves of post-mortem examinations of Chinamen to search for the parents of the embryos found in the blood. Should I have an opportunity, I intend, before opening the abdomen, to follow up any dilated lymphatics I may find in the legs or scrotum, in the hope of encountering the cause of obstruction and probably the mature worm, in the glands, thoracic duct, or their neighbourhood.

I would warn others against a hasty examination of the blood, and against concluding that, because no filariæ are found, none exist. For several years I have been in the habit of occasionally examining the discharge in lymph-scrotum and the blood also, but until lately never encountered the Filaria sanguinis hominis. In fact, I kept a man for three or four years for the purpose of watching the progress of his lymph-scrotum, and though I am convinced now that this man's blood contained filariæ, yet, on account of my examining probably only a small part of one slide and with a high power, I always missed them. At least six full slides should be examined, and every part of them carefully scrutinised. The power employed as a searcher should not be a high one—a quarter or half-inch is sufficient, but powers lower than these will do, provided they will distinctly define a blood corpuscle. If the light is too strong, the very transparent body of the hæmatozoon is apt to be overlooked—at least, it is not picked out so readily, and the eye of the observer becomes fatigued. If blood does not escape readily, or on slight pressure, from the prick in the finger or elsewhere, much force should not be used to express it, as the puncture is probably too small, and any filariæ the blood might contain will be hindered from escaping: a fresh puncture should be made. Another point the observer should attend to is, not to attempt to place too much blood under the covering-glass; a small quantity should be scraped off the finger with the edge of the glass, and this placed with the charged part near the edge of the slide, and then slid along till the blood has almost reached the circumference of the covering-glass. This is an important point, as in nine instances out of ten the filariæ are found quite close to the edge of the patch of blood, and should this escape from below the covering-glass, the chance of finding them is very small indeed. With attention to these details—which, I again repeat, are of the utmost importance to successful investigation—and with patience, I have no doubt that finds will be frequent, and I trust will be duly reported along with the failures.

Exclusion of Negro Medical Students.—The *New York Med. Record* (October 20) strongly deprecates the conduct of the Faculty of Physicians and Surgeons in having refused a student of colour ("drawn the colour line in medicine," as it is expressed) admission to lectures. It has not done this on principle, it seems, and would not have done it if it had been an endowed school, but because the presence of a negro in the lecture-rooms would be offensive to the other pupils, whose opinions on the subject have to be taken into consideration, as the College, although a public institution, is supported by private enterprise. The question was not submitted to the class, the fear of unpleasant results being sufficient to prevent the professors trying the experiment.

REPORTS OF HOSPITAL PRACTICE IN MEDICINE AND SURGERY.

STANLEY HOSPITAL, LIVERPOOL.

EXCISION OF HALF THE TONGUE, PART OF EACH JAW, SUBMAXILLARY GLANDS, AND SIDE OF PHARYNX, FOR EPITHELIOMA, WITH SUCCESSFUL RESULT.

(Under the care of Mr. RUSHTON PARKER.)

J. G., aged fifty-eight, a dock porter, under the middle height, and with a healthy history, family and personal, applied at this hospital early in May, 1876, on account of an excavated ulcerated swelling affecting the left side of the tongue rather to the under side, for a length of about an inch and a half, and extending continuously to the molar gums of the lower and upper jaws adjacent, and involving a small piece of the inner side of the intervening cheek. The glands under the angle of the jaw felt enlarged and hardened; the centre of the main sore was excavated to a depth of about half an inch, and its edges were hard, elevated, and tender. The patient had had it for two years, to the best of his knowledge, and, although a very wiry man, was now much debilitated by pain, and inability to eat with sufficient ease. The growth was judged at the time, and has been subsequently proved to be epithelioma, and the circumstances were considered to justify an operation, if complete extirpation were feasible. Accordingly, this having, after a little consideration, been proposed to him, he readily consented, and gave absolute *carte blanche* as regards extent.

On May 19, under ether followed by chloroform, the left cheek was incised from the angle of the mouth to the submaxillary region. The facial and lingual arteries and veins were sought and tied; the lower jaw was sawn through at the canine tooth, and immediately above the angle; the upper jaw was clipped with forceps at the posterior and lower corners the tongue was drawn out, and transfixed with a sharp-pointed curved bistoury from the middle line at the hyoid bone to the base of the epiglottis, and then slit to the tip; part of the soft palate and side of the pharynx were then separated with the rest. A vessel or two remained to be tied, catgut ligature being used in every instance, and the wound was closed with a pin and sutures. The operation is easily told, but it took nearly two hours to do, the patient being with the utmost difficulty influenced at all by the anæsthetic, and much time being lost in sponging out the pharynx, and giving him breathing opportunity; however, he bore it with great courage, and made a good recovery; but a large piece of skin sloughed from the cheek, and left a pharyngeal fistula, no doubt because, in the operation, about two inches of the facial artery had been sacrificed in removing the submaxillary salivary and lymphatic glands. The latter were found scarcely enlarged, while the former was very indurated.

After five months, the hole in the neck being about the size of a hazel-nut, and having assumed its ultimate shape by cicatrisation, was closed by a plastic operation on October 20. But the tip of the flap, which was taken from the neck below, and slid up along its long axis, did not hold, and the fistula became as bad as ever. Six months later (April 6, 1877) another attempt was made, but this likewise failed.

He manages very well by keeping a lump of cotton on the hole, and tying a band over it round his head and chin.

He was last seen early in November, 1877, eighteen months after the operation, strong and well, continuing his work as a dock porter, which he resumed four months after the original operation, and only discontinued again in order to submit to the plastic attempts.

Condition.—Though he has lost such a considerable part of the lower jaw, this defect is, as usual, hardly perceptible. The remaining half of the tongue is pulled over to the left, and its outer side serves as a front and tip. It is mobile to a useful extent. The pterygoid plate shows on the left side, tightly covered with cicatricial mucous membrane; and close to it, firmly attached by check and cicatrix, is the sawn end of the body of the lower jaw; while between the two is the pharyngeal fistula, about the size of a small hazel-nut. There is not much room in his mouth, it is true, for the fingers of a surgeon; but there is room enough for his own food and its efficient mastication. He has had continuous good health and

strength, which latter, however, is tested to the utmost by his poverty and the rough nature of his work.

Examination of the Specimen.—The extent of the disease was found to be even rather more wide than was expected, and the duct of the submaxillary salivary gland passed immediately under the base of the ulcerated growth.

The microscopical details are somewhat unusual. The extent to which the epithelial masses can be seen penetrating between the bundles of fibrous tissue, and the total absence of small round-cell infiltration, where the epithelial elements are most abundant, give the tissue an aspect which is astonishingly like alveolar sarcoma. Yet everywhere the large characteristic cells of the buccal epithelium—arranged in globes at the centre of each cylinder, yet nowhere forming the horny globes so usually present in cutaneous and buccal epithelioma,—and the unmistakable even front presented by the "lines" of the rete Malpighii, prevent the true nature of the disease from being denied. The round-cell infiltration is, in the adjacent muscular tissue, quite in the usual small-celled style; and where the epithelial ingrowth is more scattered, it is perfectly visible and somewhat larger-celled. The bundles of the fibrous tissue are split up, and the individual fibres widely and often almost singly separated, and singularly invaded by the epithelial columns at the surface, where all trace of papillæ or other sign of mucous membrane is wanting. The indurated salivary gland shows an abundant round-cell infiltration between the gland-tubes and acini, constituting an interstitial adenitis. The sections of slightly enlarged lymphatic gland did not show any secondary infective growth.

EXCISION OF HALF THE TONGUE, HALF THE SOFT PALATE, SIDE OF PHARYNX, SUBMAXILLARY GLANDS, AND PART OF LOWER JAW, FOR EPITHELIOMA—RECURRENCE.

(Under the care of Mr. RUSHTON PARKER.)

Wm. O., aged fifty-four, a full-bodied, strong-looking man, over the middle height, giving a family history and personal antecedents of a perfectly healthy character, came under notice on May 26, 1877. He had, until lately, had a good digestion and lived freely, eating heartily and drinking plenty of alcohol, but not getting intoxicated. His face was spotty, having bright red pimples on the forehead and cheeks; the tongue was furred, and the breath very foul. On the left soft palate was a sloughy and excavated mass, covered with granulations at the edges, which were prominent, extending from the left of the uvula to the pillars of the fauces. Under the angle of the jaw was a globular induration the size of a small walnut. The dorsum of the tongue was unaffected, and some difficulty was experienced in ascertaining the whole extent of the disease, on account of stiff closure of the jaws. But a later examination showed that the under side of the tongue and the molar gum of the lower jaw were included in the affection, which was obviously epithelioma. He was recommended to give up the use of alcohol, and to take his food (liquids only could be used) at regular meal-times exclusively; also to take a tumbler of water containing a little Epsom salts each morning on rising.

By June 6 the tongue was clean and moist, the fetor of breath was all but gone, the face was less spotty and flushed, and the complexion clearer. The epithelioma was perfectly clean, and its granulations slightly less prominent, while the submaxillary swelling was less turgid, but harder and smaller. The only inconvenience he felt was difficulty and pain in swallowing, and constant pain about the left ear. The case was not considered a favourable one for operation; and all that was hoped for was a mitigation of the inconveniences of the disease by a judicious system of diet and, if necessary, other palliative measures. After careful consideration, in fact, the operation was declined by Mr. Parker; but the patient begged, as a favour, that anything that was possible might be undertaken, saying that his prospects could not be worse than if he were left alone. So on June 8, under ether followed by chloroform, the left cheek was incised from the corner of the mouth to the back of the hyoid bone, in front of the facial artery; the lingual artery and vein were tied under the hyoglossus muscle, with the aid of an aneurism needle and catgut; the lower jaw was sawn through about the first molar tooth, and clipped across with forceps above the angle, after stripping the masseter and internal pterygoid muscles; the tongue was then drawn out and slit from base to apex, by median puncture from below to the upper surface at the epiglottis, with a sharp-pointed curved bistoury; then with a probe-pointed bistoury the soft palate was cut vertically to the right of the uvula, and separated from the posterior edge of the hard palate. The whole specimen, consisting of half the tongue, palate, submaxillary glands, etc., was then grasped, and swept off at its pedicle, close to the great vessels of the neck. Sponges were in readiness to instantly control the bleeding which was expected from this final measure. The facial artery was found cut about an inch from the carotid, and tied. A pin and a number of wire sutures were put in to close the wound.

It was hoped that the operation might have been more quickly performed, but the time occupied was at least an hour and a half. The anæsthetic was admirably managed, and the operation unfelt by the patient, except for a few minutes at the finish. For a few days he had a good deal of smarting, but he made a good and rapid recovery, as far as minor matters are concerned. Food was almost withheld for the first few days, a little warm water containing boiled sago being given. A month after the operation there was a glandular enlargement under the sterno-mastoid, and in the pharynx a rosy crop of granulations, quite soft, but which looked ominous.

On July 13 the lump was exposed, and in doing so at least half the thickness of the sterno-mastoid was broken through. On almost completely isolating the growth, it was found to enclose the carotid artery, the jugular vein, and pneumogastric nerve. It was not considered proper to sacrifice the last structure, although the vessels might have been readily extirpated with the epitheliomatous mass of glands; so the latter were burst, and scooped out with the finger-nails and other instruments, and the wound left to heal. A day or two before this second operation his diet was changed with obvious benefit. He had had beef-tea and milk given him by the attendants, and it was noticed that his tongue was persistently furred white; moreover, he spat pints of saliva in the day. He was now ordered three meals daily, to consist of any one, or even two, of the following articles:—Bread, pea-flour, sago, and oatmeal, prepared with hot water or tea; milk was interdicted. In a day or two the tongue cleaned, and salivation ceased. The wound of the first operation healed at once, and was firm in ten days, except a minute hole where the tip of the jaw necrosed, and which closed after the separation of the minute exfoliation. The second wound became the seat of slough, deep down about the fasciæ and vessels. Much fetor was set up by decomposition here, but was completely corrected by filling the wound with magnesia powder. The sloughs then separated amid antiseptic suppuration, which gradually subsided. After all decomposition had ceased, he had a severe attack of erysipelas of the neck and head. His bed had been in a draught, so he was put in another, and the only treatment adopted was the administration of a little morphia, and the limitation of his diet to bread and sago, while the erysipelatous skin was coated with thick boiled starch. Within five days he was desquamating, and walking about as if nothing had happened. But the patch in the pharynx was increasing, and the deep parts of the neck, although the wound was closing, were enlarging again.

He was discharged on August 15 exceedingly well in health, perfectly satisfied with his daily diet of a little bread-and-butter and tea, and pea-flour mixed with boiling water and butter. There was no emaciation, and he was perfectly free from hunger. Since that time it has been ascertained that recurrence had advanced still farther beyond the reach of operative remedy.

Remarks.—It is plain that no operation less extensive than the one performed would have been of any use in either case. When the gum is affected, the whole thickness of the mandibular arch need not always be severed; but when the tongue and reflected mucous membrane are also concerned, the greater sacrifice of bone is of little or no account to the patient (in view of the issues at stake), while it immensely facilitates an operation which is at best not one of the easiest, by permitting the free exposure of the parts involved, and leaving a perfectly accessible wound. The fact that each lingual artery is confined to its own side of the tongue allows the vertical median division of that organ to be bloodlessly effected, while the preliminary ligature of the vessel renders the removal of the corresponding half of the tongue equally bloodless. The submaxillary salivary gland (with or without the sublingual) is better removed, in order to effect a clean sweep; while the lymphatic glands and the whole track of lymph-vessels leading to them from the diseased part were specially included (themselves healthy or diseased) among the tissues whose removal was most thoroughly desired and anxiously attempted. The perfect success of the first case, and the strictly limited area to which recurrence was at first confined in the second, suggest the probability that, in spite of all precautions, the operation in the latter instance may have fallen a little short, in extent, of what ought to have been done. If that could really be proved to be the case, no

better justification of the procedure could be found. The singularly spare diet (as it would seem) which sufficed, in the same case, to fully satisfy and to maintain in good condition a big, strong man, is regarded as a feature of much clinical importance, not only as having afforded an easy means of nourishing an individual who could not masticate at all, and only with difficulty swallow, but as being one out of many instances where the condition of a "sore place" can be improved and kept apparently within bounds by the dietetic amelioration of the "constitutional state."

SATURDAY, DECEMBER 1, 1877.

THE LONDON WATER-SUPPLY.

The majority of the Board of Works lost no time in taking advantage of the snap-vote which enabled them to carry their scheme for the regeneration of the London water-supply. Before, indeed, the matter could be discussed at an ordinary meeting of the Board, a Parliamentary notice of the scheme had been advertised in the papers—the advertisement appearing on the 23rd, the ordinary meeting not being held till later on the same day. Thus a measure which is avowedly to cost five and a half millions of money, and may cost nearly as much more, was promptly disposed of, many of the members of the Board of Works having no opportunity of considering it, or even of voting on it. Still less was it given to the parochial bodies, which will have to supply the money, to express an opinion upon it. Everything had apparently been arranged beforehand. By a small majority, of which the chairman, Sir James Hogg, seems to have constituted one, it was resolved to proceed with the new scheme, and promptly steps were taken to carry this vote into effect.

It was hardly likely that such proceedings should be allowed to pass without protest, and accordingly, at the last ordinary meeting, an earnest attempt was made to reverse the decision already come to; and it was probably in anticipation of some such attempt that the advertisements had appeared that very morning. Accordingly, the whole reply vouchsafed to the discontented members was that the Board could not stultify itself. There seems to be no very active opposition on any side to the scheme for buying up the Water Companies, and probably there will be none except on the part of the Companies themselves; but assuredly there will be opposition to the proposition to provide London with a double water-supply, when one would suffice. It has indeed been hinted that this proposition has been introduced into the scheme merely for the sake of frightening the Companies into terms; but the Companies would be sorry fools to be thus frightened. The new supply is only calculated at 16,000,000 gallons daily: how much it would reach to is unknown; but, even if we accept the estimate of Sir Joseph Bazalgette (who we are now assured is one of the authors of the scheme) and his allies, this quantity would be altogether inadequate to the wants of London. It must be supplemented; and of course the authors of the scheme would stultify themselves if they proposed either to do away with the old supply and the costly plant of the present Water Companies, or to mingle the chalk water with that of our present river supply. There is nothing for it but a total new set of works, reservoirs, mains, pipes, and taps all over the districts of London and its suburbs supplied at present, and to any other districts requiring water-supply in the future. We do, then, most heartily sympathise with those members of the Board of Works who complained that the two schemes—viz., that for the purchase of the rights of existing Water Companies, and the scheme for procuring a double supply—should have been inseparably connected in one resolution; and, moreover, that there had been no opportunity of fully discussing the whole scheme, or any of its parts.

The only two replies of the slightest moment urged against these important arguments were—first, that no one had publicly opposed the scheme on behalf of the Water Companies; and secondly, that the scheme had been amply discussed in the newspapers. When arguments so trivial as these can be soberly advanced by members of the Board of Works sitting in council on a matter which is to cost millions, it is but too clear that they have little to say for themselves. The Water Companies are keeping their own counsel, but they are girding themselves for an arduous and costly Parliamentary campaign. Is it likely they will let their opponents know their line of defence? But to urge that, because a scheme has been discussed in newspapers by more or less skilled and irresponsible writers, the body on whose shoulders the whole responsibility of making provision for carrying out the scheme rests should be deprived or should despise an opportunity of carefully discussing its merits, is surely a profound joke. Some feeling of the same kind must have actuated that member of the Board who, in his noble indignation, declared that they came there as free agents, not as delegates, because some one suggested that it might have been well to ask the local bodies, who have to supply the money, what they thought of the matter. In short, as already said, we have found in this discussion no single good argument in favour of the action of the Board save this—We have done it, let us stick to it! Nevertheless, so strongly had the members been moved by the difficulties of the proposed scheme, that on a show of hands only twenty-one voted for it in its entirety, and twenty for the cancelling of its latter portion; and on a call of names only twenty-three, as against twenty, voted "not to stultify the Board." We have not heard whether Sir James McGarel Hogg, the chairman, this time voted with the splendid majority of three which now appeals to Parliament. Meanwhile, what are the City authorities doing? Are they prepared to give up their autonomy at the bidding of the Board of Works?

THE VACCINATION ACTS.

Probably very few educated people doubt that a person may be repeatedly punished for repeated offences against a law; yet that this applies to the execution of the Vaccination Acts

has been frequently questioned before magistrates and justices of the peace, and has been just lately brought, for the second time, before the Court of Queen's Bench, by an application to quash a second conviction. It may, therefore, be useful to our readers to place formally on record here the case of Tebbs *v.* Jones, which was tried on the 22nd inst. in the Queen's Bench Division of the High Court of Justice, before the Lord Chief Justice and Mr. Justice Mellor. The question in dispute arose under Section 31 of the Act of 1871, (30 and 31 Vic., c. 84), that if any officer appointed by the guardians to execute the Act shall give information to a justice of the peace that he has reason to believe that any child under fourteen has not been successfully vaccinated, and that he has given notice to the parent to have the child vaccinated, and that the notice has been disregarded, the justice may summon the party, and if he shall find that the child has not been vaccinated, and has not already had the small-pox, he may make an order to have the child vaccinated within a certain time, and, in case of disobedience, the party may be proceeded against, and subjected to a penalty. The question was whether, if the order is still disregarded after conviction, the party may again and again be proceeded against. This question was before the Court in April, 1872, not long after the passing of the Act of 1871, and on that occasion the Lord Chief Justice said, "The continued disobedience to the order may constitute fresh offences, and be subject to fresh proceedings," and Mr. Justice Blackburn observed that, "It might as well be contended that because a man has been fined yesterday for beating his wife, he could not be fined for beating her to-day." It is well-known, however, that, notwithstanding these clearly expressed opinions of the judges, many persons, and especially persons dwelling in towns, have held such strong objections to having their children vaccinated, that, even after conviction under the Act, they have continued to refuse to have their children vaccinated, and the officers have been driven to institute fresh proceedings against them. The case of Tebbs *v.* Jones, which arose in the parish of St. Pancras, was one of these cases. The appellant had been convicted for not having his child vaccinated, and, as he still refused obedience, the parish officer gave a fresh notice, and then laid a fresh information before the magistrate, Mr. Mansfield, who convicted the defendant, but granted a case for the Court; and the question raised was whether fresh proceedings could be instituted. Mr. Baker, the counsel for the appellant, did his best for his client. He urged that the enactment, being a penal one, was exhausted by the conviction under it of the same party in respect of the same child; but, as to this, the Lord Chief Justice observed that it would enable every obstinate man, who thought himself wiser than the rest of the world, to set the law at defiance. Mr. Baker urged that there were men so strongly opposed to vaccination, that, rather than have their children subjected to it, they would go to gaol; but this only drew from the Lord Chief Justice the remark—"Then let them go to gaol: but the law must be obeyed;" and Mr. Justice Mellor said, "Until the child is successfully vaccinated, the enactment is applicable, and is to be enforced." It was urged that, according to this, the parent might be sent to gaol again and again until the child was fourteen, so as to be continually in gaol for twelve or fourteen years; but Mr. Justice Mellor replied that "the object of the Act was to protect the public health, and that object was paramount to the inconvenience of the individual." It was further argued that there was a provision in the Act that proceedings should not be taken after the lapse of twelve months; but the Court pointed out that this applied to each offence. And the Lord Chief Justice remarked that the construction contended for would render the Act entirely abortive and ridiculous. To hold that because a man persisted in not having his child vaccinated he may endanger the public health as well as the life of his child, and may continue to do so with entire immunity from the law, would be to make the legislation on the subject as worthless as waste-paper. Again, it was urged that men would retain their opinions, and could not be deterred from doing so by being called idiots; on which the Lord Chief Justice observed that this was, no doubt, true, for the more idiotic men were, the more obstinate were they. Counsel for the appellant again contended that it never could have been the intention of the Legislature that a man, on account of his conscientious objection to vaccination, should be kept for years in prison. The Court replied, however, that the Legislature could not have intended that their legislation should be rendered abortive and ridiculous. It was not merely an opposition to vaccination, but to the law which prescribed it, and which all were bound to obey.

Eventually the Court, without calling on the counsel for the respondent, the parish officer, proceeded to give judgment in his favour. The Lord Chief Justice said "there was really nothing in the objection raised in this case to the conviction—that because a man had been once convicted for non-compliance with the enactments, therefore he could not be convicted again, or only once in twelve months. Such a construction would make the Act perfectly abortive, and a man would be allowed, at his pleasure, to endanger the life of his child and the health of his neighbours. The penalty was not heavy, and it was evidently intended that it should be inflicted as often as the offence was committed and an order for vaccination disregarded." Mr. Justice Mellor concurred; and said, "The great object of the Act is the public health, which requires that it should be enforced so as to carry out the object. The object was to compel and obtain successful vaccination of children under the age of fourteen. As there were always some persons who thought they knew better than the Legislature, the Legislature had provided that penalties should be inflicted in such cases, and it was evidently intended that the penalties should be inflicted as often as the offence was committed—that was, as often as there was a refusal to have the child vaccinated. It was not enough for the man to set up 'conscientious objection' to vaccination. No one was more disposed than he was to allow for conscientious objections; but they could not be yielded to when contrary to the law, and opposed to the welfare of society and the common experience of mankind."

It is no doubt vexatious to have the time of one of the superior courts of justice taken up by the discussion of such a question as that which was raised in this case—a question which had been argued and decided only five years ago. But we are not disposed to regret it much, and we have given the case in full, because it is just as well that people should now and then be reminded that a law for insuring the public safety against any disease demands complete and unqualified obedience, just as much as do laws for securing public safety from robbery, murder, or any other legal crime; and when set at defiance they must be pressed against the offender with like rigour. All stand on the same footing, and of each alike the object—the public safety—is "paramount to the inconvenience of the individual." At the same time, we are willing to admit that, as our contemporary the *Times* says in commenting on the case, the law for compulsory vaccination, "though it answers to an urgent necessity, and has a superabundance of evidence in its favour, comes into conflict undoubtedly with some powerful hallucinations, which it is not easy to dissipate by force. It is a law which peculiarly needs to be put into operation discreetly and with moderate views of what is immediately possible," though we can hardly believe that "a too rigorous application of it might easily make it odious to the people, and provoke a dangerous resistance." And it is because we agree, to some extent, with these statements, that we insist so often that

Government ought to supply the means of animal vaccination. One of the objections to vaccination as ordinarily performed—that is, to what is called arm-to-arm vaccination, or vaccination with humanised lymph—is not an hallucination. Vaccination, like every other operation, great or small, must be performed with care, with attention to health, to the perfect cleanliness of the lancet or other instrument employed, etc. But it also demands some special precautions. It is a proved fact that in using humanised lymph which has not been selected and taken with due caution and care, a vaccinator may inoculate, and has inoculated, children with another and a terrible disease. No other objection to careful vaccination possesses any pretence, even, to validity, nor with any other can we have any sympathy; but this objection can be entirely met by the offer of the alternative of vaccination with lymph from the calf, and that this can be done easily and most successfully has been amply shown by very extensive experience in Belgium and in America. We do therefore contend that it is the duty of a Government which makes, and rightly makes, vaccination compulsory, to offer the alternative of animal lymph when the use of humanised lymph is objected to. It is no real reply to this to say that syphilo-vaccination is extremely rare, or that the results of animal vaccination are not always satisfactory. Neither are the results of arm-to-arm vaccination always satisfactory; and as human machinery must always be employed to select vaccinifers and to take lymph, the human fallibility which has caused vaccino-syphilis may cause it again, and the only possible absolute guarantee against this is the employment of animal lymph. And it is becoming more and more important to urge this upon Government, inasmuch as accumulating experience and knowledge point with increasing distinctness and force to the desirability of making revaccination as well as vaccination compulsory.

SATIRE AND MEDICINE.

No history of Medicine can be nearly perfect which does not include an attempt, at least, to give a fair account and estimate of the influence that satire has exercised upon the progress of Medical Science and Art. Those unpleasant but effective educators, the satirists, have certainly not spared us in times past, and we probably really owe them not a little gratitude. In thinking of the amount of satire which has characterised conversational and literary comments on the medical profession, we experience also some sense of regret that no satisfactory attempt has ever been made to compile such a book of medical table-talk as would place within the reach of busy doctors a record of the bright witticisms, and both satirical and pleasant banter, which have been directed against themselves and their predecessors in the science and art of Medicine. Such a collection would not only have a great amount of what may be called domestic interest to the medical profession, but would possess considerable intrinsic literary value. Both the characteristics of medical men, and the nature of medicine as a science, have invited displays of bitter satire, keen wit, and irresistible humour. Looked at from a personal point of view, the disciple of medicine has, in all ages, possessed that amount of individuality which lays men open to either hostile or favourable criticism. Satire in literature, like caricature in art, depends for its success upon the appropriation of some feature already well pronounced, and the magnification of it to such a degree as to produce a ludicrous effect; and those angularities of character which are so apt to accompany all forms of earnestness, and which the satirist seizes with such avidity, have always been strongly marked in the disciples of Æsculapius. The prevalent weakness of medical men has, at all times, been a tendency to mon-ideism, and to the consequent distortion of judgment and deformity of character, which supply as valuable material for the use of the satirist as that which the caricaturist finds in a distinctive nose or in a striking mannerism. It may be observed, also, that the empiricism which during so many eras has been the leading feature of the science, has exposed the profession, as a whole, to the satire which has been so freely lavished on individual members of it. In a pursuit in which, till recent times, so little was known for certain, dogmatism was the substitute for scientific precision; but unfortunately the dogmatism of assumption can be, and usually is, as strongly accentuated in one opposing doctrine as in another; and a process of reasoning open alike to educated and uneducated can show that antagonistic doctrines cannot both be right, while a tendency to contemptuous self-satisfaction too readily prompts the suspicion that both are likely to be wrong. Consequently, Dr. Sangrado with his drenching and bleeding, and Dr. Cuchillo with his desiccating regimen, come equally under the fire of the satirist. And even in more advanced stages of the science, when theories are extensively acted upon before they have been logically established, and when the personal influence of a teacher is accepted by his followers as equal to proof, while by others holding different views it is regarded as the surest guarantee of error, sufficient scope is afforded for the play of all those forms of witty, satirical, and humorous criticism, which require only intellectual sharpness as the agent, and an open question as the field of operations.

In another respect, also, the medical profession has been naturally adapted for the exercise of satire. The satirist to be completely successful must deal with questions of universal interest—his words must express parallelisms which the populace can recognise; and the consequence of this necessity for breadth in the employment of satire is that the weapon has been most freely used upon those whose duty it is to watch the interests either of the soul or of the body. Thus, Boccaccio's fame rests securely upon that response which rises in all honest hearts to his merry strictures upon the depraved ecclesiastics of his time. Rabelais, by sketching the character of his Friar John, who could drink best in his frock, finds generations of readers. People of all ages join in the detestation of the friar who looked upon his cloak as an incentive to drunkenness and gluttony. "If I should lay it aside," said he, "I should lose my appetite, but if in this habit I sit down at table I will drink both to thee and thy horse, and so courage frolic, God save the company! I have already supped, yet I will eat never a whit the less for that, for I have a paved stomach as hollow as St. Benet's boots, always open like a lawyer's pouch."

For similar reasons no comedy has surpassed in popularity Molière's *Tartuffe*, and well-known instances show that the great and lasting interest which is taken in satire directed against the erring devotees of religion is extended also to that levelled at the votaries of medicine. If there is nothing in Boccaccio to show that the medical men of his time had any more reprehensible qualities than the frolicsomeness which is now the popular characteristic of medical students, and if Rabelais—himself a doctor of medicine—could find no more productive field for medical satire than is exemplified in the discourse of Rondibilis the physician upon marriage, Montaigne, in his pleasant gossip of a century later, could find occasion to employ his humour to show that if bodily ailment constituted one disease the only effect of medicine was to produce another. Still later in the history of society, Butler, the author of "Hudibras," did not fail in his running comments on the vanities of his time to satirise the astrological tendencies of medicine, and to recount the pretensions of

> "A cunning man hight Sidrophel."

And it is not difficult to see that at the time when Butler wrote, the practice of medicine was open to the gravest satire, when, in a text-book issued from the press seven years after the first

publication of "Hudibras," we find formulæ for ordinary use, of which the following recipe for a poultice may be taken as a favourable example. The receipt is from Shroder's "Chemical Dispensatory," published in 1669, and is recommended under the designation of *Mynsecht's Poultice*:—Take "A swallow's nest; Album Græcum 2½ ounces; Althea, White lily roots, of each one ounce; figs and dates, of each number three: Boil them in water to a poultice, and add—oil of violets, camomile flowers; fœnugreek, linseed, white meal, of each 6 drachms; the brain of a cat; the powder of a burnt owl and of a burnt swallow, of each 2 drachms; yelks of 2 eggs; saffron one scruple. Make a cataplasm." "It is good in a desperate quinsey, applied often hot to the neck." And the internal remedies indorsed by the same authority show that common sense had so completely become isolated from medicine that satire was eminently required for its correction. Thus we find for various diseases the commendation of such therapeutic agents as the following:—Rasped man's skull, spirit of man's blood, shavings from man's skin, or bones calcined, foxes' lungs, live spiders, etc. On reading these contemporary items of therapeutics, we cease to think that Butler's quaint sarcasms were not completely justifiable, because it becomes evident that medicine had in some degree been perverted into a form of fetichism, in which virtue was ascribed to particular substances on account of obscure modifications of astrological influence. At the same time the nature of Butler's comments shows how grossly the medicine of his time was mixed up with exorcism and magic, when he says that Sidrophel could

> "Fright agues into dogs, and scare
> With rhymes the toothache and catarrh;
> Chase evil spirits away by dint
> Of sickle, horse-shoe, hollow flint."

Immediately afterwards, as if to show the universality of error, and the rise of intellect against it, we have the racy satire of Lesage in the Adventures of Gil Blas of Santillane, in which he depicts the honest but perverse performances of Dr. Sangrado, in his advocacy of vegetarianism, venesection, and hydropathy. And prosecuting the history of medicine still further, we find excellent materials for the satirists in the tendency which many men, ignoring the advantages of exact science, have shown to accept the speculative notions of Mesmer; of Hahnemann, whose doctrines were tinged with belief in Mesmer's theories; and the hundred other forms of error which spring up as easy means of attaining to the notoriety, so easily confounded with celebrity, which can only be attained legitimately by the patient pursuit of truth.

There is still another opening by which satire can readily find access to medical science. That opening is voluntarily formed by the occasional recoil from one mode of treatment to some mode completely antagonistic. When one thinks of the absolutely matter-of-fact way in which our predecessors of the first half of this century practised venesection and mercurialisation, and of the revolution which with comparative suddenness banished every lancet to its sheath and branded mercury as a despicable or pernicious metal: when one thinks of the calm reasoning that within a few years has restored the former as an agent which, when judiciously employed, may be a potent means of preserving life in the last extremities of disease, and restored the latter to an honourable position as the only safe antagonist of a virulent and insidious disorder: we are compelled to think that we owe our later exemption from satire, not to the absence of occasion, but to the fact that the censer of Sangrado has not been represented in modern society, and that the mantle of Butler, who, with exquisite humour, threw into rhyme the vagaries of Sidrophel, has not yet fallen upon any poet of recent times. And, to those who may have occasion to dread the venom of the satirist, it may be some consolation to be told that the medicine of the present is not so openly amenable to general criticism as that of the past. Thanks to the progress of exact science, a store of facts has been accumulated, which must be studied by critics as well as by scientists, before censure can be rendered effective; and there are few who combine in themselves the capability of brilliant satire and the power of mastering scientific detail. The consequence is, that when the modern critic turns his attention to the demolition of modern science on the strength of a telegram or of a police-court trial, he finds that his sharpness is turned against himself by gross errors of his own in science, and that his satire is more than neutralised by his display of unjustifiable ignorance.

THE WEEK.

TOPICS OF THE DAY.

At a meeting of the Wandsworth District Board of Works, held last week, the General Purposes Committee reported that they had inspected the works of the Southwark and Vauxhall Water Company at Nine Elms and Hampton. The Committee found at the works at Nine Elms that the filter-beds were being cleansed and reconstructed, and that improvements were being made there for the purpose of more effectually filtering the water: but, after a careful inspection of these works, the Committee came to the conclusion that such works ought to be entirely removed from their present position, where they are exposed to a deleterious atmosphere. The Committee were informed that land had for some years been obtained by the Company at Hampton for the purpose of improving the character of the water-supply. They were, however, surprised to find that nothing had hitherto been done there towards constructing subsiding-tanks and additional filter-beds, so repeatedly insisted on by the Government Inspector as the only way of insuring the supply of pure water; and the Committee now recommended that the Local Government Board be requested to insist upon the immediate construction of such subsiding-tanks. The Committee also recommended that a communication be addressed to the Local Government Board, strongly urging that some measures should be at once adopted to prevent, or at least to decrease, the pollution of the water at and above the intake. The report was unanimously adopted without discussion.

A munificent donation has just been made by Mr. Edward Pugh, who was formerly extensively connected with the iron trade of the Wolverhampton district, of £1000 towards the erection of a medical and surgical reference library in connexion with the Wolverhampton Hospital. Mrs. Bell, widow of the late Dr. Bell, of Wolverhampton, after whom the proposed library is to be named, had previously given 1000 guineas for the same object.

When taking into consideration the excessive price of that necessary but expensive alkaloid, quinine, the following piece of information will not be considered unimportant. The cinchona plant has been introduced into the West Indian Islands, and promises to become a remunerative industry; the first seed was planted in Jamaica in 1860, and, according to recent advices, the plantations of cinchona now cover 300 acres, containing about 80,000 trees. These have been favourably reported upon by competent chemists, and the most advanced trees are stated to be at the present time worth £1 each; it is further estimated that in the course of a few years their value will be doubled, on account of their increased size, and the corresponding value of the bark arising from the increasing development of the alkaloids it contains. The cinchona has become so naturalised that hundreds of thousands of seedlings are said to be growing over the fields. The introduction of the tree is ascribed to the Government, to whom, as yet, all the plantations belong; but the report adds that no doubt private enterprise will now step in, seeing that large profits are likely to result from the successful undertaking.

A prize of 150 marks has just been awarded to Otto Hehner, F.C.S., Public Analyst for the Isle of Wight, and Arthur Angell, F.R.M.S., Public Analyst for the County of Hants, for their essay on butter analysis. The award was made by Professor Heintz, and Professor Knop, of Leipsic, examiners for the Pharmaceutical Association of Leipsic. Six essays were sent in for competition—two from Germany, one from Austria, one from Italy, and two from England.

The third inquiry under the 12th Section of the Rivers' Pollution Act was opened last week at the Town Hall, Barnet, by Mr. R. Rawlinson. The Local Board of Barnet have been put to great expense for some time past through legal proceedings which have been successfully brought against them at the Hertford Assizes, and in the High Court of Chancery, for the pollution of a stream known as Dallas Brook with sewage from their sewage outfall works. A short time ago they applied for a certificate under the 12th Section of the Rivers' Pollution Act, and Mr. Rawlinson attended upon the occasion in question for the purpose of inquiring into the circumstances of the case, and of deciding as to the granting of the certificate. After considerable discussion the inquiry was adjourned. At Canterbury and Sandown, the only other places where, up to the present time, inquiries under the 12th Section of the Act have been held, no certificates have been granted.

The first lecture in connexion with the Volunteer Sick Bearers' Association was delivered last week by Surgeon-Major Staples, at the rooms of the Society of Arts, Colonel Loyd-Lindsay, M.P., presiding. The lecturer observed that he should prefer that this Association should be known as the Volunteer Ambulance Department, and would advise that the administration should be vested in the Government. He desired to impress upon the meeting the uselessness of spasmodic efforts in a work of this kind, and indicated the means which, in his opinion, were calculated to perpetuate the movement. It would be important to secure an organisation which would be efficient for use in time of war, so that assistance could be promptly rendered to the wounded on the field of battle. At the termination of the discussion which followed, the chairman announced that the Government were willing to supply the teachers, and consequently it only remained to insure a full attendance of pupils.

The facts detailed in a case recently heard before Vice-Chancellor Sir Richard Malins—Davis *v.* Nathan,—when carefully considered, will assuredly convince all thinking men that in the carrying out of the lunacy laws in France they do *not* "manage these things so much better" than we in England. A Madame Mégret, mother of the plaintiff in this action, an English Jewess, married M. Mégret, a Frenchman domiciled in England; in 1870 she suffered from an attack of puerperal mania, and, with her own consent, was placed in the asylum of Dr. Jules Luys, at Ivry. Within a year she had perfectly recovered, but was detained, against her will, in this asylum till the end of 1875. In the December of that year the family solicitor, having proved that she was of sound mind, communicated with the family, and steps were immediately taken which resulted in her release. In the year 1876 she was induced to live once more with M. Mégret, and he shortly took the opportunity of again placing her in an asylum at Charenton. In delivering his judgment, his Lordship earnestly hoped that what had occurred in this case could not happen in England; and under the present condition of our lunacy laws we think he may rest assured that such an occurrence is not to be feared. In making this assertion we would call attention, however, to the case of Mr. Arthur Henry Nowel, who, although an inmate of an asylum at Stoke Newington, was, after a protracted inquiry, conducted by Mr. N. Nicholson, the new Lunacy Master, adjudged to be of sound mind, and capable of managing his own affairs.

The Sanitary Commissioner of the Punjaub has issued a most satisfactory weekly report for the period ending September 15 last. The annual death-rate of the province, from all causes, which in the two previous weeks had been equal to 17 and 16 per 1000, was again only 16 during the week under notice. Only one death was registered under the head of cholera, and this occurred in the village of Langa, in the Gurdaspur district. From small-pox fifty-six deaths were registered, against seventy-three in the previous week; and from fever 3281, against 3257 in the preceding week. The health of the province is therefore pronounced to be very satisfactory.

The great amount of infant mortality in Birmingham has been occupying the attention of the public authorities of that town, and last week a meeting was held, under the presidency of the Mayor, to consider what steps should be taken for its reduction. In opening the proceedings the Mayor said the question of infant mortality had long engaged the attention of the Health Committee of the Town Council, and they had called upon Dr. Alfred Hill, the Medical Officer of Health, to make a report upon the subject. This report had now been rendered and in it Dr. Hill estimated that there were between 1300 and 1400 deaths of infants under one year of age annually arising from preventable causes. Dr. Hill was further of opinion that the evil could only be partially dealt with by a sanitary authority. An organised society of ladies to visit low-class houses, and instruct women in a simple manner on the best mode of feeding and nursing children, together with the establishment of nurseries or crêches, where infants could be properly taken care of while the mothers were at work, would be most valuable. Resolutions were then passed, deploring the high rate of infant mortality in Birmingham, and declaring that as ignorance about diet and management caused probably half the deaths of children under one year old, efforts should be made for a wider dissemination of knowledge on health subjects. Should these efforts take a practical form we shall carefully watch for the result, in order that other localities may benefit by the experience of Birmingham in this important matter.

At the last meeting of the Uxbridge Rural Sanitary Authority, the inspector reported that 208 cases of scarlet fever had occurred, exclusive of upwards of forty cases at the St. Marylebone Schools. For a long time the disease was confined to Southall-green, and principally among the children of the poorest inhabitants, but within the last few months it has spread to other parts in the neighbourhood. Five deaths have occurred in the Schools, and twenty-nine outside; but of seventy-three cases treated in hospital, only four have proved fatal. It is still thought that the patients' clothing has not been properly disinfected before their discharge from hospital.

Dr. Thomas Stevenson, Lecturer on Chemistry at Guy's Hospital, and Medical Officer of Health for St. Pancras, has been appointed to the chair of Medical Jurisprudence at Guy's Hospital—a vacancy created, it will be remembered, by the resignation of Dr. A. Swayne Taylor.

SMALL-POX HOSPITALS AS SOURCES OF CONTAGION.

A CORRESPONDENCE has been forwarded to us by Mr. Walters, surgeon, of Faringdon, Berks, which is so instructive that we make bold to give its substance to our readers. A girl named Rosa Ball, belonging to Faringdon, had been a servant in Marylebone, and was there attacked with scarlet fever. She was taken and admitted to the Stockwell Fever Hospital, where, during her recovery from the scarlet fever, she was attacked by small-pox so severely as to be in danger of her life. Her father was informed of this, and on July 29 left Farringdon, and went to the Hospital, where he was permitted by the authorities to see his daughter. He was told she was very ill, and he was not to stay long with her, but was not informed of the nature of her disease, and no other precautions were taken against his receiving or conveying contagion. He

returned to Faringdon, was taken ill on August 11, and died of small-pox on the 16th. His wife caught the disease and recovered. A woman who laid out his body also caught it, and died. Her daughter conveyed the infection to four other houses, although herself escaping. This woman's furniture was, after some attempt at disinfection, sold, and the wife of the purchaser became infected, was prematurely confined, and died. One of her children now lies ill of it. Thus, writes Mr. Walters in a letter to the Local Government Board, through the man Ball being allowed to visit his infected daughter in the Hospital, we have had nine cases of small-pox out of which four have proved fatal. The evidence as to the source of the disease is in this case exceptionally clear, and is doubtless an illustration of the way in which outbreaks sometimes arise, although tracing their origin may present insuperable difficulties. It cannot be supposed that, where it is *the rule* to admit visitors to see relatives lying dangerously ill of infectious disease, misfortunes of this kind are infrequent. The Local Government Board communicated with the authorities of the Stockwell Fever Hospital, and in reply they wrote that the facts as stated, and as far as they knew, were correct, and that the following were their rules in respect to such cases:—"That when any patient is, in the opinion of the Medical Superintendent, in a dangerous condition, his or her name be placed in a book, to be sent down to the gate-porter, and that the nearest relative of such patient be allowed to see him or her; that, except in such cases, no visitors be allowed to patients; and that, as soon as a patient is out of danger, his or her name be removed from the visiting-book." In addition, each visitor to a patient suffering from small-pox is furnished with a printed copy of the following notice, before being allowed to go into the wards, viz.:—"The Committee hereby give notice to the friends of patients that they run great risk in visiting the hospitals, unless they have been previously properly vaccinated. It has come to the knowledge of the Committee that persons not thus protected, who have been allowed to see relatives lying dangerously ill in the hospitals, have themselves caught the disease and died; no person, therefore, should attempt to enter the wards of the hospitals without having been revaccinated; and the Committee recommend all persons residing in a house where a case of small-pox occurs, at once to call on the Public Vaccinator, whose address may be obtained from any of the parish officers. In the public interest it is necessary to limit the visiting of patients to the nearest relatives or intimate friends of persons lying dangerously ill, and even then the Committee would urge such persons not to enter the wards unless they have been properly revaccinated; and these visits, which can only be made by the permission of the Medical Superintendent, must be strictly limited in their duration." They add: "The difficult question of the visitation of the sick in these hospitals has, on many occasions, engaged the attention of your Committee, who, while fully conscious of the danger attendant upon entering infectious wards, are not prepared to recommend the entire prohibition of the visiting of patients by their friends. The Committee are convinced that, were they to enforce the complete isolation of patients, as suggested in the letter of Mr. Walters, and prevent parents from visiting their children, and husbands their wives, when lying dangerously ill, such a rule would be so repugnant to the general feeling that great opposition to the hospitals would arise from all classes, concealment of disease would follow, the usefulness of the hospitals would be much impaired, if the object for which they were established were not entirely defeated, and worse consequences would result to the community than are likely to accrue by the occasional contraction of the disease by visitors admitted under the restrictions already laid down. Of two evils, therefore, your Committee have chosen that which they believe to be the least, and have adopted a practice which is most in accordance with humanity, and with a respect for the feelings of the sick poor themselves. Your Committee, however, believe that while nothing will absolutely insure the safety of persons visiting the patients in these hospitals, the danger may be very much reduced if proper precautions are taken by the visitors themselves. The avoidance of actual contact with the patient or the bedclothes, with the breath or cutaneous emanations, together with an ablution of the hands and face with carbolic soap before leaving the building, would do much to protect the visitor and prevent the exportation of the poison." There is no doubt we are here face to face with a serious difficulty, but we fear that weakness to the verge of imbecility is the prime characteristic of the Committee's procedure—certainly it is of their final suggestions; for they seem utterly to forget that though visitors may not contract disease themselves, still they may become its vehicles to others, when washing the face and hands with carbolic soap may not quite arrest its ravages. It seems to us that there is no middle way—either complete seclusion, or complete disinfection of all visitors; and certainly the number of visits ought to be limited in all cases for the good of both patients and friends. We think Mr. Hopkins Walters has done good and loyal service in thus laying so clearly open to the public the dangers likely to arise from the present system as existent at Stockwell.

ARTIFICIAL ANÆMIA AS A MODE OF TREATMENT FOR DISEASES OF THE LIMBS.

A NEW application is suggested for Esmarch's elastic bandage, namely, as an anæsthetic and curative agent in painful inflammatory affections of the extremities. Dr. Bernhard Cohn, of Steglitz, relates (*Berl. Klin. Wochenschrift*, October 29, 1877) two cases in which the induction of artificial anæmia by the bandage was followed by great relief—a case of phlegmonous inflammation of the foot in a man of sixty-three, and one of simple œdematous inflammation of the forearm in a maid-servant; and he gives the details of a third case in which a practical cure resulted from Esmarch's method after all other modes of treatment had been exhausted. The patient, a boy of three and a half years, had white swelling of the left knee-joint of eighteen months' standing, with considerable enlargement of the condyles of the femur, and thickening of the tissues around the patella and the head of the tibia.. There was great sensitiveness of the parts to pressure, movement was impaired, and walking only possible for a step or two, with lowered pelvis, and with the tips of the toes alone reaching the ground on the left side. After a few weeks' daily application of the bandage for fifteen to sixty minutes, the improvement was so great that the limb could be moved in all directions or handled without pain, the entire sole of the left foot could be brought to the ground in walking, and the gait was even on the two sides—in fact, all that was left of the former affection was a little swelling and limitation in the movement of the joint. Dr. Cohn, in his remarks on the cases, declares that in practice the idea that the increase of blood in the capillaries, which follows the removal of the bandage, will entirely undo the effect of the previous anæmia, is not sustained. He considers that the bandage acts mainly by relieving the congestion of the inflamed part, and perhaps by improving the conditions of diffusion between the tissues and the bloodvessels. He recommends an elastic band, one inch and a half wide, encircling the limb so that each turn overlaps the one below, and finished off with five to eight turns completely covering each other. He thinks that the bandage may be allowed to remain on the limb longer than we might *à priori* think justifiable, and that there is less danger of gangrene if both arteries and veins are completely compressed than if the compression be imperfect so as to close the veins and hinder the escape of blood, while it is still allowed to enter by the arteries. In the latter case, œdema,

with enormous rise in the blood-pressure, must be the result. To avoid pain as much as possible, the final turns must not be tighter than absolutely necessary to stop the circulation. The questions, "How often can and ought the constriction to be renewed?" and "Is it better to use single *long* compressions, or frequent short ones?" require further experience to answer them satisfactorily.

EFFECTS OF SEWING-MACHINES ON HEALTH.

A REPORT on the health of persons who work sewing-machines was lately presented by Dr. Nicholls to the State Board of Health, Massachusetts. From observations made by medical men, it was inferred that a healthy person, of average strength, who does not make a business of sewing with a machine, may work one for three or four hours a day without much fatigue or perceptible injury to health; but that among workpeople, disorders of digestion, due to sedentary life and bad ventilation are frequently met with, also pains in the muscles of the trunk and the lower limbs, because these latter are always in motion. There occur also congestions of the ventral organs, weakness, and in some rare cases neuralgias of the legs and spinal irritations. It is recommended to the proprietors of works in which the sewing-machine is used to have (1) a good ventilation; (2) a shorter time for work, with periods of rest; (3) another motor force than that of the feet—*e.g.*, a steam-engine.

PEMPHIGUS NEONATORUM.

EPIDEMIC pemphigus attacking infants, and independent of syphilis, is a well-attested fact, but its etiology is by no means clear. Professor Dohrn, of Marburg, lately related to the Medical Society of that place the history of a midwife living at Wiesbaden, in whose practice thirty-four children out of seventy-three were attacked with pemphigus within a few months. The eruption generally appeared at the end of the first week after birth, and was unattended with danger or much discomfort to the infants. Cleanliness, repeated disinfection, the use of new instruments, and all other preventive measures, were tried in vain. She was advised by Professor Dohrn, to whom she applied, to go away from Wiesbaden for a month and have a holiday. On her return, the first three children she attended remained healthy; the fourth, fifth, and seventh were attacked with pemphigus. She left home again for a month, and, on recommencing practice, the same series of events was repeated. Where does the infection work in such a case? and what is its nature?

WILLIAM GALE AT THE ROYAL COLLEGE OF SURGEONS.

ON Friday, November 23, Gale, the famous pedestrian, attended at the Royal College of Surgeons, by the invitation of the President, for the purpose of undergoing an examination as to his condition of health, after the prolonged exertion of walking 4000 quarters of a mile in 4000 consecutive ten minutes, or a period of twenty-eight days, terminating on the 17th. The examination was conducted principally by Mr. Erichsen, Professor Humphry, Mr. Marshall, and Mr. Holden. Gale is forty-five years of age; his height is only five feet three inches and a half, and average weight eight stone seven pounds. The examination showed that he was not of marked muscular development; the muscles of the lower limbs were small and soft. The heart-sounds were found to be perfectly normal, and the impulse remarkably strong; the pulse was seventy-six, full, strong, and regular. Circumferential measurement of the thorax, just below the axillæ, thirty-two inches; deep inspiration gave an additional inch—thirty-three inches. There was no tendency to hernia, and no varicocele. In the left leg the external saphena vein was largely varicose, in the form of an eel-like convoluted mass on the back of the calf; and below the flexure of the knee a more dilated and thin-walled sacculus appeared ready to yield further. This state of the veins in the left leg had existed for some years in a slight degree; but, during the previous walk of 1500 miles in 1000 hours, at Lillie-bridge, the varicosity rather suddenly and rapidly increased, and when Mr. Gant first saw Gale on that occasion, he at once applied a bandage until an elastic support could be obtained, which was worn throughout the recent long walk. The sense of weight and weakness in the limb, which had occasionally rendered the pedestrian somewhat lame, had thus been entirely relieved, and the varicose condition had not increased. Gale's appearance is remarkably fresh and vigorous, notwithstanding the arduous feats he has achieved in former years. In July of the present year, after being ten years out of practice, he first accomplished the marvellous undertaking he has just now repeated; and, in the interim, the extraordinary performance at Lillie-bridge, which eclipsed Captain Barclay's previously unequalled walk of 1000 miles in 1000 hours. After his examination at the College, Gale gave an illustration—so far as the confines of the theatre permitted—of the style and rapidity of his walking.

THE HEALTH OF BIRMINGHAM.

IN his quarterly report on the health of the borough of Birmingham to September 29 last, Dr. Alfred Hill, the Medical Officer for the district, takes occasion to call attention to the decrease in the death-rate for the period under notice, compared with that for the summer quarters of the last four years; and this, notwithstanding the large number of deaths from diseases of the respiratory organs, measles, and whooping-cough, he considers is entirely owing to the unusually small mortality for this season of the year from diarrhœa, the deaths from which during the quarter have not amounted to two-thirds of the number from this cause in the summer quarter of last year, or to one-half as many as they were in the corresponding quarter of 1875. This diminution, Dr. Hill thinks, is without doubt to be attributed to the remarkably low temperature which prevailed throughout the whole of the quarter. The mortality was equal to an annual death-rate of 22·25 per 1000 of persons living, and must be looked upon as fairly satisfactory. But some steps are evidently required to be taken to still further reduce the mortality, when it is announced that since the commencement of the present year no less than seventeen persons have died in one street of Birmingham from zymotic diseases, nine of them in the period we are now discussing. Dr. Hill refers this unsatisfactory state of things to the water-supply, as on several occasions he has had samples of well-waters, taken from wells in the street, submitted to him for analysis, and has invariably found them to be highly impure, and to contain large quantities of ammonia and other substances indicating sewage contamination. Might it not prove more satisfactory to close these wells compulsorily, and substitute for them an improved water-supply?

THE METROPOLITAN WATER-SUPPLY FOR OCTOBER LAST.

THE reports of the Water Examiner, and of Dr. Frankland, on the metropolitan water-supply for the month of October last, show that the river-water supplied to London during that period was of unusually good quality, that abstracted from the Thames being fully equal to what is usually obtained from the Lea; whilst the water from the Lea delivered by the New River and East London Companies was, on the average, equal in purity to deep well water. Moreover, all the river-water was efficiently filtered before delivery. Such a generally satisfactory state of things has rarely, if ever, been recorded in these monthly reports, and at once excites the reflection whether the proposed scheme of the Metropolitan Board of Works for purchasing the rights of the London water companies can have had anything to do with it. An exceptionally propitious state of the rivers may have contributed to this

happy result, but if this has not been the case, the present agitation must have induced greater attention to the filtration of the water on the part of the companies' officials; and if this latter solution should be at all correct, it would afford an additional proof of the necessity of placing our water-supply in the hands of one central authority which would be responsible for its uniform purity. The reports further state that the water drawn from deep wells by the Kent Company and the Tottenham Local Board of Health was palatable, wholesome, and of its usual excellent quality for dietetic purposes. The Colne Valley Company's water, on the other hand, was exceptionally contaminated with organic matter of vegetable origin, and although such contamination need not excite alarm, Dr. Frankland suggests that the cause ought to be sought out and removed.

SURGICAL SOCIETY OF IRELAND.

The opening meeting of the Surgical Society of Ireland took place on Friday evening, November 23, in the Albert Hall, Royal College of Surgeons, Dublin. The inaugural address was given by Dr. Robert McDonnell, President of the College and of the Society. After alluding to the losses which the Society had suffered since its last meeting, especially by the death of Drs. Cronyn and Henry Wilson, and quite recently of Dr. H. Griffiths, the President delivered a discourse, taking for his theme—"What has experimental physiology done for the practice of surgery?" He first pointed out the effect on practice of the general light thrown on it by physiological discovery. Many excellent practical surgeons, he said, knew but little of physiology; they applied in practice every day principles discovered and worked out by the experimental physiologist, yet oftentimes they knew not the steps by which these principles had been discovered. Like Molière's "Bourgeois Gentilhomme," they were talking prose without knowing it. He who works an electric telegraph may do it admirably well, yet know nothing of Galvani's or Volta's discoveries. So it is with the surgeon and physiology. In this we find the explanation of the strange fact that some practitioners whose names are well known to the public have been found to make the assertion that experiment on animals has done little for practice. Dr. McDonnell then proceeded to compare the surgery of some centuries ago with that of to-day. He set side by side an operation in the olden time with one at the present time. How surprised and delighted, he said, would Sir Astley Cooper be could he witness an operation at once painless and bloodless, and a convalescence disarmed of dangers of fever and suppuration. He then showed *seriatim* the share experiment has had in bringing about these happy results. Several recent specimens were subsequently exhibited by members, after which the Society adjourned.

PATHOLOGICAL SOCIETY OF DUBLIN.

The first meeting of the session 1877-78 took place on the afternoon of Saturday, November 24, in the Anatomical Theatre of the School of Physic, Trinity College, Dublin. The chair was taken by Dr. Hayden, the outgoing President. The business of the meeting was confined to the election of annual officers, and to the making of arrangements for future meetings of the Society under the new system. It will be remembered that last session it was decided to admit students no longer to the meetings, and to have discussions on the specimens exhibited. The Society is to meet in future at 4.30 p.m. on Saturdays, the place of meeting being, as heretofore, the School of Physic. The following officers of the Society for the session were elected:—*President:* Edward Hamilton, M.D. *Vice-Presidents:* John Thomas Banks, M.D.; Samuel Gordon, M.D.; Thomas Hayden, F.K.Q.C.P.; George H. Kidd, M.D.; Robert McDonnell, M.D.; and J. Jolliffe Tufnell, M.D. *Council:* Lombe Atthill, M.D.; Anthony H. Corley, M.D.; George F. Duffey, M.D.; Charles E. Fitzgerald, M.D.; Arthur Wynne Foot, M.D.; James Little, M.D.; Thomas Evelyn Little, M.D.; Benjamin George MacDowel, M.D.; William Moore, M.D.; John William Moore, M.D.; John Mallett Purser, M.D.; Henry J. Tyrrell, F.R.C.S.I. *Honorary Secretary:* William Stokes, M.D. *Secretary and Treasurer:* Edward Halloran Bennett, M.D. *Secretary for Foreign Correspondence:* Robert D. Lyons, M.D. The newly appointed President, Dr. E. Hamilton, having taken the chair, a vote of thanks to the outgoing President, Dr. Hayden, was passsed by acclamation. The Society adjourned to December 1.

BETTER LATE THAN NEVER.

The following order, dated the 27th inst., has been issued at all the metropolitan police-stations, by command of Colonel Henderson:—"Whereas, dogs suspected of being mad having been recently found within the metropolitan police district, I, Edmund Yeamans Walcott Henderson, the Commissioner of Police of the Metropolis, pursuant to the Dogs Act, 1871, and in exercise of the powers vested in me as the local authority under the said Act for the metropolitan police district, do hereby order that no dogs, not being under the control of any person, shall be henceforth, for the period of sixty days, suffered to be in or upon any thoroughfare or public place, or any place open to the public, within any part of the metropolitan police district, except within such parishes and places as are now within the jurisdiction of the Metropolitan Board of Works, and to which the provisions of the Metropolitan Streets Act, 1867, already apply and are in force." An addendum states that "all dogs not being under control will be seized by the police, and disposed of in accordance with the law."

THE ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

It has long been matter of complaint that authors are not allowed to read their own papers before the Medical and Chirurgical Society, but that they are entrusted to a secretary who may have had little or no opportunity of acquiring that mastery over them necessary to good reading. Of this we had an unfortunate illustration last Tuesday evening. Everyone is aware of the style in which Sir James Paget's papers are written, yet through the misfortune of bad reading the paper became nearly unintelligible. Would it not be wise to give authors the option at least of reading their own productions, as is done elsewhere? Might we at the same time suggest to the worthy President that bulletins as to the state of any Fellow's health may sometimes be found out of place.

PRIZES IN BOTANY FOR WOMEN.

The Society of Apothecaries have decided to offer two prizes for competition by young women under twenty years of age, in the science of botany. The prizes will consist of a gold and a silver medal and books, to be awarded to the first and second candidates respectively in order of merit. The Rev. M. J. Berkeley (the examiner for the prizes given by the Society to medical students) will conduct the examinations. The date of the examination and the conditions of competition will be published shortly.

HEALTH OF DR. STOKES.

We have pleasure in stating that the latest accounts of Dr. Stokes's condition are somewhat more favourable. There has been no return of apoplectic seizure since that which on Saturday week excited the liveliest apprehensions of his host of friends.

ROYAL MEDICAL SOCIETY, EDINBURGH.

At a meeting of this Society, held on the 23rd inst., the following gentlemen were elected Annual Presidents:—Robert Roxburgh, M.B., L.R.C.S.; Johnson Symington, M.B., C.M., M.R.C.S.; David Hart, M.B., C.M.; George A. Gibson, M.B., D.Sc., F.G.S.

HYDATIDS OF THE LUNGS.

"Unbidden guests."—*Shakespeare.*

The subject of hydatid cysts in the lungs is one of great importance, not only to Australian practitioners, but also to practitioners nearer home. A valuable contribution to the subject has recently appeared,(a) and we propose to briefly notice it, in the hope that it may prove useful to those whose opportunities of seeing the disease are not so frequent as those of the author to whom we allude.

Dr. Bird's little book is the result of sixteen years' experience in the colony of Victoria, where the disease may be said to be endemic. We need not more than glance at the subject of the origin of hydatid cysts in the human body. The researches of Cobbold and Küchenmeister show that the ova of the Tænia echinococcus, a parasite which infests the bowels of dogs, will, if introduced into the human body, develope into what we call the hydatid cyst. Dr. MacGillivray, in a paper in the *Australian Medical Journal*, 1869, gives an interesting account of the special facilities afforded by mining and agricultural life for contracting this disease; but other causes than these must be at work, as the inhabitants, both rich and poor, of the city of Victoria are equally liable to it. It is believed that the droppings of the sheep-dogs, dried by the hot winds, and readily pulverised by the traffic in the streets, are inhaled as a fine dust during respiration. Not only does it seem highly probable that this supplies the *materies morbi*, but it explains also the remarkable frequency of lung hydatids as compared with those in the liver or elsewhere. It is well known that the sheep is obnoxious to the echinococcus, as well as its more familiar parasite the fluke; but whether either is communicable to the human subject by the vehicle of partially cooked mutton, as is the popular belief, we have no positive data at present to determine. The use of half-washed watercress, and such-like plants, growing in creeks and water-holes readily accessible to dogs, as food, affords one common explanation of the entrance of the larva into the digestive canal.

The most important part of the subject is, of course, the diagnosis, especially while the parasite is still in its integral state. The author's experience is "that the only absolute evidence of the existence of hydatid in the lung, whether originating there or in process of passage from the liver, is the appearance in the sputa of the characteristic cysts or portions of them, or fragments of the hooklets of echinococci." This unfortunately does not happen till what we may call the second stage of the disease, when the entozoon has begun to die, and be expelled from the body. An examination of the sputa with the microscope becomes of great importance, almost as a matter of routine. So long as the cysts remain entire, and no definite information can be got from an examination of the sputa, we must fall back upon a systematic physical examination of the chest—"a successive exclusion of morbid states within the thorax other than hydatid, which may give rise to a group of signs more or less resembling it, being the safest and most scientific method of procedure." The symptoms are (1) general, (2) special. The general symptoms may at first be very slight. If the cyst be of moderate size and of slow growth, it does not much interfere with surrounding structures, and thus may cause little disturbance; indeed, often it remains unnoticed by the patient for a considerable time, especially if, as often happens, he have a capacious chest. The accommodating power of healthy lung-tissue to increased work is indeed most wonderful when there is no constitutional mischief at work. But as the cyst enlarges, which it invariably does if not interfered with, symptoms of pressure or irritation, or both, begin to show themselves. Dyspnœa and duskiness of the skin may be observed, and are more or less marked, according to the size, locality, and rapidity of increase of the tumour, and the capacity and mobility of the affected chest. In women, if the cysts occur in the upper lobes, these last-mentioned symptoms are usually very prominent. The presence or absence of pain, and its character, acute or otherwise, are determined by the same conditions. A more or less phthisical appearance, *even when the case is not complicated with tubercle*, is often noticed, with progressive loss of flesh; and in some instances Dr. Bird has seen well-developed clubbing of the finger-ends, and incurvation of the nails (all which symptoms have disappeared after the hydatid cyst had been tapped or expectorated). Cough nearly always occurs, and it varies in character in the early stages; but when the cyst is large and situated near the base of the lung, the cough is usually violent and paroxysmal in character. Expectoration at first is simple mucus, which may or may not be stained with blood; as the case progresses it becomes more or less purulent. Dr. Bird has seldom or never seen profuse hæmoptysis, though he has "seen several ounces at a time in an aggravated case when tapping had been long delayed." Should these symptoms—dyspnœa, deficient aëration, wasting, clubbed fingers, cough and expectoration—remain persistently after the expulsion or death of the hydatid, the probability of course is in favour of further complications. 2. The special symptoms include the physical signs given by auscultation and percussion. It is just this part of the subject which our chief texts-books pass over without giving us much information. The physical signs vary very much according to the *size* and *locality* of the sac. Out of 150 cases of hydatid disease in the thorax, which Dr. Bird's personal experience embraces, one occurred in the mediastinum, one in the cavity of the pleura, two in that of the pericardium, and the remainder were seated in the lung-substance. Dr. Walshe believes that the hydatid sacs are rarely surrounded by healthy lung-substance. Dr. Bird, on the contrary, has frequently seen them so, and hence he considers that the condition of the surrounding lung-tissue is of great importance from a diagnostic point of view; he says, "the small amount of irritation caused by a slowly enlarging cyst in the lung, and the very trifling modification in the breath-sounds in the immediate neighbourhood which may be caused by it, are most important negative signs in the diagnostics of hydatid." There is "a nullity of respiration sound, no air whatever entering the compressed lung, though beyond the clearly defined margin of the cyst the breath-sounds are at once normal." He sums up the physical signs of a hydatid tumour of *moderate* size as follows:—"Expansion more or less deficient on the affected side; mensuration but little affected; absolute dulness on percussion, with absence of respiratory sounds, over a space of of the chest-wall not smaller than the palm of the hand, generally in the lateral and infra-clavicular regions, with absence of vocal fremitus in most cases. This dull space always presents a rounded outline, is limited by a line of demarcation so exact that it can be mapped out with pen and ink, and is unaltered by position. Beyond the boundary-line percussion is clear and normal. The respiratory sounds, though inaudible over the dull surface, commence immediately beyond the pen-line; and, though probably rather harsh and puerile in character, are indicative of healthy lung-tissue. . . . Thus one is reduced to the conclusion that there is a sac containing fluid within the chest-wall, slowly enlarging, causing little or no pain or local irritation, not the result of any inflammatory effusion, but foreign to, though growing in, the thoracic viscera. A hydatid cyst alone combines all these characters, so that the diagnosis may be reduced almost to a certainty." Should the disease progress without interference until the pressure of the surrounding tissues is more than they can bear; or if the enlargement take place much more rapidly than usual, very serious effects are produced, which greatly complicate the diagnosis—patches of pneumonia, with rusty or bloody sputa, sometimes even with gangrene, obstinate bronchitic symptoms limited to the affected side, occasionally effusion into the pleura, or perforation of that membrane, or even of the diaphragm, as related by Laennec. But such complications are rare in this colony, as the disease is almost always recognised at an earlier stage. When a cyst has attained a large size without relief, and degeneration of its wall ensues, with rupture into a bronchus, the symptoms become distressing indeed. Intense prostration, hectic, the ceaseless expectoration of blood, pus, and half-putrid acephalocysts of excessive fetor, and often portions of gangrenous lung-tissue, go on sometimes for months, till the patient, in most cases, sinks from exhaustion, unless relieved by the evacuation of the sac and its contents by a free incision between the ribs. The distinction between cases of hydatid expectoration from cysts in the lungs and those where a liver-hydatid has burst into the lung is generally easy, from the previous hepatic symptoms, and the staining of the sputa with bile.

(a) "On Hydatids of the Lung: their Diagnosis, Prognosis, and Treatment." By S. Dougan Bird, M.D., Lecturer on Therapeutics in the University of Melbourne. Second edition. Melbourne: Robertson. 1877. Pp. 64.

The diseases most likely to be mistaken for hydatids of the lung or pleura are:—(1) An unbroken cyst in the liver, high up and far back on its convex surface, may not be distinguishable from one in the base of the lung immediately over the liver, or one in the cavity of the pleura; (2) phthisis; (3) localised pleuritic effusions; (4) circumscribed abscess of lung; (5) mediastinal tumour, or abscess; (6) a solid tumour of the lung.

Concerning *treatment*, Dr. Bird looks upon an exploratory puncture with a fine trocar as the only appropriate treatment for such cases; "and in exceptional cases of old standing, when there is a thick adventitious external wall to the cyst, which is generally closely adherent to the ribs, or in cysts of the pleura, free incision." He recommends that the trocar should be not less than six inches long, and of the smallest diameter that is made, always providing that it is strong enough to bear the strain of a firm pressure. Speaking of the aspirator, he says, "they always do so well if tapped early enough with the simple trocar and canula, that the evidence in its favour is not very conclusive." Dr. Bird has seen it used on two occasions; both cases did well as usual, but recovery was not quicker than if the ordinary instrument without the suction apparatus had been used. "Theoretically, however, the more complete emptying of the cyst, and possibly its dislocation from its nidus, should aid in destroying the vitality of the parasite. If the cyst is tapped early, and has not been much irritated or interfered with till then, the limpid fluid will flow freely through the fine canula; and the expansion of the lung, which commences immediately the pressure of the fluid is removed, is generally sufficient to empty the sac, especially if aided by efforts of coughing, which indeed are generally involuntary." The treatment of old suppurating cysts is rather different; the centre of the sac, as nearly as can be judged, is fixed upon, an incision is then made through the skin and muscles, and the largest-sized trocar and canula that will pass between the ribs is introduced into the sac. This gives exit to a quantity of pus, and fragments of cysts of various sizes. Dr. Bird thinks it better to leave the canula in for some days or even weeks, and to wash the sac out frequently with some disinfecting solution. He considers some delay is always necessary to allow of the separation of the parent cyst from its nidus, and the gradual expansion of the lung. "Immediate attempts at its removal by forceps are generally unsuccessful, and portions are very apt to be left behind." The opening must be free, and kept patent with perforated drainage-tube. For cysts which are separated from the chest-wall by a layer of healthy lung-substance the fine trocar is the most appropriate, because it is almost impossible to perforate comparatively healthy lung-tissue with a large trocar. This, the surgical treatment of hydatids, is the most important; it occasionally, however, cannot be adopted, and then medicinal treatment has to be resorted to; but it is preferable to combine the two whenever it is practicable. Turpentine, from its well-known anthelmintic powers and ready diffusibility, has naturally suggested itself as a remedy, and it has proved of great service in many cases, while in others it has signally failed. Dr. Bird thinks it ought to be tried in all cases. He recommends also "that the bromide or iodide of potassium, combined with kamela, be given continuously for several weeks"; it has a distinctly sickening and irritating effect on the acephalocyst.

The *prognosis* is one of no less moment nor of lesser interest. An early diagnosis, and tapping with a fine trocar, with persistent and appropriate drug medication, render the death of the individual parasite almost a certainty; and this being accomplished, the danger is done with as far as it is concerned. But there is always the possibility of *other* hydatids making their appearance in the lung or *in other organs*. Everyday experience shows the peculiar liability which some persons betray to parasitic disease. "Weakness or strength of constitution seems to have little to do with it, but rather idiosyncrasy." "An individual who has once had hydatid thereby proves his title to susceptibility to such disease, and has therefore, *cæteris paribus*, more chances of again contracting it than his neighbour, who has hitherto escaped it." "Such susceptible persons can but avoid drinking any water but what has been boiled or stone-filtered, the former being by far the safest; and if, in spite of this, they contract hydatid, it is their misfortune, and not their fault."

The question of probability of recurrence of hydatid is one of special importance in reference to the selection of lives for assurance. Should an applicant be refused because he has formerly had hydatid of an internal organ? Dr. Bird says, "not always, but he certainly requires considerable 'loading' to bring him to the level of others who have been unaffected. . . . He has proved his susceptibility, and should the disease reappear, no human foresight can predict that it will not be in the brain or heart, where it is probably fatal."

We have endeavoured to pick out the most interesting points of this little book. Dr. Bird earns our best thanks for having given us the benefit of such an extensive experience of this rare disease. His book is a model of what a book should be: it is concise, agreeably written, and contains a digest of other writers' views; but its chief recommendation is, that it is the author's own experience and views of a disease on which he speaks with the authority of a master. We heartily commend it to the further attention of our readers.

FROM ABROAD.

The Paris Faculty of Medicine.

The Paris Faculty of Medicine continues to resist the high-handed decree, to which we have before referred, by which it was sought to force on it two supplementary professors, without its consent being asked. It has taken the matter before the Conseil d'Etat, and there can be little doubt that there will be a decision given in its favour. According to a statement made by M. Alglave, the editor of the *Révue Scientifique* (No. 18), the matter resolves itself into what with us is denominated a "gross job" for the purpose of finding places for two favourites. One of these gentlemen is M. Voisin, brother of the Préfet de Police of the De Broglie Ministry; and the other M. Mauriac, who acted as electoral agent for M. de Fourtou at Riberac. They had to be provided for, and it was desirable to give them posts which they would not have to give up on the retirement of their patrons from office.

For several years past the Faculty has been in the habit of supplying deficiencies in its professorial staff by creating a certain number of temporary supplementary chairs for special diseases. About eighteen months since, the Minister of the day offered to convert four of these chairs into permanent professorships; and, as was thought at the time, the Faculty most injudiciously declined his offer. One such chair, however, was so created for mental diseases, and M. Ball, the successful competitor, was presented to the Minister and nominated to the professorship. Five other specialties remained in the position of supplementary clinics, for diseases of children, ophthalmology, syphilitic diseases, diseases of the genito-urinary organs, and diseases of the skin. These were confided to *agrégés* of the Faculty for a period of five years. On August 20 last, however, a decree was issued declaring that supplementary lectures might be founded, and that they might be entrusted to hospital medical officers, who need not be *agrégés* (or deputy professors) of the Faculty, from among whom all such appointments had hitherto been made. They also were declared capable of participating in the examinations. Many of the Faculty being absent from Paris, this decree did not receive the prompt opposition it would have done, while various similar projects had passed away as dead letters. However, on October 11 a new decree was issued, appointing for ten years the five *agrégés* who had been already chosen by the Faculty, but requiring M. Fournier, the *agrégé* appointed for the clinic of venereal diseases, to confine himself to the secondary and tertiary forms of syphilis, the primary forms being confided to a new professor, M. Mauriac, the friend of M. de Fourtou—two clinical courses on syphilitic diseases! The case of M. Voisin is still more extraordinary, for he is provided for at the expense of M. Ball, the new Professor of Mental Diseases, and who, notwithstanding his strenuous efforts, has never yet been able to get any hospital service assigned to him. M. Voisin, in fact, is to deliver a supplementary course of lectures on mental medicine, and a service is ordered to be at once prepared for him—M. Voisin (who has an appointment at the Salpétrière, conferred upon him formerly by ministerial nomination, like any other *employé*) not being even a hospital medical officer, and never having furnished the guarantee of capability supplied by the *concours*. The professors and *agrégés* have each protested against these nominations, and the Faculty has announced its determination to resist the carrying out the decree. It is true that

MM. Mauriac and Voisin may deliver lectures in spite of the Faculty; but they can have no right to participate in the examinations, which can only be conducted by professors and *agrégés* nominated by the Dean of the Faculty. It seems that the only professor who refused to sign the protest was Prof. Chauffard, the Inspector-General of Medical Schools and Faculties; and this, joined to his clerical proclivities, caused him to be met with a most stormy reception at his lectures.

Transfusion in a Case of Cancer Uteri.

A woman, aged fifty, was admitted to the St. Pierre Hospital, Brussels (*Presse Méd. Belge*, November 4 and 11), with cancer uteri, the hæmorrhages which had taken place having had great effect upon her. In a clinical lecture which he delivered on her case, Prof. Thiry stated his conviction that the disease must terminate fatally before long, and added that for some time past he had asked himself whether, in cases of this kind, it would not be proper to try the effect of transfusion of blood. Up to the present time all measures employed against cancer have proved of no avail; and we are justified in trying all the measures at our disposal for the relief of the accidents the patient is exposed to, and for investigating one of the resources of art which has as yet been but little experimented with. If we infuse into her veins a rich and young blood we may find important transformations take place. The vital activity thus considerably increased may induce notable changes in her condition; and if we do not succeed in obtaining a modification of the terrible diathesis under which she suffers, we may at least place her in a condition which will allow of her resisting for a longer period the disease which is exhausting her. We have a precedent which authorises us to believe that, if we do not effect a cure, we may obtain an amelioration. Thus, at the Hopital St. Jean, transfusion was performed on a woman who had undergone an operation three times for cancer of the breast, and who had arrived at a point of extreme debility. Transfusion was executed *in extremis*, and perfectly succeeded, the immense wound rapidly healing; and the woman, who was believed to be at the point of death, left the hospital six weeks afterwards, dying only a year later, cancer being found at the autopsy in all the organs except the other breast. "Is it nothing," M. Thiry asked, "to prolong the life of a mother of a family for even a year?" And this is what transfusion did. In two other cases the operation was also tried by the same surgeon under analogous circumstances, and in both the patients found the hæmorrhages diminish, and their general state improve. This ought to induce us to make new trials, and even in the present case, which seems desperate, success may follow. It would be a crime on the part of the practitioner not to try, even in cases that afford little hope, all the means which therapeutics places at his disposal.

Prof. Thiry represented to the patient how desirable it was that she should submit to treatment that had already been followed by encouraging results, but, alarmed at an operation of which she had never before heard, she refused. The actual cautery and various caustics were several times employed during the subsequent four weeks, when she consented to the transfusion. This was performed on November 18 by M. Casse, who, having chosen a very small vein, in view of other transfusions being required, demonstrated to the pupils that the injection of blood (thirty grammes of defibrinated in this instance) can be effected even in the smallest vessels. He further called their attention to the innocuity with which bubbles of air may be allowed to enter. Without considering it desirable that air should be injected, he protested against the exaggerated views generally held of the mischief ensuing on its entrance. Accidents which may ensue on the admission of a large quantity at one time, are never met with when some bubbles are slowly introduced. Considerable improvement ensued, although blood still continued to be lost; and on December 2 a second transfusion was practised, and on the 16th a third, the losses of blood abating considerably upon the whole, although recurring. The woman, however, was very indocile, and at last, feeling herself better, she, in spite of remonstrances, left the hospital on January 8. Arrived at home, she refused all further transfusion, and died in February. One consequence of her indocility while in the hospital was the production of phlebitis, which, unlike what is usually the case, assumed a centrifugal direction. Upon the whole, in spite of the fatal issue of the case, enough was observed during its progress to encourage further trials of transfusion in cases in which the disease has not advanced so far.

Croup and Diphtheria.

Dr. Lewis Smith (*New York Med. Record*, October 13) enters his protest against the doctrine laid down by Prof. Steiner, in "Ziemssen's Cyclopædia," that these two affections are only varieties and modifications of one and the same process, which, in consequence of special influences and collateral causes as yet imperfectly understood, makes its appearance at one time as croup, and at another as diphtheria. On the contrary, he maintains, "Croupous laryngitis and diphtheritic laryngitis, however closely their anatomical characters may approximate each other in certain cases, are totally distinct maladies." In support of this view he adduces the following reasons:—

1. Difference of causes. Croupous inflammation, like any other inflammation of the larynx, is usually due to what is called "taking cold," and is especially prevalent in the cold and changeable months, and in moist and cold climates, those children suffering who are most exposed to cold and changeable temperatures. These are the exciting causes, although there are also probably predisposing causes in many instances existing in the individual. The cause of diphtheritic laryngitis is a *materies morbi*, which acts independently of thermal changes in the atmosphere. The conditions required are the presence and reception into the system of the diphtheritic poison. Thermal atmospheric changes can only be a cause of diphtheritic laryngitis by the fact that, in an individual suffering from diphtheria, surfaces that are already the seat of catarrh, which usually occurs in cold and changeable weather, are more likely to be the seat of the diphtheritic deposit than those which are in a normal condition. 2. Croupous laryngitis occurs upon all parts of the earth's surface, though it is said to be more common in high latitudes than in tropical regions—as would be expected from the nature of its cause. Diphtheritic laryngitis only occurs in localities where diphtheria prevails. Many towns in the United States have never yet been visited with diphtheria, but from time to time, in these, cases of obstructive laryngitis with pellicular exudation occur, a considerable number of which prove fatal, and which can only be considered as cases of croup. 3. The supposed anatomical differences which able pathologists have insisted upon—viz., that while the croupous pellicle lies upon the surface of the larynx, and does not penetrate it, the diphtheritic exudation pentrates the mucous membrane. "I am not prepared to state to what extent this distinction holds true as regards croup, but I know that the diphtheritic pellicle does penetrate the mucous membrane of the larynx; while it lies upon, but does not penetrate, that of the trachea and bronchial tubes." 4. "The highest authorities in pathological histology, as Rokitansky, state that croupous inflammation may occur upon all the mucous surfaces, but that it is more common in the respiratory tract than elsewhere. And it is to be observed that Rokitansky made this remark after observing 30,000 dissections in Vienna, where diphtheria had not yet appeared. Now, it seems to me unreasonable to deny this statement, and to regard those isolated cases which have been long known under the name of croup, and which occur in localities that have not as yet been visited by epidemic diphtheria, as a form of diphtheritic inflammation, when we admit that an inflammation occurring further down the respiratory tract, and which appears to have similar anatomical characters, is croupous and not diphtheritic. I refer to croupous bronchitis and croupous pneumouia." 5. Croupous laryngitis is neither epidemic nor contagious. This is testified by numerous observers in New York. Diphtheritic laryngitis is but one manifestation of an epidemic and highly contagious malady.

Education of Men and Women together.—The Board of Visitors of the Wisconsin University condemn the system of co-education in that institution, on the ground that it entails loss of health among the females in their efforts to keep up with their classes and overcome the physical frailties of their sex. "Education is greatly to be desired," the report concludes; "but it is better that the future matrons of the State should be without a university training than that it should be obtained at the fearful expense of ruined health—better that the future mothers of the State should be robust, hearty, healthy women, than that by over-study they entail upon their descendants the germs of disease. And there is no more certain law than that of heredity. The overwrought nervous system undermines the general health stealthily but certainly, and its evil consequences are prolonged in many cases through life."—*New York Med. Record*, October 20.

GENERAL CORRESPONDENCE.

THE SUBCUTANEOUS INJECTION OF CURARA IN HYDROPHOBIA.

LETTER FROM DR. E. W. COLLINS.

[To the Editor of the Medical Times and Gazette.]

SIR,—While attention is directed anew to the pathology and treatment of hydrophobia, owing to its recent prevalence in some parts of England and of Scotland, the records of any recent and well-authenticated cases of this dreadful malady, in which treatment has been rewarded with success, are of importance. We can thus determine whether any new line of therapeutic action, which can be based on rational physiological principles, is indicated as deserving of extended trial, and whether the special manner in which it should be put into practice can be approximately arrived at.

For the treatment of hydrophobia it would appear that in curara we have a valuable therapeutic agent; and I desire to strengthen the hands of the Editors of the *Lancet* and *Medical Times and Gazette* in their recent able editorial comments on this subject. In these articles it has, I think, been too hastily assumed that no proof exists that any case of genuine hydrophobia has ever been cured, unless it be that recorded by Dr. Offenburg, of Wickrath, in 1874, to which allusion is made (*Medical Times and Gazette*, October 6, 1877). It is my object to show that this statement, which so far has escaped criticism, does not represent the sum of our therapeutic knowledge regarding the successful treatment of this disease. The other two recent cases, which I shall bring under notice, are besides of much value, as they point in exactly the same direction as that of Dr. Offenburg, and, taken together with it, warrant the hope that, in similar cases, curara, when pushed rapidly to the manifestation of its peculiar physiological effects, may be found equally efficacious.

In the *Amer. Jour. of Med. Sci.*, July 1876, page 81, Dr. B. A. Watson, of Jersey City, minutely discusses, and gives the fullest particulars of, a case which he and Professor Austin Flint regarded as an instance of true rabies canina. The symptoms of rabies developed themselves forty-seven days after the individual—a strong, healthy man, forty-five years of age—had been bitten in the finger by his own rabid dog. His servant-girl, who had been bitten at the same time and by the same animal, died five days before the commencement of her master's illness, of unmistakable hydrophobia. In this man's case there was a gradual increase in the severity of the symptoms till after the subcutaneous administration of curara in full and rapidly augmenting doses ($\frac{1}{16}$ grain : $\frac{1}{3}$ gr. : $\frac{1}{6}$ gr.) every third hour. The unfavourable symptoms forthwith subsided, and disappeared completely after the third injection.

The second case was treated by Dr. Polli, and an abstract of it appeared in *Le Paris Méd.*, May 17, 1877. A child, twelve years old, had been bitten by a rabid dog eighty days before the manifestation of the hydrophobic symptoms. Subcutaneous injections of morphia and chloroform inhalation having been tried without success, curara was injected subcutaneously on seven different occasions within the short space of five hours and a half. During this period twenty centigrammes (three grains) of curara were injected. The hydrophobic symptoms quickly subsided, being replaced by paralytic phenomena of a very pronounced character. Two days subsequently some renewed hydrophobic symptoms were completely banished by a fresh injection of three centigrammes (nearly half a grain) of curara. The child slowly recovered.

In Dr. Offenburg's case (*Medical Times and Gazette*, October 6), where characteristic symptoms of rabies manifested themselves in a woman aged twenty-four, eighty days after she had been bitten by a rabid dog, the subcutaneous injection of one-third of a grain of curara at intervals of fifteen minutes at first, and subsequently at intervals of an hour, resulted in the cessation of the hydrophobic symptoms, and the supervention of general paralysis, rendering artificial respiration necessary. In this case, within the space of four hours and a half, seven injections were used, representing altogether nineteen centigrammes (nearly three grains) of curara. On the evening of the third day renewed hydrophobic symptoms, which had assumed a serious aspect, were permanently controlled by one other injection of curara.

If it be conceded that these well-authenticated cases were instances of genuine hydrophobia (as their narrators with good reason maintain, from a careful consideration of their history and all the symptoms), they are uniformly and highly suggestive as regards a method of treatment of this malady which hitherto has not received the attention it thus demands. More than ten years ago, Trousseau, when suggesting the possible advantage of the subcutaneous administration of curara in hydrophobia, was not deterred by the want of success which had attended its use in tetanus. "Perhaps the want of success," he remarks, "may be largely due to the mode of administration of the drug" ("Clinique Médicale," vol. ii., page 380). This, it appears to me, is the point on which these three cases are so instructive. They demonstrate that, to be of service, curara must be employed in full and (probably best of all) in rapidly augmenting subcutaneous doses, varying from one-tenth to one-half a grain, at short intervals, until the paralytic symptoms, which experimental physiology has taught us to recognise as the manifestation of the full influence of the drug, begin to develope themselves. At this stage artificial respiration may even become necessary, as in Dr. Offenburg's case. The variation in strength of specimens of curara renders it important that the injection fluid should be procured from those who are likely to have exercised special care in the selection of the drug. A solution so concentrated (half a grain in five minims) as that prepared by Messrs. Gale, of Bouverie-street (*Lancet*, November 10), if reliable, seems to supply such a desideratum. I am, &c.,

EDWD. WOLFENDEN COLLINS, M.D., F.R.C.S. Ire.,
Surgeon to Jervis-street Hospital.

33, Lower Baggot-street, Dublin, Nov. 25.

THE TREATMENT OF SPINA BIFIDA.

LETTER FROM DR. JAMES MORTON.

[To the Editor of the Medical Times and Gazette.]

SIR,—In your issue of Saturday last (November 24), I rejoice to see a notice of the success of both Dr. J. S. Caradoc, of Brest, and Dr. Rosebrugh, of Hamilton, Canada, in treating cases of the above malformation. It is the first notice of either case that has reached me, and it may be admitted that all medical men, myself included, ought to have known of Dr. Caradoc's case; but we, unfortunately, do not all read *L'Union Médicale*. This ignorancee proves that I did not borrow anything from Dr. Caradoc; and Dr. Rosebrugh does not say that he published his case till now. In a former note I remarked that the injection of iodine was not a novelty; the solution I use and recommend is a novelty, which no one on this side of the Atlantic has called in question (I suspect Dr. Rosebrugh does not yet know its composition), and I ground my preference for it on its comparative non-diffusibility, and consequent safety. Moreover, one injection of it often suffices, and in no case have four or five been required. I regard water as one of the worst diluents for tincture of iodine, as precipitation of the iodine is certain to occur, and will continue to use the iodo-glycerine solution till a better method of treatment is devised. I am sure Dr. Rosebrugh will be glad to know that now eighteen cases have been treated by myself and others, that fifteen of these proved successful, and in no case did the operation appear to do injury. He must excuse me for still claiming the moral right to call the method "a new method," and to say that it has been recognised as such. Full credit ought to be accorded to Dr. Caradoc, in which I most cordially join, taking leave to remark that his case, and that of Dr. Rosebrugh, serve to strengthen my position in regard to the management of this malformation; and I thank the latter gentleman for calling my attention to them, and shall be pleased to hear of many more successes, though failures should also be stated. I am, &c.,

199, Bath-st., Glasgow, Nov. 26. JAMES MORTON.

THE FRENCH CENSUS OF 1876.—The population of France in 1872 amounted to 36,102,921 inhabitants, and, according to the census of 1876, had increased to 36,905,788. Of these, 18,373,639 were males, and 18,532,149 were females. Of the 18,373,639 males, 9,805,761 were unmarried, 7,587,269 were married, and 980,619 were widowed. Of the 18,532,149 females, 8,944,386 were unmarried, 7,567,080 married, and 2,020,683 widowed. Thus there was an increase of 802,867 (or 2·17 per cent.) inhabitants since 1872.—*Rév. Scientifique*, November 17.

REPORTS OF SOCIETIES.

OBSTETRICAL SOCIETY OF LONDON.

Wednesday, November 7.

Charles West, M.D., F.R.C.P., President, in the Chair.

Tarnier's Forceps.

Dr. Wiltshire exhibited a pair of Tarnier's forceps, and explained to the members the latest modifications which had been made in it.

Dr. Fancourt Barnes applied the forceps to the fœtal head on a model invented by Messrs. Budin and Pinard.

Dr. Playfair asked if the instrument would permit rotation in occipito-posterior presentations. The greater the curve of the instrument, the more difficult was its application in such presentation.

Dr. Braxton Hicks said the great desideratum in instruments was simplicity. There were two or three advantages claimed for Tarnier's forceps: one was that it indicated the rotation of the head; but the English forceps did this also. Traction was made with the new instrument by means of handles attached to the back of the blades, but it appeared to him that they did no more than the long straight forceps. The perineum presented a difficulty in the use of both instruments. The blades of Tarnier's were less curved than those of the French forceps generally, so that they might not injure the fœtal head. The instrument was too complicated to come into general use.

Dr. Matthews Duncan observed with satisfaction that no provision was made in Tarnier's forceps for the use of the pendulum movement. He did not like the fixing of the blades by a screw-nut, for it ensured a constant pressure on the child's head. In the ordinary English forceps there was a great deal of latent ingenuity; the instrument permitted of relaxation of the pressure on the head.

Dr. Galabin said there were two imperfections in the instrument—the indicators were too heavy, and it did not permit free extension of the head, by reason of the point of insertion of the traction handles. They would endanger the perineum.

Dr. Fancourt Barnes observed that when applied to the head above the pelvic brim the head was drawn backwards into the hollow of the sacrum, and did not exert pressure on the symphysis, as was done in the use of the ordinary long forceps.

Dr. Aveling said that the sigmoid form of these forceps was correct. Dr. Johnson first introduced the perineal curve; the idea was further developed by Hermann, Hubert, Morales, Tarnier, and ten years since by himself.

Dr. Wiltshire said the compression could readily be intermitted by unscrewing the handles, which he thought could be made lighter.

Dr. Galabin showed his forceps, and pointed out that the instrument was similar in principle to several named by Dr. Aveling. It had straight handles, a large perineal curve, and an English lock, and permitted of traction being made in the axis of the brim of the pelvis.

Dr. Braxton Hicks said there was danger of displacing the blades backwards when traction was being made with this forceps.

Dr. Aveling said that they were identical in form with those of Morales. He thought the long straight handles unnecessary.

Phantom.

Dr. Fancourt Barnes described the model of Messrs. Budin and Pinard.

Dr. Braxton Hicks showed and described the phantom he had used for years.

Dr. Routh thought that the dead body would be much better than phantoms; it was used in Vienna.

Mr. Brown asked if the uterus was natural, as well as the rest of the body.

Dr. Edis objected to operations on the dead body, because they would unfit the physician for practice.

Dr. Gervis thought the pelvis in Dr. Hicks's phantom was placed too far from the edge of its stand.

Dr. Hicks said it was placed so in order that students might be taught to apply the forceps without moving the patient to the edge of the bed.

On a Diagnostic Sign of Vaginal Hæmorrhage during Parturition.

Dr. Paul Budin, of Paris, communicated a paper as above. The author pointed out that when, during the birth of the child, a stream of blood ran over the neck and back (the presentation being occipito-anterior), such hæmorrhage was not from the uterus, but from the anterior wall of the vagina, a little behind the clitoris.

Dr. Edis had met with a case of this kind. He found a rent near the clitoris, applied perchloride of iron and a T bandage with success.

Dr. Wiltshire asked if sloughing followed the application.

Dr. Edis said it was a question of saving life.

Cancerous Growth.

Mr. Worship showed a cancerous growth involving the ovaries.

On the Choice of the Leg which should be Seized in Version for Presentation of the Upper Extremities.

Dr. Galabin in this paper said that the case referred to is that in which the liquor amnii has escaped, and bipolar version is no longer possible. The doctrine commonly taught in England is, that in such cases it is necessary or desirable to seize the upper knee or that opposite the presenting shoulder. This is recommended on the ground that in this way the child is rotated on its longitudinal as well as on its transverse axis, and by that means the presenting shoulder more effectually carried away from the os uteri. By taking the lower leg the fœtus is rotated on its bilateral plane. By taking the upper leg it is intended to rotate it in the antero-posterior plane, which passes through the presenting shoulder and the opposite hip—a movement which is equivalent to rotation on its transverse and longitudinal axis at the same moment. In dorso-posterior positions, however, this rotation often fails, as is proved by the back being found still directed backwards immediately after version. In such case the same kind of rotation is produced by taking the lower leg, but at a less mechanical advantage. By two figures drawn to the same scale, representing sections of the fœtus, first in the bilateral plane, secondly in the antero-posterior plane through the presenting shoulder and opposite hip, it is shown that traction on the lower leg acts at a greater mechanical advantage in effecting rotation on an antero-posterior axis than traction on the upper leg in effecting the combined rotation on a transverse and longitudinal axis. A more important advantage in seizing the lower leg is, that if a noose be placed on the prolapsed arm the operator will have in the after-extraction complete command of the anterior arm, which is always the one which gives trouble in liberation, and often thereby causes the death of the fœtus. Moreover, if the lower leg be seized, the more usual dorso-anterior position is not converted by the version into a dorso-posterior—a point of very minor importance, but one which may sometimes be worthy of consideration. The author has practised this method in eight consecutive cases without being obliged in any one of them to bring down afterwards the opposite leg. In some cases, however, if the fœtus be dead and flaccid, the shoulder fails to rise if version be performed in this way. In these instances the upper leg may be brought down afterwards with as much advantage as if it had been seized in the first instance. In such difficult cases of version there is an actual benefit in bringing down both legs, for not only is a means thereby afforded for more powerful traction, but more room is furnished within the uterus. Moreover, if the breech be first drawn down as low as to a transverse position by traction upon the lower leg, traction upon the upper leg will afterwards act at greater mechanical advantage in rotating the fœtus on its longitudinal axis, and so aiding the elevation of the shoulder. The conclusion drawn by the author is that in the majority of cases it is preferable to seize in the first instance the nearer and lower knee, or that on the same side as the presenting shoulder.

Dr. Matthews Duncan said he had for many years taught the preference of the leg homonymous with the presenting arm, according to the views which Dr. Galabin had now so elaborately and successfully advocated.

Dr. Holman said he had for many years followed the practice of bringing down the nearer or more dependent knee, and had always succeeded in effecting version.

ASSOCIATION OF MEDICAL OFFICERS OF HEALTH.

FRIDAY, NOVEMBER 16.

DR. STEVENSON, President, in the Chair.

In consequence of the destruction by fire of the accustomed place of meeting—the Scottish Corporation Hall—a room was engaged at the Cannon-street Hotel for this meeting. The Secretary having read the minutes, letters of sympathy from kindred societies were submitted for consideration. Allusion was made to the generous offer of the use of "the Library of Social Science for meetings on that day and any future occasions when not required for other purposes." Mr. Chadwick also made a similar offer on behalf of the Society of Arts.

Dr. DUDFIELD proposed a vote of thanks to the societies for their kind offers, and it was referred to the Council to make suitable replies.

Dr. TRIPE urged the Society to give full powers to the Council to arrange a place of meeting for the next and all subsequent meetings. Ho hoped that any unnecessary outlay would be spared, as he desired to see the Reports of the Society published with less condensation than heretofore.

Drs. WHITMORE and RADCLIFFE also spoke on this subject.

The PRESIDENT, at the suggestion of Dr. Dudfield, moved a vote of sympathy with the Scottish Corporation (whose hospitality they had enjoyed for some years past) for the irreparable loss by fire of many valuable works of art and ancient records.

The report of the Council was read on the following subjects:—The Registration of Epidemic Infectious Diseases; the Proposed Metropolitan Buildings Bill. The Council decided to reaffirm the two regulations framed last session on the Registration of Diseases, with the addition of the words "legal obligation" on the person in charge to report the fact without delay; and that the medical officer in attendance be required to give "written" (not verbal) information of the nature of the disease to the person in charge. Consideration of the Buildings Bill was postponed till copies could be obtained.

Dr. TRIPE urged the Society to advise the authorities as to the desirability of making the Metropolitan Board of Works and the Local Government Board the confirming authority of by-laws under the proposed Act. There are many matters of drainage and water-supply over which the health officer has no control at present. He moved that it is desirable for the vestries and district boards to have the power of framing by-laws, subject to confirmation by the Metropolitan Board. This, being agreed upon, was added as a rider to the report.

Mr. Henry Armstrong was proposed as an extra-metropolitan member, and Dr. G. A. Heron as an associate.

Dr. DUDFIELD alluded to the desirability of officers of health being placed in direct communication with School Board visitors, who are alike interested in checking the spread of infectious diseases. He also requested that the Council be empowered to report upon the proposal to frame by-laws for the management of cow-sheds.

RIVERS AND THEIR RELATION TO PUBLIC HEALTH.

Professor ANSTED then commenced reading his paper. In his opening remarks he referred, with regret, to the unfortunate death of Dr. Letheby, conjointly with whom, from a chemical point of view, the subject of river pollution was to have been worked out in the paper, of which we subjoin an extract:—

From time immemorial river-banks have been selected in every part of the world as the most convenient and the best situations on which to build towns. No doubt this selection had reference to facility of transport, as well as to water-supply, and was partly due to the fact that the river afforded a means for the removal of sewage and other impurities. From the very nature of water a proximate element capable of holding in solution almost every known substance, absorbing atmospheric air and almost all known gases, existing to some extent in all solids, present as a vapour in the gaseous atmosphere that envelopes the earth, an essential and even large component part of every form of organic existence, and a necessary article of food both directly and indirectly, the circulation of water on the earth is a phenomenon of the highest interest and of the greatest importance. This circulation is effected by evaperation, rainfall, and rivers. The evaporation takes place largely from the whole surface of the earth, but especially from the surface of the warm seas within the tropics. Conveyed over the surface by the winds, the evaporated water first becomes cloud, and then falls to the earth as rain. The proportion of the rainfall that runs off the surface is never large if calculated for any such period of time as shall include all seasonal changes. The daily flow of some of the streams in the Wharfe Valley during the six summer months was less than three millions and a half gallons, whereas, in the month of December only, it amounted to fifty millions. The river Thames carries only about one-seventh of its rainfall to the sea, while the Severn is believed to deliver nearly half, by far the greater part running off during floods. It will readily be understood that the physical features of a drainage area and its geological composition must affect the proportion of water that runs off the surface very considerably, and also affect the quality of the water. The presence of large surfaces of absorbent rock in one part of a drainage area, contrasts strongly with extensive tracts of country elsewhere, covered with thick beds of clay, or occupied by hard, unfissured limestone, gritstone, quartz rock, slate, or granite; and these conditions affect not only the amount of supply of water obtainable from the surface, or running off to the sea, but also by their mineralogical character they influence the quality of the water, and thus effect sanitation. We may consider rivers in their relation to public health—first, as receiving by innumerable channels water nearly pure; secondly, as the receptacles of foreign substances regarded as impurities, and caused by the conditions of animal and vegetable life on the land which the river drains; thirdly, as affording means by which these foreign substances of organic origin become exposed to the action of the atmosphere, and are thus oxidised or rendered innocuous; fourthly, as channels for carrying off material that would otherwise accumulate, suffer decomposition, and taint the atmosphere. First, then, we regard rivers as obtaining pure water from the atmosphere, and becoming charged with mineral matter as they pass on their way. The mineral matter that enters river-water, and is dissolved by it, can only be derived from the rocks over which the water flows in its course, or those through which it passes before joining the stream. The Severn, which rises in the metamorphic rocks of the Welsh mountains, and which is fed by large and important streams proceeding from the same sources, is known to yield waters of unquestionable excellence, little affected by the mineral contents of the rocks it crosses. On the whole, it may be safely asserted that river-waters are, for the most, very pure, and sufficiently soft to be well adapted for domestic use if taken near their sources, especially when these sources are in rocks of the older or Palæozoic period. The quality of the water of rivers must depend, so far as mineral impurities are concerned, on the nature of the rocks of their drainage area. In all drainage areas in the British Islands the rocks are apt to be covered with, and concealed by, superficial deposits, sometimes derived from the disintegration and decomposition of the rocks themselves, and sometimes due to a comparatively recent deposit of clay and gravel of sufficient thickness to affect the nature of the water flowing over the surface, or derived from springs. Few things are more important than the influence thus produced. The water from gravel in towns, obtained from land springs and shallow wells, is always of doubtful, and generally of bad quality, and being often tainted by drainage from graveyards, it may be almost assumed to be dangerous. It is known that water containing mineral impurities is liable to change or to lose them in long transmission through the earth. In the second place, rivers cannot run over the surface of the land without conveying mechanically large quantities of material lying on the surface, and thus becoming charged with foreign substances regarded as impurities, derived from the presence of decaying animal and vegetable life, and the natural excreta of animals of all kind, whether healthy or diseased. Life is everywhere; death follows life; and before or after death, water falling from the skies sweeps away into the river all this vast wealth of organic existence, past and present. It follows, as an inevitable consequence, that if the presence of decaying and decomposing matter is injurious, there must be in water some means of purifying itself, or the earth would be rendered uninhabitable, and become a vast pest-house. We know that such a means exists. We know that water absorbs atmospheric air, and that the oxygen of the absorbed air is separated from the nitrogen to oxidise or burn off so much of the impurity as can be done in the time

during which it is exposed. When the oxygen thus leaves the water, a further supply is obtained from the same source, and thus every large body of water exposed to the air, however it may at one time be loaded with organic matter, is purified and becomes once more clear and potable. In a thickly peopled country such as England the work required of the river is a maximum, and we sometimes overtask the power of running water to retain its purity and fitness for food in especially crowded districts. The inorganic matter carried down by floods is rarely injurious, except to property; but a quantity of organic matter, whose decomposition might seriously injure life, is carried away at once, and removed from the chance of doing mischief. The value of running streams can hardly be overestimated; and the assumption that, because in a few instances our smaller rivers are polluted and rendered noxious by the amount of industrial work carried on near their banks, rivers generally are not valuable for purposes of health, is one not justified by facts. All the larger rivers of England, and many of the smaller streams, are utilised, but, in spite of the uses made of them, and the impurities to which they are exposed, it is not a little due to them that our country enjoys so large a share of health; and it is a fact that towns near rivers are generally more healthy than those not so situated. It is certain that there is a limit, and a very well-defined limit, to the quantity of pollution that a river can receive per mile of its course without its waters being sensibly injured. That this limit was reached and passed a few years ago in the neighbourhood of London, below the point where the tide terminates, there is no doubt. I believe there is equally little doubt that, with moderate care and reasonable attention, the natural purification of the stream by oxidation may be sufficiently secured to permit the river-water to be safely used for household purposes when taken at a moderate distance below well-drained towns, whose direct sewage is kept out of the stream. It must not be supposed that I ignore or deny the nature of that previous sewage contamination of which we have all heard so much of late years. No doubt the presence of nitrates and nitrites may indicate the presence at some former time of animal contamination, although nitrogen may certainly also be derived for these purposes from other sources. The water from lakes and reservoirs is generally more free from foreign mineral substances in solution; the water from springs has fewer nitrates and nitrites, and less ammonia; but the water of rivers, whose course has been for a considerable distance through open country, exposed to sun and air, is not in reality more liable to induce fatal disease than the others. Are rivers to be avoided because they once received sewage, if the whole of the sewage received has been oxidised? I do think that the value of rivers for sanitary purposes has been neglected. The possible danger from the use of river-water has been exaggerated, and the certain good insufficiently considered. There are causes of possible mischief affecting springs, quite as powerful as those affecting rivers, the consideration of which has been neglected, while some of the advantages of spring-water have been exaggerated. A complete interference with any of the natural uses of rivers, whether for cleansing purposes, manufactures, conveyance of goods, or removal of sewage, seems to me so serious and so likely to add to the many difficulties under which all branches of industry are now suffering, that I cannot but urge the extreme importance of caution in carrying to an extreme the endeavour to remove all sources of pollution from our rivers. It is doubtful whether, if we were to succeed in appearance, the sanitation of towns and the value of human life would be increased. It is certain that we should inflict a mortal injury on some most important industries. In Yorkshire, Lancashire, and the adjoiuing counties we should so far interfere with manufacture as to produce more deaths by starvation than will be produced by permitting rivers to be utilised.

In the discussion following the reading of the paper several inquiries were made by the speakers.

Mr. Whitmore asked the Professor to state what he considered the best potable water, and what amount of carbonate of lime per gallon would be tolerable. At Norwich, for instance, the water was very hard, and it was supposed that the prevalence of calculous disorder in Norfolk was due to the large quantity of lime in the water. It has been stated that hard waters are more healthy than soft.

Dr. Bartlett remarked that it was doubtful whether, because rivers in their flow will oxidise impurities, these bodies were rendered innocuous. Nearly all are agreed that the purity of a water is tested chiefly by the absence of organic matter, not by the proportion of mineral constituents. In the deep chalk springs considerable filtration takes place through the chalk. Rivers are made up for the most part of surface water; a very small part of the water has passed through strata. It is needful to decide definitely what should be considered as mineral impurities, and what as organic, and how much filtration is necessary to render impure waters potable.

Dr. Bischoff remarked upon the statement, "if all the organic matter is oxidised the water is wholesome, but all depended upon the conditional 'if.'" The reports of the Registrar-General show that large quantities of organic matter are detectable by the microscope in many drinking-waters. If we are to rely upon rivers for our water-supply, what is to be done in time of floods to oxidise all the organic matter?

Mr. Bailey Denton inquired whether the Professor would allow sewage to be discharged into the river-water used for drinking purposes, and if not, how are towns to dispose of their sewage? Is it to be "treated" first? There are rivers in the North so dark that the Commissioners said they might have written their report with water from them instead of ink.

Dr. Tripe remarked that it was a question whether rivers could be so purified by oxidation as to make them fit for drinking purposes, with as little risk to life as other eventualities of daily occurrence. We are bound to protect the public from secret dangers as much as possible. If typhoid and other germs get into water, it is impossible to ascertain when they have been destroyed. It may be that they are capable of propagation in this medium. A filter may remove cells of organic origin, but the spores remain.

The President remarked that the mineral constituents are not so important as the organic. People get acclimatised to drink with impunity the water of a given locality, whereas by changing their residence they often suffer from impure water. When water is polluted by excrementitious matter it is undoubtedly injurious to health, and may produce disease of an infectious nature. Water in which unoxidised matter exists must be regarded as bad, although by oxidation important changes are being effected in its constitution. Filtration will not remove infecting organisms. Undoubtedly rivers are more polluted now than formerly. Some of the members might remember when the water of the Thames was pumped up from the river at London-bridge for drinking purposes.

Professor Ansted, in his reply, said that the question of filtration did not rightly belong to the subject under discussion. We have filtration through the surface, and that through rocks. The water of chalk wells passes quickly through fissures, and not through the chalk itself, in much the same condition as it entered. The quantity of water obtainable from chalk wells is very limited. Rivers, in their passage through a sparsely peopled country, become purified. In some cases the water is too much polluted for drinking purposes. Some populations, under certain idiosyncrasies of health, suffer from waters which would not affect other people. There are so many other causes which produce disease that water is not the only factor to be considered. Disease germs may exist in spring-water as in river-water. A potable water is one in which no impurity is discoverable. Undoubtedly sewage should be excluded from rivers. Often where old churchyards are dug over, fever-germs are disturbed. Long-continued residence on the same soil may cause fever-germs to remain buried and dormant—*e.g.*, the prevalence of fever in Rome may be due to the thousands of dead bodies lying in the Catacombs. It is still an undecided question as to the desirability of sewage farms. The method of burning sewage, as at Manchester, seems well worthy of more extended trial.

THE PATHOLOGICAL SOCIETY.

Tuesday, November 20.

Charles Murchison, M.D., LL.D., F.R.S., President, in the Chair.

Aneurism of the Hepatic Artery in the Cavity of an Abscess of the Liver.

Dr. Pearson Irvine showed this specimen. The patient, a soldier, aged forty-five, had served in India nineteen years, and had suffered from frequent attacks of dysentery and ague. He was discharged in 1876, and until six weeks before his admission into Charing-cross Hospital, on October 10, 1877, had for a year enjoyed good health. Then he began to suffer from perversion of taste, disinclination for and swelling after

food, and from a peculiar throbbing in the epigastrium. A fortnight later he had a severe hæmatemesis, and fainted in the street; six days later another attack of a milder kind; and a few days before admission he again vomited large quantities of blood, which "came up in streams," and was followed by fainting. When examined on admission a distinct localised fulness, with sense of resistance, was found in the epigastrium; but next day this was gone, and the patient passed tarry blood by the bowels. He had on several occasions quasi-convulsive seizures, and attacks of fainting; frequently passed blood by the bowels; but did not vomit until shortly before death, which occurred on October 25. He complained for some time of epigastric pain and tenderness. Post-mortem the stomach was adherent, not very firmly, to the under surface of the left lobe of the liver, over the seat of an abscess the size of a small orange. Perforation had occurred between the hepatic abscess and the stomach, and in the latter a large blood-clot was found. The abscess contained a quantity of greyish-yellow odourless pus. On a primary branch of the left hepatic artery, which ran along its wall, was an aneurism the size and shape of a large almond, filled with moderately firm clot, and having well-defined walls. It fitted into irregularities on the inner wall of the abscess, and had evidently caused perforation of the abscess into the stomach, and ruptured at the point of least support. The spleen was not enlarged. Dr. Irvine thought the specimen interesting as analogous to what happens in the cavities of phthisical lungs, where aneurisms, from want of support of vessels, are now so commonly met with. There seemed no doubt that this aneurism arose in exactly the same manner as pulmonary aneurism. Possibly, also, as was pointed out at a late meeting, some of the aneurisms met with in the brain, in the vicinity of softened tissues, were due to want of support of the vessels. The specimen had also an importance in association with such cases as that of aneurism of the cœliac axis, which Dr. Irvine showed at the last meeting of the Society, where suppuration had, by involving the walls of the vessel, led to their failure. Clinically the case was interesting, as in it much the same group of symptoms as those met with in some of the cases of aneurism of the hepatic artery outside the liver (five only recorded) existed. It was worthy of note that Dr. Ross, of McGill University, has lately described an aneurism of the right branch of the hepatic artery, which was associated with suppurative hepatitis.

The PRESIDENT said that perhaps aneurism in this situation might prove not to be so rare as was supposed, if it were carefully looked for. Free hæmorrhage was not uncommon from opened abscess or hydatid of the liver. Dr. Irvine's case was probably the first on record of the kind.

Aneurism in Wall of Ulcer of the Stomach.

Dr. DOUGLAS POWELL showed this specimen. A man had been in the Brompton Hospital for three months, suffering from excavation of the lungs, and localised empyema of the right side. On October 17 he suddenly brought up a quantity of purulent matter. The pleura refilled, and signs of peritonitis supervened. He was improving under treatment by opium, etc., when, seven days later, he was suddenly seized with copious hæmorrhage from the mouth, and died in a few minutes. Post-mortem: The stomach contained much blood. On the lesser curvature, midway between the pyloric and œsophageal openings, was found a shallow ulcer, as large as a florin. On its floor was an oval aneurism, as big as a pea, with an aperture at its free extremity. It proved to be connected with a branch of the gastric artery. In the duodenum was found a second ulcer, and the base of this was adherent to the liver by lymph, which appeared to have lately been partly disturbed. General peritonitis was present in an early stage. Dr. Powell said that this specimen belonged to a set of aneurisms, which had now been found in the lung, the liver, and the stomach, and of which the specimens which he had brought forward from the lungs of patients of all ages, and the specimen just shown by Dr. Irvine, were examples.

Dr. C. T. WILLIAMS asked whether these ulcers might not have been tubercular.

Dr. POWELL replied that no other ulcers were found in the intestinal tract.

Influence of Pleuritic Effusion on Tuberculosis.

Dr. POWELL also described the condition of the lungs in the subject from which the preceding specimen had been taken. A large cavity occupied the apex of the right lung, and a smaller cavity the apex of the left; there was old caseous disease of the extreme left apex, and scattered miliary tubercles pervaded both lungs below. In the left lung the fresh tuberculosis was general, but in the right lung the process involved that part only which was not compressed by pleuritic fluid. At the distance of an inch below the apical cavity the tubercular growth terminated abruptly. Dr. Powell said that he believed that pressure on the lung exempted it from tuberculisation, and that effusion might even cure a pre-existing tuberculosis.

Hyperostosis associated with Cancer.

Dr. CAYLEY showed specimens of bones from a case of this nature. The patient, a man of sixty-five, died on October 6, in the Middlesex Hospital. There was no family history of cancer, and he had previously enjoyed good health. In 1873 he consulted Mr. Nunn for fistula connected with the alveolus of the lower jaw. He was also dyspeptic. Two years and a half ago he had rheumatism in the legs. For fifteen months before his admission he had been suffering from bronchitis, and he came under Dr. Cayley's care with dyspepsia, vomiting, cough, expectoration mixed with blood, pain, and emaciation. Physical examination indicated shrinking of the right lung; and there was a loud systolic murmur over the heart. The skin was studded with the small nævi to which De Morgan had drawn attention in connexion with cancer. The tibiæ were curved and enlarged, but not painful nor tender; the lower jaw was considerably enlarged generally, and the left parietal bone and clavicle were also affected. The patient improved at first, but died suddenly from dyspnœa. Post-mortem the right lung was found to be carnified and adherent, with cancerous masses and cavities at the apex. The liver contained eight or ten cancerous nodules. The mucous membrane of the stomach was atrophied. The tibiæ were much increased in circumference, and this enlargement proved to be chiefly due to thickening of the compact tissue: the medullary cavity was enlarged, and filled with gelatinous marrow. The compact tissue was remarkably porous. The lower jaw was greatly thickened and almost edentulous, a bicuspid that remained being lodged in a cavity, and presenting nodulation of the crusta petrosa. The bones of the calvaria were greatly thickened and of a porous character, and the left clavicle was in a similar condition. Dr. Cayley said that this case belonged to the group described by Sir James Paget in the new volume of the *Medico-Chirurgical Transactions*. In some of these cases also the disease was associated with cancer.

Dr. CAYLEY also exhibited, for Mr. Nunn, a cast of the left lower limb, showing hyperostosis of the tibia. A lady, aged seventy-five, when she was first seen by Mr. Nunn in 1871, presented swelling of the left leg, which exceeded its fellow in circumference by one inch and a half. The condition was attributed to a fall out of bed. At that time there was severe rheumatic pain of the knee. Twelve months later the pain had gone, but the tibia had increased in size and was curved. Next year (1873), similar enlargement was found of the right humerus. In 1874 there was a constant distressing cough, with expectoration. At the present time the lady was in fair health, being eighty-one years of age. The family history was one of remarkable longevity; rheumatism had appeared in several of the members.

Mr. BUTLIN asked Dr. Cayley what the nature of the "cancer" of the lung was in his case.

Dr. CAYLEY replied that it was medullary cancer.

Syphilitic Tumour of Cerebral Artery.

Dr. GREENFIELD gave a further report of the microscopical appearances of a syphilitic tumour of the anterior cerebral artery, which he had shown to the Society two years ago. The tumour had been as large as a pea, and had given rise to thrombosis and softening. There was no certain history of syphilis in the case. The microscopical examination was somewhat imperfect on account of the softness of the growth. It illustrated well the character of an early gummatous growth; its centre being caseous, and the outer portion fibrous. The chief interest was connected with the bloodvessels. The main structure of the tumour was of roundish cells, with a reticulum between them. The growth had probably taken place around small vessels; and the new vessels of the growth were in both parts of the tumour much thickened by a fresh growth from their endothelium, which had gradually obstructed them. In the case of pre-existing vessels, the new growth appeared in the outer coat; but in the new vessels it was purely endothelial in origin. Dr. Greenfield considered this an excellent example

of the special characters of a syphilitic growth. It had long ago been shown at the Society that caseation was probably due to obliteration of vessels. Some pathologists had stated that the mode of growth described occurred in certain other diseases; but it certainly did not occur to anything like the same extent.

The PRESIDENT remarked that the evidence of syphilis was doubtful in this case; but the point was of great pathological importance, whether this kind of growth was peculiar to syphilis or not.

Dr. GOODHART said that he had a specimen of fibroid change without syphilitic history, in which both vertebral arteries were blocked by growth inwards. There was no other evidence of syphilis in any other part of the body.

Dr. COUPLAND asked whether Dr. Greenfield had seen psammoma of the dura mater arising from the endothelium in connexion with the bloodvessels.

Dr. GREENFIELD replied that he had a specimen of psammoma, which was a fine endothelioma. With respect to his present tumour, it had occurred in a man who was a sailor, and its naked-eye appearances were all those of syphilitic growth. An almost precisely similar change might occur in cases of old thrombosis. But the change was, in this instance, found not in one vessel only, but in all the minute vessels of the new growth. He considered it something quite peculiar.

Hæmorrhagic Pachymeningitis.

Dr. GREENFIELD also showed this specimen of a disease which, if regarded as common in chronic mental disease, did not appear to occur frequently in connexion with alcoholism. The subject, a man of thirty-nine, was admitted into St. Thomas's Hospital with a simple comminuted fracture of the leg. He was drunk at the time of the accident, and had had delirium tremens more than once. Delirium tremens supervened soon after the man's admission, and he was treated with chloral and bromide of potassium. One evening, convulsions came on, the temperature rose, and death occurred in three hours, the urine being loaded with albumen. Seventeen hours post-mortem, in cold weather, the body was warm to the hand, and the blood was fluid and of a deep plum colour. The organs generally were healthy. On the arachnoid surface of the left half of the dura mater was a cyst containing blood, and presenting the appearances of a "hæmatoma." There was no hæmorrhage in the brain itself, in the pia mater, or on the surface. Evidences existed of old atrophy of the brain. The vessels in the wall of the cyst next to the contents appeared cavernous. In the lower part of the spinal canal was a quantity of semi-coagulated blood. In the lungs the blood was very fluid. This condition of pachymeningitis hæmorrhagica was also known as hæmatoma of the dura mater, and, though said to be of frequent occurrence among the insane, had never been brought before the Society. With respect to the connexion between it and delirium tremens, the disease had been produced experimentally in dogs by the administration of alcohol; and had been observed in cases of chronic alcoholism and of delirium tremens. Virchow had described the lesion as produced by a growth from the dura mater, into which hæmorrhage afterwards occurred; but Wilks and Moxon had stated their belief that all might be due to hæmorrhage. In this case there was evidence of hæmorrhage in the spinal canal.

The PRESIDENT asked what the state of the spleen was, because similar appearances on the dura mater occurred occasionally in fevers. It was a fact that when Kremiansky's many cases of hæmorrhagic pachymeningitis were published in *Virchow's Archiv* there was abundance of relapsing fever and typhus along with them in St. Petersburg. It was therefore a question whether this cranial lesion was not due to fever. Sir William Jenner had observed it in typhus, and he (the President) had done the same.

Dr. GREENFIELD replied that the spleen in the present case was described as "resembling that in typhus"; and all the viscera were in a state of parenchymatous degeneration. But the pachymeningitis must be considered old, for the delirium tremens was of but four days' duration, and supervened on a sudden accident.

A Case of Chyluria.

Dr. RALFE brought forward this case, and exhibited specimens of the urine and the blood. The patient, a gentleman of thirty-seven, was seen on October 31 for dyspepsia. He was a native of Barbadoes; was ruptured at the age of five; had ague between the ages of twelve and twenty-one; and at twenty-seven went to live in New York, where he had no ague, but where he suffered from his first attack of "hæmorrhage from the kidneys." Returning to Barbadoes, he had ague again more than once, and frequent attacks of chyluria, one of which lasted for two months on end. Coming to London, the patient had here two attacks of chyluria. The "ague" took the form of dyspepsia, "agueish" feelings, pain in the calf of the left leg, and flatulence, abdominal pains, and vomiting. The periods of chyluria were characterised by pain in the back and milky urine. The urine was always clear in the morning, but became milky in the course of the day. The patient was a sallow man of middle size; the hepatic and splenic dull areas were somewhat enlarged. On November 10 he passed the specimen of urine exhibited, three days after being seen. The liquid was of a milky appearance, without urinous odour, was slightly alkaline, and coagulated in a few hours. Its composition was as follows in 100 parts:—Water, 94·35 parts; solids, 5·65 parts. The solids consisted of—albumen 1·45, fats 0·78, extractives 1·88, and salts 1·02 parts. The albumen comprised—serum-albumin in small quantities; fibrin; and albumen precipitated by acetic acid, a considerable amount. The fatty matters were saponifiable. The extractives contained urea and glucose. Of extreme importance was the fact that the milky urine readily passed through filter-paper, and along with it even its bloody deposit. It therefore appeared that some of the albumins had passed into the conditions of peptones. Microscopically, the urine had been examined by Dr. Mitchell Bruce, who found that it presented the following characters:—A grey fluid, semi-opaque from the presence of excessively minute granules; red blood-corpuscles slightly altered in appearance; a few highly refracting protoplasmic particles; masses of corpuscular matter, from the borders of which large oil-drops were escaping; a few peculiar elongated spear-shaped bodies, which were possibly filariæ sanguinis hominis altered by the urine; abundant bacteria; and a few casts. Dr. Ralfe said that, considering the diffusibility of some of the albumins in this specimen of urine, the fluid might easily have been pressed through the walls of the renal capillaries by ordinary tension, without rupture of the vessels.

Dr. DICKINSON said that it was doubtful whether the bodies found in the urine were filariæ, for these had never been observed but in the East Indies. With respect to the association of chyluria and ague, he believed that this was rare; ague was rather associated with intermittent hæmatinuria. Lewis's discovery of the filaria in chyluria was certainly most remarkable, but the bloodworm had not been found in all cases of chylous urine. At present he had a case of chyluria under his care in St. George's Hospital, in a young woman who had never been out of England; neither in the blood nor in the urine was filaria to be found.

Dr. MORISON related a case of chyluria, at present under his care, in a lady of fifty-six, an Algerian by birth, but for the last eighteen years a resident in England. Since the climacteric period she had had almost constant chyluria, the urine being clear in the morning, but becoming milky as the day wore on. The patient suffered from pain in the right side of the back, increasing in severity until something seemed to burst, when mucoid clots were passed in the urine. Neither the urine nor the blood presented filaria. The urine always contained sugar, being of specific gravity 1030 to 1020; while an etherial solution of the urine deposited crystals of margaric acid. If the milky fluid was diffusible, the agency of filaria was not necessary to account for its passage from the vessels.

Mr. BERKELEY HILL said that he had seen a case of chylous discharge from the thigh of a man, who passed as much as six ounces at a time by orifices, from which the fluid "wept" or even squirted at times. The occurrence of the discharge was preceded by nausea and shiverings, and followed by lassitude. The fluid was pinkish in colour from its mixture with blood; it contained no filaria, and diffused through filtering-paper. The man had never been out of England.

Mr. MORRANT BAKER said that Mr. Hill's patient had been in several London hospitals, and his case had been reported at the Society years ago (see vol. xix. of the *Transactions*). Why was not the fluid clear, and not milky, that came from the thigh?

Dr. DICKINSON said that he doubted greatly whether the chylous discharge came from the kidney. Casts were rare; and one could hardly conceive the molecules of chyle coming through the walls of the renal capillaries. There was more probably a discharge of chyle through the walls of the bladder.

Dr. RALFE replied that his patient had pain in the testes, and other symptoms pointing to the kidney.

The PRESIDENT requested Dr. Dickinson and Dr. Morison to send specimens of the urine from their cases of chyluria for examination by the Chemical Committee of the Society.

OBITUARY.

ROBERT KERSHAW, M.R.C.S.

MR. KERSHAW was born at Heywood, in Lancashire. He was educated at Middleton, and afterwards at the Liverpool Collegiate School. He had a decided desire to enter the medical profession, but he belonged to an old and well-known family, which at that time had an extensive business as cotton-spinners, and, in compliance with the wishes of his friends, he also went into business. Shortly after the cotton panic, however, he relinquished business; and at the age of thirty-nine entered as a medical student at the London Hospital, thus carrying out what would have been his own wish from the very first, had not circumstances rendered it desirable that he should adopt a different course. While engaged in trade he had taken an active part in the Militia movement, and for some time was Captain of the 4th Royal Lancaster Militia. He was an expert rifleman, and one of the "crack shots" of his neighbourhood. His business training, however, fitted him to enter on his medical studies with an earnestness and methodical regularity which from the first were a guarantee of success. These qualities were manifest in all he did and undertook, and were advantageous to many others besides himself, for the example of such a man is infectious. He gained several prizes during his studentship, and finally carried off the medical scholarship—a fitting termination to a very successful career. The resident appointments, under these circumstances, were all open to him, but he was obliged to decline them for family reasons. He filled, however, important non-residential appointments, both medical and surgical, one of the most important being that of private assistant to Dr. Sutton in the pathological laboratory; here his precise, regular habits and love of order were of the greatest importance, no less than his mechanical skill in all the kinds of practical work, including microscopy, which now engaged his attention. He received a well-merited tribute in connexion with this work from Sir William Gull and Dr. Sutton, at the reading of their remarkable paper on arterio-capillary fibrosis at the Pathological Society last session. In 1876 the London Hospital Medical College was reconstituted on the basis of closer amalgamation and co-operation of the College and Hospital authorities. The latter felt the importance of having all their resident medical officers as highly trained as it was possible to get them, and in order to secure this they determined to pay over to the school funds an annual sum of money. A contingent of lay members was then added to the Medical Council, which was henceforth to be called the "College Board"; and this Board was to watch over the College and control it in all its departments. It can easily be imagined that this reformation, unless carried out very carefully, would have met with great opposition. The Board, in electing Mr. Kershaw as their secretary, not only paid a great compliment to him personally, but they gained just the man who was of all others—by his age, his previous business training, his professional education and status, and his habits of mind—best fitted to fill such an appointment; for he moreover brought with him an accurate knowledge of all the defects and shortcomings of the old system: he was personally known by, and of course knew personally, both the members of the staff and the students of the school, and was esteemed by all alike. Under his management the new scheme has worked remarkably well, and is already beginning to bear fruit. The duties of such a position are necessarily of a delicate and not always agreeable nature, but Mr. Kershaw discharged them admirably and so conscientiously as to gain the entire approval of his Board.

About three years ago he had had a rather severe attack of perityphlitis, but, thanks to careful nursing, he had pulled through. Three days before his death he was seized with severe and sudden abdominal pain, and symptoms of collapse coming on very quickly, it was feared that perforation of the colon or vermiform appendix had taken place. A post-mortem examination, however, revealed volvulus of the small intestines. Mr. Kershaw will long be remembered, and always regretted, at the London Hospital; and it will be very difficult to find a man as well adapted as he was for the duties of his vacant post.

MEDICAL NEWS.

APOTHECARIES' HALL.—The following gentlemen passed their examination in the Science and Practice of Medicine, and received certificates to practise, on Thursday, November 22:—

Bigger, Samuel Ferguson, 2, Albert-street, N.W.
Crick, Samuel Arthur, Cosby, near Leicester.
Evans, Charles Walter, Arlington-road, N.W.
Rugg, James Foster, Middle-street, Brighton.

The following gentlemen also on the same day passed their Primary Professional Examination:—

Atkinson, John Mitford, London Hospital.
Evans, James William, University College.
Fox, Joseph Tregelles, London Hospital.

APPOINTMENTS.

*** The Editor will thank gentlemen to forward to the Publishing-office, as early as possible, information as to any new Appointments that take place.

LAWSON, ROBERT, M.B., Senior Assistant Medical Officer to the Third Middlesex Asylum—Medical Superintendent of the Wonford House Lunatic Hospital, Exeter, *vice* Thomas Lyle, M.D., appointed to be a Consulting Physician to the Hospital.

NAVAL, MILITARY, &c., APPOINTMENTS.

ADMIRALTY.—Staff-Surgeon William Robert Bennett, M.D., has been promoted to the rank of Fleet-Surgeon in her Majesty's Fleet, with seniority of October 31, 1877.

WAR OFFICE.—Surgeon-Major Andrew Knox, half-pay, Medical Department, has been permitted to commute his retired allowance.

BIRTHS.

BREWER.—On November 25, at 201, Queen's-road, Dalston, the wife of Alexander Hampton Brewer, L.R.C.P. Lond., M.R.C.S.E., of a daughter.

DURANT.—On November 19, at Cheltenham, the wife of E. Durant, L.R.C.P., M.R.C.S., L.S.A., of a son.

TAYLER.—On November 25, at 224, Lewisham High-road, S.E., the wife of Francis T. Tayler, M.B., L.R.C.P. Lond., of a daughter.

WOOD.—On November 25, at 86, Seymour-street, Hyde-park, W., the wife of Henry Thorold Wood, M.R.C.S., of a son.

MARRIAGES.

HOPKINS—FENN.—On October 29, at Manora, Kurrachee, India, Nathaniel Hopkins, M.R.C.S. Eng., Surgeon-Major, Civil Surgeon of Kurrachee, to Lucy Vanderzee, youngest daughter of the late Thomas Harrold Fenn, Esq., of Nayland, Suffolk.

HORNE-STREET.—On November 21, at the Church of St. John the Baptist, Westbourne, Sussex, Thomas Horne, L.R.C.P. Edin. and L.R.C.S. Edin., of Sandwich, Kent, to Mary Pauline, second daughter of the late James C. Street, C.E., of Penge.

LUSCOMBE—ROBINSON.—On November 22, at the parish church, Esher, William Edmund Luscombe, L.R.C.P. Edin., M.R.C.S. Eng., second son of the late Rev. Edmund Peard Luscombe, M.A., of Melbecks, Richmond, Yorks, to Catherine, fifth daughter of the late Edward Robinson, Esq., of Milbourne Lodge, Esher, Surrey.

NICHOLS—HARRISON.—On November 17, at St. Luke's, Chelsea, John Moore Nichols, L.R.C.S.I., to Margaret Mary, second daughter of the late Thomas Harrison, Esq., of West Hampton, County Dublin.

VANNECK—ARMSTRONG.—On September 24, at St. James's Church, Toowoomba, Queensland, the Hon. Walter Vanneck, fourth son of Lord Huntingfield, of Heveningham Hall, Suffolk, to Catherine Medora, eldest daughter of William Armstrong, M.D., Toowoomba.

DEATHS.

CLARK, JAMES, eldest and last surviving son of Samuel Clark, M.D., of Folkestone, at Burgess-hill, near Brighton, on November 21.

DRURY, JOHN THOMAS COCKIN, M.D., at Mentone, Alpes Maritimes, on November 24, aged 44.

GIMBLETT, JOHN, M.D., of Lydney, Gloucestershire, at Weston-super-Mare, on November 13, aged 37.

GUPPY, WM. GOOD, Surgeon, eldest twin son of Thomas Stokes Guppy, M.D., of Falmouth, at Erzeroum, of fever, on November 17, aged 22.

HALLETT, JOHN JAMES, M.D., at Buninyoung, Victoria, Australia, on September 19, aged 69.

MARSON, JAMES TURNER, F.R.C.S E., late Resident Surgeon to the Small-Pox and Vaccination Hospital, Upper Holloway, for upwards of forty-one years, at 11, Liverpool-terrace, Worthing, on November 15.

MOORE, PERCY ST. AUBYN DANIEL, only son of J. Daniel Moore, M.D., F.L.S., at 3, Queen-street, Lancaster, on November 17, aged 7 years.

PIRRIE, GEORGIANA ISABELLA, youngest daughter of William Pirrie, M.D., Professor of Surgery in the University of Aberdeen, at Clapton, London, on November 23.

VACANCIES.

In the following list the nature of the office vacant, the qualifications required in the Candidate, the person to whom application should be made and the day of election (as far as known) are stated in succession.

Inverness District Asylum.—Assistant Medical Officer. Candidates must be duly qualified and registered. Testimonials to Dr. Aitken, the Medical Superintendent, on or before December 12.

Queen's Hospital, Birmingham.—Resident Physician and Resident Surgeon. Candidates for these appointments must be registered practitioners. Testimonials, with certificates of registration, to the Secretary, on or before December 1.

UNION AND PAROCHIAL MEDICAL SERVICE.

*** The area of each district is stated in acres. The population is computed according to the census of 1871.

RESIGNATION.

East Ward Union.—Mr. J. P. Brumwell has resigned the Ravenstonedale District; area 33,200; population 2907; salary £17 per annum.

APPOINTMENTS.

Berkhampstead Union.—Augustine Dennis, L.R.C.P., M.R.C.S., to the Berkhampstead District and the Workhouse.

Keynsham Union.—Nathanael Crisp, M.R.C.S., L.S.A., to the Workhouse.

Newark Union.—George K. Barton, F.R.C.S. Eng., M.D. Aber., to the Fulbeck District.

Rochdale Union.—Thomas Collingwood, M.R.C.S., L.S.A., to the New Workhouse.

Thingoe Union.—Charles E. Wing, M.R.C.S. Eng., L.R.C.P. Edin., L.S.A., to the Third District and the Workhouse.

The Middlesex Hospital.—Dr. Robert Liveing has just been appointed Lecturer on Dermatology at this hospital, a post recently created by the Committee with a view to further the study of that important subject among the students.

Treatment of Burns and Scalds.—Dr. Watson, of Boston, recommends the bicarbonate of soda as an application, this being sprinkled over the injured part, and a wet cloth applied over it. The pain is almost immediately relieved, and the healing process goes on very rapidly.—*New York Med. Record*, October 20.

The Royal Academy.—Professor John Marshall, F.R.S., on Wednesday last, at Burlington House, commenced his fifth course of nine lectures on Anatomy. Some of the Royal Academicians were present as well as his large class of most attentive students. These lectures, which are delivered on Mondays, Wednesdays, and Fridays, at eight o'clock, will be brought to a close on Monday, December 17.

The German Universities.—Professor Köbner, of Breslau, has been obliged to resign the direction of his clinic for skin diseases and syphilis at Breslau, owing to bad health; and Dr. Oscar Simon, of Berlin, the author, *inter alia*, of an excellent monograph on "The Localisation of Diseases of the Skin," which has failed to attract the attention it deserves in this country, has been called to succeed him as Professor Extraordinary. Dr. Linhard, Professor of Surgery at Würzburg, has lately died, at the age of fifty-six. Professor Gegenbauer, of Heidelberg, was recently offered the chair of Anatomy in the University of Amsterdam, but has refused it.

Death of M. Bouvier.—The Académie de Médecine has just lost one of its oldest and most zealous members in the person of M. Bouvier, of the Section of Anatomy and Physiology. M. Bouvier, who had almost entirely lost his sight, was walking on Wednesday in the Tuileries Gardens, and went too near the great basin, so that he fell into it. Although he was immediately rescued, the fright and cold induced pulmonary congestion, to which he succumbed a few hours afterwards. He was born in 1799, and was elected into the Academy in 1839. His works on Orthopædics created for him a very honourable reputation, which in 1837 was acknowledged by the Académie des Sciences conferring on him a prize of 6000 fr.—*Union Méd.*, November 24.

The New West Herts Infirmary.—The old Infirmary at Hemel Hempstead was founded in 1826 by Sir John Sebright, who expended no less than £13,000 on its building and endowment. The whole cost of the new building just opened, when completed, will considerably exceed £13,000. The site of the new building adjoins that of the old, and is admirably suited for the purpose. The building, which is in the Italian style, perfectly plain, and constructed entirely with a view to hygenic requirements, has a very pleasing appearance. It is divided into three blocks: the centre is for the administrative offices and the out-patients, while the in-patients will occupy the two wings. It will hold fifty patients. The sum actually received on account of the building fund is £8018.

Vaseline as an Excipient.—In the name of Dr. Galezowski, Dr. Guéneau de Mussy directed the attention of the Société de Thérapeutique to the importance of the new substance, vaseline (*Gelatum petroleum*), as a substitute for fatty matters now in use, inasmuch as it undergoes no alterations, and possesses the power of preserving the properties of the substances it is mixed with, without modifying them—even nitrate of silver. M. Limousin, after corroborating the above opinion, added that vaseline had been known in France for eighteen months, and that its price, although considerably higher than that of lard, is still not excessive. Mixed with lard, also, it is capable of rendering great services. It is much employed in perfumery united with lard (one part of lard to three of vaseline), because used alone it does not retain the odours. Unlike lard, after having been liquefied, it regains all its primitive properties on cooling.—*Gaz. Hebd.*, November 23.

Royal College of Surgeons.—The half-yearly examination for the Fellowship of this institution was brought to a close on Saturday last, when ten candidates were reported to have acquitted themselves to the satisfaction of the Court of Examiners, and at the next meeting of the Council will, in all probability, be admitted Fellows of the College. Only three candidates were rejected. We cannot publish the names until confirmed by the Council. The following were the questions on Pathology, Therapeutics, and Surgery at the written examination on the 22nd ult., when it was necessary to answer all four of the questions:—1. Describe the methods adopted for excision of the whole or part of the superior maxillary bone; and state what vessels and nerves are likely to be implicated in these operations. 2. Give the pathology of acute specific bubo, from its commencement to its termination in spontaneous cure. In what way may treatment modify the progress of such a case? 3. On what morbid changes may stricture of the rectum depend? Describe the diagnostic characters of each variety, and its appropriate treatment. 4. What are the accidents and risks incidental to lithotrity? How are they to be avoided? and, if they occur, how are they to be treated?

The Philadelphia Centennial Exhibition.—It seems, from the report of the Medical Director, that there was an enormous percentage of very serious illness among the Japanese exhibitors, due partly to the change in mode of life and climate, and largely to their mode of living. Their dwellings were so slightly built as to afford very little protection against either heat or cold; and in cold weather the occupants were crowded into rooms almost hermetically sealed, with no outlet whatever for the emanations from the body or for the fumes of the charcoal braziers which furnished the only means of heating. No wonder that 18 per cent. suffered from typhoid fever. At the Centennial Hospital were treated 6463 cases of injury and disease. Although there were acres of moving machinery, and the railway carried around the grounds 3,784,142 passengers, there was no serious accident; there were only four deaths upon the grounds, no births, and but one abortion. These facts furnish strong proof of the admirable management of the authorities, of the modesty which keeps the American female secluded during the latter months of her pregnancy, and of her retentiveness during the earlier days of her sorrow. Dr. Pepper, we think, makes out a very clear case that there were no foci of fever-poison on the grounds, and that the water-supply and drainage were very carefully attended to, and were good.—*Philadelphia Med. Times*, Sept. 29.

German and French Medical Services.—Signora Jesse White Mario, in her paper in *Fraser* for November, "Garibaldi in France," speaking of Dijon during the temporary evacuation by the Prussians, says:—"The spacious Lycéum and chief Hospital were full of Prussian wounded, left by General Werder in charge of their own doctors, surgeons, and *infirmiers*, money being consigned to the Syndic for their maintenance. Never have I seen a hospital in which such order, cleanliness, and discipline reigned. Compared with the hospitals in which the poor French soldiers were crowded, these wards were cheery homes. I could not then account for the difference, as, assuredly, the French surgeons are a most humane and able set of men, and the French authorities could not have willingly allowed the enemy's wounded to be better cared for than their own; but before the war ended I convinced myself that no small portion of the success of the Prussians was due to the perfection of their ambulances and hospital system, to the absolute independence and responsibility of the Medical Corps, and to the fact that that body, in

other countries so slighted and rendered subordinate to the military, is in Prussia honoured and respected, and placed on an equal footing with the other departments of the army.

UNIVERSITY INTELLIGENCE.—CAMBRIDGE.—Mr. A. M. Marshall, Senior in the Tripos of 1874, has been elected to a Fellowship in Natural Science at his own College, St. John's. His able papers on Embryology have been an important addition to the researches which are making the British school again famous in this subject, and he is the first Doctor of Science in Comparative Anatomy in the University of London. Two of the newly elected fellows of St. John's are studying Medicine—viz., Dr. Marshall and Mr. McAlister, the last Senior Wrangler. At Trinity the open fellowship has been adjudged for the first time to a non-member of the College, Mr. J. N. Langley, B.A., of St. John's, whose services as Demonstrator of Physiology to Dr. Foster are highly appreciated, while his originality and perseverance in research promise to make him, before long, much more widely known than at present. The new buildings for anatomy and physiology are advancing to completion, and are partially occupied, Mr. Balfour's two practical courses of Comparative Anatomy being accommodated in them. Dr. Foster will transfer much of his work here after Christmas. The new buildings will be almost too small as soon as completed, as Dr. Foster has fifty men and several ladies working in his elementary classes this term—a very large number when it is considered that this is voluntary and not prescribed work. Dr. Foster, we understand, sets his senior pupils to lecture on the subjects they make a special study; thus during the present winter the advanced class will receive lectures from Dr. Gaskell, Mr. Langley, and Mr. Lea. Mr. Vines has returned from working in Germany with Sachs, and is lecturing to a large class on Vegetable Physiology.

NOTES, QUERIES, AND REPLIES.

He that questioneth much shall learn much.—*Bacon.*

Dr. J. Bagnell, Pau.—Received with thanks.

Amicus, Suffolk.—We understand the statue to be erected in the Pavilion grounds, Brighton, in memory of the late Sir Cordy Burrows, is completed, and ready to be conveyed to Brighton from the London studio.

Picnic.—The Corporation of London at the present time are the owners of 2975 acres of land in the northern portion of Epping Forest, and seventy-three acres in the southern portion. When the purchase is completed of the manors of Epping, Bury, and Chambers, already formally agreed to, the quantity in the northern portion will be increased to 3466 acres, lying together, and which can be made available for the recreation of the public.

M. C., Bayswater.—The last Indian Government *Gazette* shows that in the current year 19,273 persons had been killed by wild animals and snakes. In the Central Provinces the deaths from this cause increased from 617 in 1875 to 1098 in 1876.

Gymnastics.—The London School Board propose to erect in the playgrounds of eighteen schools suitable gymnastic apparatus.

A Young Doctor.—The new "Volunteer Sick-Bearers' Association" is completely organised. Ambulances, and all the *matériel* required for instruction, have been provided for the Association by the Order of St. John of Jerusalem. A series of lectures and drills have already begun at the rooms of the Society of Arts, John-street, Adelphi, for training the officers and men of the metropolitan volunteers.

Veritas.—Of the three presidencies of British India, Bombay is the most sparsely populated, having only 131 persons to each square mile, while Madras has 243, and Bengal 395.

Argus.—Professor Huxley's observation, both as to the value of scientific doubt, and as to the nature of that sort of doubt which the student should alone permit himself, was—"There is a path that leads to truth so surely, that anyone who will follow it must needs reach the goal, whether his capacity be great or small. And there is one guiding rule by which a man may always find this path, and keep himself from straying when he has found it. This golden rule is: give unqualified assent to no propositions but those the truth of which is so clear and distinct that they cannot be doubted. The enunciation of this first commandment of science consecrates doubt. It removes doubt from the seat of penance among the grievous sins to which it had long been condemned, and enthrones it in that high place among the primary duties which is assigned to it by the scientific conscience of these latter days." But "you must remember that the sort of doubt which has thus been consecrated is that which Goethe has called 'the active scepticism, whose whole aim is to conquer itself,' and not that other sort, which is born of flippancy and ignorance, and whose aim is only to perpetuate itself as an excuse for idleness and indifference."

M.D.—We are not aware whether there is any foundation for the rumour that Mr. Albert Grant's house, at Kensington, is to be converted into a hospital for the well-to-do classes. It is estimated that nearly half a million of money would be required to complete the scheme.

Lex.—The Council of the College of Surgeons have the power to remove the name of any of its members *convicted* of misdemeanour, etc., and, we believe, have invariably exercised it, except in the case of the person mentioned—the late William Brett, whose name, as usual, was ordered to be removed, but at the ensuing meeting of Council the decision was reversed. A superior power to the Council of the College of Surgeons removed his name about two years after—viz., Death. You will find the particulars in the "Proceedings of the Council," published at the time in the *Medical Times and Gazette.*

Dr. Williams, Manchester.—At the suggestion of Dr. Rugg, Mr. Silverlock is about publishing the description of book to which you refer, and which he calls the "Medical Practitioner's Day-Book and Visiting List" combined, being a simple record of the daily work of the medical practitioner. Judging from the few sheets submitted, it appears admirably adapted for the purposes required.

Old Mortality.—It would no doubt be very interesting to preserve such a record. The celebrated Sydenham was buried in the Church of St. James, Piccadilly, with the remains of Drs. Arbuthnot, Akenside, and Benjamin Stillingfleet the naturalist.

L.S.A.—It is a very good qualification. Many past and present members of the Council hold the licence.

Dr. Campbell.—The paper on "Ephidrosis Cruenta" was read by Dr. Anderson. The celebrated Dr. Mead gives some illustrations of bloody sweat in his "Medica Sacra."

A Member.—As the Midwifery Board has ceased to exist, there has not been for some time past any examination for the licence in midwifery of the College of Surgeons.

Professor Flower, F.R.S.—It is a slight mistake on the part of our contemporary; the gentleman who offers the large subscription is the brother, and not the father, of this gentleman.

A Would-be Nurse.—Miss Stephen, in her essay on "The Service of the Poor," writes thus on the subject of your inquiry:—"I have heard a surgeon and a stewardess speak in precisely the same terms of their first six months' experience. They did not think that any earthly consideration would induce them to go through it again, but they laughed at the idea of shrinking from any of the incidents of their respective employments in later years. I am sure, from many inquiries, that this is the common experience of nurses, whether religious or secular. Many of their duties are painful and disagreeable at first, but after a short apprenticeship they infallibly get over the first shrinking from these things, and after a time their painfulness is scarcely felt as a drawback to the employment."

Observer.—It was Faraday, in a lecture at the Royal Institution, who remarked—"Society, speaking generally, is not only ignorant as respects education of the judgment, but is also ignorant of its ignorance. Correct judgment with regard to surrounding objects, events, and consequences becomes possible only through knowledge of the way in which surrounding phenomena depend on each other."

MEAT-SUPPLY OF PARIS.

Official statistics show that the quantity of meat brought into Paris during the year 1876 was 158,972,756 kilogrammes. Of this quantity, 190,270 kilogrammes were seized as unsound, which was bought by the Jardin des Plantes for the food of the animals, and, according to old custom, the proceeds were divided among the renters of the central markets.

A SLASHING BARBER.

Dr. Dudfield reports to the Guardians of the St. George's Union:—"I regret to have occasion to call attention to the way in which the barber carries out his duties. Either from want of care, or want of attention to his razors, he is constantly cutting the men's chins, so that I have many times seen the blood running down a man's face after his visit to the ward. I have spoken to him about it several times, and the nurses have complained as well, but without effect." The matter was ordered to be inquired into.

ADULTERATION À LA FRANÇAISE.

"Some manufacturers," says *Galignani*, "to adulterate sweetmeats, resort to products of coal-tar. For instance, for imparting the flavour of the pear to any composition, the maker, has recourse to the oxide of amyl or to the formiate of propyl, both of which produce an essence with a very agreeable flavour of that fruit. If sherbets, ices, or sugar-plums are wanted with a pineapple taste, coal-tar can furnish a butyric ether, or an acetate of butyl, both of which produce on the palate and the tongue precisely the same effect as the pineapple."

THE INSANITARY CONDITION OF ALEXANDRIA.

A correspondent writes from Alexandria, on November 12, that the health of the country has not been good this autumn—fever has been prevalent both in city and country. Alexandria and Cairo both suffered, and the present cooler weather was anxiously awaited. Ismailia is still in a bad state, and the business of the capital of the Canal is much impeded by sickness. More than one-half the members of the *personnel* of the Tribunal, for instance, are prevented by illness from doing their work. Dwellers in Alexandria must find in the insanitary condition of their city an easy explanation of the occasional sickness. The state of the streets is disgraceful: they may be blocked up with dirt, and the Municipality does not move a finger; and as often as not a man's dust-heap is outside his front door.

COMMUNICATIONS have been received from—

Mr. F. W. Lowndes, Liverpool; Dr. Sullivan, Rome; Dr. Collins, Dublin; Mr. N. Martindale, London; The Registrar of the Apothecaries' Hall, London; Dr. Ross, Manchester; Dr. Sparks, Mentone; Mr. Swan, London; Mr. F. Mason, London; Dr. Greenfield, London; Dr. J. Wickham Legg, London; Dr. Octavius Sturges, London; Dr. Whipham, London; The Secretary of the Obstetrical Society; Mr. W. W. Reeves, London; Dr. Fearnside, Preston; Dr. White, Dublin; Dr. J. W. Moore, Dublin; Dr. Stevenson, London; Mr. G. Brown, London; The Secretary of the Harveian Society; Dr. W. R. Williams, London; Mr. F. J. Gant, London; Dr. Byrom Bramwell, Newcastle-on-Tyne; Dr. J. Morton, Glasgow; Dr. Sturge, London; Mr. J. H. Wathen, Fishguard; Mr. St. V. Mercier, London; Mr. Pugin Thornton, London; Sir Joseph Fayrer, London; Dr. A. E. Sansom, London; Mr. John Chatto, London; Dr. J. Mitchell Bruce, London; Mr. T. M. Stone, London; Mr. Rushton Parker, London; Dr. Thomas Barlow, London; Mr. B. R. Wheatley, London; Mr. W. E. Poole, London; Dr. F. Churchill, London.

BOOKS AND PAMPHLETS RECEIVED—

Transactions of the Clinical Society of London, vol. x.—William Goodell, A.M., M.D., The Mechanism of Natural and of Artificial Labour in Narrow Pelves—J. L. W. Thudichum, M.D., On Polypus in the Nose and other Affections of the Nasal Cavity - John Blair, M.D., F.R.C.S., On Paying Wards in Public Hospitals—Charles H. Burnett, A.M., M.D., The Ear: its Anatomy, Physiology, and Diseases—Bulletins et Mémoires de la Société Médicale des Hopitaux de Paris, 1876—Robert Brudenell Carter, F.R C S., On Defects of Vision which are Remediable by Optical Appliances—Report of the Health Officer of the City and County of San Francisco for the Year ending June 30, 1877—Alfred C. Pope, M.D., On the Causes of Professional Opposition to Homœopathy.

PERIODICALS AND NEWSPAPERS RECEIVED—

Lancet—British Medical Journal—Medical Press and Circular—Berliner Klinische Wochenschrift—Centralblatt für Chirurgie—Gazette des Hôpitaux—Gazette Médicale—Gazette Hebdomadaire—Le Progrès Médical—Bulletin de l'Académie de Médecine—Pharmaceutical Journal—Wiener Medizinische Wochenschrift—The Louisville Medical News—Boston Medical and Surgical Journal—Nature—Philadelphia Medical Times—Cincinnati Clinic—Home Chronicler—La Province Médicale—Sunday at Home—Leisure Hour—Révue Mensuelle de Médecine et de Chirurgie—St. Louis Clinical Record - Students' Journal and Hospital Gazette.

APPOINTMENTS FOR THE WEEK.

December 1. *Saturday* (*this day*).

Operations at St. Bartholomew's, 1½ p.m.; King's College, 2 p.m.; Royal Free, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.

3. *Monday.*

Operations at the Metropolitan Free, 2 p.m.; St. Mark's Hospital for Diseases of the Rectum, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.

Royal Institution, 2 p.m. General Monthly Meeting.

Medical Society of London, 8½ p.m. Dr. Woakes, "On the Connexion between Stomachic and Labyrinthine Vertigo."

4. *Tuesday.*

Operations at Guy's, 1½ p.m.; Westminster, 2 p.m.; National Orthopædic, Great Portland-street, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; West London, 3 p.m.

Pathological Society, 8½ p.m. Mr. Butlin—Multiple Sarcoma in a Boy (living Specimen). Dr. P. Irvine—Multiple Tumours of the Brain. Dr. Dickinson—Specimens of Chylous Urine. Dr. Ralfe—1. Urine from a Case of Phosphatic Diabetes; 2. Gangrene of the Lung in a Case of Lead Poisoning. Dr. Wilks—Case of Softening Syphiloma of the Liver. Mr. Wagstaffe—Dermoid Cysts growing along line of Branchial Fissures. Dr. Dowse—Specimens from a Case of Paralysis Agitans. Dr. Goodhart—1. Symmetrical Sarcoma of Ossa Ilia, with Hyperostosis of Cranium; 2. Cerebral Tumours in a Monkey. Dr. Morison—Case of Chyluria. Dr. Ord—Fat from Case of Chyluria. Dr. Garlick—Diaphragmatic Hernia.

5. *Wednesday.*

Operations at University College, 2 p.m.; St. Mary's, 1½ p.m.; Middlesex; 1 p.m.; London, 2 p.m.; St. Bartholomew's, 1½ p.m.; Great Northern, 2 p.m.; Samaritan, 2½ p.m.; King's College (by Mr. Wood), 2 p.m.; Royal London Ophthalmic, 11 a.m.: Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.; St. Peter's Hospital for Stone, 2 p.m.

Obstetrical Society, 8 p.m. Dr. Redwood, "On Secondary Puerperal Hæmorrhage." Dr. John Bassett, "Cases of General Dropsy in the Fœtus." Mr. Thompson, "On Complete Rupture of the Perineum." And other Papers.

Royal Microscopical Society, 8 p.m. Meeting.

6. *Thursday.*

Operations at St. George's, 1 p.m.; Central London Ophthalmic, 1 p.m.; Royal Orthopædic, 2 p.m.; University College, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; Hospital for Diseases of the Throat, 2 p.m.; Hospital for Women, 2 p.m.; Charing-cross, 2 p.m.; St. Thomas's (ophthalmic operations), 4 p.m.

Harveian Society (Ballot, 8 p.m.), 8½ p.m. Harveian Lecture—Dr. Graily Hewitt, "On the Mechanical System of Uterine Pathology."

7. *Friday.*

Operations at Central London Ophthalmic, 2 p.m.; Royal London Ophthalmic, 11 a.m.; South London Ophthalmic, 2 p.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. George's (ophthalmic operations), 1½ p.m.; Guy's, 1½ p.m.

VITAL STATISTICS OF LONDON.

At the Royal Observatory, Greenwich, the mean reading of the barometer last week was 29·44 in. The highest reading was 30·12 in. at the beginning of the week, and the lowest 28·91 in. on Saturday evening.

* The figures for the English and Scottish towns are the numbers enumerated in April, 1871, raised to the middle of 1877 by the addition of six years and a quarter's increase, calculated on the rate which prevailed between 1861 and 1871. Salford, however, forms an exception to this rule, as the estimate is based upon the rate of increase of inhabited houses within the borough during the six years ending July 1, 1877. The population of Dublin is taken as stationary at the number enumerated in April, 1871.

ORIGINAL LECTURES.

A LECTURE ON

THE PATHOLOGY OF HYDROPHOBIA.

ILLUSTRATED BY A CASE AT ST. MARY'S HOSPITAL.

By W. B. CHEADLE, M.D., F.R.C.P.,
Senior Assistant-Physician and Lecturer on Pathology.

At the present moment, when hydrophobia is unusually prevalent, and is engaging much public attention, there has been revived the old doubt whether the disease has any real existence as a distinct affection, or is merely a nervous disorder, the product of an excited imagination, grafted, perhaps, upon some tetanic condition set up by the irritation of the wound.

Sir Thomas Watson, who has described hydrophobia from actual observation with a vividness and reality which renders his account of it as fascinating as it is accurate, refuted this theory very effectually long ago. Speaking of Sir Isaac Pennington, a former Regius Professor at the University of Cambridge, who had never seen a case of hydrophobia, and who was profoundly convinced that it was nothing more than a nervous complaint produced by the alarmed imagination of the patient, he says—"If you meet with such incredulous persons, and think it worth while to argue with them, you may object to their unbelief the improbability that so many persons who have been bitten by mad dogs should have suffered so precisely the same train of symptoms, and at last have died, from the mere force of morbid imagination. You may urge them with the fact that many of these persons" (as in the present case) "have been under no apprehension at all until the disease has seized upon them; that many of them have been men of naturally strong and firm minds, not at all likely to be frightened into believing that they were seriously ill unless they really were so, and still less likely to be terrified into their graves. And if this has no weight with such reasoners, you may bring forward the conclusive fact that the disease has befallen infants and idiots who had never heard or understood a word about mad dogs or hydrophobia, and in whom the imagination would have had no power in calling forth the complaint. And if they are proof against this you must give them up. I can suggest nothing more." I may point out, in addition, that the fear presumed to be so petent is not a sudden fright such as produces chorea, or an attack of convulsions, but a persistent horror or dread, such as exists under varied other circumstances, without in any case producing any nervous disorder dangerous to life. The production of hydrophobia in this way would be without a parallel. Nor does the theory that the disease is a tetanus modified by the imagination seem a whit more feasible. In another passage the eminent authority I have quoted points out the striking features which distinguish tetanus from hydrophobia—viz., the universal tonic spasm of the former, as contrasted with the intermittent spasms of certain groups of muscles in the latter; the absence of thirst in tetanus, as compared with its intensity in hydrophobia; the accumulation of mucus about the mouth and fauces in the latter, from which the tetanic patient is free; the vomiting so constant in hydrophobia, but absent in tetanus; the calm serenity of the sufferer from tetanus, as compared with the restless excitement and irritability so conspicuous in the sufferer from hydrophobia. But indeed the fact that the mental influence is often wanting disposes of this hypothesis, as of the first; and if these criticisms are founded, as I believe they are, upon correct data, they form a sufficient answer both to the theory that hydrophobia is a purely nervous delusion, or is a tetanus modified by mental impressions. The case I here record gives further, although perhaps unneeded, evidence against these hypotheses—first in the important fact that the patient did not appear to apprehend or suspect that he might be suffering from hydrophobia, or indeed to connect his sufferings with the bite in any way; and secondly, in the material changes found in the body, which were such as certainly could not be produced by any feat of imagination. Nor is it conceivable that they could be induced by any extreme of nervous disorder, the offspring of trouble, dread, or violent mental excitement.

Case.—Hydrophobia from the Bite of a Cat—Death on the Thirty-sixth Day after the Injury—Post-mortem Examination, including the Microscopic Examination of the Pons, Medulla, Spinal Cord, and Nerves of the Injured Limbs.

Henry C., a man, aged twenty-three, came to St. Mary's Hospital on August 8, 1874, complaining of some difficulty of swallowing, and was referred to the department for diseases of the throat. The Surgeon in charge, Mr. A. T. Norton, examined the patient's throat, but could find nothing amiss there; he observed, however, that the man's manner was strange—that he was very restless and excitable. Mr. Gascoyen chanced to be present, and Mr. Norton called his attention to the case, which they then examined more minutely together. The man thereupon explained that the original ground on which he had come to the hospital was that he suffered from pain in his arms, but when he arrived there his throat troubled him very much, and he had asked for advice specially for that. The pain in the arms he attributed to rheumatism; he had a brother ill at the time with rheumatic fever in St. George's Hospital, and thought he had got the same complaint. The arms were examined, and the man then mentioned that he had been bitten in both hands by a cat about five weeks previously. The marks were visible enough—one on the forefinger of the right hand, and the other through the nail of the left thumb. He did not appear to attach any importance to this circumstance, or to connect his condition in any degree with the injury; but the surgeons, suspecting that he might be suffering from hydrophobia, advised him to come into the hospital without delay. Nothing whatever was said to him of the suspicions entertained, and he insisted upon returning home to communicate with his family, and to fetch the necessary clothes. He reappeared in a couple of hours, having walked a considerable distance in the meantime, and was at once admitted as an in-patient. The following additional particulars of his story were then obtained:—It appeared that he was a porter at an hotel, but resided when off duty in rooms of his own somewhere in Paddington. There he kept for his amusement some pigeons, and on going to visit them on his return home as usual on the evening of July 5, he found in the cote a strange cat, which had entered, as he supposed, with evils designs upon the birds. He forthwith seized the animal with his right hand, and in return it bit him through the right forefinger. He instinctively seized it with his other hand, and it bit him again through the left thumb. The cat, which he described as a young, gaunt, miserable-looking creature, then made its escape. During the next few days there was some pain and swelling about the wounds, which was relieved by poultices, and the wounds then healed. No caustic or other dressing was applied. From this time the patient continued perfectly well until the thirtieth day, when he noticed some puffiness of the hands, and loss of power in both of them. On the thirty-first day he complained of want of appetite and general *malaise*, and two days later he consulted a medical man, who treated him for cold and bronchitis. The following day—or the thirty-fourth after the bite—the irritation of the throat and difficulty of swallowing definitely commenced, and he was so restless and distressed and noisy during the night that the people at the hotel who slept near complained of the disturbance he created. On the following day his arms were more painful, and he applied to the hospital.

When examined on admission the pupils were widely dilated, the pulse quickened, and the tongue rather foul. The patient was very restless and excited, almost hysterical in manner, and he stated that he had not eaten or drunk anything for four days. On water being offered to him he turned shuddering away, saying that he could not swallow. A hypodermic injection of morphia was given him, after which he became calm, and swallowed three or four spoonfuls of beef-tea. Five hours after, he became again restless, and asked constantly for water to be pumped into him to relieve his terrible thirst, continuing to grow more excited for the next four hours, when he became unmanageable, shouting and crying out, and struggling so violently that it required three or four persons to keep him in bed. He now spat up viscid mucus, and the convulsions were noticed to be made more violent by the breath of persons standing near him. During the convulsive attacks he was quite conscious and sensible, and when quieter he explained that he could not help struggling, and begged not to be tied down. He continued in much the same state for the next three hours, or until about an hour before his death, when he became exhausted and vomited a large quantity of

chocolate-coloured fluid. His skin now became cold and perspiring, and the breathing stertorous, and he gradually fell into a state of coma, which continued until he died, thirteen hours after admission, and before, unfortunately, I had an opportunity of seeing the case. The patient was admitted in the evening after I had left the hospital, and died in the early morning, before his admission was reported to me. Throughout nothing had been said to him of the nature of his complaint, nor did the man himself indicate in any way the suspicion that it might be connected with the bite he had received.

The foregoing history is taken chiefly from the notes of Mr. F. J. Marshall, who was Registrar at St. Mary's at the time, and to whom I am much indebted for this assistance. The symptoms in this instance resembled very closely those which have been observed with little variation in similar cases before. The acute and final stage of the disease, or period of recrudescence, set in after a considerable interval, was ushered in by a return of irritation in the wounds and injured limbs, and ran its course in the brief period of six days, or within the regular limit of a single week, which appears to be so seldom exceeded. The mental excitement, the extreme reflex sensibility, the dread of swallowing, the great thirst, the fierce paroxysms of convulsion and struggling without loss of consciousness, their cessation before death, the vomiting of dark fluid, the preservation of consciousness almost to the end, the supervention of exhaustion and collapse in the final stage, appear to be almost invariable phenomena. Incontinence of urine and fæces, priapism and seminal emissions, frequently observed in hydrophobia, were not here recorded, but it is possible enough that their occurrence may not have been noted down in all the hurry, horror, and excitement of the night. Death in a state of comatose insensibility following exhaustion is by no means invariable. It appears most commonly to result from pure asthenia, consciousness being retained until the last. Sometimes death occurs suddenly during a convulsion from apnœa.

Post-mortem Examination.—For the following account of the rough appearances observed I am indebted to the record of Mr. S. J. Knott, the late Curator at St. Mary's. The microscopic examination of the nervous structures was made by myself from sections prepared after hardening in a solution of bichromate of ammonia and alcohol. The whole of that portion of the cerebro-spinal axis lying between the anterior border of the pons Varolii and the cauda equina was examined with great minuteness in many hundred sections taken in almost unbroken succession throughout the entire length. For some large complete transverse sections of the pons I am indebted to the skill of Mr. G. M. Giles, of St. Mary's Hospital. The nerves leading from the cord to the injured parts were also examined, both teased out when fresh, and transverse and longitudinal sections prepared in the same way as those of the cord. The cerebral hemispheres were not examined.

Post-mortem Examination made twenty-six hours after Death.—The body was found to be well nourished and in good condition. There was a small punctured wound through the right forefinger, and another through the nail of the left thumb. The general condition of the internal organs was as follows:—Fauces and pharynx highly congested. Œsophagus congested in the lower portion. Stomach highly congested at the cardiac end, and patches of extravasated blood were visible beneath the mucous membrane, which was intact; it contained a few ounces of dark grumous fluid. The larynx was much congested down to its lower border. The trachea was slightly congested at its upper part, the hyperæmia being excessive towards the lower portion, and continued beyond the bifurcation to the small bronchi. The lungs were highly congested throughout; full of dark liquid blood. The heart was healthy in appearance and of normal size; it contained one very small soft clot in the right ventricle. The liver was congested—black, treacly blood oozing from it when it was cut—otherwise its structure seemed healthy. Brain: The membranes were intensely congested, the superficial veins distended with blood; the vessels of the pons were especially conspicuous, engorged and dilated. The brain-substance throughout was extremely vascular, showing innumerable puncta oozing dark blood on section. The lining of the spinal canal in patches, and the dura mater of the cord universally, were highly congested. The cord had a corrugated appearance, and was marbled in a striking manner by veins running more or less longitudinally. The blood was extraordinarily dark and fluid everywhere.

Microscopic Examination of the Pons, Medulla, Spinal Cord and Nerves leading thence to the Seats of Injury.—The Pons: The vessels throughout the entire area of the anterior portion near the crura cerebri, of every size and character, were enormously distended with blood, forming a complete injection of the vascular system down to the smallest capillaries (a marked contrast to the normal condition of empty, or nearly empty vessels); in one or two places a few blood corpuscles could be seen lying outside the medium-sized vessels, having apparently made their way through the walls. Immediately round some of these vessels was a zone of refracting, fibro-granular material, which had not taken the staining, and which resembled fibrinous exudation matter. No intermingled leucocytes could be distinctly made out, however, and I confess to some doubt at first whether the appearance might not be due to the partial displacement of the vessel from its greater resistance to the knife in the act of cutting, and the filling in of the space with *débris* and reagents. A careful re-examination and comparison with other specimens, normal and pathological, convinced me, however, that the appearance was due to actual exudation. The nerve-cells of the grey matter were less distinct in outline, and their contents more cloudy and granular than natural. The fibres of the white matter did not appear granular, and nothing abnormal could be distinguished in this structure. Middle Portion of the Pons: This was injected in the same remarkable manner; even small capillaries, capable of holding only a single row of corpuscles, were thus distended. Here and there vessels of medium size had ruptured, and red corpuscles were visible in the tissues outside. At one point linear or rod-like bodies resembling bacteria could be distinctly seen amongst the corpuscles escaped from ruptured vessels. As a rule, the vessels fully occupied their bed in the nervous substance, but in one or two places a zone of colourless refracting material, previously described, could be observed. The large pigmented cells of the nucleus of the fifth pair appeared more turgid, opaque, and dull than natural. In most the nucleus was fully hidden in the dark contents. Posterior Region adjoining Medulla: In this portion, as in the rest of the pons, the vessels were uniformly intensely injected (crammed with blood corpuscles), and at a few points blood-cells were visible, lying outside the vascular walls, and some of the exudation-like material encircling the arterioles. At several points near the raphe, and along the lower portion of the middle line, where the larger vessels were numerous, blood corpuscles in greater numbers were visible, extending more widely into the surrounding tissue. Hæmorrhages still more marked were discoverable in the vascular area immediately below the nucleus of the facial. The cells of the grey matter were also more granular and opaque, and less bright and well defined than usual, but the white structures showed nothing abnormal. Medulla Oblongata: In the upper portion, contiguous to the pons, the same excessive hyperæmia existed everywhere; in two places, close to the nuclei of the eighth pair, were some well-marked hæmorrhages, with extravasation for some distance into the surrounding tissues. Scattered blood-cells were observed outside unruptured vessels here and there. There were also the same zones of refracting material round the vessels in this district which were so observable in the pons. The caudate and rounded cells of the nuclei were perhaps less bright and distinct than normal, but not granular or fatty; nor could any change of the kind be discovered in the white matter, the axis-cylinder and sheath of the tubes showing bright and distinct. Central Portion of Medulla: The same appearances of intense congestion and exudation were observed in this region, but there were fewer escaped blood-corpuscles, and no distinct hæmorrhagic points. Both grey and white matter appeared healthy. Lower Medulla, next the Cord: The congestion was well marked, but less extreme than in the higher portions, the small capillaries being no longer mapped out by blood-injection in the same way. It was supposed at first that this might be due to the drainage of the vessels of the liquid blood by section near this point on removal of the parts from the body; but this was not supported by the condition of the cord still further down. The ganglionic cells and nerve-fibres were healthy. Cervical Portion of the Spinal Cord: The only change observable in this region was the general distension of the vessels by blood-corpuscles, which was most noticeable in the grey matter of both horns. Dorsal Portion of the Cord: The hyperæmia, although still great, showed further decline, becoming less and less marked in successive portions. There was no hæmor-

rhage or exudation observed. Lumbar Cord: This portion highly congested, but in less degree than the preceding; no other change could be detected. Nerves running between the Cord and the Injured Parts: Portions were examined in the fresh state when teased out, and also longitudinal and transverse sections prepared with bichromate of ammonia. Brachial Plexus: The teased-out specimens in the fresh state showed the nerve-fibres in the normal condition. In the hardened sections the vessels generally were seen to be greatly distended with blood, but the congestion was not so extreme as in the nervous centres. In one place extensive extravasations within the nerve-sheath had ploughed up the nerve-fibres. Generally the fibres themselves were cloudy and their white substance finely granular. In the transverse sections the nuclei of the connective tissue appeared unusually bright and numerous; here and there were nerve-bundles which were clear in colour and not granular. The Median and Ulnar Nerves: The condition of these was closely similar. The vessels were full, but there was no exudation or hæmorrhage visible. The nerve-fibres themselves appeared somewhat granular, cloudy, and opaque. The Nerves of the Injured Finger and Thumb: These had been carefully dissected out to their finest branches distributed to the seat of injury. They appeared perfectly normal to the naked eye, and in specimens teased out while fresh no morbid change could be detected. Hardened sections showed some congestion; the septal vessels contained blood, but were not distended. No hæmorrhages were observed, but the nerve-fibres were slightly cloudy and granular.

ORIGINAL COMMUNICATIONS.

CASE OF

PSORIASIS TREATED WITH PHOSPHORUS "PERLES" AND CHRYSOPHANIC ACID.

By BALMANNO SQUIRE, M.B. Lond.,
Surgeon to the British Hospital for Diseases of the Skin.

It is now scarcely ten months ago since I first brought chrysophanic acid under the notice of the profession as a remedy in psoriasis.(a) In the *Medical Times and Gazette* of February 10 of this year I referred more fully to the subject. Since then the remedy has come into extensive use. The account I gave of the first trials of chrysophanic acid in psoriasis was of so surprising a kind, that others soon began to put statements apparently so extravagant to the test of a practical trial. It was easy to do so; and anything that would promise to cure so obdurate a disease within a short space of time was obviously at least worth a trial which seemed to require so little exercise of patience and trouble. Several communications on the subject have accordingly since been made by different observers to the various medical journals. But if my original account of the effect of chrysophanic acid in psoriasis was rather a startling one, the further accounts of other observers have been no less so. Most of those who have tested my observations by repeating them in their own practice have expressed themselves as scarcely less astonished by its efficacy than I myself was when its effect first became unfolded to me. The last observer who has thus expressed himself is Dr. Whipham, who has quite recently recorded his experience.(b) This observer relates that he at first treated a particularly obstinate case of psoriasis by such well-reputed means as "careful attention to the diet," including the special inhibition of beer, a course of arsenic, the use of nitrate of mercury ointment, then a mixture designed to stimulate the action of the kidneys, then another mixture designed to correct disorder of the stomach (if any), then Donovan's solution of arsenic and mercury, "until finally the gums showed evidence of mercurial poisoning." He further states that this treatment was carried on in the case unsuccessfully for the greater part of three years, until he at length made trial of chrysophanic acid, which cured the case in three weeks. He adds that "it was not without a feeling of despair that I had recourse to chrysophanic acid. The result, however, and the rapidity with which that result was brought about, surprised me extremely—a surprise which is not lessened by the fact that the girl had suffered from the skin disease for five years and a quarter at the time when the acid was employed, and that she was entirely free from psoriasis in twenty-one days." He concludes with the remark that "at present our knowledge of the drug is limited, and recorded cases are few in number." I need, therefore, scarcely apologise for adding another case to the number, the more especially as it illustrates the means of avoiding the more important of those drawbacks to the remedy which, in some of the commentaries that have been made on my views, have been particularly insisted on.

A gentleman, aged sixty, affected with psoriasis, was recently sent to London to be under my care, by his medical attendant, Dr. James Adams, of Glasgow. Our patient had been affected with his disease continuously for the past twenty-seven years, and had latterly become anxious about it. He had begun, as he said, to think that "this thing would never leave him," and he had in consequence got to worry himself very much about the matter. Dr. Adams sent me a complete account of this gentleman's history, so that I was enabled at once to learn that he had experienced a battery of well-directed skill, which would only a year or two ago have convinced me that I had nothing to cap it with. The patient was affected with psoriasis in a fairly copious manner over his scalp and forehead, his belly and back, and his forearms, thighs, and legs. Some of the patches, more especially those on his loins and his forearms, were of very considerable size, and the eruption annoyed him by occasioning him considerable irritation. After inspecting him, I decided to treat him with chrysophanic acid ointment and phosphorus *perles*. Dr. Adams had given me a *carte blanche* to treat him in any way I pleased, with the solitary proviso that I was to cure him if I could. He had directed his patient to remain in London until I was in a position either to say that he was well or that I had found myself baffled. It is not often that so free a course and such ample discretion are offered to anybody. I knew perfectly well that such double-edged weapons as phosphorus internally and chrysophanic acid externally were not without their risks, but I determined to push both of them to extremity with all due speed, so that I might yet have time to resort to other means if they should chance to disappoint me. The full effect of phosphorus in psoriasis, I knew by previous experience,(c) would take a month to assert itself. The effect of chrysophanic acid would, as I knew quite positively, be declared, for yes or no, within a week. My patient was, as is the rule with patients affected with psoriasis, a remarkably robust and healthy man. The firmness of his fibre, his clear ruddy complexion, his bright eyes, and his hearty demeanour, were sufficient justification for the trial of "heroic" measures. He was moreover a man of considerable intelligence, and, as he happened to be a chemical manufacturer, he at once fully appreciated those precautions which are essential in the employment of chrysophanic acid ointment. His scalp and forehead had to be treated in *some* way; and the ointment when used to the scalp, and more especially the forehead, in my own practice, as well as already in the practice of others, has occasionally come to inflame the eyelids and conjunctivæ, and to give rise in some cases to marked œdema of the lids. I accordingly enjoined the use of benzol (the best solvent of the ointment) as a means of freeing the fingers completely from the latter after applying it, and I recommended furthermore the wearing of a nightcap, to avoid the smearing of the ointment at night on to the pillow, and so possibly on to the eyes.

The patient was treated with chrysophanic acid ointment of the strength of two drachms of the acid to the ounce of lard, the former being fully digested in the latter at a temperature of 360° Fahr. (oil bath), to insure the requisite incorporation of the acid with the lard.

The phosphorus, exhibited in the form of "perles"—that is to say, the little capsules containing each one-thirtieth of a grain of phosphorus dissolved in oil, which may be obtained of Messrs. Corbyn, or, indeed, as I believe, of almost any chemist,—was regulated in the first instance to one-tenth of a grain per diem, but was speedily increased to rather over a third of a grain per diem, which proved to be the greatest dose that the patient could tolerate without experiencing gastric pain. The patient was taught to soften his scales efficiently with soap and water, and then to remove them thoroughly by scraping them away with a dull-edged knife before each application of the ointment.

I began treatment on September 24, 1877. By October 1 the greater part of the eruption had disappeared. Certain portions, however, of the disease—that is to say, the circumferential

(a) In the *British Medical Journal* of December 23, 1876.
(b) In the *Medical Times and Gazette* of September 22, 1877.
(c) *Vide* my paper in *British Medical Journal* of November 3, 1877.

part of a good many of the patches (the most difficult of all in every case of psoriasis to cure)—proved themselves to be unwontedly obstinate. However, on October 26 the patient left London for Glasgow in a condition of complete freedom from his long-experienced disease. Dr. Adams is well known as one of the examiners of the Faculty of Physicians and Surgeons at Glasgow, and I therefore quote from a letter he wrote me on October 30, 1877, as a sufficient authority for the nature of the result. He says:—"I saw Mr. —— on the day after his return. I had him stripped, and overhauled him in a state of surprise that gave him intense delight. I am truly astonished. He has had the disease now for twenty-seven years, and, though there have been ups and downs, you got him at the worst." In reporting this case I have deviated from a custom that I prefer as a rule to follow. It is therefore necessary that I should say that I have in my previous papers, herein referred to, contributed the results obtained by me in the treatment of psoriasis by phosphorus used separately, and by chrysophanic acid used separately. It is only on the data acquired by the separate use of these two remedies in this disease that I have ventured, as here, to employ them in conjunction. I must not omit to say that the patient succeeded by the means I have named in avoiding any irritation of his eyes which might otherwise have arisen from the use of the ointment, and that although my desire to acquit myself speedily of my task led me to pushing the effect of the ointment to some erythematous inflammation of the skin, this was, by due care, always kept within fair bounds. The temporary yellow discoloration of the patient's hair occasioned by the use of the ointment was readily removed (when the time arrived for doing so) by means of a weak solution of caustic potash. And, lastly, I must admit that his under-linen was irretrievably stained by the acid of a dingy purple colour. But he, good-naturedly, made light of this annoyance. His only real grievances throughout were that his hair, which properly was white, had become temporarily converted by the colour of the ointment to a brilliant yellow colour; and for the rest, that for one night only (this was at the climax of treatment by the ointment) the tingling sensation awakened in his skin kept him awake.

A CASE OF OVARIOTOMY.

By H. AMBROSE LEDIARD, M.D., F.R.C.S.,
Medical Superintendent, Central London Sick Asylum, Cleveland-street.

M. T., aged fifty-eight, a charwoman, was admitted May 24, 1877, into the Cleveland-street Sick Asylum. Has had three children, and one is now living, aged twenty. Father died of pleurisy; mother died of old age. Has had pretty good health all her lifetime up to September, 1876, when she first noticed some swelling in her abdomen, which in a few months increased so as to prevent her stooping and getting about. She was tapped in a hospital in April last. On admission she was found to have fair general health, but the face was anæmic-looking and yellowish. The abdomen was much swollen and very tense. Dulness on percussion on the left side up to the middle line, the right flank being clear. No albuminuria; suffers from constipation and flatulence.

On May 29 paracentesis was performed, and 224 ounces of thick semi-gelatinous brown fluid, which deposited a fatty-looking matter in lumps and granules, were withdrawn from the cyst. This afforded her great relief for the time being; but on June 19 the belly was again far from comfortable from reaccumulation of fluid, and the girth was thirty-nine inches. I tapped her a second time on June 27, and obtained 176 ounces of fluid presenting the same characters as the first drawn.

After some days of hesitation she consented to have the tumour removed, and this was done between 10 and 11 a.m. on July 24. The operation-room in which she was placed was a small ward with four beds, which had been just occupied by a case of amputation of the thigh, which recovered; this ward then was vacated for two days, cleansed thoroughly with carbolic soap, windows thrown open, and all unnecessary furniture taken away, fresh bedding, etc., being supplied. The patient was carefully chloroformed by Mr. H. C. Horner, and during the operation I had the kind assistance of Mr. R. W. Lyell and Dr. S. Rees Philipps. An incision of about four inches was made in the middle line, between the navel and the pubes, and the cyst emptied, but not without a mess, for the fluid escaped by the side of the trocar, and was with trouble only prevented from passing back into the abdomen. The cyst was found free from any adhesion at the upper part; but on withdrawing the tumour, extensive omental adhesions were found requiring patient separation, and very tedious application of catgut ligatures to the numerous bleeding points which came into view. One portion of omentum, the size of the little finger, was ligatured and cut off. The pedicle was found to be of fair size and length, and there was no difficulty in fixing the clamp used. Sponges were freely introduced into the abdominal cavity, and the wound was closed with silk sutures passed from peritoneum to skin. Altogether, more than twenty ligatures were sewn up in the omentum and abdominal wall. The intestines were not seen from first to last, and the operation was fairly straightforward. The pedicle was then touched with perchloride of iron, and the wound fixed with lint pads, cotton-wool, and a binder. The fluid was so spilled that it could not be well measured; but it is sufficient to say that the quantity removed was considerable. The tumour was made up of one large cyst, and numerous small ones at its base within, which, when cut into, presented fluids of various colours and degrees of fluidity. There was no sickness from the chloroform; and to obviate shock, a quarter of a grain of morphia was given hypodermically some hours after the operation. The wound was kept as dry and clean as possible from first to last, and carbolised tow used to cover the clamp, which came away on the tenth day. Around the clamp there was a little superficial suppuration; and the stitches producing some irritation, were removed, and gradually replaced by plaster. There was some abdominal pain occasionally, but very little distension; and she was relieved by a grain of opium now and then. The bowels acted on the eighth day in response to castor oil; and subsequently trouble ensued from the rectum getting loaded and requiring the use of a scoop and enema.

The tongue was moist and never foul throughout. Her temperature never rose to 100°, except on one occasion alluded to, when the rectum became overloaded, and the pulse was also only once over 100. She had a cough for some days, with scanty sputa, due possibly to the increased lung space; but this was troublesome only on account of its causing pain in the abdomen. On the twentieth day she sat up in a chair for a little while, and two days after was moved to a general ward. Food was taken well all the while.

Subsequently, constipation and back-pain were complained of; the latter improved by a good binder made to lace. Before leaving for the country she was well in all respects, and much altered for the better in appearance.

THE STRUCTURE AND FUNCTIONS OF THE NERVOUS SYSTEM.

By JAMES ROSS, M.D., M.R.C.P.,
Honorary Physician to the Southern Hospital for Diseases of Children, Manchester.

(*Continued from page* 459.)

FUNDAMENTAL PROPERTIES OF NERVOUS TISSUES.

We have seen that, when an organism consists of an aggregation of units without any definite arrangements, each part is able to perform all the vital functions. Each part is irritable, automatic, contractile, metabolic, excretory, and reproductive; and it is only as fast as this originally uniform tissue becomes differentiated, that each part acquires the power of performing more perfectly a few functions, and ultimately one habitual function, while losing to a more or less extent the power of performing the other functions. The expanded tentacle of a zoophyte, on being touched, immediately contracts, and after a time it expands, apparently from its own inherent activity. The same tissue is sensitive to external impressions or irritable, as well as automatic and contractile. Of essentially the same nature appears to be the mechanism concerned in the movements of the leaves of carnivorous plants: the tissue which receives the impression also closes the leaves by its contraction, and after a time expands them by its own inherent activity. Such actions foreshadow the functions of nervous tissues, but they fall short of true nervous action. In *Hydra* the internal end of an ectodermic cell is prolonged into a process, which assumes the contractile function; while the external end of the cell becomes specially sensitive to external impressions. The internal end being shielded from external influences, tends to contract only when it receives a stimulus through the external end; and the latter ever tends to lose its contractile property, the more its exposed position requires it to determine when

the former shall be made to contract. In other words, the internal end performs the work, while the external determines when the work shall be done: the one is operative, the other regulative.

This differentiation of structure is carried still further in *Beroe*, where the internal and external ends of the ectodermic cell are represented by two different cells connected together by a thin fibre. The changes set up in the external or sensitive cell are conducted through the fibre to the internal cell, which it excites to contract. This new arrangement of fibre introduces us to a new special function. A part of the tissue is set apart for conveying waves of disturbance from the sensitive cell to the work cell. By this means a molecular motion is followed by a molar motion at some distance from the former in the interior, the two motions being co-ordinated by the internuncal function of the fibre. The next step of development consists in the differentiation of the external or sensitive cell into two cells; the one of which becomes specialised for responding to external stimulation alone, and the other for automatic action. The latter will perform its functions best by being shielded from external influences, and it will therefore be withdrawn from the surface of the body; while the former will retain its superficial position in order that it may respond the better to external changes; and each of these, by being relieved of one kind of action, will perform more efficiently the action or actions it retains. The fibre which originally connected the ectodermic cell and the contractile process now connects the latter with the automatic cell; and a new fibre is required to connect the automatic with the sensitive cell. The automatic cell is a centre to which disturbances originating in the sensory cell are conveyed, and from which issue impulses to the work-organs; hence the fibre which connects it with the sensory cell is rightfully called the *afferent*, and that uniting it with the work-organs the *efferent* fibre. The automatic cell is at present represented as being engaged, both in spontaneous action and in modifying afferent impulses previous to their being passed on to the efferent fibres. But the central cell becomes by-and-by differentiated into two cells, the one of which is restricted mainly to automatic action, and the other to the co-ordination of sensory impulses previous to their conversion into the outgoing discharge. The latter constitutes what is called reflex action.

The fundamental fact, however, which concerns us at present, is that the active elements, of which the nervous tissues are composed, consist of cells and fibres. We must now glance rapidly at the more important properties of these cells and fibres.

Ganglion-Cells.—The cells possess granular contents and a vesicular nucleus with a nucleolus. They vary much in size and form. Some are small, generally spherical or ovoid, and have a regular, uninterrupted outline. Others are much larger, possess a definite cell-wall, and have one or two or more long processes issuing from them. The latter are called caudate or stellate nerve-corpuscles, according to their form; or unipolar, bipolar, or multipolar, according to the number of their processes. The processes often divide and subdivide, and appear to be tubular and filled with the same granular material which is contained in the corpuscles. Of these processes some appear to taper to a point, and to terminate at a greater or less distance from the cell; some anastomose with similar processes from other cells, while others are continuous with nerve-fibres. The latter process is always unbranched as it leaves the cell, and possesses all the characters of the central portion of the nerve with which it unites.

We may expect that the contrast exhibited in the structure of these two kinds of cells will be paralleled by a corresponding contrast in their functions. The first contrast which we notice is that of size. It is evident that a large bulk of the cell will enable it to give rise to a powerful discharge of energy; and we may expect that the more powerful discharges will be required from those cells which are in immediate relation with the outgoing currents to the work-organs, and that the smaller cells will be in relation with the incoming currents, which require to be arranged and elaborated before being reflected outwards. This expectation is realised. The large cells are met with in the spinal cord in connexion with the motor, and the small cells in connexion with the sensory nerves.

The next contrast between the spherical and the caudate cells is, that the former do not possess a definite cell-wall, and have no definite connexions; while the latter not only possess a definite cell-wall, but have also, by means of their processes, extremely definite connexions with one another and with nerves. It is manifest, therefore, that the currents through the former must pass in a somewhat diffused manner, while in the latter they will pass through exceedingly defined channels. The former, then, will be adapted for the first elaboration of the incoming currents, and the latter for the final co-ordination of the outgoing currents. If the afferent currents are few in number, and if they are at the same time exceeding well organised in the race, they may pass more or less directly to the caudate, without the intervention of round cells. The actions to which the internal organs are subjected are extremely uniform in kind, and relatively few in number. The stomach, for instance, passes through the same kind of actions day after day with great uniformity; its actions are also thoroughly organised in all animals; hence, the afferent currents from it to the sympathetic ganglia pass directly into bipolar cells, and issue from these as efferent currents. The afferent currents ascending from the feet during locomotion are also few in number, simple in kind, and thoroughly organised in the race, and it is probable that these pass from the sensory nerves directly to the large motor cells, without previously passing through the small round cells of the posterior horns.

The next contrast I shall notice is one existing between the caudate cells themselves. Some are unipolar or bipolar, and others multipolar, with exceedingly ramified connexions. Some anatomists doubt the existence of unipolar cells; but we may expect to meet with the bipolar cells where the co-ordinations to be effected are few and simple, and the multipolar where the co-ordinations are numerous and complicated. We have already noticed that the movements of the internal organs are comparatively simple and uniform; and it is mainly in the ganglionic centres which preside over the functions of those organs that the bipolar cells are found, while the best examples of the multipolar cells are found in the anterior horns of the cord in direct relation with the nerves which convey efferent impulses to the organs of external relation, where numerous and complicated movements require to be effected.

The order of the development of the nervous system, structurally regarded, is from the round cell without membrane, to the caudate cell with membrane; and from the caudate cell with few and indeterminate connexions, to those with multiform and defined connexions: just as the order, functionally regarded, is from actions which are diffused and simple, to those which are less diffused and simple; and from the latter, to those which are exceedingly defined, multiform, and complicated. This order is equally true, whether the progress of development is contemplated under the aspect of the transition from the lower to the higher animals, or from the initial to the adult stages of animals; or under the aspect of the process known as education in the higher animals.

Nerve-Fibres.—Each nerve-fibre is a tube filled with partly fluid contents. The walls of the tube consist of an elastic membrane provided with large nuclei, and called the primitive sheath or neurilemma. A thin cord, consisting of a large number of primitive fibrillæ, runs in the centre of the tube termed the axis-cylinder. A third constituent of most nerves is a transparent, oily, shining material, which surrounds the axis-cylinder, termed the medulla, medullary sheath, or the white substance of Schwann. When the fibres are packed together so as to form an organ, they are surrounded and held together by a kind of connective tissue called the neuroglia, which must not be confounded with the primitive sheath.

Three kinds of nerves are met with; the simplest kind are called the fibres of Remak, and consist merely of what represent the axis-cylinders of other fibres. These fibres are also termed grey from their colour, or varicose fibres from the regular varicose enlargements which they present in their course. The second kind consist of an axis-cylinder and a sheath, but do not possess a medullary sheath; hence they are called non-medullary nerve-fibres. The third class of nerve-fibres, in addition to the axis-cylinder and sheath, possess a medullary sheath, and are consequently called medullated nerve-fibres.

The axis-cylinder, therefore, is the essential constituent of a nerve-fibre, and has been aptly compared to the "core" of copper wire strands in a submarine telegraph cable. The next most essential constituent is the primitive or nucleated sheath, which has been compared to the outer coating of rope of the cable. The last constituent, and therefore that which distinguishes the most highly differentiated fibre, is the medullary sheath, which has been compared to the layer of guttapercha in a telegraph cable.

It may be noticed, in passing, that the medullated fibres can be made, by a certain method of treatment, to exhibit, at definite distances apart, annular constrictions, at which the medullary sheath is said to be interrupted, and which may be taken as indications of the original formation of a nerve-fibre out of a row of cells, the constrictions corresponding with the divisions between the primitive cells. The nerve-fibres and caudate

ganglion cells are, undoubtedly, connected with one another. Some of the processes of the latter have all the characters of an axis-cylinder, and they may therefore be compared to the fibres of Remak; but by-and-by the exterior of the process becomes more distinct, and then becomes continuous with the primitive sheath, the interior becomes continuous with the axis-cylinder, and the medullary sheath becomes interposed between them.

Glancing now at these three kinds of fibres, the most noticeable feature is, that all of them are adapted for conveying impulses in the direction of their length; but when several of the fibres of Remak are arranged side by side, free lateral diffusion of the currents will take place, while the primitive sheath of the non-medullated fibres will check this diffusion to a considerable extent, and it will be entirely prevented by the medullary sheath of the medullated fibres. We may expect, therefore, to find that the first order of fibre will be found when the function is of a very diffused character, the second when the function is less diffused, and the third when it is very defined, and when consequently any lateral diffusion, or irradiation, as it is called, would mar the effect. The fibres of Remak are mainly found in the intracranial portion of the olfactory nerve; and it is well known that, of all the special senses, the olfactory is the most diffused and least localised. The non-medullated fibres are met with in the sympathetic nerves, which preside over the actions of the organs of internal relation—actions which are much more diffused than those of the organs of external relation; while the medullated fibres alone are fitted to preside over the definite actions of the latter organs. Any lateral diffusion of the nerve-currents would entirely mar the definite and delicate movements of the hand required for writing; while some degree of this diffusion would appear to be necessary for that continuous and diffused contraction of the muscular coat of the bowels which causes peristalsis.

Functions of Ganglion-Cells.—Ganglion-cells contain a store of material possessing potential energy, which, on the application of a liberating force, becomes kinetic. The chemical process which underlies the transformation is probably of the nature of oxidation, since the blood, returning from the brain, for instance, is as venous as that returning from any other part of the body; but we possess no direct evidence of the nature of this change. In reference to the liberating force, it may be noticed that the ganglion-cells do not appear to respond to the usual mechanical and chemical stimuli. By employing strong electrical stimuli to masses of ganglionic cells, such as those of the cortical part of the brain, a response has been obtained from them in the form of muscular movements. These cells are, however, connected with each other by innumerable fibres; and there lie immediately beneath them large masses of nerve-fibres to which the currents, from the strength employed, must undoubtedly be conveyed; hence it is extremely doubtful, to say the least, how far the muscular movements in such a case can be taken as evidence of the direct action of the current on the cells. When the ganglion-cell lies between two nerve-fibres, as those engaged in reflex action, the potential energy of the cell is set free by means of the energy already liberated of the stimulated fibre; and the energy thus set free renders kinetic the potential energy of the second fibre. The cell largely increases the amount of energy rendered kinetic during the action; but, except in degree, the function of the cell in this case does not greatly differ from that of any portion of a conducting fibre. But even in such a simple case the cell generally becomes the point of union of several fibres; and thus it helps to direct the disturbance it receives through one fibre, into two or more fibres, and becomes the active agent in giving a new direction to the current.

The manner in which the energy of the cells is liberated in automatic action is not so easy to understand. It is probable that a great many of the actions included under the title of "automatic," are due to an operation of a reflex nature. There is another way in which the energy of the automatic cell may be supposed to be liberated. The energy set free during one moment may perform the part of a liberating force the next moment on the store of potential energy, which store is being constantly replenished from the blood, just as a fire, when once kindled, may be kept burning if supplied with combustible material. But the liberation of energy effected by this means would be continuous; while the liberation of energy in a stimulated nerve-fibre is interrupted or intermittent. It is quite possible, however, for a continuous liberation in a ganglion-cell to give rise to an interrupted or rhythmical stimulation of a nerve-fibre. Suppose that the energy liberated in the cell has to overcome a certain resistance before acting as a stimulus on a nerve-fibre, a certain tension must be reached prior to stimulation; and when the requisite tension is reached, a discharge takes place through the nerve. This discharge diminishes for a time the tension of the energy liberated in the cell; and as it is probable that the molecules of the axis-cylinder have fallen during the discharge from an unstable to a stable equilibrium, so the resistance to a second discharge through the fibre will be increased. The continuous liberation of energy within the cell soon raises the tension again; while by restorative processes in the axis-cylinder its molecules are once more restored to their position of unstable equilibrium, and the conditions for a second discharge are immediately restored, succeeded by the conditions of a second interval. When the resistance is great it will require a high tension to overcome it; and this implies that the liberation of energy must continue for a long time before the necessary degree of tension is reached, and that when the discharge takes place it will be a powerful one. Strength of discharge, then, involves length of interval between the discharges; or, in other words, the strength of every discharge of energy through a nerve is inversely proportional to its frequency.

Functions of Nerve-Fibres.—Nerve-fibres exist in the conditions of rest, death, and activity. In passing from the one state to the other their physical properties undergo no change similar to muscle; hence, these different conditions cannot be distinguished from each other in nerve by simple inspection. A nerve is living if it possess irritability. When the irritability is not called into activity by any stimulus, the nerve is at rest. No doubt a certain amount of material exchange takes place in a nerve, as in other tissues, during a state of repose; but as nerves are almost destitute of bloodvessels, the extent of material exchanges which take place in them must be slight. When the nerve-fibre gives evidence of evolving energy when acted on by a stimulus, it is in an active condition; and when it gives no response to the action of a stimulus, it is dead. Death of nerve-tissue is also recognised by the appearance of an acid reaction, and by certain electro-motor phenomena, as well as by the loss of irritability.

Irritability.—The laws of irritability have already been considered in a general way; but we must now establish empirically the conditions which influence the degree of nerve-irritability.

1. Continued inaction of a nerve diminishes and finally destroys its irritability, and leads at last to fatty degeneration. It is very probable that the first effect of inaction is to increase the irritability.

2. The irritability of a nerve, after it ceases to be connected with a living central organ, increases considerably at first, but afterwards diminishes, and finally disappears. When the separation is effected by transverse section, the process is accelerated, and it also takes place more quickly in the central than in the peripheral part of the nerve. In this case, some part of the effect is no doubt due to the mechanical stimulus of the section. If the cut nerve be allowed to remain in the body, it undergoes fatty degeneration. But if the cut ends be kept in apposition, they grow together after a time, and they have even been known to grow together when the cut ends were half an inch or more apart.

3. Gentle stimulation of a nerve increases its irritability; over-stimulation diminishes it, and may destroy it at once (shock). Continued activity diminishes the irritability, and may gradually destroy it (exhaustion).

4. Mechanical irritants, such as crushing or pinching, destroy the irritability. If the mechanical stimulus, however, is not too violent, such as section of it with a sharp knife, the irritability is first increased.

5. A decided disturbance of chemical composition, such as desiccation and treatment with strong alkalies or acids, destroys the irritability. Certain agents absorbed into the blood, such as strychnia, first increase and then destroy the irritability of certain nerve-fibres, and probably also of some ganglion-cells. Curara lowers the irritability of the peripheral terminations of voluntary motor nerves; but Bernard found that a moderate dose first increases the irritability, which then becomes diminished and ultimately lost.

6. The state of the nutrition of a nerve has a great effect on its irritability. If the nutrition is wholly arrested, the irritability disappears. But a nerve whose nutrition is defective discharges its energy more readily than one whose nutrition is perfect.

7. Gradual withdrawal of heat diminishes, and gradual addition of heat (within certain limits) increases, the irritability. Too much heat lowers and may instantly annihilate it by inducing chemical change. A sudden rise of temperature acts as a stimulus and causes the nerve to energise.

8. If a constant galvanic current be passed through a portion of a nerve, it acts as a stimulus at the moment of making and breaking contact. When the current is passing through the nerve, it appears to be at rest, but its irritability is profoundly affected. This condition is called electrotonus or the electrotonic condition, but it would serve no useful purpose were we to enter on its consideration here.

Stimuli.—All mechanical impressions, as blows, pressure, section, etc., which cause alterations of the form of a portion of a nerve, act as stimuli while producing the change. Irritability and conductivity are destroyed if the nerve has been permanently injured. Agents which alter the chemical constitution of a nerve with a certain degree of rapidity, act as stimuli. Some substances, as ammonia and solutions of metallic salts, produce death so rapidly as to prevent the development of the stimulating effect. A sudden rise of temperature in a nerve also acts as a stimulus.

Variations in the intensity of an electrical current stimulate a nerve, the stimulation being the more powerful the more suddenly the variations occur. The variation generally employed is that produced on making or breaking a current through the nerve; but a sudden increase or diminution in the strength of a current also acts as a stimulus. The shocks of frictional electricity have a very powerful stimulating effect, since the currents it forms are extremely rapid in their appearance and disappearance.

(To be continued.)

REPORTS OF HOSPITAL PRACTICE IN MEDICINE AND SURGERY.

ST. BARTHOLOMEW'S HOSPITAL.

CASES OF CEREBRAL HÆMORRHAGE FAR BACK.

(Under the care of Dr. BLACK.)
[Recorded by Dr. ABERCROMBIE, House-Physician.]

Case 1.—*Hæmorrhage into the Pons Varolii.*

M. A. B., aged fifty-two, admitted into Hope Ward under the care of Dr. Black, September 4, 1877. Good health up till to-day, but has been drinking heavily for the past five months. Went to her work as usual this morning; suddenly fell off her seat, and became unconscious. There was no convulsion; no cry.

On admission, deeply comatose; face very livid; pupils equally contracted; no strabismus; conjunctivæ insensible; respiration stertorous; heart-sounds natural; no facial paralysis. She did not rally at all, and died about nine hours after the seizure.

Examination of Body, twenty-three hours after Death.—Right crus cerebri and pons Varolii almost destroyed by extravasation of blood, which has extended into the fourth ventricle. Rest of brain natural. Arteries at base not atheromatous. Lungs congested. Heart: Hypertrophy of left ventricle; no endocarditis. Kidneys contracted, granular.

Case 2.—*Hæmorrhage around Pons Varolii and Medulla from Rupture of Aneurism of Basilar Artery.*

T. I. B., aged fifty-two, slaughterman, admitted into casualty ward, under the care of Dr. Black, October 26, 1877. On the same day, whilst at work, fell off his seat; felt giddy; no loss of consciousness; no convulsion.

On admission, complains of frontal headache; right side of face flatter than left; right pupil slightly dilated; tongue protruded straight; could stand and walk; no loss of power in upper extremities.

About five hours after admission he uttered a cry and put his hand to the back of his neck; there was no convulsion. He at once became deeply comatose; pupils small and fixed; right pupil not so small as left. Pulse 92, regular; respirations fell to six in the minute. After a few minutes the pulse and respirations quickened a little; there was a slight tonic spasm of all his muscles, with convergent strabismus, followed by a cry, after which the coma became absolute. His respirations now became extremely infrequent, and finally ceased. His pulse could be felt for two or three minutes after the breathing had stopped. His urine was free from albumen.

Examination of the Body, eighteen hours after Death.—At the base of the brain there was a large clot of blood surrounding and pressing upon the pons Varolii and medulla oblongata. The left vertebral was much dilated, the right natural. The basilar artery at the place of formation by the two vertebrals was yellow, thickened, and dilated to the size of half a pea; about the middle of this on the left side was a small ragged opening. No atheroma of the other arteries at the base of the brain. Pericardium universally adherent; no hypertrophy of left ventricle; no valvular disease; aorta, as far as end of arch, highly atheromatous. Kidneys granular.

TWO CASES OF EMBOLISM OF THE CENTRAL ARTERY OF THE RETINA.

(Under the care of Mr. SIMEON SNELL, Ophthalmic Surgeon to the Sheffield General Infirmary.)

Case 1.—George S., a collier, forty-three years of age, came under observation on October 27, 1874. He stated that two days previously he had suddenly lost the sight of the left eye. On the day of the occurrence (Sunday) he felt in his usual health, but having been, as he said, "fresh" the night before, he went at four o'clock in the afternoon to lie down, fell asleep, and did not awake until eight the same evening, when he was called by his wife. He awoke as readily as usual, but felt somewhat giddy and bewildered, and everything looked dark and dull before him. He said to his wife, "I feel queer; there's something come to my eye; I can't see." At his request a lighted candle was brought to him, but he found on covering the right eye that he was unable to see it. He experienced no pain or discomfort in the eye. With the right eye he could see perfectly.

On October 27 (just forty hours after the occurrence) the external appearances and movements of the left eye were normal. The pupil was somewhat dilated, and responded to light only in conjunction with its fellow. Vision was absolutely lost in all parts of the retina; strong reflected light from the mirror was not perceived. Examination with the ophthalmoscope showed that the media were clear, but disclosed an emptiness of the vessels, and a general appearance of anæmia of the fundus oculi. The optic disc was pale, its edges ill-defined and merging into the opaque, hazy-looking surrounding retina. The retinal arteries were greatly reduced in size, in some parts appearing as fine threads, and one vessel in particular, coursing downwards (inverted image), was seen to be quite devoid of blood for some little distance after it left the papilla. The veins were also smaller, and contained less blood than those of the healthy eye. No pulsation was produced by pressure. The disc was surrounded by a whitish hazy halo, somewhat obscuring the vessels; it was less marked on the inner side, but became more opaque in the region of the macula lutea. The yellow spot was noticed as a bright reddish dot, surrounded by this film, in which minute arterioles were observable. The right eye was normal. He stated that he had been a free drinker and smoker, but had enjoyed excellent health. There was no history of rheumatic fever, nor had he had syphilis. The heart was free from valvular disease;(a) there was no tortuosity of temporal arteries or rigidity of radials, nor any manifest evidence of atheroma. There was nothing to point to any cerebral lesion. His urine was free from albumen. He was ordered iodide of potass in five-grain doses three times daily.

During the next few days the effusion became more intense, and on October 31 the disc could hardly be distinguished from the surrounding hazy retina; the vessels were more veiled, and the brightness of the macula more marked. Ten days after the occurrence the effusion began to disappear, and about a fortnight later only a little haziness remained in the neighbourhood of the macula. The disc was now whiter, and the branches of the central artery lying on the disc were quite bloodless; their two walls were visible, but there was no blood between them; the arterial branch, coursing downwards for a little distance after it left the optic papilla, was seen as a whitish band, and then again to contain blood to its termination, but, like the other branches, it was thread-like and yet distinct. The veins were also smaller. Vision remained the same, and during an ophthalmoscopic examination he was unconscious of any light, but merely a feeling of warmth in the eye. He continued to present himself for examination until May 1, 1875, when his condition was thus noted:—No

(a) He was afterwards brought before the Sheffield Medico-Chirurgical Society, and examined by several good stethoscopists, who verified the healthy condition of the heart.

return of sight; papilla presented the papery appearance of progressive atrophy; arteries were only distinguished as minute threads, and even then only for a short distance here and there. Since this date he has been lost sight of.

Case 2.—George R. R., aged forty-one, a plumber, had been more or less out of health with bronchitis since the preceding Christmas, and feeling worse on Sunday, August 29, 1875, decided not to go to his work the next day. At about 8.30 on the evening of this day (August 30) he went to lie down on the sofa. After lying there for ten minutes, he rose, with the intention of retiring to bed, and, as he did so, felt as if his left eye were shut. He tried to open it, but it made no difference. He then closed the right eye, and found he could not even see the gaslight. He experienced no giddiness, faintness, or sickness.

On August 31 (nineteen hours after the occurrence) he came under my care. There was total abolition of sight in the left eye, not even retaining the barest perception of light. The pupil was slightly dilated, and it acted only with its fellow. Ophthalmoscopic examination showed that the vessels were much reduced in size, and contained less blood than normal. The portions of artery on the disc were bloodless. The edges of the papilla were indistinct. There was effusion round the macula, which appeared as a red dot with a milky halo surrounding it, in which tiny vessels were coursing. There was very little effusion on the contrary side of retina. Pressure produced no pulsation in the vessels. The right eye was perfect. He had never suffered any ill effects from working with lead, but thirteen years ago had rheumatic fever, and had had two or three subsequent attacks. His urine was free from albumen. The area of cardiac dulness was increased, its action was irregular, and a mitral systolic bruit was plainly audible.

On September 9 it was noted that the effusion generally was more marked; the disc was hardly distinguishable, and the vessels at the lower border of the papilla were quite enveloped in effusion; the tiny vessels coursing round the macula were very distinct, and the halo more milky; there was effusion also on the opposite side of the retina. He was under observation for a considerable period, and the optic disc gradually assumed a white atrophied appearance, as in the previous case, with a thready condition of vessels. The heart-mischief occasioned him a great deal of suffering; and, knowing his end might come at almost any moment, I had prevailed on his wife to give me warning of his decease, so that, as he had given me his consent, I might obtain the eye for examination. Towards the latter end of last year (1876), however, not having seen or heard anything of him for some time, I called at his house, and found, to my disappointment, that he had been buried a week or so previously.

Remarks by Mr. Snell.—These cases present the sudden and complete blindness characteristic of embolism of the main trunk of the central retinal artery. The diagnosis of such cases is generally easy; but hæmorrhage into the nerve-sheath, or interstitial, closely resembles it in the sudden loss of vision, and requires to be distingushed from it. In hæmorrhage, however, the loss of sight is not so complete, and the vessels, instead of being bloodless, are merely filiform. The production of a venous pulse by pressure in a case would point also to hæmorrhage, rather than embolism, as indicating incomplete interruption of blood-current.

THE Council of University College, London, have awarded the Sharpey Physiological Scholarship to Mr. Patrick Geddes.

PHENICATED CAMPHOR IN DIPHTHERIA.—Dr. Souley called the attention of the Société de Thérapeutique to the great utility of this substance as a local application in those cases of diphtheria in which the deposits of false membranes constitute the initial and chief phenomenon—the danger arising from the steady and rapid propagation of these membranes, or the ulterior intoxication of the economy. Under the contact of the phenicated camphor the pseudo-membrane seems to lose its vitality, without that irritation of surrounding parts being produced, whether of the skin or mucous membrane, which is almost always caused by the various solid or liquid topical applications now in use. The solution employed by Dr. Souley is formed by dissolving powdered camphor in crystallised carbolic acid previously dissolved in alcohol (nine parts of the acid and one of alcohol), and which may be employed either in its pure state, or mixed with equal parts of sweet almond oil. He related four cases in support of this mode of treatment.—*Gaz. Hebd.*, November 23.

HYDROPHOBIA AND RABIES.

SIR THOMAS WATSON has once again made use of the pages of the *Nineteenth Century* to teach and enlighten the public, taking this time Hydrophobia and Rabies for his theme; and undoubtedly the paper will be read as eagerly by the profession as by the public to which it is addressed. It is full of information, and is written with the felicity of style and the simple force of which Sir Thomas Watson is such an incomparable master; and to which the only fault that can be attributed is, that it is so delightful that the reader is too apt to read only, and not to study it. The style carries him along so easily and pleasantly that he thinks the subject is easy too, and that he has digested the article and learnt its lessons, when he has only read it.

Sir Thomas first points out that though there would be no hydrophobia were there no rabies, and there can be no rabies unless it be communicated by a rabid animal, yet the two diseases are not identical. "The term hydrophobia is often erroneously applied to both diseases, but the rabid dog is never hydrophobic." The error here spoken of is unhappily a common one, notwithstanding the frequency with which it has been pointed out; and it is a dangerous error, because it has led to the belief that "the rabid dog, like the hydrophobic man, will shun water, and that if he takes to a river, it may be safely concluded that he is not mad"; while the truth is, as Sir Thomas points out, that, on the contrary, "there is no dread of water, but unquenchable thirst: the animal rushes eagerly to water, plunges his muzzle into it, and tries to drink, but often is unable to swallow from paralysis of the lower jaw, which prevents him from shutting his mouth." Sir Thomas does not believe that hydrophobia can ever reproduce itself. Mr. Youatt believes that the saliva of a human being afflicted with hydrophobia is capable of inoculating another human being with the same disease; and he says that the disease has unquestionably been so produced. This is, however, doubtful, to say the least; though some writers on

hydrophobia hold that it has been proved that a dog can be successfully inoculated with rabies by the saliva of a hydrophobic man. We ourselves, it may be remembered, a short time ago spoke of this as a fact; and Bollinger, in his article on Hydrophobia in "Ziemssen's Cyclopædia," says—"Attempts of this sort have been made with positive results by Busnout, Berndt, Löffler, Majendie, and Breschet," though numerous like experiments have failed; but Sir Thomas Watson, with scientific caution, points out that in Majendie and Breschet's experiment the disease in the inoculated dog "might have had some unknown and unsuspected origin." He admits, however, that it is sufficient to make it "too probable that disease, though seldom or with difficulty communi*cated*, may yet be communi*cable*," and that it is enough to demand from us all requisite precaution when engaged in attending upon a hydrophobic patient. There can be no question that hydrophobia can arise in man by the contact of the saliva of a rabid dog with an abrasion or breach of surface of the skin; but Sir Thomas mentions some remarkable cases that support Mr. Youatt's belief that it may also be communicated by the mere contact of the saliva with the mucous membranes. And we should be inclined to add to these instances a history which Sir Thomas Watson gives from Mr. Wrench, of Baslow, as a proof "that the disease is transmissible from the mother to her offspring through the medium of her milk": —In May, 1876, on Mr. Twigg's farm, Harewood Grange, near Chatsworth, a mad dog bit eighteen sheep out of a flock of twenty-one, which were at the time suckling thirty lambs. The sheep were all bitten about the face, and had evidently been defending their lambs during the night in which the attack had been made. Mr. Twigg examined both sheep and lambs, and could not find a single wound on any of the latter. In about a month both sheep *and lambs* began to die at the rate of two or three a day. The sheep ran wildly about, sometimes carrying stones in their mouths, and the lambs ran away. Of the eighteen bitten sheep sixteen died; and of the thirty lambs, not one of which was believed to have been bitten, fourteen died. On the next farm the same thing happened to a smaller extent.

Now, is it not much more probable that the lambs had been infected by licking the wounded faces of their mothers, than that the milk of the latter should be poisonous, and so poisonous as to be deadly when taken into the stomach? We think so, though we are quite ready to agree with Sir Thomas in holding that Mr. Fleming, who has published some conflicting evidence as to the safety or danger of drinking the milk of a rabid animal, acted wisely in recommending the avoidance of such milk.

Sir Thomas gives admirably graphic descriptions of rabies in the dog, and hydrophobia in man; and he says, as we believe every medical man who has once carefully observed a case of hydrophobia will say—"I feel sure that no one who has even once watched its actual symptoms could fail to recognise it again, or could mistake any other malady for it," or it for any other malady.

When speaking of the interval between the bite and the outbreak of the disease, Sir Thomas observes that prolonged periods cannot be regarded as periods of genuine or normal incubation, and in explanation of them re-states a hypothesis suggested by him some forty years ago, to the effect that "the virus implanted by the rabid animal may remain lodged in the bitten spot, shut up perhaps in a nodule of lymph, or detained somehow in temporary and precarious union with some of the animal tissues, without entering the blood itself, for a longer or shorter time—in some cases perhaps never." He shows that a similar suggestion was made by Dr. Anthony Todd Thompson in 1826; and he quotes two curious cases of what we may call delayed vaccination which appear to support his hypothesis. In one, a girl aged fourteen years was attacked with influenza. "She complained of pain in each arm at the spots where, when an infant, she had been vaccinated; and, in fact, in these places vaccine vesicles now became perfectly developed. An elder sister was revaccinated with lymph thence obtained; beautiful vesicles formed, and ran a natural course."

With respect to preventive treatment, Sir Thomas says:—"The early and complete excision of the bitten part is the only means of prevention in which much confidence can be placed, and even that is open to a source of fallacy. In the majority of cases no hydrophobia would ensue, though nothing at all were done to the wound. No doubt many persons undergo the operation needlessly. But in no given case can we be sure of this. If excision should for any reason be impossible, the wound should be cauterised." And, after quoting Mr. Youatt's evidence of having operated with lunar caustic on more than 400 persons bitten by dogs unquestionably rabid, without losing a case, he adds—"Moreover, a surgeon of St. George's Hospital told him that ten times that number had undergone the operation of excision there after being bitten by dogs (all of which might not, however, have been rabid), and it was not known that there had been a single fatal issue." The method of excision approved of by Sir Thomas is that recommended by Abernethy:—"Let a wooden skewer be shaped as nearly as may be into the form of the tooth, and then be placed into the cavity made by the tooth, and next let the skewer and the *whole* cell containing it be removed together by an elliptical incision." And he adds—"In all suspicious cases, if the operation has been omitted in the first instance, it will be advisable to cut out the wound or its scar within the first two months, or at any time before preliminary symptoms in the spot foreshow the coming outbreak. Later would be too late." He gives the following useful and wise advice for the management of a bite when there is not access to immediate medical help:—"First, a bandage tight enough to restrain the venous circulation should be applied just above the wound, between it and the heart; and next, without any delay, a continuous stream of tepid or cold water should be poured from a height, and therefore with a certain degree of force, upon and into the wound. This might be done from the spout of a tea-kettle, and it should be persevered with, even for an hour or two, or until the arrival of medical aid." In combating the arguments used in favour of the sometimes spontaneous origin of rabies, that it often springs up where no contagion can be traced, and sometimes where contagion seems impossible, Sir Thomas brings forward two striking instances—which, however, we cannot give here—"in which contagion had been deemed impossible, but in which it was at length detected by some very singular circumstances."

Sir Thomas Watson strongly approves of the plan proposed by Mr. Youatt and by Sir James Bardsley for stamping out rabies—viz., the establishment of a universal quarantine for dogs within the kingdom, and a total prohibition of the importation of these animals during the existence of this quarantine. We have noticed this lately, and confess that we doubt the possibility of carrying it out perfectly; but we entirely agree with Sir Thomas that "*all* dogs should be narrowly watched, most especially dogs known to have been bitten or to have been quarrelling, sick dogs, wandering and ownerless dogs, and such as are the playthings of dog-fanciers and others," and that "the superfluity of dogs in the kingdom must be abated by the unshrinking destruction of many." He speaks of the immense number of dogs, and of the enormous extent to which the dog-tax is evaded, and observes that this discloses "the presence among us of a national nuisance, and a growing source of national dishonesty and a serious national peril." A very striking proof of the great number of unowned or carelessly looked-after dogs in the metropolis only may be

given here from an article in the *World* of November 21, on "Colonel Henderson at Scotland-yard." That officer is reported to have said, "Since the duty of catching stray dogs was imposed upon the police—that is to say, during the last ten years—we have caught more than 100,000 stray dogs (which were taken to the Home for Lost Dogs); last year nearly 19,000 canine arrests were made—without detecting," he adds, "a single case of rabies."

Having shown that we do not possess any proof of the spontaneous origin nowadays of rabies in the dog or in any other animal, and that rabies arises solely by inoculation by a rabid dog in the first instance, or by rabid animals of the same species with the dog, Sir Thomas points out that "large portions of the habitable world abounding in dogs are now, and have always been, entirely free from rabies and hydrophobia"; and he gives on this subject "authentic and valuable information" derived from some of his own friends and acquaintances. Thus, the Bishop of Lichfield, who lived more than twenty-five years in New Zealand, never heard of a mad dog in those islands; and his experience is supported by that of Bishop Abraham, who resided there for seventeen years. Bishop MacDougall informs him that during his twenty years' residence at Sarawak he never head of a single instance of rabies. Sir Henry Young and others have assured him that rabies is utterly unknown in Tasmania and in Australia; and similar testimony has been received by him with respect to Madeira, South Brazil, and the Arctic regions. Sir Thomas has also "been assured upon unquestionable authority" that "Demerara had not within the memory of man been afflicted by the presence of hydrophobia till the year 1872, when rabies was imported by the influx of a large number of dogs from Barbadoes, in avoidance of a tax which had there been imposed upon those animals"; and Colonel Horne, C.B., an engineer officer, who last year lived for some months at Constantinople, informed a friend of Sir Thomas's that "he made repeated and special inquiries there, and was assured that no instance of the disease (hydrophobia) was ever known in that city." It is fair, however, to add to this that Bollinger, in the essay before referred to, states that "in Constantinople hydrophobia rages in some years—*e.g.*, 1839—very widely; as a rule, however, according to one writer (Fauvel) it is rare, while according to another (Zoeros) it is not so unfrequent." He states, also, "that in February, 1860, hydrophobia broke out as an epizootic in Upernavik, the northernmost settlement of Greenland"; and that "in like manner, in 1863, hydrophobia prevailed in epizootic form in the northern portion of Greenland, completely destroying all the dogs in certain districts"; but it is to be observed that he does not mention that the people were infected; and Sir Thomas Watson says, "All those who have been personally conversant with the Arctic sledge-dogs agree in stating that they are subject to a fatal kind of insanity quite distinct from true rabies, and accordingly not productive of hydrophobia." Bollinger comes to the conclusion "that no land or climate is free from hydrophobia"; but it must be admitted, we think, that at any rate some countries enjoy for long periods perfect freedom from rabies and hydrophobia.

We have been led to give more space than we had intended to our notice of Sir Thomas Watson's admirable article, but we must add yet a very few words more. Sir William Gull, in a letter to our contemporary the *Lancet*, three weeks ago, speaks of hydrophobia as a disease "where treatment has always failed, and where the conditions of the disease are such as to lead to the reasonable conviction that failure will still attend our efforts at cure"; and now Sir Thomas Watson, with whom it may be said that

> "Old experience doth attain
> To something like prophetic strain,"

writes, "There are no authentic cases on record that I am aware of in which a hydrophobic person has recovered. As it has been it is still, Ἰατρὸς ἰᾶται θάνατος—the physician that cures is Death. It would be idle to discuss any curative measures after the peculiar symptoms of disease have once set in." We must, with the utmost deference, enter a protest against statements like these. Two or three cases have been recorded lately of recovery from what was firmly believed by the attendant medical men to be hydrophobia—and one of the cases was seen at its commencement by Dr. Austin Flint, of New York, who then considered the disease to be most probably hydrophobia—under the employment of curare. But even if it be disputed that they were not cases of true hydrophobia, the power of curare over spasm was clear and encouraging; and it is surely the part and the duty of medical science never to despair of finding a cure for *any* disease, so long, at least, as it has not been proved that, when its first recognised symptoms appear, irremediable organic change already exists. This has not yet been proved with regard to hydrophobia, and we therefore urge, most respectfully, that the tone of the sentences we have quoted is unscientific. Medical science, like all true science, is ever ready to acknowledge ignorance or confess defeat; but, on the other hand, very slow to recognise an impossibility of advance, or to even seem to discourage inquiry. It may be said that the utterances we object to were intended only to prevent the public from trusting in any boasted remedies instead of relying on prevention. That, indeed, is a good object, but, on the other hand, one result would be the fostering in a patient of that utter despair which is so potent an ally of disease. Happily, however, "hope springs eternal in the human breast," and neither the true physician nor the born scientific inquirer will ever be daunted by any prophecies of failure; so that the above-given utterances need not, perhaps, after all, be much regretted.

SOUTHERN HEALTH-RESORTS.

No. V.—Hyères.

Unlike the other health-resorts of the French and Italian Riviera, Hyères is situated at a distance from the sea, and separated from it by a plain about three miles broad. A common superstition in England represents it as placed on an island, but the idea is based on a confusion of the town with the group of islands of the same name (Iles d'Hyères), which lie off the coast, and consist of three principal islands and several islets, forming a chain nearly parallel to the shore, and from two to three miles distant from it. Hyères is the southernmost watering-place of the Riviera, lying in 43° 7′ North latitude, or very nearly in the same latitude as Elba. It is a town of 12,000 inhabitants, according to the most recent statistics, and is built around the base and on the south-eastern flank of a conical hill about 700 feet high, which is known as the Château Hill, owing to its upper portion being enclosed by the fortifications, and its top crowned by the remains of an old castle of the tenth or eleventh century, which, especially on the north and east side, present a very picturesque appearance. An excellent idea of the general relation of the town to its surroundings may be obtained by climbing to the top of the Château Hill, the view from which commands a wide extent of country. On the east and north-east rise up the Montagnes des Maures, which close in the plain of Hyères, and project in the form of a promontory into the sea, sheltering the district to the west of them to some extent from the easterly winds. The western and south-western boundary of the view consists of the fir-clad Montagnes des Oiseaux, the highest peak of which is about 1000 feet above the sea, and a lower ridge, La Colline de l'Ermitage, which runs in a southerly direction from them to within half a mile of the sea, where it slopes rapidly to the plain, and is crowned by a votive church

revered by mariners, some of whose votive tablets date back to A.D. 1612. Between these two ranges of hills the ground is nearly level, except within about a quarter of a mile of Hyères, where it rises at a very moderate gradient. The neighbourhood of the sea is swampy, and to the east-south-east there are well-defined marshes, but the bulk of the land is under careful cultivation, and the eye readily distinguishes large tracts of pasture and arable land in the distance, and acres of market gardens nearer the town. To the right and left of us, close to Hyères itself, there are considerable numbers of olive-trees, and the red-brown roofs of the older houses lie nearly below us massed together near the base of the Château Hill, but more on its eastern than its western face; while the visitors' district (hotels and villas) spreads out like wings on either side. The Islands of Hyères (already mentioned) must not be omitted in describing the view. The two easternmost of the three—L'Ile du Levant and L'Ile de Port-Cros—are separated by a wide gap from the third, or L'Ile de Paquerolles, which is the largest, and lies nearly due south of Hyères, very close to the Presqu' Ile de Giens, an island which is converted into a peninsula by two narrow parallel banks of sand about two miles long, so that the entrance of ships between it and the land is only possible from the south on the side of the islands. The strip of sea thus embraced between the peninsula, its isthmus, and the mainland, is called the road-stead, or Rade d'Hyères, and is a most valuable harbour. It is utilised by the French Government as a station for their training-ships, and as a practice-ground for gunnery. From the western side of the Château Hill there is also a good view over the wide valley of Hyères, which runs down from Toulon in an easterly direction; and is traversed by the carriage-road to Toulon, and the recently opened railway which now connects Hyères with the main line between Marseilles and Nice. The southern boundary of this valley near Hyères is formed by the spurs of the Montagnes des Oiseaux, and the northern and north-western by a range of high hills which run from the back of Toulon nearly parallel to and a few miles from the coast, and culminate about ten miles north of Hyères in the grim bare peak of the Coudon, above La Farlède. Still nearer Hyères, a spur of the Château Hill, running in a north-westerly direction for two miles to its highest point at the Mont Fenouillet (900 feet), narrows the termination of the valley at its entrance into the plain of Hyères. The valley of Hyères is thus protected to a considerable extent on the south, and almost completely on the north, but is exposed on the west, north-west, south-east, and east. We shall presently see that the chief blot on the climate of Hyères depends on the permeability of this valley by wind in these latter directions. To the *east* of the Château Hill, the spurs of the latter (Les Maurettes) form a very fair protection from northerly winds for about a mile and a half due east, as far as the valley of the river Gapeau, a small stream overshadowed by poplars and wych-elms, and more resembling a quiet English river than almost any we have seen along the Riviera, and which runs into the sea in the south-eastern corner of the plain of Hyères, near the Old Salterns (Vieux Salins).

The amount of protection from north-easterly winds enjoyed by Hyères is very considerable. By ascending the highest point of the Montagnes des Oiseaux to the west of the town (about 1000 feet high), at least four graduated ranges of hills and mountains can be counted behind the Château Hill, the most distant being capped with snow even as late as May. Due north of the town the protection is less complete, and to the east and east-south-east the mountains (Des Maures) are not nearly so high as, and are further off than, on the north-east.

The climate of Hyères is in many respects a very mild one, as might be expected from its latitude and its sheltered position. Roughly speaking, it is about 10° warmer than England. In the depth of winter the thermometer rarely falls below 44° or 45° Fahr., and very rarely indeed reaches 32°. The mean temperature in December, January, and February ranges between 50° to 55° in the shade, and 77° to 86° in the sun (Honoraty). The town and its immediate neighbourhood are about 2° to 3° Fahr. warmer than the district near the sea. Valcourt gives 59·9° as the mean shade temperature for the autumn, 46·4° for the winter, and 59° for the spring; and a present resident at Hyères tells us that the highest shade temperature he has seen *in his house* in summer is 81°. The curse of Hyères, if we may so express it, is the north-west wind, or mistral, which not unfrequently rages with great violence, sweeping in tremendous gusts (*experto credite*) down the valley of Hyères on to the town and plain. This wind, the magistral (*magister*), or master wind, as far as our own observations go, almost invariably blows when the sky is clear, and the sun warm. It rises about 10 a.m., and blows until sunset, or for an hour afterwards, and occasionally continues also to blow during the night. The simplest explanation of its mode of origin appears to be that it is due to the inrush of cold air from the north into the partial vacuum caused by the ascent of rarefied air from the heated coast; it seems, in fact, to be strictly analogous to the sea-breeze which springs up with the sun and subsides after the heat of the latter is withdrawn. The mistral blows with the greatest severity during the prevalence of northerly currents; and the reason why its direction is from the north-west appears to be, that the high mountains prevent the immediate descent of cold currents from north to south, and compel them to turn round their western flank, and so find access to the coast. The mistral is said to blow at Hyères during upwards of sixty-four days in winter, spring, and autumn. We ourselves noted it this year (1877) fifteen times between April 12 and May 21, and on six of these days it is marked as "rough," and on two others as "furious." However, the inhabitants of Hyères pronounced our experience as "exceptional," though from collateral evidence we are inclined to the belief that the so-called exception is in this case really the rule. We by no means desire, however, to utterly condemn the mistral as a downright bad and injurious wind, as some persons do. When it blows with moderate force it is not extremely unpleasant, especially if the sun is hot, and the chief inconvenience it causes arises from the dust it raises along the streets and roads. In parts free from dust a moderate mistral is *per se* not nearly so noxious as an east wind of even less severity. Easterly winds are not unknown, unfortunately, at Hyères, especially in winter and spring. According to Ajello ("Hyères, son Climat, etc.," 1874), the statistics of twenty years give sixty-five days of east, twenty of north-east, and twenty of south-east wind per annum. We can ourselves testify to the occurrence of fresh easterly winds at Hyères. The great advantage of the position of the town, especially in certain cases, is its distance from the sea (three miles), for the sea-breeze which blows along the Mediterranean coast from 10 a.m. to 3 or 4 p.m. on sunny days is scarcely at all felt so far inland, and in any case its force is much broken by the Iles d'Hyères, which form a kind of wall to the south of the town. These islands are really loftier than they appear at a distance, and the strip of sea enclosed between them and the land contributes very little in itself to the formation of the sea-breeze, which flows in from the open sea.

Dr. Griffith, who has resided at Hyères for the last eighteen years, informs us that the cases of phthisis to which the climate is peculiarly adapted are those of an acute florid type with high fever. Invalids of a nervous temperament, and for whom the neighbourhood of the sea at Mentone or Cannes is found to be too exciting, also get on better at Hyères, and

sleep better, whereas lymphatic persons find that the climate of the former places suits them best. Patients with a tendency to hæmoptysis are also said to do better at Hyères, and no doubt rheumatic cases might be sent there with advantage.

We must now say a little about the town itself, and the general characters of the district. Hyères is entered on the west side by a single rather straggling street, about a quarter of a mile long, which is called the Boulevard National, and skirts the base of the Château Hill, running at first from north-west to south-east, and afterwards nearly due east, when it merges in the town itself. Two of the best hotels, and several *maisons meublées*, are situated in the Boulevard National—an unfortunate selection of site, as this part of the town is the most swept by the mistral. Some of the houses on the north side of the street are considerably raised on a kind of terrace above the carriage-road, so that their view is but little affected by the houses opposite. The course of the Boulevard National through the town of Hyères, where it gradually assumes the character of a high street, and is termed the Route Nationale, is broken at two points by open spaces or squares—the first, the Place des Palmiers (so designated from the seven very fine palms which form its chief attraction), being the smaller; and the second, the Place de la Rade, or market square, with the oblong Place Royale opening out of it on the north, the larger. Several roads enter the main street from the south, and two of these enclose between them the very picturesque Boulevard des Palmiers, which runs parallel to the high street, with its centre nearly opposite the Place de la Rade, and is planted with two rows of date-palms, upwards of sixty in number, which after a few more years of growth will give the street a decidedly Eastern character.

The north-east corner of the Place de la Rade is connected by a short street with the new Boulevard d'Orient, which is north of, and nearly parallel with, the Route Nationale. The villas which have been, or are still being, erected on either side of it, are efficiently sheltered from the north by the ridge of the Maurettes, underneath which they lie, and they are also to a great extent out of the line of the mistral. They have a south or south-west aspect, and nice gardens, and enjoy an excellent view over the plain and roadstead. Below this Boulevard, the Route Nationale, which is bordered by villas on its north side, runs for about two miles eastward towards the valley of Gapeau already mentioned, but it is a very dusty road, and traverses a shallow, draughty cutting bordered by vines and olives, and hence is not a very good promenade for invalids. The old part of the town of Hyères clusters round the Place de la Rade, especially its western side, and most of the narrow streets are built on the ascent, and are only available for foot-passengers.

The town as a whole is not kept as clean as it might be. The streets want better paving and draining; in fact, in the old town there appear to be no drains, but the slops and refuse from the houses are allowed to accumulate and run down open gutters in the centre of the streets. This is especially true of the Rues St. Bernard, de la Croix, and Fonouillet, and some of the back lanes above the cemetery are horribly filthy. The best shops are in the Rue Massillon, leading to the Place Massillon, and along the Route Nationale and in the Place de la Rade. There is a general poverty-stricken look about the shops, and they are very inferior to those of Cannes or Nice. The Hôtel de Ville, or town hall, is situated in the little Square Massillon, which is adorned by a bust of the celebrated preacher who was born in one of the houses close by; and a curious old tower which belonged to a Templar church on the same spot is now the official residence of the Commissaire de Police.

(*To be continued.*)

THE WEEK.

TOPICS OF THE DAY.

At the recent November Sessions for the transaction of the business of the county of Middlesex, the Committee for Accounts and for General Purposes, in recommending payment of the County Coroners' accounts, called attention to an entry in the account of Dr. Diplock for a charge of two guineas paid to Dr. E. L. Tyler Smith for attendance as a medical witness, and for making a post-mortem examination in the case of an inquest held at Heston. The deceased gentleman was eighty-one years of age, and died in the presence of his wife and of a neighbour; and his son, who had strongly objected to any examination being made, addressed a letter to the Clerk of the Peace on the subject. So favourable an opportunity was not, of course, lost by Captain Morley—present on the bench of magistrates,—who proceeded to deliver some very strong views on the question, pronouncing the examination illegal, and entirely opposed to the wishes of the relatives, because the deceased had died at the advanced age of eighty-one. The Court eventually disallowed the charge of one guinea for the post-mortem examination, and Captain Morley proceeded to express a hope that in the ensuing session the Home Secretary would take in hand some legislation on the subject of coroners' duties. Dr. Smith has since addressed a letter on this subject to the Marquis of Salisbury, the chairman of the magistrates, which he has sent to several of the papers for publication. In this letter he impugns the veracity of several of the statements made as to his conduct, and asserts that he received instructions from the coroner's officer to perform the post-mortem examination in the same manner as he has always done before on similar occasions.

A disgraceful case of recklessly endangering the spread of infectious diseases, and defrauding a sanitary authority, was last week heard at the Hammersmith Police-court, where Thomas West, a furniture dealer, at Walham Green, was re-examined on a charge of being concerned with the Sanitary Inspector of Fulham in obtaining various sums of money from the District Board of Works by false representations. A warrant had been granted for the apprehension of the sanitary inspector, but he could not be found. It appeared that during the outbreak of small-pox in the parish the inspector received instructions to destroy the infected bedding, and supply the sufferers with other articles. For that purpose he employed the prisoner to supply bedding, and the practice was to pay him after the items in the accounts had been initialed by the inspector. It was, however, discovered that in many cases a charge had been made for articles which had never been supplied. The prisoner said he acted under the instructions of the inspector, and that he had intended to "let out" about the inspector burning "dummy" beds on the common, and selling the beds themselves. The prisoner was committed for trial, but the greater criminal is undoubtedly at large.

The following extract from the last report of Professor Bernays, Public Analyst for the parish of Camberwell, is of some interest in connexion with the recent controversy on the subject of the admixture of salt with beer sold to the public:—"In the past quarter I have examined eleven specimens of beers, ales, and porters. As to alcohol, the variation was only between 8 and 10·5 per cent. The same lack of hops is exhibited as of old; at least, a little goes a long way. But the most curious feature is in the increase of salt. It will perhaps be remembered how often I have mentioned the almost absence of salt in days gone by. Now, however, we have arrived at a quantity, in the case of No. 70, so large that I ventured to obtain a magisterial decision and a penalty. The results of other analyses are:—No. 57, not estimable; 58, 5·60; 59, 11·20; 68, 13·30; 67, 30·10; 63, 34·30; 61, 44·10; 60, 47·69; 69, 58·10; 72, 82·60." Here, then, we have, from a merely nominal

presence, as much as eighty-two and three-fifths grains in a gallon—a quantity sufficient to induce thirst and encourage drunkenness.

It may be interesting to some of our readers to learn that the dissection of the Berlin gorilla, Pongo, was performed last week by Professor Virchow and Professor Hartmann, in the presence of several eminent Berlin physicians, and it was ascertained that the sudden death of the animal was caused by acute inflammation of the bowels—the same disease which carries off young children so rapidly. The dissection explains the cause of his previous illness, and supplies valuable information with regard to the treatment of anthropoidal apes. The button of a glove, iron wire, and pins were found in the animal's stomach.

In speaking of the sanitary measures which are being taken to render Marlborough House a safe residence for the Royal family, the *Sanitary Record* states that a clean sweep has been made of every old drain and cesspit about the premises; other drains have been removed from beneath the basement, where every floor is being taken up. The entire site will be covered beneath the wood floors with Portland lime concrete, and the flagged portions will be laid on a solid bed of Portland concrete. The drains will be fully ventilated at six points by iron pipes carried above the roof, and every old closet-pipe of soldered lead will be removed, and new pipes of solid lead substituted. In fact, so far as sanitary science can improve an existing house on an old site, everything is now being done to make Marlborough House a healthy residence. Meanwhile, it is not reassuring to learn that Clarence House, which the Prince of Wales and his family will occupy until their own residence is completed, is built on a site originally occupied by a hospital for leprous women, which was pulled down about the year 1660 to make room for the erection of St. James's Palace—a date at which sanitary science, as we now understand it, certainly did not exist.

A town's meeting was held at Birmingham last week, under the presidency of the Mayor, for the purpose of authorising the Town Council to apply to Parliament for an Act "to empower the Mayor to acquire the disused burial-grounds within the borough, and to appropriate the same as open spaces accessible to the public, and for other purposes." The Mayor having moved the resolution, Councillor Matthews, in seconding it, said that when Mr. Cross was in Birmingham he strongly denounced the existence of such a plague-spot as the Park-street burial-ground, and said he would give any assistance in his power for the conversion of such places into more healthy areas. The motion was unanimously adopted.

A large audience, including the Vice-Chancellor, Dr. Sewell, assembled at the Museum, Oxford, on the 30th ult., to hear a lecture by Dr. Acland, the Regius Professor of Medicine in the University, on "Rabies and Hydrophobia." In the course of a lengthy address he said that it may be admitted that there was as yet no cure known for that disease when once established in man. Many extravagant remedies had been suggested; it was, however, almost certainly preventable by prompt measures taken at the time when the injury was inflicted; and the weight of evidence showed that active cauterisation and excision were the most efficacious preventives. With regard to other measures, he was of opinion that the State should impose a rigid dog-tax, and should compel every dog to wear a collar with the name of its owner and number of the licence affixed, and that all unregistered dogs should be mercilessly destroyed if found in the streets. Nothing could be more reassuring than the knowledge how entirely this disease may be brought under control; the marvel was that they were, and had been, so careless.

Redruth, in Cornwall, must be an exceptionally healthy place, if gauged by the important salary paid to its medical officer of health. At a recent meeting of the Local Board a long discussion took place as to the reappointment of the medical officer. Dr. Hudson decidedly objected to the ratepayers' money being spent on nothing; they had no report of any kind from the medical officer of health. If it was their opinion that such an official was useless, which they seemed to think by giving him five guineas a year only, they should do without one, and tell the Local Government Board so. They did not want the medical officer to do anything. They had no by-laws, and no instructions to give him. When Dr. Hichens was appointed at £25 a year, it was understood he was to work under the by-laws, but those by-laws were not now in force. The medical officer was not going to do the work as it ought to be done for five guineas a year, but all they required of him was to do nothing. Several members of the Board said Dr. Hichens did the work as satisfactorily and well for five guineas a year as he had previously done for £25. Ultimately, Dr. Hichens was reappointed medical officer with the liberal salary of five guineas per annum, and a vote of thanks was accorded to him for his past services and attention to the duties of his office. There would certainly seem to be some warranty for Dr. Hudson's assertion that the Board required this officer to do nothing, or Dr. Hichens sets an exceedingly modest value on his services.

The final meeting of the Hospital Saturday Fund Committee for the present year was held on Saturday last in the board-room of the London Hospital. Mr. John Hughes, chairman of the Council, presided, and congratulated the meeting on three important facts—namely, that the fund had collected £275 more than last year; that it had spent £300 less than last year; and that it had made its awards three months earlier than after last year's collection. A larger sum would have been divided amongst the hospitals, but that there was a sum of £150 to pay on last year's accounts, and a balance had this year been carried forward. The reports of the Council and the Distribution Committee, together with the list of the awards, having been approved, votes of thanks to the officials connected with the Fund closed the proceedings.

At last week's meeting of the Metropolitan Board of Works the question of Thames floods was again brought forward by Mr. Runtz, who had previously given notice of his intention to propose a motion on the subject; this was duly seconded, and an amendment by Mr. Richardson having been put to the meeting and carried, on its being put as a substantive motion Mr. Roche moved the "previous question," observing that the subject was already before the Committee of Works and General Purposes, and when they had come to an agreement on some principles, it might be brought before the Board, and then possibly Parliament would pass the Bill. The "previous question" was carried by a majority of eleven, and therefore negatived both motion and amendment. But the high tides will not hold off until the Board of Works has ceased to disagree, and it is seriously to be hoped that a Bill for thoroughly dealing with the question will be passed early next session.

Small-pox would appear to have broken out again rather severely at the East-end of London. At the Limehouse Board of Works, Dr. Rogers reported that the disease was seriously on the increase in the district under his charge, and instructions have been issued to take every precaution for the isolation of the disease, in order to prevent its spread in a contagious form. The question also came before the Stepney Board of Guardians, and they have been in communication with the Local Government Board, Dr. Stevens recommending house-to-house visitation, in order to quarantine the houses where the disease raged. This recommendation was not adopted, but it was determined to wait and see whether the disease increased in virulence. In Poplar, Bow, and Bromley, the three parishes forming the Poplar Union, a few years ago said to be the best vaccinated locality in the metropolis, small-pox has again

appeared, and the Board of Works, being aware of this, are pushing on the erection of their own asylum, the first in London for the treatment of non-pauper cases of infectious disease. In all the districts, however, it has been found that the persons affected were principally immigrants, who had probably evaded the law by moving from one district to another.

The Registrar-General reports a high death-rate last week from scarlet fever at Wolverhampton, Norwich, and Sheffield. In London 31 deaths from small-pox were registered, 1 in Liverpool, and 1 in Birmingham, but none in any of the seventeen other principal towns. In London 81 deaths occurred from measles, 52 from scarlet fever, 5 from diphtheria, and 27 from whooping-cough. The deaths referred to "fever," which had been 28 and 38 in the two previous weeks, were 36 last week, and included 1 from typhus, 30 from typhoid, and 5 from simple fever.

A GOOD EXAMPLE.

We extract the following from a back number of the *Home Chronicler*, the editor of which is to be congratulated on having for once presented the readers of the journal with a bit of sound sense:—"The International Association, for the Total Suppression of Vivisection has been using its influence with the Austrian Government, with a result that may be gathered from the subjoined reply received from the Minister for Ecclesiastical Affairs and Education at Vienna." The translation of the reply runs thus:—"Imperial Royal Ministry for Ecclesiastical Affairs and Education.—The letter of July 7 (14), received by me, in which the Association, referring to the English Act of Parliament for Restricting Vivisection, which was passed in consequence of cruelties proved by evidence to have been practised in laboratories upon living animals, proposes to me that it would be desirable in the interests of humanity that the Austrian Government should institute an inquiry into the experiments carried on in physiological laboratories and elsewhere in Austria; and the subject has received my most serious consideration. The firm conviction, however, that no abuses in connexion with experiments on living animals are taking place in the western half (or division) of the empire, over which alone my jurisdiction extends, and the apprehension lest restrictive Government measures might perhaps mischievously interfere with the noblest efforts of medical investigators to elucidate pathology, have restrained me from setting on foot the suggested inquiry. I have, nevertheless, felt myself bound most strongly to impress upon the institutions concerned that in the course of their scientific investigations they should allow every humane consideration as much weight as is compatible with the object of the investigation itself. I consider that I have hereby, without any injury to scientific interests, done my best to satisfy the claims of humanity.—(Signed by the Minister for Ecclesiastical Affairs and Education, Vienna, August 16, 1877.)" We regret that there was not to be found in our own Government a Minister who could return an equally straightforward and sensible reply.

THE NEED OF A CENTRAL WATER AUTHORITY.

Just at the present time, when the question of the expediency of placing the water-supply of the metropolis in the hands of one central authority is being mooted, the famous Southwark and Vauxhall Company have provided a most cogent reason in favour of such a step. At the end of last week the Company mentioned were summoned at the Southwark Police-court by Charlotte Snook, of Albert Cottage, St. James's-road, Old Kent-road, for refusing to supply her with water after tendering the rates due. The complainant said she had been a customer of this water company for twenty years, and had been upwards of four years in her present abode. She unfortunately allowed the water-rate to be in arrears in the sum of twenty-eight shillings, but because she was not able to pay that sum when last demanded, they had cut the water off. She begged the collector to call again before doing such a cruel act, but he took no heed of her appeal, and she had since been without water. The magistrate asked if she had paid the arrears due. Complainant replied that she had tendered the money, but the Company refused to put the water on again, unless she paid all expenses for cutting off and replacing the pipes, as well as a quarter in advance. She could not do that, and the consequence was that the water was stopped and the public health endangered. The magistrate strongly animadverted as to the conduct of the Company in cutting off the water when they had the power to summon her to his court for the arrears. The complainant reminded his Worship that small-pox and fever were on each side of her, and it was essential she should have a good supply of water; if they had waited only two hours before they cut it off, she would have been able to pay them. Mr. Partridge said their monopoly and their powers under the Act enabled them to do what they had done; but he thought they had been to blame in cutting off the water where small-pox and fever were raging. The complainant being a poor but respectable woman, who had paid the rates for so many years, he thought the Company might restore her supply of water on payment of the arrears due. The Supervisor of the Company, who was in attendance, promised to lay his Worship's recommendation before the directors, but reminded the magistrate that the Company had not exceeded their powers. Mr. Partridge said he was aware of that, and, in dismissing the summons, he directed the costs of it to be returned to the complainant. No one will suppose that such a reckless act would have been committed had the water-supply been vested in the hands of the Metropolitan Board of Works, who would have been compelled to study, first, the health of the district, and after, the payment of their claims for water supplied. This notorious Company is getting on: after attempting to coerce Richmond, they have fallen foul of an old woman.

PATHOLOGICAL SOCIETY OF DUBLIN.

At a meeting of the Society on Saturday, December 1, Mr. Edward Hamilton, President, in the chair, Dr. Finny showed a remarkable example of displacement of the kidney, the supra-renal body being in the normal position. There was a "sling" ureter. Three arteries supplied the kidney, and three corresponding veins emptied themselves into the middle sacral, internal iliac, and inferior cava, respectively. The kidney was lobulated. Dr. Nixon exhibited specimens which illustrated the etiology of intermittent aortic murmur and Quincke's murmur. The latter—a peculiar grating murmur—was heard at the junction of the second left costal cartilage with the sternum, except at the end of a very full inspiration. The margin of the upper lobe of the left lung overlapping the heart was airless and carnified; so that the absence of the pressure usually exercised by this part of the lung on the pulmonary artery produced Quincke's murmur. The murmur of aortic patency was intermittent, because the murmur was caused by occasional entangling of pieces of fibrin in the otherwise healthy aortic valves. Dr. Banks showed the liver of a boy, aged ten, who had suffered from enormous ascites. The superficial abdominal veins were much distended during life. Peculiar polypoid masses, apparently caseous or tubercular in character, sprang from the lower edge of the liver, and were scattered over its surface. The specimen was referred to a committee to report on its pathology. Dr. Lyons presented a striking example of hydronephrosis, from the body of an intemperate man, who had been tapped for ascites eleven times, but whose liver was not cirrhosed. Both kidneys were lobulated; the right one was fatty in a marked degree, and was connected by a band—apparently of fibrous tissue—with

the left kidney. The latter was in a state of advanced cystic degeneration, caused in no slight degree, it would seem, by pressure exercised by the left renal vein on the corresponding ureter, which was quite pervious. The ascitic fluid contained an appreciable quantity of urea, which had apparently passed by exosmosis from the vast cysts in the left kidney into the peritoneal cavity.

PROVIDENT DISPENSARIES FOR BIRMINGHAM.

The Sub-committee appointed by the Birmingham Charity Organisation Society to inquire into the subject of the abuse of gratuitous medical relief have presented their report, and also an additional report containing suggestions for the establishment of provident dispensaries for the district. According to the former, the Sub-committee express their belief that the amount of gratuitous relief at the present time afforded is even largely in excess of the legitimate demands of an industrial population, and that it is an urgent public necessity that it should be reduced. In the latter they explain that the two largest centres in which provident dispensaries have been established are London and Manchester, and upon the history of the institution in this last city (as being very analogous to Birmingham in the character and requirements of its population) they chiefly base their recommendations, always remembering that if any such scheme is to command success it must be established on a wide and popular basis, and obtain co-operation on the part of the governing bodies of existing medical charities. In connexion with the foregoing subject we have received a copy of the resolutions passed at a public meeting held in the Town Hall, Birmingham, the Mayor presiding, for establishing provident dispensaries in Birmingham and the district, with rules for their government and management.

DIFFICULTIES OF RURAL SANITATION.

According to a report of the Town Council, Haverfordwest is in a very filthy condition. Mr. Alderman W. Davies, speaking on the subject, said—"Our town is getting into a very filthy state. I can point out to the inspector—I have no wish to do so publicly—places which are a disgrace to a community. I speak openly, and I wish the reporters to report what I say. There are places in this town in a filthy condition: fever is raging from one end of the town to the other." Other speakers seemed to confirm these remarks. Mr. Green, another alderman, said—"There is great truth in the statement that the Corporation has not backed up the Superintendent as we ought to have done." This seems indeed to be the gist of the whole matter. Neither medical officers of health nor sanitary inspectors can avail if their recommendations are not effectually and efficiently carried out. Dr. Brown, also an alderman, is credited with the following remarks:—"You cannot stem the course of fever. We know nothing about it: it is not in the water. It is a high decree passed long ago that there shall be diseases, which visit the land with terrible power. It comes from a Wise Power, and we are unable to stem it." Perhaps there is some mistake. We should hope so, for Dr. Brown's sake. It is said the Welch are nearly as fatalistic as true Mohammedans. Is this Dr. Brown's view?

ROYAL INSTITUTION OF GREAT BRITAIN.

At the general monthly meeting on Monday last (George Busk, Esq., F.R.S., Treasurer and Vice-President, in the chair), the Earl Stanhope, Mrs. Robert S. Faulconer, Colonel Henry Macfarlane Norris, Mrs. Henry Pollock, J. Lyons Sampson, Esq., and Miss Elizabeth M. Steedman were elected members of the Royal Institution. The presents received since the last meeting were laid on the table, and the thanks of the members returned for the same. The following arrangements of the lectures before Easter, 1878, were announced:—*Christmas Lectures:* Professor Tyndall, D.C.L., F.R.S.—Six lectures adapted to a juvenile auditory, on Heat, Visible and Invisible; on December 27 (Thursday), 29, 1877; January 1, 3, 5, 8, 1878. Professor Alfred H. Garrod, M.A., F.R.S.—Twelve lectures on the Protoplasmic Theory of Life and its Bearing on Physiology; on Tuesdays, January 22 to April 9. James Dewar, Esq., M.A., F.R.S.—Twelve lectures on the Chemistry of the Organic World; on Thursdays, January 24 to April 11. R. Bosworth Smith, Esq., M.A.—Seven lectures on Carthage and the Carthaginians; on Saturdays, January 26 to March 9. Rev. W. Haughton.—Three lectures on the Natural History of the Ancients; on Saturdays, March 16, 23, 30. Ernst Pauer, Esq.—Two lectures on the Clavecinistes and their Works (England and Italy; France and Germany); with musical illustrations; on Saturdays, April 6, 13. Professor Tyndall will give a course of lectures after Easter. The Friday evening meetings will begin on January 25, at 8 p.m., when Professor Tyndall will give a discourse at 9 p.m. Succeeding discourses will probably be given by Matthew Arnold, Esq., Dr. Philip L. Sclater, Dr. R. Liebreich, Professor Goldwin Smith, Lord Rayleigh, Professors Huxley and Dewar, and Sir Joseph D. Hooker. To these meetings members and their friends only are admitted.

THE ADELAIDE HOSPITAL, DUBLIN.

The ceremony of laying the foundation-stone of extensive new buildings in connexion with the Adelaide Hospital, Peter-street, Dublin, was performed last Tuesday, the 4th inst., by the most noble the Marquis of Headfort, in presence of a distinguished gathering of the friends and supporters of the institution. The new buildings and improvements, which will cost about £13,000, of which between £3000 and £4000 has yet to be collected, will include a fever hospital, several new wards, and an operating theatre. The additional wards will constitute a new wing—the Madeline Wing—in Peter-street, having a frontage of some fifty feet, with handsome portico entrance. The basement floor will be used as servants' bedrooms and dining-hall, and patients' clothes-room. Over these, on the ground floor, will be a board-room, secretary's room, etc. On the first floor will be the children's surgical ward, on the second floor the men's surgical ward, and on the top floor the women's surgical ward, each ward being constructed for fifteen beds. Besides this wing, and on a line with the entrance-hall, there is to be a return wing, the basement of which will contain the new kitchen, etc. On the principal or ground floor there will be the operating theatre and two operation wards. Over these will be the children's medical ward and men's pay wards. All the wards will be unusually high, and special care will be taken as to ventilation. The floors will be of teak, and the walls plastered in Parian cement tinted in different colours. The staircase will be a fine open one, and the steps and landings throughout will be of Portland stone, and on each landing there will be a fire-plug, etc. The additional buildings also include a fever hospital, which is entirely separated from the general hospital. The works are being carried out after the designs of Mr. J. Hargrave Bridgford, who has devoted himself much of late to hospital and sanitary works.

Fatal Wound of the Heart by means of a Piece of Glass.—In *Eulenburg's Vierteljahrschrift*, the case of a lunatic is related, who, having procured from a broken window a pointed piece of glass measuring nineteen centimetres, thrust it into his left side, and died a few minutes after its extraction, which was only accomplished with some force. At the autopsy there was found a penetrating wound just below the fifth rib (the walls of the chest being loaded with fat), which pierced the pericardium and the left ventricle of the heart, the sharp point of the glass having passed between the trabeculæ without dividing them.—*Centralblatt*, October 27.

FROM ABROAD.

The New German Scientific Institutes.

The Berlin *Deutsche Med. Wochenschrift* for November 17 contains two short accounts of the opening of two new Institutes —establishments that have done so much for the advancement of scientific investigation in Germany, and which are now being imitated with some success in France, or, at all events, in Paris. It is in what was once France that one of these institutions has just been inaugurated, a large assemblage of professors and students having assembled at Strasburg to witness the opening of the new anatomical building. After an introductory address, delivered by Prof. v. Recklinghausen, he and Prof. Waldeyer conducted the audience over the new edifice, which seems to be quite on a colossal scale, and supplied with every possible appliance; and as the space at the command of the architect seems to have been ample, he has succeeded in supplying every part of the building with an ample share of air and light. The portion devoted to pathological anatomy is divided into two sections, one of which is devoted to clinical autopsies, with its theatre for ninety auditors attached. The second is to be used both for non-clinical autopsies, and for lectures on surgical operations. This communicates with the laboratory, furnished with all the appliances for microscopical vivisection and chemical investigations. The portion of the building devoted to normal anatomy contains the dissecting-rooms, large theatre, and a splendid room for the museums. Other rooms are devoted to the library, and for abodes for the assistants and servants, while there are more than twenty rooms devoted to special work. Beneath the building ample room is provided for a *morgue* and for the stowage of bodies for dissection. In his introductory address, Prof. v. Recklinghausen gave a vivid sketch of the development which pathological anatomy had heretofore undergone at Strasburg in the hands of Ehrmann, Lauet, and Lobstein. He dwelt at length upon the merits of his predecessor, Lobstein the younger, who, as first Professor of Pathological Anatomy at Strasburg, had assembled a large circle of students around him, and enriched the heretofore insignificant anatomical museum with more than 3000 preparations. In thankful recognition of his services, his marble bust had been placed in a conspicuous place in the new edifice.

The other account we referred to relates to the new Berlin Physiological Institute, but it consists only of an extract from the address delivered on that occasion by Prof. Du Bois-Reymond. He expressed his satisfaction at the completion of this palace, devoted and consecrated to the service of science, and heartily thanked all those who had directly or indirectly contributed to this great work. The two men, he said, whose statues adorned the entrance of the Institute—Albrecht von Haller, the founder of physiology as an independent branch of natural science; and Johannes Müller, its hitherto most successful cultivator—represent the spirit in which it will be here pursued and taught. With thankfulness should they seize this opportunity to acknowledge that it was Purkinje who first called into life the idea of the "physiological laboratory," he having, forty years since, founded the first Physiological Institute at Breslau. During the few years that have passed since then, the problems and methods of physiology, and with them the demands for larger and more complete places of work, have multiplied. The Berlin Institute, provided with all the best appliances of advanced workmanship (*Technik*), is resolved to do all that is possible for the united advancement of the various branches and aims of physiological inquiry. Little shall we allow ourselves during these efforts to be tempted into the faint-hearted direction, which of late, and especially in England, has gained a footing, and through the prohibition of vivisection strives to effect a complete paralysis of experimental physiology. The mere fact that for every life of a dog so saved, human life under circumstances might have to be sacrificed, should amply suffice to exhibit the falsehood and folly of these ill-regulated humanitarian strivings.

Warm Baths in Secondary Puerperal Hæmorrhage.

Dr. Bailly, Professeur-Agrégé of the Faculty of Medicine, contributes a paper to the *Bulletin de Thérapeutique* for September 30, on the efficacy of this method of treating secondary uterine hæmorrhage, devised by Prof. Tarnier. By secondary hæmorrhages he understands those which are produced from the second day to a month after delivery. These are generally due to a congestion of the uterus, usually spontaneous, but sometimes caused by the presence of a foreign body in the cavity, too early getting up, a violent effort, or vaginal injections injudiciously employed. Such hæmorrhages are rarely dangerous, but they recur frequently and often obstinately, and cause great alarm to the patient. The ordinary measures for arresting them are far from being always successful, and are usually tedious; and, at Prof. Tarnier's suggestion, the author of this paper commenced in 1874 the trial of warm baths. The success attending the use of these has been so great that he publishes two of the cases in which he employed them. In the first of these the hæmorrhage commenced only on the eighteenth day after delivery, in a woman of feeble habit of body. The uterus was enlarged and congested, and the hæmorrhage, without being alarming, resisted all the usual hæmostatics during ten days. Prof. Tarnier now advised warm baths. The first of these greatly modified the discharge, and the second suspended it completely. Recurring at the end of thirty-six hours, it was definitively arrested by the third. The uterus gradually diminished in size, and at the end of a week the patient was able to get up. In the second case the hæmorrhage came on only on the twenty-seventh day after delivery, the uterus being as much developed as at the third month. The liquid blood discharged was not very considerable, but it became continuous, and was accompanied by coagula. Ergot in different forms, and vinegar injections, having been tried in vain, a warm bath of half an hour at once suspended the discharge; and, on this recurring next day, a second bath completed the cure.

Although in possession of several cases in which their efficacy proved as complete as in these two, Dr. Bailly observes that their success is not always so prompt. He has always found them less efficacious at the commencement of the hæmorrhage than when this had persisted for some time; but, as they produce no inconveniences at the earlier periods, they may also be then employed concurrently with other measures. The only objection to the method that he is aware of is, that at first it shocks the prejudices and alarms the patient. They should not be resorted to prior to the tenth day after delivery, in consequence of the fatigue and danger which their application might then give rise to. Care must be taken, also, that the temperature of the water (about 34° C. or 93° Fahr.) should be rather raised than lowered, all chilling being avoided. From twenty to thirty minutes is a long enough duration to secure the general revulsion sought for; and as one bath rarely proves enough, they may be repeated daily. Prof. Tarnier was induced to try the procedure in puerperal metrorrhagia in consequence of having observed its efficacy in the hands of M. Salgue, of Dijon, who successfully employed it in non-puerperal metrorrhagia; he adopted it for this form of hæmorrhage after delivery, and has for many years recommended it.

In another number of the *Bulletin* (October 30) we find an article by Dr. Constantin Paul, Professeur-Agrégé, upon the great utility of hypodermic injections of ergotine in various forms of metrorrhagia. The formula which he has employed has been—ergotine two grammes, water and glycerine of each fifteen grammes. The solution assumes the brown colour of the extract of ergot, and keeps well, not losing any of its activity in even three months after its preparation. In the fourteen cases in which he has employed this, Dr. Paul has found it succeed in almost a marvellous manner; the hæmorrhage, which was always severe and often dangerous, having in all been arrested in sixteen minutes at latest, and in several much earlier. The patients were either the subjects of more or less advanced cancer of the uterus, or in the puerperal condition. The advantageous action of ergot, taken internally, on uterine hæmorrhage, has been long known; but on comparing this with the effect of hypodermic injection, the latter proves of much greater value. The time required for the operation of ergot varies from a quarter of an hour to thirty-six hours; while ergotine arrests the hæmorrhage in from five to ten minutes,—and in hæmorrhages time is everything. Not only is the action of powder of ergot less rapid than the injection, but it is also less constantly efficacious, three or four doses being sometimes required. Ergot in powder also always gives rise to colicky pains, of which the patients complain much; but this is not so with the ergotine. The injection is not very painful, and does not produce any local inflammation, sometimes only leaving a slight hyperæsthesia at the point of

insertion. So employed, intolerance of ergotine has never been noted. As Prof. Gubler has already observed, it is most remarkable that while a dose of even four grammes taken by the mouth is very doubtful in its action, a dose sixty times less, given by injection, exerts so marked an effect. Certainly there is a far greater discrepancy in the doses required, according to the mode of administration, than is observed with regard to most medicinal substances. In the cases related by Dr. Paul in his paper, an injection of sixty-six milligrammes of ergotine arrested the hæmorrhages in from five to ten minutes.

Dr. Hans Hebra on Continuous Baths.

To the *Wiener Med. Wochenschrift* (September 8 to 29), Privat Docent Dr. Hans Hebra contributes a paper reporting the results of the employment of continuous baths first proposed by his father, Prof. Hebra, fifteen years since. An old prejudice against prolonged continuance in a bath, and its employment just after meal times or during menstruation, had to be overcome. In order, too, that a man should remain for days, weeks, or months in a warm bath, the ordinary bath will not suffice, and a special apparatus has to be devised. Almost all baths are too short to admit of the patient's lying down, and they are too deep, so that the vapour of the water, which gets commingled with the air, interferes with respiration. The new apparatus (which was exhibited in London in 1862) allows of the patient's lying comfortably in the horizontal position, and so high as to be but little inconvenienced by the vapour. For its description we must refer to the paper itself, and content ourselves with stating the results of its employment. In such a "water bed" as this people find themselves quite comfortable, and, when once accustomed to it, can sleep as well in it as in an ordinary bed. The appetite, fæcal and urinary evacuations, remain normal, the respiration is not hurried, and the debility usually attributed to prolonged baths is not observable. During the first four or five days, the whole surface, with the exception of a slight rising of the epidermis of the fingers and toes, undergoes no perceptible change. After that time there occurs in almost all, especially those who have much swelling of the feet, sharp pains in the plantar surface, which last for some days. For the alleviation of this suffering it suffices for the patient either to have placed under the soles of the feet a firm horse-hair pillow, against which he can press, or, if this is not enough, to have cushions placed under his feet, so as to keep them for some hours above the water. In individuals with a delicate skin, there are frequently produced, after they have been in the water a week or two, large broad patches of artificial papulary eczema, which are accompanied by great itching. Frictions with *oleum rusci*, while still remaining in the water, are always sufficient to cause the disappearance of this eruption. With the exception of this local result of the irritating effect of the water, no bad consequences have been observed. Among the many women for whom the bath has been employed, none were removed from it during the menstrual period, the water being found, indeed, to assuage their suffering. In no one of them did any disturbance of the functions of the sexual organs arise.

Since 1862 more than 500 persons have been treated by these continuous tepid baths, so that a very strong opinion may be expressed as to their harmlessness. Of the early cases in which they were employed, sufficient notes were not taken to state the proportion of recoveries; but during his period of service as clinical assistant, Dr. Hebra had 200 of these patients under his care, and is able to speak strongly in favour of the procedure. At the Vienna General Hospital a special place is devoted to this treatment, in which are set up seven of the apparatus, and the results of its employment are stated in the reports of that institution. Burns in the third degree—a very fatal injury—constituted 127 of the 203 cases treated, and of these 56 (56 per cent.) recovered. Among the other cases there were numerous examples of pemphigus and gangrenous bubo.

Temple Bar Doomed at last.—The City Lands Committee, at a meeting held at Guildhall on Tuesday, December 4, gave instructions to the City Architect forthwith to cause Temple Bar to be pulled down, and removed to vacant land in Farringdon-road. The external stones are to be numbered, with a view to the Bar being reconstructed on some site to be decided on by a future vote of the Court of Common Council.

REVIEWS.

The Functions of the Brain. By David Ferrier, M.D., F.R.S. With numerous illustrations. London: Smith, Elder, and Co. 1876. Pp. 323.

Few new subjects have so quickly come to take such a prominent place in men's minds as the subject of cerebral pathology; and it is obvious that before any important advances could be made in this direction, a study of the normal function of individual parts of the brain was absolutely imperative. Dr. Ferrier dedicates his work to Dr. Hughlings-Jackson, "who, from a clinical and pathological standpoint, anticipated many of the more important results of recent experimental investigation into the functions of the cerebral hemispheres." This is a just and graceful tribute to the accuracy of Dr. Jackson's clinical observations, and the doctrine he deduces therefrom: in thus rendering homage to previous workers in the same field, Dr. Ferrier does much to enlist the sympathies of his readers—a gain which cannot but be advantageous to him.

The book commences with an account of the structure and function of the cord and medulla; but as this is, for the most part, but a summary of the views now generally held and taught, we need not more particularly refer to it. The essential feature of this work is the establishment, on a sound basis, as the result of a large number of experiments, of the doctrine of localised motor centres in the grey matter of the cerebral cortex.

Some very shrewd guesses at truth, it seems, had been made by Hughlings-Jackson and others; but since Hitzig's discovery of the electric excitability of the brain, experiments have been extensively carried on, in the hope of being able to clear up disputed points, as well as in the view of extending our knowledge of this interesting subject. "We are still only on the threshold of the inquiry," says our author in his introductory chapter; and this is true. Nevertheless, there are now certain well-established facts for which we are largely indebted to Dr. Ferrier among others; and we look forward to the time when we shall be able to congratulate him on further advances in this field of work.

It has long been known that the complete removal of the cerebral hemispheres of some of the lower animals could be effected without very much interfering with certain functions and complex movements. On more detailed investigation of such movements, however, the conclusion was arrived at, that they were nothing more than responsive actions, called into play, through the primary or acquired specialisation of the nerve-centres, by certain forms of peripheral stimulation, independently of any intelligent adaptation of means to ends on the part of the animal itself. From the facts of human physiology and pathology, by which alone the question can be answered, it was concluded that consciousness was inseparable from the activity of the cerebral hemispheres, and that, therefore, however much the responsive actions of the lower ganglia might resemble conscious actions, they did not come within the sphere of truly psychical phenomena.

Until quite recently, the cerebral hemispheres, like some other parts of the nervous system, had not been found to give a reaction to any form of stimulation, whether mechanical, chemical, thermal, or electrical. As regards the first three forms of nerve-stimuli, experimenters are still, with one or two exceptions, agreed: no reaction is produced by cutting, tearing, or burning, or otherwise mechanically injuring the surface. Animals in full consciousness are apparently utterly insensible to all these powerful stimuli. Human beings who have had the brain lacerated or cut likewise testify to the absence of pain. Such facts as these would seem fatal to the belief that any special functions resided in a part which not only might be removed without any obvious paralyses, but which, when irritated or torn, further seemed to be devoid of sensibility. Nevertheless, clinical observation had long pointed to the probability that at least some functions were definitely located; and the cases of aphasia occurring with softening of the frontal convolutions on the left side (as first definitely described by Broca) supported the view. There was a vigorous opposition to the new views, and many eminent physiologists endeavoured, both by experiments and reasoning, to explain what they believed to be the fallacies of the argument. It was not until Fritsch and Hitzig, in 1870, discovered that the direct application of the galvanic current to the surface of the hemispheres caused movements, and the still more

important fact that these movements varied according to the part irritated, that the older views of Flourens and others began to be doubted. Dr. Ferrier's experiments, however, which have now been repeated over and over again by a large number of competent observers, seem at present to set at rest this important question, and to show almost beyond doubt that the grey substance is the seat of motor centres; further, that by faradising certain points on the cerebral surface, definite, and often complex, movements are systematically obtained. The question of course arises,—and this is still a vexed question,—Are these movements produced directly or indirectly: *i.e.*, is the brain cortex sensible to faradic stimulation, or does this stimulation simply pass through to the white substance or to the basic ganglia, and through them bring about the manifestations to which we have just briefly alluded? This much, however, is absolutely certain: Dr. Ferrier, by faradising given parts of the surface of the brain, can not only produce certain definite movements—he can also *predict* what movements *will be* produced. Against the opinion which has been expressed by some observers, that faradic currents pass through the cerebral substance to the basal ganglia, and *through them* produce the various movements which result, is Dr. Ferrier's statement that "the effect of irritation of the basal ganglia is capable of exact estimation. Irritation of the corpus striatum is followed by general contraction of the muscles of the opposite side of the body, and *it is impossible* by applying the electrodes directly to the surface of this ganglion to produce localised contraction in *any one muscle* or *group of muscles*." (The italics are our own.) A further "conclusive overthrow of the theory of conduction" is the fact that stimulation of the island of Reil, which immediately overlies the corpus striatum, causes no movements; while the more distant parietal regions at the *same time react, actively and definitely, to the same stimulus.*

We must pass over the experiments themselves, inasmuch as our space will not permit us to transcribe them, and nothing short of this would enable us to rightly place them before our readers. It is satisfactory to note that similar sets of experiments were tried on different classes of animals, including monkeys, dogs, jackals, cats, rabbits, guinea-pigs, rats, pigeons, frogs, and fishes; and thus not only are homologies fairly established, but also a natural check on the results is obtained. The experiments on monkeys are especially valuable, and many of the differences in results arrived at by Ferrier and by Hitzig may, in our opinion, be explained by the fact that the latter gentleman used dogs exclusively, at least in his earlier experiments.

Passing on now to a short consideration of the motor centres, we will first just point out the importance of our author's experiments "as a basis of topographical homology between the brain of the monkey and the lower vertebrates. The motor regions of the brain of the monkey are situated farther back than the corresponding regions in the lower animals, occupying more properly the parietal than the frontal lobes. The fissure of Rolando of the monkey is shown, by the homology of the centres surrounding it, to correspond to the crucial sulcus of the carnivorous brain. This is an important landmark by which we may determine the respective development of the frontal region proper in these various animals. In the brains of the carnivora the centres in advance of the crucial sulcus become reduced to very small dimensions as compared with the frontal convolutions of the brain of the monkey; and these are insignificant, in turn, when compared with the homologous parts of the human brain."

"The question, however, with which we are more particularly engaged is the determination of the physiological significance of these regions. The mere fact of the excitation of movements is no proof that the regions stimulated have a motor significance, for the stimulation of a sensory centre may give rise to reflex or associated movements. . . . The definitely purposive character clearly perceivable in many of the movements, and their correspondence with the ordinary volitional activities and peculiarities of the animals, apart from other considerations, point rather to the conclusion that they are the result of the artificial excitation of the functional activity of centres immediately concerned in effecting volitional movements, and as such truly motor. . . ."

Suffice it here to say that the motor centres are found to lie in the convolutions which cluster around the fissure of Rolando. In the upper convolutions are found the centres which move the hinder limb; in the middle convolutions the centres for the anterior extremity; while in the lower, including Broca's convolution, are situated the centres which govern articulation and the movements of the head, face, and eyes.

To show the bearing of these results on disease, we will quote the following experiment:—"The right hemisphere of a monkey had been exposed, and subjected to experimentation with electrical irritation. The part included the ascending parietal, ascending frontal, and posterior extremities of the frontal convolutions. The animal was allowed to recover, for the purpose of watching the effects of exposure of the brain. Next day the animal was found to be perfectly well. Towards the close of the day following, there were signs of inflammatory irritation and suppuration; it began to suffer from choreic spasms of the left angle of the mouth and left arm, which recurred repeatedly, and rapidly assumed an epileptiform character, affecting the whole of the left side of the body. Next day, left hemiplegia had become established, the angle of the mouth drawn to the right, the left cheek-pouch flaccid and distended with food, which had accumulated outside the dental arch; there being almost total paralysis of the left arm, and partial paralysis of the left leg. On the day following, the paralysis of motion was complete over the whole left side, and continued so till death, nine days subsequently. On post-mortem examination it was found that the exposed convolutions were completely softened, but beyond this the rest of the hemisphere and the basal ganglia were free from organic injury." In this we have a clear case of morbid irritation producing precisely the same effects as the electric current, and then destruction by inflammatory softening, resulting in complete paralysis of voluntary motion on the opposite side of the body, without affecting sensation.

Dr. Ferrier goes on to explain some apparent superficial discrepancies which result when repeating these experiments on animals of a lower scale. They add much to the general interest of the subject, besides tending, in our opinion, to a full confirmation of the theoretical function of the basal ganglia. We have already said that the entire removal of the hemispheres operates differently in different classes and orders of animals. In the fish, the frog, and the pigeon the removal of the hemispheres exercises little or no appreciable effect on the faculties of station and locomotion. In the rabbit, while decidedly impairing the mobility of the fore-limbs, it does not quite destroy the power of station or of co-ordinated progression in answer to external stimuli. In the dog, however, the removal of the hemispheres exercises a much more marked influence on these powers, rendering station and locomotion absolutely impossible. The independent or automatic organisation of the lower centres is thus seen to vary, according as we ascend or descend the scale. In proportion to the degree of independence, complexity, and variety of the forms of motor activity of which the animal is ultimately capable, the more volitional and less automatic are its movements, and the longer is the period of infancy during which the animal is slowly acquiring volitional control over its limbs. Many of the lower animals start from birth with all their powers of movement already fully organised; in most the period of helpless infancy is extremely short as compared with that of the simian or human young, in whom every exact movement is the result of a long and laborious process of education. Clinical observation has long shown that in hemiplegia, from disease of the motor centres in the opposite hemisphere, the individual movements are not all equally affected, and also that recovery, when it takes place, always does so in a certain order. Just as the movements of the hand are more varied and more delicate than those of the foot, so are they the more obviously affected, and the last to recover after an attack of hemiplegia. To express it otherwise, we may say that automaticity is at its highest in fish, and at its lowest (or absent) in man. The more the control of the limbs depends in the first instance, and continues to be dependent, on voluntary acquisition, the more does destruction of the cortical centres cause paralysis, and the more permanent is that paralysis. In proportion, however, as movements at first requiring volitional education tend to become organised or rendered automatic, the less are they affected by injury to the cortical centres. Hence, in the dog, in which the acquisition of the control of the limbs is speedy, the destruction of the cortical centres produces a much less marked effect, the movements having become in a great measure independent of these, *through organisation* in the *subordinate centres*. Observers, however, are not all agreed on the interpretation which is to be placed on the recovery of function after its temporary suspension. A process of compensatory substitution has been evoked,

and found much favour. The theory, however—for it was nothing more—has been quite upset by experimental investigation. If the compensation were affected by the cortical centres in the other hemisphere, it ought to follow that extirpation of these also, in an animal which had recovered from a former operation, should re-induce the paralysis, which at first resulted from unilateral destruction of the motor centres; but experience has shown that this is *not* the case. "Functional substitution" has also been advocated, but as this is in direct contradiction to the facts of specific localisation of function, now universally accepted, we need not go into the subject further.

We must not forget, in connexion with this subject, the reflex movements which are produced when a sensory cortical centre is stimulated. May not movements continue, therefore, after the abolition of this motor centre, by possible excitation through the sensory centre of convergence of the motor centre of convergence, the corpus striatum—provided always this latter ganglion have been sufficiently trained for the purpose?

One of the most interesting subjects to further work out is, whether a trained dog, after having had its motor centres destroyed, would permanently lose all its tricks? They are the result, no doubt, of education. But are the dog's tricks volitional movements in the same sense as is writing or carving in man? In human beings "*every exact movement* is the result of a long and laborious process of education." Can the same expression apply to any artificial tricks that a dog may learn, as the result of thrashing, rather than of inherent, or even acquired, *volition*, in the physiological sense of the word? Some experiments have, we believe, been made; but the results are not sufficient to warrant a conclusion either way. Indeed, it will be impossible to solve this question all at once, for highly trained dogs must be had for the purpose, and for this a lengthened period of time must necessarily be allowed. If further research should prove that while all *natural* movements of a dog, being therefore *automatic*, can be recovered after a temporary suspension from pathological causes, but that artificial movements—so-called *tricks*—being the result of volition (in this case, of course, man's volition), cannot be regained except by a slow process similar to that which obtains in man, it will open up a rather new and a very wide field for speculation. We may have to admit that the dog's brain contains all the necessary cortical centres for volitional (purposive) movements of a complex kind, but that they are in abeyance, much as, perhaps, the centres of speech in the right hemisphere in man.

Concerning the sensory centres, though more difficult of demonstration in animals than the motor, yet the experiments given warrant a fair presumption of their existence. Of the senses, sight and hearing are those which are obviously the most easily tried; and if the evidence in these cases is sufficient, we might venture, even on simple analogy, to accept the whole doctrine without further question. To our mind, the evidence in favour of special centres, both for sight and hearing, is sufficient and decisive; and further, there is quite enough in favour of special centres for the other senses to enable us to accept Ferrier's demonstrations without calling on physiological analogy to support them.

Dr. Ferrier destroyed the angular gyrus of the left hemisphere of a monkey, and then securely bandaged up the left eye. As soon as the animal recovered from the effects of the chloroform, "it began to grope about a little *in loco*, perfectly alert, but would not move from its position. It did not flinch when held close to the gaslight. Placed in a cage beside its companions, it took no notice of them, but sat still. Hearing and other senses remained unaffected, and stimuli of these senses caused active reaction. After it had remained in this condition for an hour without alteration, the bandage was removed from the left eye. When placed on the floor, it immediately looked round and ran nimbly to the cage and joined its companions. When again held up to the light as before, it flinched and turned away its head. The change in the animal's manner after the removal of the bandage was of the most striking character. Next day, however, on the left eye being again bandaged, the animal gave evidence of sight by running up to its cage, the door of which was shut, and lapping water from a dish, which it reached by inserting its hand between the bars." Other experiments have confirmed this one; and it has been further proved that loss of sight occurs in both eyes if the angular gyrus is destroyed on both sides. The results of the first experiment, which we have given in full, clearly show that the loss of sight was the *only* faculty which had been damaged. "Another fact of great importance brought out by these experiments is, that sight with both eyes is still possible after complete destruction of the visual centre on one side. A process of compensation takes place if the visual centre in one hemisphere remains intact;" and that the compensation depends on the integrity of the other centre is shown by the fact that total blindness of a permanent character ensues when both centres are destroyed.

As regards hearing, Dr. Ferrier finds that irritation of the superior temporo-sphenoidal convolution "is followed by certain definite results—viz., sudden retraction or pricking up of the opposite ear, wide opening of the eyes, dilatation of the pupils, and turning the head and eyes to the opposite side." These phenomena exactly correspond with the effects of a sudden start, caused by any unexpected *noise*. The destruction of this part on the two sides of the brain simultaneously leaves an animal with all its faculties intact, except that of hearing; this being proved by placing two animals—the one healthy, the other an *opéré*—in a room together. The healthy animal responded at once to sounds by looking round, and appearing startled; while the other remained motionless. These tests were applied more than once, invariably leading to the same conclusion—"that whether the animal heard or not, it certainly gave no signs of hearing that which in another animal excited lively curiosity." In both these cases it will be remarked that, besides the sensory function, motor functions were also produced. In regard to this, we quite agree with Dr. Ferrier in concluding "that the movements are the outward manifestations of the arousal of subjective auditory sensation, and that we have in the temporo-sphenoidal convolution, not a motor centre, but a centre of auditory sensation, stimulation of which causes in a reflex manner the movements in question." The hippocampal region contains the tactile centre; the subiculum cornu ammonis and its neighbourhood contain centres of smell and taste; and the centres of organic sensation are found in the occipital lobes.

Our space will not allow more than the briefest notice of the basal ganglia, though the subject is one of first importance. The basal ganglia—the *corpora striata* and the *optic thalami*—are the centres of convergence of the sensory and motor tracts of the projection system. Pathological as well as experimental facts go to show that in these ganglia are stored up, so to speak, the energy and labour which our voluntary movements cost us to acquire. In the lower animals, the corpora striata, after being properly organised, suffice for the performance of movements, which at first can only be performed through the agency of the cortical centres: the higher in the scale we ascend, the more difficult is the organisation; in man it is doubtful whether even the most habitual or most automatic actions can be performed without the co-operation of the centres of conscious activity. It seems to us, however, that there are some facts which speak in favour of absolute automaticity. We know that by constant and habitual repetition, modes of action which were acquired by long and painful education and conscious effort ultimately become so easy as to be performed *without attention*, if not absolutely without consciousness. Have not soldiers been known to sleep during a forced march? And may not this absolute automaticity possibly explain the manifestations also of somnambulism?

Even "though the basal ganglia may not of themselves suffice for the execution of the habitual movements in man, there is every reason for believing that they do so to a large extent, from the fact that the performance of habitual actions exercises but little interference with the conscious activity of the hemispheres in other directions. . . . We may express it thus: that in actions requiring conscious discrimination and voluntary effort the larger circle of the hemispheres is involved, but that in the actions which have become habitual and automatic the larger circle is greatly relieved by the organic nexus between impression and action, which has been established in the sensory and motor basal ganglia."

We must here leave Dr. Ferrier's "Functions of the Brain," not because the remaining chapters are not as interesting or instructive as those we have already noted, but because we cannot here do them the justice they deserve. We congratulate the author on the work he has accomplished. His name will in future time be inseparably associated with a subject of vital interest both from a pathological and prognostic point of view. We shall gladly welcome his promised work on disease of the brain, observed, recorded, and discussed on the lines laid down in the work we have attempted to analyse.

Army Medical Organisation: A Comparative Examination of the Regimental and Departmental Systems. By Surgeon-Major G. J. H. Evatt, M.D., Army Medical Department. Allahabad, 1877.

It would be vain to expect to find in any large body of men perfect unanimity of feeling, and Dr. Evatt's pamphlet is an excellent illustration of this fact: he has entered exhaustively into a comparison of the real merits of the old regimental and present unification system of the Army Medical Department, and, without the least reservation, he finds that the latter is undoubtedly the best. His arguments are clear, and he certainly writes with a full knowledge of the subject, but the ominous fact still remains that the Service, and the medical profession generally, do not appear to have adopted similar views. He concludes his pamphlet by appending a list of the few grievances which the Army Medical Service yet requires to see remedied; amongst these are the present absence of honorary distinctions, such as the want of the word "Royal" as a prefix to the title of the Department, the absence of military control over the Hospital Corps (this, however, has been remedied since Dr. Evatt's pamphlet was published), alterations in dress, rank, etc. Even if Dr. Evatt's work should fail to convince the bulk of his brother officers, and the younger members of the profession who now hesitate before accepting service in the Department, it is at least worth reading for the clear explanation it gives of the working of the old and new systems.

The Physicians' and Surgeons' Visiting List for 1878. London: John Smith and Co., Long-acre.

We are reminded by the receipt of specimen copies of Messrs. Smith and Co.'s diaries and pocket-books for next year, that the year 1877 is rapidly drawing to a close. Of these useful publications, the one we would now direct the attention of our readers to is "The Physicians' and Surgeons' Visiting List," which is in its thirty-second year of publication, and which is especially adapted to the requirements of the general practitioner, although it may be used with almost equal advantage by the consulting physician or surgeon. In the present edition Dr. Bartley's "Pharmacopœial Companion to the Visiting List" takes the place of the incomplete Posological Table of former editions—an improvement which will doubtless be generally appreciated, especially as the price of the Visiting List is unaltered, notwithstanding that the change must have been attended with considerable extra cost.

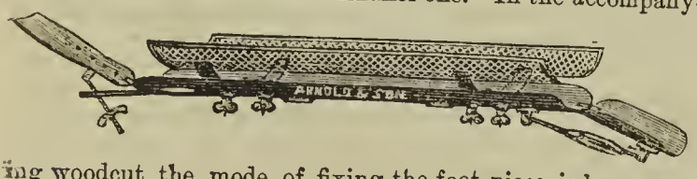
GENERAL CORRESPONDENCE.

HANCOCKE WATHEN'S NEW LEG-SPLINT.

Letter from Mr. J. H. Wathen.

[To the Editor of the Medical Times and Gazette.]

Sir,—I wish to draw the attention of the profession to a new splint which Messrs. Arnold and Son have made from my suggestions. The splint consists of a back splint of metal perforated with large holes for coolness, ventilation, and (if required) drainage. Attached to this back splint on each side is a lateral splint of perforated zinc slightly hollowed; these lateral splints are connected with the back splint by brackets, which travel through slots and are fixed by thumb-screws. By these means the splint can be enlarged to fit a large limb, or reduced to the needs of a smaller one. In the accompanying woodcut the mode of fixing the foot-piece is by a screw which projects below, but in later instruments Messrs. Arnold have devised an improved plan, which has added to the neatness and compactness of the splint. The lateral splints being provided with hinges, permits them to be folded over each other above the foot-piece and back splint, thus packing into a space of twenty inches by four. The weight of the splint is three pounds five ounces. The advantages claimed for this splint are adaptability to limbs of varying size in girth, facilities for dressing, coolness, portability, and cheapness—its price being twenty-five shillings.



I am, &c.,

J. Hancocke Wathen.

REPORTS OF SOCIETIES.

CLINICAL SOCIETY OF LONDON.

Friday, November 23.

George W. Callender, F.R.C.S., F.R.S., President, in the Chair.

A Case of Acute Suppurative Synovitis of the Knee—Evacuation of the Pus with Antiseptic Precautions—Recovery.

Mr. Godlee read for Dr. Marriott, of Sevenoaks, the report of this case. The patient, aged three years and a half, was of a family predisposed to tubercular disease. He fell on the knee in July last, and next day complained of pain; on the following day the joint was painful and swollen, and the boy feverish. For sixteen days these symptoms increased in severity, the limb being placed on a splint all the time; about an ounce of serum was then allowed to escape by a very small puncture from the joint. Temporary relief followed. Again, however, the symptoms increased in severity, a rigor ensued, and the joint became greatly swollen. Five days subsequently to the first tapping, a second withdrawal of an ounce and a half of liquid, which was this time pus, was made with full antiseptic precautions, a drainage-tube was inserted, and the limb again placed on a splint. Great relief at once followed. On the fourth day the drainage-tube was removed, and ten days subsequently the wound was quite healed. The limb still remained on the splint, bound in carbolic gauze. Passive movement of the joint for an hour a day was begun about a fortnight afterwards, and soon the boy walked, and his splint was entirely removed. Dr. Marriott thought the good result due to his strict attention to antiseptic precautions.

Mr. Morrant Baker doubted whether the successful issue could be solely attributed to the antiseptic precautions. Quite recently, he had under his care a child two or three years of age, whose case closely resembled that just read. It was a case of acute suppurative synovitis of the knee, and he had treated it by opening the joint in two places—namely, one incision above and to the inner side; the other below and to the outer side of the joint. Poultices were then applied, but no antiseptic precautions were taken, and the joint has now completely recovered. He believed that a month hence it would show as free movement and as little deformity as Dr. Marriott's patient.

Mr. Maunder said that acute suppurative synovitis of the knee-joint was such a formidable matter that everyone would congratulate Dr. Marriott upon the happy result in his case. Doubtless most surgeons present could recall similar cases successfully treated, especially in the young subject, on the same principle as acute abscesses elsewhere—namely, by free incision.

The President suggested that Mr. Baker should, on the completion of the case, also bring his patient to the Society.

Popliteal Aneurism, for which the Femoral Artery was twice Ligatured.

Mr. Christopher Heath read notes of this case. The patient, a man aged thirty-six, an engine-driver, applied at University College Hospital with pain in the right knee, and was found to have a small popliteal aneurism. He was admitted on July 2, when pressure by Carte's tourniquet, by Esmarch's band and rope, and by flexion of the knee, was carefully kept up without relief. The femoral artery was tied above the sartorius on July 26. A catgut ligature was used, and the operation was performed antiseptically. Pulsation returned in the aneurism in nineteen hours, and lasted fourteen days, and then ceased for eleven days, when it reappeared. Four days later (twenty-ninth day), pulsation was found in the whole length of the femoral artery. Pressure was again applied to the vessel; but the aneurism continued to increase, and, on September 19, the femoral artery was tied with a hempen ligature below the sartorius. Pulsation returned in the sac the following day, but gradually grew weaker and ceased in seven days. The second operation was not antiseptic, and the ligature gave rise to a good deal of suppuration; but the patient made a good recovery, and left the hospital on October 20.

A Case of Popliteal Aneurism treated by Ligature of the Superficial Femoral Artery with Carbolised Catgut, followed by the formation of an Aneurism at the Seat of Ligature.

Mr. Thomas Smith related the case of a man, aged forty-two,

who had been under his care at St. Bartholomew's Hospital with popliteal aneurism, which had existed two months before admission. The case was at first treated unsuccessfully by digital compression. Subsequently, the superficial femoral artery was tied with carbolised catgut, Mr. Lister's antiseptic method being employed. The ligature controlled the circulation for forty-eight hours, at the end of which time pulsation was again felt in the aneurism, and the operation failed as regarded the cure of that disease. The wound healed rapidly, without suppuration or constitutional disturbance. The patient left the hospital, contrary to advice, sixteen days after the operation, with the aneurism feebly pulsating. He returned in a month, with the circulation in his femoral thoroughly restored and the aneurism pulsating forcibly. He refused to undergo any treatment, but was supplied with an elastic stocking to the whole limb. Six months later, he again showed himself with the popliteal aneurism larger in size, and with a second aneurism, about the size of a large walnut, just beneath the scar of the operation-wound. It pulsated very forcibly; had a well-marked thrill and a loud, rasping bruit. After a few days' rest in bed, an unsuccessful attempt was made to cure the aneurisms by the application of the Esmarch bandage. Finally, the superficial femoral was ligatured just below the upper aneurism. Carbolised silk was used for the ligature, both ends being cut off, and antiseptic precautions adopted. Pulsation in the lower aneurism at once ceased, and never returned; recovery was rapid; there was no local disturbance or any constitutional irritation. After the operation, the pulsation in the upper aneurism gradually diminished in force, and at the end of five days the swelling was much smaller, and pulsation was scarcely perceptible in it; in a few days, however, it had regained its former size, and pulsated as on admission. As it caused the patient but little inconvenience, he declined further treatment, and left the hospital. Mr. Smith, after bearing testimony to the advantages of carbolised catgut as a material for ligature to wounded vessels, doubted whether as at present prepared it was trustworthy when applied to large vessels in their continuity. Until the occurrence of this case now related, he had had no occasion to find fault with this form of ligature from his own experience, and he had been disposed to attribute the untoward results which had occurred in others' hands to some avoidable defect in the catgut employed. The very ligature used here was, however, kindly sent to him by Professor Lister; it might, therefore, be supposed that it was as good as could be made. Mr. Smith remarked that, while it was open to anyone to think that the fault lay in the operator, and not in the material employed, yet that we now possessed abundant evidence to prove that carbolised catgut, when employed for the ligature of large arteries in their continuity, was not thoroughly trustworthy; it was uncertain in its effects on the arterial coats, this being chiefly due to its varying degrees of solubility in the tissues of the living body. In confirmation of this statement, he referred to Mr. G. Y. Heath's paper published this year in the *Lancet*, to Mr. Bryant's cases recently read before the Clinical Society, and to a paper by Mr. James Lane in the *British Medical Journal* for November 10. Mr. Smith drew attention to the following facts—viz., that in three of Mr. Bryant's cases the ligature was found to have divided the vessel completely, and to have been itself absorbed. In Mr. Lane's two cases, which were examined, the one thirty-two days after ligature, and the other twenty-eight days the external coat of the vessel was found uninjured in both cases, while the ligatures had disappeared. In one case published by Mr. Heath, at the end of three days the ligature was found softened and partially absorbed. In another case, the catgut was found on the subclavian *in situ* at the end of fifteen days, while the vessel was perforated. In the same patient, another ligature applied to the carotid at the same time had wholly disappeared, the artery being uninjured. Mr. Smith expressed a hope that ere long some improvement might be discovered in the method of preparing the catgut, which, without destroying altogether its solubility, would enable it to constrict an artery for such a time as might be sufficient for a firm clot to form within the vessel. In estimating the possibility of the occurrence of aneurism at the seat of ligature, Mr. Smith drew attention to the peculiarity of the patient in this case, who, by his rashness, did all in his power to contribute to the untoward result.

Mr. Maunder said that although he had recently spoken upon this subject at that Society, yet he deemed it to be one of such vast importance, and felt so strongly upon the matter, that he would venture to address the meeting again. He would say at once that he would not use catgut again to ligature an artery in continuity. He had been gradually led to the conviction of the dangers associated with it, not by his own personal experience—which had been as good as when silk was used—but from a knowledge of the disasters which had happened to other surgeons. Mr. Bryant's and Mr. James Lane's cases had been alluded to, and he found it difficult to understand how Mr. Bryant arrived at the opinion that catgut was the best material to use, when it had behaved in an unexpected way on the arteries, when secondary hæmorrhage had occurred in two of his cases, and when this "ligature dissolves within an uncertain period." Mr. Lane's cases had not been attended by any peculiarities inconsistent with safety, but in one or two instances rather the reverse. He (Mr. Maunder) had tied twenty-eight arteries in continuity—nineteen with silk, and nine with antiseptic precautions, and of these five with catgut. He had not had an instance of secondary hæmorrhage in his practice; but he contended that if serious and sometimes fatal consequences had attended a method of treatment in the hands of surgeons like Spence, Ebenezer Watson, Callender, and as was now illustrated by the cases of Heath and Tom Smith, equally competent to tie arteries as himself, the material ought to be abandoned by him as peculiarly unsafe. It is, however, only fair to Mr. Lister that, if catgut be used at all, it should be used with strict antiseptic precautions; otherwise those surgeons who employ it only repeat, with the addition of a modicum of carbolic acid, the experiments of Sir Astley Cooper and others who abandoned it in favour of silk. In his first antiseptic case he (Mr. Maunder) used a carbolised silk ligature cut short antiseptically. The wound healed rapidly without suppuration, and his patient, a gentleman actively employed, has the ligature on his common carotid artery at the present moment, the operation having been performed in September, 1868. He was glad to find that Mr. Smith had used antiseptic silk, and had obtained primary union. This was the ligature which he (Mr. Maunder) would use in future.

Mr. Barwell said that he must differ from Mr. Maunder, although he concurred in much that had been said as to the unreliability of catgut. Secondary hæmorrhage was not unknown to occur when the silk ligature was employed, and it was not a common result in cases where catgut was used. So, again, the formation of the aneurism at the seat of ligature in Mr. Smith's case did not merely depend on the material used; it might have followed any form of ligature. Again, in Mr. Heath's case, he could not see what connexion there was between the recurrence of pulsation for a second time, after it had ceased for fourteen days, and the form of ligature used. Possibly the catgut was too rapidly absorbed, and perhaps the inner coat insufficiently divided. He thought that if the gut had been kept long in oil, and if the ligature were tied too tightly, its absorption would be hastened. It ought to last from three to six days. For himself, he usually tried to avoid doing more than simply divide the inner coat, so far as that was possible; not tying the second knot more firmly than the first. Thus occlusion of the artery was obtained without the risk of rapid absorption of the gut or ulceration of the vessel-wall.

Mr. Godlee asked Mr. Heath what form of ligature he intended to use in the future. From his using silk in the second ligature, he implied that the accident was due to the catgut. Was he going to discard catgut in favour of silk.

Mr. Heath, in reply to Mr. Barwell, supposed that in his case the ordinary changes took place in the artery after its occlusion by the ligature, and the return of pulsation in the aneurism a few hours later was ordinarily seen. Then he believed that some coagulation took place in the aneurism, and that when the current in the artery was restored by the loosening of the ligature, the flow was sufficient to wash away the obstructing clot. The second ligature produced complete obliteration of the artery. To Mr. Godlee he would say that he had not made up his mind as to what form of ligature he should use in future, and he regretted that Mr. Lister had not been present to give them information as to his own practice, which should be a guide to those who were now groping after truth. Certainly it was only fair to use antiseptic precautions when using the catgut ligature.

Mr. T. Smith thought that all the differences of opinion in vogue as to the mode of tying the ligature, as to the time for its solution, etc., depended upon the very great variation shown by the ligature with regard to its absorptive qualities, it remaining in various cases undissolved from twenty-four hours to thirty days. No one knew how long it should be soaked in the oil to render it perfect, and the ligature given to him by Mr. Lister himself was not available for compressing the artery for more than forty-eight hours. He would like to

know why Mr. Lister finally discarded the use of carbolised silk. Was it because in one case a secondary abscess had formed? He differed from Mr. Barwell in his opinion that the material had nothing to do with the formation of the aneurism in his case; for, if silk had been used, the vessel would have been thoroughly divided, and pulsation would not have recurred in it within forty-eight hours of its application. It had been shown by experiments on animals that an aneurism could be produced by traction on an artery leading to division of its inner coats. For himself, he would again use an antiseptic catgut ligature to-morrow if Mr. Lister would give it him.

Iodide of Potassium Eruption.

Dr. Tilbury Fox read a paper upon this subject. After a brief review of what is at present known concerning the toxic action of iodide of potassium in inducing eruption of the skin, the author related the particulars of two cases in which a few doses of the iodide produced an acneiform rash, which gradually developed into what at first sight appeared to be a bullous eruption, the bullæ varying in size from a pea to a shilling and more, but which it was contended was a modified phase of acne, the iodide, as in the case of the bromides, stimulating the sebaceous glands and their surrounding parts to an excessive degree, and, as a consequence, altered serum (*i.e.*, liquid) was rapidly poured out, causing rapid elevation of the cuticle, and giving rise to the appearance of ordinary bullæ with opalescent contents. In some instances, these bullæ-like bodies had burst and given place to fungoid masses. The author drew attention to the fact that patients in whom this disease was produced must be regarded as possessing a peculiar idiosyncrasy as regards the iodide, and that the rash resembled closely that induced by the administration of bromide of potassium in some cases. The paper was illustrated by water-colour drawings of the eruption.

The President agreed that the form of eruption described must be rare. He had never seen it. He thought that, as a rule, these eruptions from drugs were met with less often when the latter were given for affections not complicated with skin eruptions. In some cases the iodide might be continued without causing an increase in the rash produced by it.

Dr. Broadbent said that the second case related by Dr. Fox was the second of that form of eruption from iodide of potassium which had come under his notice, and he was thus able to recognise its nature, the iodide being subsequently given, by way of experiment, to reproduce the eruption. The patient was extremely ill with hæmoptysis complicating renal disease, and she also had ulceration of the tongue. The first case seen by Dr. Broadbent was that of a young girl with an albuminoid liver and enlarged spleen, who subsequently died in a fit. In her case small doses of the iodide (three grains) were followed by a bullous eruption over the body; and here, again, after the skin had returned to its natural state, the eruption was recalled by again resorting to the drug. In both there was, no doubt, a marked idiosyncrasy as to iodide of potassium. He had never seen any such effects produced by large doses in syphilitic patients. The contents of the bullæ so rapidly formed seemed to be serous, and not products of altered gland secretion.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Tuesday, November 27.

Charles West, M.D., President, in the Chair.

On the Removal by Operation of a Hairy Mole occupying Half the Forehead.

Mr. Morrant Baker said that the case which formed the subject of this paper was that of a child, who, when ten years old, was admitted into St. Bartholomew's Hospital, under his care, on account of a congenital hairy mole which occupied half the forehead. Its greatest diameter from side to side was three inches and a half, and its vertical diameter two inches and three-quarters. The integument composing it was deeply pigmented, being of a dark, blackish-brown tint, with a very uneven surface, and in some parts almost warty. A quantity of brown, coarse hairs grew from nearly every part of the surface, some of them being an inch or two in length. The mole was vascular, and always bled profusely when in any way hurt; but it was not distinctly nævoid, and had only grown in proportion to the rest of the body. The treatment was begun by cutting away, under chloroform, the surface of the mole, taking care to keep the incisions from extending to the subcutaneous tissue. The bleeding was controlled by a pad and bandage, and the surface was allowed to heal under the scab which subsequently formed, and which was but little disturbed during the progress of the case. The whole of the surface was removed by two operations of this kind, and the result obtained was on the whole satisfactory, especially with regard to the total absence of any unevenness or contraction of the scar. But a good many of the hairs grew up again, and there was partial reproduction of the pigment. The treatment was continued, after an interval, by the application of nitric acid, the scab being but little disturbed, as on the occasions on which the knife was used. It was necessary to apply the acid on several occasions before the whole of the disease was eradicated, a considerable interval being sometimes allowed to elapse between the times of application of the caustic, in order to test the effect. At the date of the patient's readmission into the hospital for the third time, in October last, the disease was found to have almost completely disappeared, the only traces of its presence being here and there a spot of pigmented skin, with a few fine hairs growing from it. The scar-tissue was smooth, whitish, glazed, and supple; not in the slightest degree contracted, and not dragging at all on neighbouring parts; it was quite level with the adjacent healthy integument. The author remarked that the result of the case related justified the conclusion that large hairy moles and similar deformities of the skin, hitherto supposed to be beyond the reach of surgical operation, may be safely removed by simple measures, if these are carried out with sufficient care. The patient had been shown to the Society at the previous meeting, and the paper was illustrated with a drawing and photographs.

Mr. Dalby exhibited a rudimentary ear, removed from a child two years old, and which was the seat of a fistulous opening. The child had one good ear, but the other was rudimentary and farther back than usual. There was an opening in front, but it was small. The cartilaginous portion of the ear was extant.

Sir James Paget had no doubt but that this was an example of the branchial fistula to which he referred.

Mr. Doran said that two classes of openings were common: ectopiæ of various organs from imperfect closure in the median line, which might be described as always abnormal; and such as normally occurred in some of the lower animals, but were abnormal in man. To the latter group these branchial fistulæ belonged. These abnormal conditions generally originated before the cartilages were perfectly segmented into bones. The arrests of development in the head and neck were not so important as those occurring lower down; and so the subject survived, though malformed.

Mr. Callender would refer to two points—first, that there were some cysts, as certain examples of ranula, which probably occurred in this way, as his own investigations indicated. Again, as regards the cartilages found in the tracts of the fistulæ, he would venture to refer to the curious masses of cartilage which proceed from the skull to protect the nerves in the growing fœtus. These masses of cartilage were not connected with the vertebral column, but with the skull, and he thought the cartilages referred to might have this origin.

Mr. Francis Mason referred to a case which had been seen by Sir James Paget, and which had been under his own care. This, however, was a fistula of the neck, and not of the ear. It was deep, and probably reached close down to the pharynx, though not opening into it.

Cases of Branchial Fistulæ on the External Ears.

Sir James Paget contributed a paper as above. After briefly describing the general characters of the cervical branchial fistulæ, which have long been known as due to the incomplete closure of one or other of the lower branchial fissures, the author gave an account of similar fistulæ observed on the ears of seven members of one family. The persons in whom they were found were a gentleman and his sister, and five of his eight children; and the same gentleman, his father, his sister, and four of his children, had each one or two branchial fistulæ at the sides of the neck. The aural fistulæ were in every instance seated on the upper and anterior part of the helix, very slender canals with narrow orifices extending from above downwards, and in the adult half an inch or rather more in length. None of them secreted or gave any

distress. After references to the six or seven similar cases that had been published, and to some other malformations of the external ear, which were, he said, probably due, as these were, to imperfect closure of the first post-oral branchial fissure, the author pointed out that there are now sufficient evidences of malformations due to incomplete closure of every one of the branchial fissures, and then referred to the association between these cases and those of supernumerary ears. Such ears, he believed, were found only over the lines of former branchial fissures, and might be considered as cutaneous opercular growths, homologous, though abnormally, with the natural auricles. He pointed out also that many of the persons born with aural branchial fistulæ had become deaf, and had been, therein, instances, however slight, of the general law indicated by Dr. Allen Thomson, that malformations of the external ear were often associated with other defects in parts found in or near the first or mandibular arch.

Professor Allen Thomson exhibited some drawings, not of fistulæ of the neck, but of malformations of the ear, of the kind referred to. In two persons there was occlusion of the meatus auditorius, and imperfect development of the lower jaw. There was also cleft palate, and displaced canines or lateral incisors. In both there was great deafness, but they were not deaf mutes. The third heard pretty well, and could fairly converse with others. The passages were completely closed, and sounds could best be heard from the top of the head. In one of the females this was also the case. In these cases the ear generally presented remains of the branchial fissure, but the bony passage was completely closed, owing to absence of the tympanic bone. In some of the cases attempts had been made to open the passages, but, for the reason stated, this was vain. He could not very well understand why there should be more than one depression in the ears, except that the fissure had been, by partial adhesion, divided into more than one part.

Mr. Rivington referred to the case of a medical man who had a small aperture in the helix, which was rather deep, and whence an oily liquid exuded. This occurred on both sides. It was hereditary by the maternal side, and there were several examples in the family.

Mr. Pugin Thornton said he had seen two cases of cervical fistula. The fissures were too small for the galvanic cautery, but they had closed by electrolysis.

Sir James Paget, in reply, said that his impression that these cases were not so rare had been strongly confirmed. In this way they might be able to clear up many doubtful points; for instance, the influence of damaged textures on future development. The opening was due to the fact that a part of the fissure remained unutilised. We were not quite certain how the fissure closed; part of it might remain open. The exact mode of origin of these fistulæ was not quite certain; still, there was no other interpretation of their origin possible except this. The origin of the cartilages, too, was not quite clear. Failure of union in the middle line of the neck was very rare, though other ectopiæ were common.

The Warming of the Hôtel Dieu.—The apparatus for the purpose of warming the expensive new Hôtel Dieu has been described as very elaborate, but, according to the *Progrès Médical* (November 10), it has the serious defect of not working. While some of the wards are baked, others are chilled; and no means exist of regulating in each ward the amount of caloric to be admitted. When this has to be done, the aid of a mechanic has to be sought in the lower regions where the regulating apparatus is placed. Consequently, in place of sending for him, the nurses prefer opening the windows—this being, in fact, the only means of ventilation hitherto in force, notwithstanding the costly "system" that has been erected. Excessive heats succeeding draughts of air have been followed by numerous attacks of bronchitis among the consumptive patients, who, without leaving their wards, were passing several times a day from a polar to a tropical temperature. The Administration declares that all these evils are only temporary, not being inherent to the system of ventilation and warming adopted; but it is naturally asked why the necessary trials were not made before the patients were hurried into the new edifice. In the meantime, several patients have been seized with vertigo, nausea, and vomiting, while the persons waiting upon them complained of intense cephalalgia, and the physicians at their visits observed the smells emanating from the stoves. A committee has been appointed to investigate the matter.

MEDICAL NEWS.

University of London.—The following are lists of candidates who have passed the recent examinations:—

Second M.B. Examination for Honours.

MEDICINE.

First Class.—Smith, Herbert Urmson, (Scholarship and Gold Medal), St. Thomas's Hospital; Horrocks, Peter, (Gold Medal), Guy's Hospital, (obtained the number of marks qualifying for the Scholarship); Symonds, Charters James, Guy's Hospital.

Second Class.—Tirard, Nestor Isidor Charles, King's College.

OBSTETRIC MEDICINE.

First Class.—Tirard, Nestor I. Charles, (Scholarship and Gold Medal), King's College; Symonds, Charters James, (Gold Medal), Guy's Hospital; Smith, Herbert Urmson, St. Thomas's Hospital; Gristock, William, University College.

Second Class.—Barrow, Albert Boyce, King's College; Sedgefield, Arthur Robert Wyatt, King's College; Stevenson, Leader Henry, Guy's Hospital; Horrocks, Peter, Guy's Hospital; Giles, George Michael James, St. Mary's Hospital; Goodchild, Francis, St. George's Hospital.

FORENSIC MEDICINE.

First Class.—Tirard, Nestor I. Charles, (Scholarship and Gold Medal), King's College; Symonds, Charters James, (Gold Medal), Guy's Hospital.

Second Class.—Sedgefield, Arthur Robert Wyatt, King's College.

Third Class.—Smith, Herbert Urmson, St. Thomas's Hospital, and Stevenson, Leader Henry, Guy's Hospital (*equal*); Joll, Boyd Burnett, University College.

M.D. Examination.

Archer, Herbert Ray, St. George's Hospital; Hetley, Henry, Guy's Hospital; Hoar, Charles Edward, King's College; Hunt, J. W., B.S., (Gold Medal), University College; Jameson, Leander Starr, B.S., University College; Kidd, Walter Aubrey, B.S., Guy's Hospital; Ord, William Miller, St. Thomas's Hospital (obtained the number of marks qualifying for the Medal); Rigby, James Arthur, Guy's Hospital.

LOGIC AND MORAL PHILOSOPHY ONLY.

Ashby, Henry, Guy's Hospital; Bogg, Thomas Wemyss, University College and Manchester Royal Infirmary; Burton, Samuel Herbert, B.S., University College; Firth, Charles, St. Bartholomew's Hospital; Morley, Thomas Simmons, Guy's Hospital.

B.S. Examination.

First Division.—Symonds, Charters James, Guy's Hospital; Vercoe, Joseph Cooke, M.D., St. Bartholomew's Hospital.

Second Division.—Bury, Judson Sykes, University College.

M.S. Examination.

Pepper, Augustus Joseph, University College.

Apothecaries' Hall.—The following gentlemen passed their examination in the Science and Practice of Medicine, and received certificates to practise, on Thursday, November 29:—

Blackburn, Herbert Belasyse, Selham, Sussex.
Couzens, Charles, London Hospital.
Gamble, Ernest Langwith Gompertz, Grantham.
Landon, Arthur Jermyn, 25, Margaret-street, W.

The following gentlemen also on the same day passed their Primary Professional Examination:—

Ellison, Frederick William, St. Bartholomew's Hospital.
Hoets, Alton Kingsley, London Hospital.
Phillipps, William Alfred, Guy's Hospital.
Warren, Edwin Charles, London Hospital.

APPOINTMENTS.

*** The Editor will thank gentlemen to forward to the Publishing-office, as early as possible, information as to any new Appointments that take place.

McHardy, Malcolm Macdonald, F.R.C.S.—Assistant-Surgeon to the Royal South London Ophthalmic Hospital. Also as Ophthalmic Registrar to St. George's Hospital.

Snell, Simeon, L.R.C.P., M.R.C.S.—Lecturer on Anatomy at the Sheffield School of Medicine, *vice* W. Skinner, resigned.

NAVAL, MILITARY, &c., APPOINTMENTS.

Admiralty.—Staff-Surgeon Daniel O'Connor, M.D., has been promoted to the rank of Fleet Surgeon in H.M.'s Fleet, with seniority of November 20; Staff-Surgeon James Nicholas Joseph O'Malley has been promoted to the rank of Fleet Surgeon in H.M.'s Fleet, with seniority of November 28; Staff-Surgeon William James Eames has been promoted to the rank of Fleet Surgeon in H.M.'s Fleet, with seniority of Nov. 2.

BIRTHS.

Collison-Morley.—On November 30, at 321, Clapham-road, S.W., the wife of J. L. Collison-Morley, M.D., of 1, Edith-road, West Kensington, of a son.

Creagh.—On November 7, at Peshawur, Punjaub, India, the wife of Surgeon-Major William Creagh, L.R.C.S.I., of a son.

Moore.—On November 24, at Mount-street, Taunton, the wife of J. Murray Moore, M.D., M.R.C.S., of a son.

Pearson.—On December 1, at 23, Upper Phillimore-place, Kensington, the wife of David R. Pearson, M.D., of a son.

Shaw.—On November 30, at Banstead, Surrey, the wife of T. Claye Shaw, M.D., of a daughter.

Verchere.—On November 29, at 33, Leamington-road-villas, Westbourne-park, W., the wife of Surgeon-Major Albert M. Verchere, M.B., Indian, M.D., of a son.

MARRIAGES.

Atkinson—Shearman.—On December 5, at St. George's, Hanover-square, Charles Atkinson, Esq., J.P., of Sheffield, to Tryphena Jane, widow of Charles James Shearman, B.A., M.D. Lond., only son of E. J. Shearman, M.R.C.P. Lond., F.R.S., of Rotherham.

Hensman—Ward.—On November 29, at Gailey Church, Staffordshire, Henry Frank Hensman, M.R.C.S. Eng., Surgeon 2nd Life Guards, to Annie Barnett, eldest daughter of Henry Ward, Esq., of Rodbaston.

Lee—Powell.—On December 1, at Wickham, Hants, Arthur, son of John Lee, M.D., of Ashburne, Derbyshire, to Ellen Eliza, daughter of the late Henry Ffolliott Powell, Esq., of West Malling, Kent.

DEATHS.

Hewan, Marion Leslie, daughter of Archibald Hewan, M.D., at Chester-square, S.W., on November 30, aged 10.

Hill, Constance Margaret, third daughter of J. R. Hill, L.R.C.P., at The Oaks, Tufnell-place, Holloway-road, on December 4, aged 3 years and 4 months.

Rice, Emily, wife of Bernard Rice, M.B. Lond., at Stratford-on-Avon, on November 27, aged 48.

Stewart, Charles John, L.R.C.P. Edin., at Morpeth Cottage, Ealing, on November 27, aged 45.

VACANCIES.

In the following list the nature of the office vacant, the qualifications required in the Candidate, the person to whom application should be made and the day of election (as far as known) are stated in succession.

East Suffolk and Ipswich Hospital.—Honorary Physician. Candidates must produce evidence of being graduates in medicine of one of the Universities of the United Kingdom, or Members of the Royal College of Physicians of London, and of being registered according to the provisions of the Medical Act. Applications, with testimonials, to the Secretary, on or before December 12.

Inverness District Asylum.—Assistant Medical Officer. Candidates must be duly qualified and registered. Testimonials to Dr. Aitken, the Medical Superintendent, on or before December 12.

The Guest Hospital, Dudley.—Resident Medical Officer. Candidates must be unmarried, and Fellows or Members of the Royal College of Surgeons of England, Edinburgh, or Dublin, and possess a registered qualification in medicine. Applications, with testimonials and certificate of registration, to the Secretary, on or before January 1.

Western General Dispensary, Marylebone-road, N.W.—Honorary Physician. Candidates must be Fellows or Members of the Royal College of Physicians of London. Testimonials and qualifications to the Secretary, on or before December 10.

UNION AND PAROCHIAL MEDICAL SERVICE.

*** The area of each district is stated in acres. The population is computed according to the census of 1871.

RESIGNATIONS.

Canterbury Incorporation.—The Canterbury District is vacant; area 3830; population 16,137; salary £70 per annum. Also the Workhouse; salary £30 per annum.

Clitheroe Union.—Mr. H. Patchett has resigned the Chipping District; area 18,290; population 3301; salary £25 per annum.

Easingwold Union.—Mr. T. D. O. Pain has resigned the Alne District; area 13,438; population 2303; salary £26 per annum.

Henley Union.—The Caversham District is vacant; area 7876; population 3210; salary £75 per annum.

APPOINTMENTS.

Castle Ward Union.—James Marr, M.R.C.S. Eng., L.R.C.P. Edin., to the Ponteland District and the Workhouse. James A. B. Thompson, M.C. and B.M. Glasg., to the Stamfordham District.

Central London Sick Asylum District.—Tennyson D. Patmore, L.R.C.P., M.R.C.S., as Assistant Medical Officer and Dispenser at the Cleveland-street Asylum.

Drayton Union.—William S. Meek, M.R.C.S. Eng., L.S.A., to the Workhouse.

Poole Union.—Wm. Turner, M.R.C.S. Eng., L.S.A., to the Workhouse.

Radnor.—Edward H. W. Swete, M.D., as Analyst for the County.

Thetford Union.—Charles V. Willett, M.R.C.S., L.S.A., to the Brandon District.

Wellington (Salop) Union.—Wm. T. Hawthorn, M.R.C.S Eng., L.S.A., to the First Northern District.

Case of Idiopathic Tetanus with Rupture of the Heart.—In the *Bulletin de Thérapeutique*, September 30, Dr. Duclaux, of Nancy, relates an interesting case of a shoemaker, aged thirty-seven, who, having become chilled after being heated, in a few hours was seized with symptoms of tetanus, without having suffered any traumatic injury. The symptoms proved very formidable, the temperature reaching 42° C. (107·6° F.), the pulse numbering 140, and the tetanic spasms being generalised. Chloral was administered, and ether-spray applied to the spinal column. The patient, however, seemed on a fair way of recovery, when, a week after the onset of the disease, he suddenly dropped down dead, rupture of the heart being found at the autopsy, that organ being in a state of fatty degeneration. Seven months before, the man had been the subject of delirium tremens.

Dilatation of the Urethra by the Urine.—In the *Bulletin de Thérapeutique* of September 30, Dr. Berenger-Féraud recurs to this mode of treating stricture, which he had already advocated on former occasions. Originally devised by Brunnighausen in 1794, it fell into disuse after some successes had been obtained. Dr. Berenger-Féraud has persevered in giving it a full trial, and regards it in suitable cases as a valuable procedure. It consists in compression being exerted just behind the glans by the patient each time just before he passes urine, so that none issues until the canal has undergone dilatation by its presence in it. The practice is to be perseveringly repeated, and then, as numerous cases show, may prove very efficacious. From the trials that have been made it results—1. That dilatation so produced, performed after a gonorrhœa of some duration, may act as a prophylactic of stricture. 2. In stricture that has not advanced very far, if it do not restore the calibre of the urethra to its normal dimensions, it does so sufficiently to render micturition easy. 3. After urethrotomy it is a useful means, if not for preventing, at least for retarding, the return of the stricture. 4. It may prove of some service in varices of the prostate, neck of the bladder, and membranous part of the urethra. 5. Another class of cases benefited arises when the course of the urethra more or less deviates from its normal direction in consequence of enlarged prostate in aged persons. The small quantity first ejected from the bladder, if retained awhile in the urethra by compression, greatly facilitates the evacuation of the remainder.

Employment of Pilocarpin in Childhood.—Prof. Demme, of Bern, states that he has employed the muriate of pilocarpin by the subcutaneous method, using a 2 per cent. solution in 33 children from the ages of nine months to twelve years. Of these, 18 suffered from desquamative nephritis and dropsy consequent on scarlatina, 3 from diphtheria without scarlatina, but with consecutive parenchymatous nephritis and a high degree of dropsy. Of the other 12 cases, 2 had dropsical effusion from heart disease, and 3 rheumatism affecting several joints. As a general rule, only one injection per diem was employed, and in children between the ninth month and the second year the dose of pilocarpin employed was gramme 0·005; between the second and sixth years from 0·0075 to 0·01; and from the seventh to the twelfth years 0·01 to 0·025. The general conclusions drawn from these cases are, that pilocarpin exhibits its sialogogic and diaphoretic properties in a very marked manner in childhood, and that it is very well borne at the tenderest age in the above doses, its sialogogic effect being more prominent in the younger, and its diaphoretic effect in the older children; that any unfavourable after-effects, even in the youngest children, were quite exceptionable, and were preventable by administering minute doses of brandy prior to the injection; and that no influence on the action of the heart was perceptible. The cases best adapted for its employment are desquamative parenchymatous nephritis with dropsy, following scarlatina, diphtheria, etc. A beneficial diuresis in most of the cases ensues, the quantity of albumen which the urine contains never being increased, but rather diminished.—*Petersburg Med. Woch.*, November 17.

Cretaceous Degeneration of Arteries.—In a paper read to the Société de Médecine Publique (published in *Annales d'Hygiène* for September), Prof. Gubler observes that this change in the condition of the arteries attacks the various classes of society in a very different manner, a great contrast existing between the rich and the poor, the inhabitants of towns and the rural population. At the top of the social scale the arteries may retain their suppleness until the approach of confirmed old age, while in the lower classes the indurations manifest a remarkable precocity, so that arterial atheroma is met with in the hospitals in men of forty, thirty, or even twenty years of age. Doubtless the abuse of alcohol is one of its powerful causes; but we must avoid attributing to it a too exaggerated operation. For while in the upper classes alcoholism is not so very rare, and yet it does not give rise necessarily to this degeneration, so in certain patients in the hospitals it is impossible to attribute the atheromata observed in them to abuse of alcohol. But the different diet made use of by the poor and the rich, the inhabitants of the country and of towns, may explain the facts observed. Thus, while one class obtains its nutriment from the flesh of animals and from vegetables abounding in nitrogen, in the poorer classes, bread, potatoes, cabbages, and herbaceous vegetables form the base of their alimentation. Flesh and albuminoid substances contain very small portions of mineral principles, while a purely vegetable diet contains a considerable proportion of the earthy phosphates and carbonates. The facility of cretaceous incrustation prevails in an inverse proportion to

the vitality of tissues, so that the middle coat of arteries, but little irrigated with blood and of low vitality, is especially liable to undergo this atheromatous degeneration. If, then, this has its chief origin in earthy matters furnished by the herbaceous regimen, concurrently with potable waters loaded with earthy salts, the disease should be more precocious and more severe in calcareous regions like the Orléannois—a fact confirmed by M. Leblanc; while it should be rarer, or even absent, in siliceous, granitic, and volcanic regions, like Puy, where M. Vibert has shown it is a rarity. In monasteries, where the monks are confined to vegetable diet, the arteries are found greatly indurated at the early age of thirty-two.

COMPOSITION AND QUALITY OF THE METROPOLITAN WATERS IN NOVEMBER.—The following are the returns (by Dr Meymott Tidy) of the Society of Medical Officers of Health:—

Names of Water Companies.	Total Solid Matter per Gallon.	Oxygen required by Organic Matter, etc.	Nitrogen: As Nitrates, etc.	Ammonia.		Hardness. (Clarke's Scale).	
				Saline.	Organic.	Before Boiling.	After Boiling.
Thames Water Companies.	Grs.	Grs.	Grs.	Grs.	Grs.	Degs.	Degs.
Grand Junction .	20·10	0·046	0·156	0·000	0·007	14·8	3·0
West Middlesex .	19·40	0·042	0·160	0·001	0·008	15·7	4·2
Southwark and Vauxhall . .	20·50	0·053	0·100	0·000	0·008	13·7	3·3
Chelsea . .	17·90	0·042	0·110	0·001	0·008	13·2	2·8
Lambeth . .	20·60	0·053	0·133	0·000	0·009	14·3	2·8
Other Companies.							
Kent . . .	27·30	0·003	0·366	0·000	0·002	19·4	5·1
New River . .	20·50	0·050	0·100	0·000	0·006	14·0	2·4
East London .	19.80	0·032	0·110	0·001	0·007	15·4	2·8

Note.—The amount of oxygen required to oxidise the organic matter, nitrites, etc., is determined by a standard solution of permanganate of potash acting for three hours; and in the case of the metropolitan waters the quantity of organic matter is about eight times the amount of oxygen required by it.

The water was found to be clear and nearly colourless in all cases.

NOTES, QUERIES, AND REPLIES.

He that questioneth much shall learn much.—*Bacon.*

Dr. Henry Marais.—Received with thanks.

Cosmopolitan.—1. The question referred to will be found in Mr. Malet's report (1870) on the artisan classes in Paris. He says, "It is stated that a Paris workman has no grandchildren." This saying he explains in part by the reflux of the working population to the provinces whence they came; but he adds, "There is, however, no doubt that the life led—hard work, dissipation, and drunkenness—goes a long way to account for the fact. Not only is the man destroyed, but his children are weakly and unable to battle with the stern necessities of life. They die out early for want of stamina, and leave in their turn offspring who never come to maturity." 2. As to the myriads of Chinese, it is owing to their system of early marriages that the country becomes so densely populated, notwithstanding the great gaps caused by constant visitations of Asiatic cholera and other epidemics, some of which are described in Chinese chronicles as being so violent as to "carry off whole families, leaving no living member to bury the dead or take charge of the family property." Boiled rice or millet with salted fish, or pork with garlic, suffice to maintain Chinese in health and strength. They have no decided taste for those luxuries which, in this country, we deem necessaries.

A Parish Pluralist.—At the last meeting of the Vestry of the parish of Bethnal-green, a vestryman announced the fact that the beadle of the parish was also sanitary inspector, messenger to the Vestry, coroner's officer, custodian of the mortuary, etc. He thought the matter should be inquired into, and gave notice of his intention at the next vestry to make a motion on the subject.

City Benevolence.—The City of London livery companies, it is calculated, distribute no less than £100,000 a year in charities.

A Royal Gift.—Her Majesty the Queen has presented to the town of Heywood twenty acres of land for the purposes of a publie park. The money has been set apart by her Majesty out of a sum of upwards of £10,000 received by her as Duchess of Lancaster by the death of Mr. C. M. Newhouse, of Heywood, who left no heirs.

Explosive Lamps.—Yes; when the number of serious accidents arising from the explosion of kerosene lamps was attracting general attention in America, the New York Board of Health took steps to prosecute rigorously every violation of the ordinance forbidding the sale of dangerous illuminating fluids.

Thomas le M.—The lectures by Professors Flower and Parker are usually delivered during February and March.

Kensingtonian.—The Royal Society's Copley Medal was founded about the year 1736, by a bequest from Sir Godfrey Copley, Bart. Though of comparatively small intrinsic value (£5), it is generally esteemed the highest distinction which the Society can confer. The two Royal Medals are given by the Sovereign on the award of the Society for the encouragement of science in the British dominions. These medals aro of gold, and of the value of fifty guineas each. They arc open to persons of all countries, and were founded in 1825. These medals are termed binary medals, because each consists of a silver and a gold medal struck in the same die—an arrangement which enables the recipient to convert the more precious medal into money, while he preserves the silver one in commemoration of his success. The Davy Medal was founded by the proceeds of the service of silver plate bequeathed for the purpose by Sir Humphry Davy.

Germs.—Francesco Redi, in 1668, then forty-two years old, native of Arezzo, M.D. of Pisa University, physician to the Grand Duke of Tuscany, published at Florence a first result of his natural history studies in his book on the "Generation of Insects," and therein gave "the first distinct enunciation of the hypothesis that *all living matter has sprung from pre-existing living matter*," supporting it by experiments and arguments. "The living germs," says Redi, "are carried *in the air*, and thus deposited in the places where, by-and-by, they grow and become noticeable."

Viator.—Several distinguished surgeons formerly resided and made large practices in Lincoln's-inn-fields—as Messrs. Percival Pott, Cline, Long, Vincent, Stanley, Green, &c. The person mentioned is *not* a Fellow of the College of Surgeons.

A Successful Candidate.—We have already explained that the list cannot be published until next week. Write at once to our publishers on the subject.

University College.—The late Mr. George Cooper, of Woburn-place, was a nephew of Mr. Samuel Cooper, author of the "Surgical Dictionary," not his son.

Mystic.—The relation of the apple to health is traceable to Arabia. In England and Germany it has been deemed potent against warts. Sometimes it is regarded as a bane: in Hessia, it is said an apple must not be eaten on New Year's Day, as it will produce abscess; in Suabia it is believed that an apple plucked from a graft on the white thorn, will, if eaten by a pregnant woman, increase her pains, but generally it is curative; in Pomerania it is eaten on Easter morning against fevers; in Westphalia (mixed with saffron) against jaundice; while in Silesia an apple is scraped from the top to cure diarrhœa, and from the bottom to cure costiveness.

Philanthropist.—Lord Newry has proposed to build a cottage hospital in the village of Rostrevor, which his lordship has already assisted to make one of the most attractive resorts in Ireland.

Physiologist, Manchester.—William Gale, the pedestrian, was born on April 21, 1832, and consequently is in his forty-sixth year.

A Competitor.—Essays for the Jacksonian Prize of this year must be sent to the Secretary of the College on or before Monday, the 31st inst. The subject for this prize for 1878 is, "Glaucoma, its Causes, Symptoms, Pathology, and Treatment."

Dr. Malcolm, Portsmouth.—The General Medical Council publishes a list of those persons removed from the Register, but only, we believe, for public institutions. The name of the notorious person mentioned was so removed; but the Council of the College of Surgeons does not possess the power, at present, of removing it from the list of members, notwithstanding the severe strictures of the judges before whom he gave evidence at the Old Bailey.

Mr. Mitchell and "Mad Dog."—The Abbé Salvador Gilii, in his "History of America," states that he has seen the strongest animals succumb instantly when wounded with arrows tipped with *woorari*, but the poison does not produce any effect on their flesh. The late Mr. Waterton, of Watton Hall, the well-known naturalist, published the results of his experiments with this subtle poison.

Calcutta.—Your letter and inclosures received. The *Medical Times and Gazette* will be duly posted to you in January, and, as requested, in monthly parts.

Settler.—The population of Fiji in 1870 numbered nearly 150,000, 2000 of whom were whites and half-castes. The climate nine months of the year cannot be surpassed, the thermometer ranging from 75° to 80° at mid-day, falling at night to 55° and 60°. From December to March it is hotter, and may be termed disagreeable; a great deal of rain falls, and the thermometer runs up to 95° and 100° in the shade. At this season also high winds or hurricanes may be expected, which, although although not nearly so violent as those in the West Indies or Mauritius, are yet sufficiently strong to blow down native houses.

INCINERATING HUMAN REMAINS.

It appears there is a better system of cremation in Madras than in any other part of India. In Bengal, dead bodies are placed on an open funeral pyre, which speedily gives forth an unpleasant odour, while vultures and dogs hover round. But in Madras the body is put into a sort of mud pie, and baked until nothing remains but the calcined bones, which are duly cast into the Cauvery.

A Thriving Industry.

In the year ended March 31 last, 15,181,730 stamps were issued on "patent medicines." The amount paid was £118,221 12s. 7d.

COMMUNICATIONS have been received from—

Mr. T. D. Savill, London; The Registrar of the University of London; Mr. W. Blount, London; Dr. Crichton Browne, London; The Secretary of the Harveian Society; Mr. Cutliffe, London; Mrs. Woodhull, London; Mr. Wm. Baxter, London; Dr. J. W. Moore, Dublin; The Secretary of the London Institution; The Secretary of the Clinical Society, London; Mr. Christopher Heath, London; Mr. Arthur Lucas, London; The Secretary of King's College Hospital, London; Dr. C. M. Tidy, London; The Registrar of Apothecaries' Hall, London; Dr. J. Mitchell Bruce, London; Mr. W. E. Poole, London; Dr. Squire, London; Dr. Robert Liveing, London; Dr. Sturge, London; Mr. B. R. Wheatley, London; Dr. Barlow, London; Mr. John Chatto, London; Mr. T. M. Stone, London; Dr. Byrom Bramwell, Newcastle-on-Tyne.

BOOKS AND PAMPHLETS RECEIVED—

Samuel Gee, M.D., Auscultation and Percussion—Bholanoth Bose, M.D. Lond., Principles of Rational Therapeutics—A New System of Medicine entitled Recognisant Medicine, or the State of the Sick—Hugh Owen Thomas, The Past and Present Treatment of Intestinal Obstructions—Transactions of the New York Pathological Society, vol. ii.—The Official Handbook for the National Training School for Cookery—Health and Healthy Homes—R. C. Jebb, M.A., Greek Literature—Dr. Henri Picard, Traité des Maladies de l'Urèthre—Rickman J. Godlee, M.S., F.R.C.S., An Atlas of Human Anatomy, part 2—Cassell's History of India, part 24—Dr. Jules Godard, Du Bégaiement et de son Traitement Physiologique.

PERIODICALS AND NEWSPAPERS RECEIVED—

Lancet—British Medical Journal—Medical Press and Circular—Berliner Klinische Wochenschrift—Centralblatt für Chirurgie—Gazette des Hôpitaux—Gazette Médicale—Gazette Hebdomadaire—Le Progrès Médical—Bulletin de l'Académie de Médecine—Pharmaceutical Journal—Wiener Medizinische Wochenschrift—The Louisville Medical News—Boston Medical and Surgical Journal—Nature—Philadelphia Medical Times—Cincinnati Clinic—Home Chronicler—La Province Médicale—Hardwicke's Science Gossip—Revista de Medicina y Cirugia Practicus—Obstetrical Journal of Great Britain and Ireland—Veterinarian—Thackrah's Daily Share List—Morningside Mirror—Archives Générales de Médecine—Union Médicale et Scientifique du Nord-Est—Practitioner—American Practitioner—New York Druggists' Advertiser—Monthly Homœopathic Review—El Correo Teatral—Guy's Hospital Gazette—Transactions of the Odontological Society of Great Britain.

APPOINTMENTS FOR THE WEEK.

December 8. *Saturday* (*this day*).

Operations at St. Bartholomew's, 1½ p.m.; King's College, 1½ p.m.; Royal Free, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.

10. *Monday.*

Operations at the Metropolitan Free, 2 p.m.; St. Mark's Hospital for Diseases of the Rectum, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.

Medical Society of London, 8½ p.m. Dr. Lauder Brunton, "On the Absorption of Fat, and its Uses; with some Remarks on Fatty Degeneration."

11. *Tuesday.*

Operations at Guy's, 1½ p.m.; Westminster, 2 p.m.; National Orthopædic, Great Portland-street, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; West London, 3 p.m.

Royal Medical and Chirurgical Society, 8½ p.m. Dr. Joseph Coats (of Glasgow), "On the Pathology of Tetanus and Hydrophobia."

12. *Wednesday.*

Operations at University College, 2 p.m.; St. Mary's, 1½ p.m.; Middlesex; 1 p.m.; London, 2 p.m.; St. Bartholomew's, 1½ p.m.; Great Northern, 2 p.m.; Samaritan, 2½ p.m.; King's College (by Mr. Wood), 1½ p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.; St. Peter's Hospital for Stone, 2 p.m.

Epidemiological Society, 8½ p.m. Dr. Collie, "On Variolæ Anomalæ (Sydenham), with Suggestions and Reflections."

13. *Thursday.*

Operations at St. George's, 1 p.m.; Central London Ophthalmic, 1 p.m.; Royal Orthopædic, 2 p.m.; University College, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; Hospital for Diseases of the Throat, 2 p.m.; Hospital for Women, 2 p.m.; Charing-cross, 2 p.m.; St. Thomas's (ophthalmic operations), 4 p.m.

14. *Friday.*

Operations at Central London Ophthalmic, 2 p.m.; Royal London Ophthalmic, 11 a.m.; South London Ophthalmic, 2 p.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. George's (ophthalmic operations), 1½ p.m.; Guy's, 1½ p.m.

Clinical Society, 8½ p.m. Dr. Broadbent, "A Case of Convulsions treated by Venesection." Mr. Maunder, "Two Cases of True Subcutaneous Treatment of Exostosis" (the patients will be exhibited). Mr. Barwell, "Cases showing the Results of Excision of the Ankle,—of Operation for Rickety Bent Shins,—of Operation for Bowed Legs" (the patients will be exhibited).

VITAL STATISTICS OF LONDON.

Week ending Saturday, December 1, 1877.

BIRTHS.

Births of Boys, 1343; Girls, 1293; Total, 2636.
Average of 10 corresponding years 1867-76, 2210·8.

At the Royal Observatory, Greenwich, the mean reading of the barometer last week was 29·20 in. The highest reading was 29·85 in. on Sunday evening, and the lowest 28·67 in. on Thursday morning.

* The figures for the English and Scottish towns are the numbers enumerated in April, 1871, raised to the middle of 1877 by the addition of six years and a quarter's increase, calculated on the rate which prevailed between 1861 and 1871. Salford, however, forms an exception to this rule, as the estimate is based upon the rate of increase of inhabited houses within the borough during the six years ending July 1, 1877. The population of Dublin is taken as stationary at the number enumerated in April, 1871.

ORIGINAL LECTURES.

A LECTURE ON

THE PATHOLOGY OF HYDROPHOBIA.

ILLUSTRATED BY A CASE AT ST. MARY'S HOSPITAL.

By W. B. CHEADLE, M.D., F.R.C.P.,
Senior Assistant-Physician and Lecturer on Pathology.

(*Concluded from page* 615.)

THE results of the post-mortem examination may be thus generalised and summed up :—

1. The blood extremely fluid and dark-coloured everywhere.
2. Intense congestion or accumulation of blood in all the internal organs, the brain and cord and their membranes, the thoracic and abdominal viscera, and the mucous membranes of the respiratory and alimentary tracts.
3. Both sides of the heart almost empty.
4. Scattered hæmorrhages, sometimes large enough to be visible to the naked eye, as under the mucous membrane of the stomach ; others microscopic, as in the pons Varolii, medulla, and brachial nerves.
5. Escape of blood corpuscles through the vascular wall into the surrounding tissue, with fibrinous exudation round the vessels in the pons and medulla oblongata.
6. Increased cloudiness and opacity of the ganglionic cells of the pons and medulla. In the nerves connected with the injured part, cloudiness and a slightly granular condition of the fibres.
7. The vascular engorgement and resulting changes, such as hæmorrhage, escape of blood corpuscles, and fibrinous exudation, were at their maximum in the region of the pons Varolii and upper medulla, becoming gradually less and less in successive portions lower down the cord, and reaching their minimum in the lumbar region.

Comparing these morbid appearanees with those previously observed in hydrophobia, it appears that the dark fluid condition of the blood, the intense congestion of the brain and cord, of the viscera generally, and of the mucous membrane of the fauces, pharynx, bronchi, and stomach, are found very constantly, although it has been stated that in some instances no abnormal condition of the body was discovered. In the most reliable cases of hydrophobia, and those in which the state of the organs has been most carefully examined, excessive hyperæmia has been recorded. In men, as in dogs, the stomach usually contains treacly fluid—no doubt altered blood, —and extravasations beneath the gastric mucous membrane generally exist.

The morbid changes found on minute examination of the nervous structures with the microscope in the present case do not correspond on every leading point with those recorded by previous observers, although they confirm them in certain important particulars. The pathological anatomy of the nervous centres in hydrophobia has been investigated during the last few years by Dr. Allbutt in 1871, and by Dr. Hammond, of New York, in 1874 ; in the latter year also, Dr. Benedikt, of Vienna, examined microscopically numerous specimens of the brain and cord in dogs and other animals which suffered from rabies during the epidemic which raged in the Austrian capital at the time. The condition of the nerves running between the cord and the injured part have not, as far as I know, been previously examined.

Dr. Allbutt found intense vascular congestion, hæmorrhages, fibrinous exudation, and here and there spaces judged to arise from the disappearance of nerve-strands by granular disintegration. With this there was general softening and pulpiness of nerve-substance.

Hammond found the same intense vascular congestion, hæmorrhages, especially about the region of the medulla, with fatty degeneration of the grey matter of the cortex of the brain, medulla, and cord.

Benedikt observed in animals congestion of the vessels of the pia mater, inflammation corpuscles, and refracting colourless exudation matter consisting of punctiform nuclear substance. In the grey and white matter, too, were observed spaces or holes similar to those noted by Allbutt, filled with refracting granular matter. And he regards these appearances as the results of an acute exudative inflammation with hyaloid degeneration. Meynert, quoted by Benedikt as the only observer who had previously published trustworthy reports of microscopic examinations of the nerve-centres, found closely similar appearances. He regards the spaces or holes, however, as produced by the process of preparation. Now, it will be seen that while the vascular engorgement and the hæmorrhages observed both by Allbutt and Hammond, and the fibrinous exudation noted by the former and by Benedikt, were present distinctly enough in the preceding case, the gaps and spaces described by Allbutt, Benedikt, and Meynert were nowhere visible. A vacant space was indeed to be seen here and there, but rarely; and such defects are to be found in all sections. They are often much more numerous than in the present series, and are due, I believe, to the accidental displacement or removal of nerve-strands, or cells, in the act of cutting, the displaced element being sometimes visible when only partially dislodged from its position. Of the fatty degeneration, described by Hammond as existing in the grey matter of the cortex, medulla, and cord, or the granular condition mentioned by Dr. Allbutt, I could find but mere traces, and most in the fibres of the small nerves of the hand, which were not examined in the other cases. I believe these appearances have not the significance which has been imputed to them ; that they are not primary effects of disease, as supposed by Hammond, but merely the result of partial decomposition, which sets in with great rapidity in cases of this kind where death takes place from malignant blood-poisoning, and blood remains fluid. The soft pulpy condition of the medulla, and its distortion of shape, mentioned by Dr. Allbutt, were probably due to the same cause. The brain and cord in the present instance were firm in consistence, and most perfect sections were made from them without difficulty.

Pathology.—The theory that hydrophobia is a mere nervous state induced by an excited and morbid imagination, or a tetanus modified by the same mental influence, has been, I think, sufficiently refuted by the considerations stated at the commencement of this lecture. The nervous phenomena, the involuntary passage of urine and fæces, the hemiplegia or paraplegia which often occurs, and especially the striking material changes found in the nerve-centres, the fluid blood, the almost empty heart, point rather to a malignant blood-poisoning. We find a similar state of the blood and viscera, for instance, in malignant small-pox, and it is said to be conspicuous in poisoning by nicotine, by opium, or by carbonic acid. It has been assumed by most pathologists that the morbid changes found in hydrophobia are simply the results of the mode of death, viz., by apnœa. Similar appearances are, no doubt, found in death by apnœa, and in cases of poisoning where the immediate cause of death is occasionally the apnœa of a sudden convulsion. But in certain cases of poisoning, as, for instance, by nicotine, when the patient dies without convulsion, and apparently from pure asthenia, the blood is stated to be black and fluid, and all the organs as intensely congested as if death had been due to mechanical asphyxia, except that the right ventricle of the heart is not distended with blood. And it is thus in hydrophobia. Trousseau ventured to assume that in this disease death was always due to apnœa, sudden or gradual. But this appears to be an error. The usual mode of death is by asthenia, or by asthenia followed by insensibility, as in the case here given. In some cases, again, the patient sinks by pure asthenia. In a few, death takes place by gradual asphyxia from more or less continuous spasm of the respiratory muscles ; sometimes suddenly from a paroxysm too violent or prolonged. In all, whatever the mode of death, the post-mortem appearances are much the same. In a case recorded by Sir Thomas Watson the patient was certainly not in any degree asphyxiated, for he was able to sit up and wash his hands ; yet he was discovered at that very moment to be absolutely pulseless, and shortly after fell back exhausted and expired. The blood, however, was found to be everywhere quite fluid, and the condition generally very similar to that found in the case here given, where death took place by a mixed process of asthenia and coma ; and in others where death has taken place suddenly by apnœa. In animals, again, the chief symptoms are paralytic, not convulsive, and yet the morbid appearances are closely similar to those found in man. These cannot, then, be regarded as nothing more than the ordinary results of death from asphyxia. With regard to the actual significance of the marked changes discovered in the brain and cord I am not quite so clear. Dr. Allbutt, Dr. Hammond, and Dr. Lockhart Clarke in reviewing the observations of the latter, appear to regard the morbid appearances as signs of an inflammation which is the efficient cause of the nerve

disorder. But it is possible that the nerve disorder may be due more directly to the action of morbid blood upon the nerve-tissues, and the material changes seen may be secondary results of the blood-change, combined with the congestion caused by the convulsive seizures or by sudden or slow asphyxia. To what extent the latter may operate can only be decided from careful microscopic examination of the nerve-centres in cases where death has occurred from these causes—investigations, as far as I know, yet to be made.

In any case, however, the whole evidence afforded by the symptoms and morbid anatomy of hydrophobia seem to me to support conclusively the view that the disease is due to a virulent blood poison which acts injuriously and with special fierceness upon the nervous centres, causing in greater or less, degree the material changes found there after death. It isl moreover, a fact of extreme significance that these materiae morbid changes reach their maximum in those regions of th nerve-centres whence arise the nerves distributed to the organs whose functions are most affected by the disorder—viz , the pons, medulla, and upper cord, whence spring the nerves which preside over respiration and deglutition.

If the disease be set up, as I believe it is, by an animal poison, the interesting question arises whether it is specific, developed only in a rabid animal, or foul, decomposing matter of a less definite kind which may be derived from the mouth of a healthy carnivor. Are rabies and hydrophobia communicated by a rabid animal because that animal yields the special poison, or simply because such rabid animal, being more savage and irritable, is specially prone to bite ? Cases are recorded where the disease appears to have been communicated by animals who did not go mad themselves; and some curious facts with regard to the production of hydrophobia by the bite of the American skunk, bearing upon this point, have been recently published in the *New York Medical Record* by Assistant-Surgeon Jameway, of the United States Army, stationed at Fort Hays in Arkansas, and by Colonel Dodge, an officer of distinction in the same service, in "Hunting Grounds of the Great West." The former records eleven cases of skunk-bite which came under his observation, ten of which resulted in hydrophobia and were fatal. Colonel Dodge affirms that in the years 1872-73 he knew of sixteen cases of skunk-bite, in every one of which death by hydrophobia followed ; and further, that he has met with only one case of skunk-bite in the Arkansas country which was not fatal in this way.

The animals do not appear to be in the rabid state, and dogs bitten by them do not go mad. But the most curious part of the story, which is vouched for by Colonel Dodge on the strength of his extensive experience during many years in this part of Western America, is the statement that this fatal result of skunk-bite is limited to the district of the Arkansas River, and absolutely unknown elsewhere. Yet the animal is widely spread, and found commonly throughout almost the whole of North America. Yet I can certainly confirm the statement so far that I never heard of skunk-bite being regarded as in any degree dangerous in other parts of the continent. This limitation to certain districts would favour the theory of a specific poison. Colonel Dodge further affirms that he has never met with a case of hydrophobia in the Arkansas district in any animal except man, and, strangely enough, that dogs are free from it, and do not communicate it to man. There are, however, cases recorded of rabies in wolves, and of deaths from hydrophobia following bites inflicted by them. This account of the prevalence of hydrophobia from this cause in a limited district is given so circumstantially, and on such excellent authority, that it cannot be put aside as without foundation. The question which naturally first suggests itself is, whether the cases recorded were genuine hydrophobia or only some form of tetanus, and this point is worthy of further investigation.

HARVEIAN LECTURES.

DELIVERED BEFORE THE MEMBERS OF THE HARVEIAN SOCIETY.

By GRAILY HEWITT, M.D., F.R.C.P.,
Professor of Midwifery and Diseases of Women, University College.

Abstract of Lecture I.

Five years ago the author published in a succinct form the conclusions which his observations had induced him to come to on the subject of the "Pathology of the Diseases of the Uterus," these conclusions being formulated as follows:—

1. Patients suffering from symptoms of uterine inflammation (or, more properly, from symptoms referable to the uterus) are almost universally found to be affected with flexion or alterations in the shape of the uterus, of easily recognised character, but varying in degree.

2. The change in the form and shape of the uterus is frequently brought about in consequence of the tissues of the uterus being previously in a state of unusual softness, or what may be often correctly designated as "chronic inflammation."

3. The flexion, once produced, is not only liable to perpetuate itself, so to speak, but continues to act incessantly as the cause of the "chronic inflammation" present.

Further experience has confirmed the accuracy of these views; and having since had the additional advantage of the criticisms of other authorities, he was now enabled to develope the subject more completely.

It was explained that the use of the word "mechanical" was not intended to imply the necessity for the employment of instruments in the cure of uterine diseases. The designation, "mechanical system of uterine pathology," has reference to the important influences—mechanical influences—exercised in the production of uterine diseases, and the effects of mechanical alterations in the shape and form of the uterus.

The various forms of severe prolapsus of the uterus have long been admitted as diseases. The slighter internal displacements had been also known to occur, but not considered as important. Of late years, bendings or flexions of the uterus had attracted much attention; but the proper signification of these latter alterations is not yet known, nor their relations to other diseases and alterations properly defined. In regard to the frequency of their alterations in shape, the author's observations at University College Hospital, over a period of a little more than four years, was cited. Of 714 patients suffering from uterine symptoms, 620 were examined: of these, 182 were affected with fibroid tumour, cancer, or pelvic cellulitis, 61 cases offered various conditions, but in 377 the uterus was materially altered in regard to shape or position; in 184 cases anteflexion was present, in 112 retroflexion, in 81 there was prolapsus. Thus in 60·8 per cent. of the cases actually examined, distortion or displacement existed in a marked degree.

As an introduction to the subject, the "mechanics of the uterus" were then considered. The position of the uterus offers a certain degree of protection from external injury. Its motion is comparatively restricted, the fundus having more motion than its centre, lateral motion little, upwards and downwards more, forwards and backwards more superiorly, little in the middle, and more inferiorly. Tilting also to a slight extent is admissible.

Slight bending only is possible in a healthy uterus under normal circumstances, owing to the natural rigidity the organ possesses, and this is, in fact, its chief safeguard against the occurrence of flexion. The bladder offers some resistance in front. Behind there is no protecting organ. The thickness of the uterine walls renders it almost a solid organ. The blood-vessels are numerous, and their healthy distension aids also in giving the organ firmness. In a state of health the uterus probably moves a little, and indeed bends a little, but quickly recovers itself when the disturbing force is withdrawn. Possible alterations in position and shape are—(1) slight version, anterior or posterior; (2) slight descent of the whole uterus; (3) considerable version, generally associated with flexion; (4) considerable descent of the uterus, as a whole, in the pelvis. All combinations of these may be met with. Particular attention was directed to the necessity for a definition of anteflexion and anteversion. The fact that slight curvature forwards is natural has apparently prevented many from attaching due importance to anterior displacements, and consequently severe anteflexions and anteversions are not seldom overlooked. When the uterus is healthy, and in its natural position and shape, by an ordinary digital examination it should not be possible to reach and define the outline of the body of the uterus. Descent forwards of the uterine body, such as to render its outline evident, constitutes a displacement. Anteversion or anteflexion may exist separately, but generally the two are associated. The sound, unless judiciously employed, may readily mislead the observer, the uterus becoming often straightened, or its position altered by its introduction.

The various forces of a dislocating character were next described. Severe falls, slipping on the pavement, severe muscular exertions, continuous overwork in nursing and lifting heavy articles, excessive walks, certain gymnastic exercises, straining of the abdominal muscles, long-continued sitting, and other causes, are frequently found to have produced uterine distortions and displacements. The resistance which

the uterus offers to these varying disturbing forces has next to be estimated. Whatever tends to soften and relax the ligaments and attachments of the uterus, so far diminishes its resisting power. Pregnancy often leaves behind it such softening and relaxation. But more important is the softening of the tissues of the uterus itself as a predisposition to flexion or distortion. This point was particularly made the subject of an essay recently read by the author at the meeting of the British Medical Association at Manchester. Several cases were then narrated, in which marked degrees of uterine flexions were present, associated with very undue softness of the uterine tissues. The cases in question were those of patients in whom the disturbing influence of pregnancy had not been present. This softness was met with in cases where the attendant circumstances left no room for doubt that the cause of the undue softness was really malnutrition of the uterus. The subjects of these cases had long been out of health, feeble, and weak, and for various reasons had taken very little food. In unmarried women, undue softness of the uterus, so produced, predisposes to flexion. In married women, or in those who have been pregnant, other conditions liable to produce undue softness of the uterus are present.

In cases of slow involution after delivery, the uterus remains soft and unduly pliable, and flexions are very liable to be originated as a consequence of this. The frequency with which uterine troubles are known to have had their starting-point after a certain pregnancy is thus explained. After abortions the same liability to distortion of the uterus occurs, and in the same way.

Next the author entered on an examination of the clinical aspect of cases of uterine disease, and an investigation of the symptoms, abnormal sensations, and discomforts experienced by the patient, with the view of determining the importance and influence of the mechanical diseases of the uterus. The necessity for close attention and analysis of these symptoms was urged. In two lists are arranged—*A*. The symptoms of all kinds which may be observed in connexion with diseases or affections of the uterus (these symptoms being indicated, as nearly as possible, in their order of frequency); and *B*. A list of the various non-organic physical changes which the uterus may undergo.

A.—Pain: Spontaneous; Produced by Motion (Dyskinesia); Undue Sensitiveness of the Uterus to Touch—Leucorrhœa—Dysmenorrhœa — Menorrhagia — Amenorrhœa—If Married, Sterility—Abortions—Various Reflex Phenomena: 1. Sickness or Nausea; 2. Hysteria; 3. Convulsions; 4. Cephalalgia—Disturbance of Functions of Bladder; of the Rectum; of Sexual Functions.

B.—Change in Position—Change in Size of Walls; of Cavity; of Cervix—Change in Shape—Change in Patency of Canals—Change in Texture: Undue Hardness or Undue Softness; Increased Vascularity—Disorders of Innervation—Increased Secretion.

The importance of any one of the possible uterine changes should be approximately, at all events, indicated by the frequency with which it occasions uterine symptoms. If any particular change or combination of changes has a decided pre-eminence in this respect, it will be natural to consider that change or changes important. Further, if the particular symptoms the patient complains of are those in question, this will be additional reason for this belief. Such belief will be strengthened when it is shown that there is a rational and intelligible explanation of the association of these particular changes with those especial symptoms.

Académie des Sciences.—At the meeting of this learned body on December 3, Sir William Thomson was elected a Foreign Associate, in place of the late Prof. v. Baer. He obtained the votes of twenty-seven of the fifty-two Academicians who were present, Prof. Van Beneden receiving twenty-five.

The Monument to Pouchet at Rouen.—A marble bust has just been publicly inaugurated to F. A. Pouchet, the celebrated defender of spontaneous generation, not, however, on account of his scientific opinions, but in gratitude for the great benefactions he had conferred on the city of Rouen. M. Pennetier, Director of the Rouen Museum, read, amidst loud applause, the following passage from a letter which he had received from M. Pasteur, on sending his subscription for the monument raised to his adversary:—"This conscientious *savant* deserves the gratitude of all for what he has done of good and useful, and even in his errors he has a right to every respect."—*Union Méd.*, December 6.

ORIGINAL COMMUNICATIONS.

NOTES OF A CASE OF

EXTRA-UTERINE FŒTATION—OPERATION—RECOVERY.(a)

By J. HANCOCKE WATHEN, L.R.C.P. Edin.

On Monday, January 22 last, a request was made by the wife of a clergyman that either my father or myself would visit a poor woman residing in their parish, some four miles distant, who was said to have been in labour nearly three weeks. My father visited the case, and found the patient a young, healthy woman of twenty-five years, pregnant with her second child.

The history given was, that the previous Wednesday fortnight (nineteen days ago), having arrived at about her full time, she was taken with labour-pains. These pains continued until the following Sunday, when the services of a medical man were sought for. This gentleman, however, could not attend, but sent another to take charge of the case. The latter, after making an examination, prognosticated that the labour would be terminated in a very short time. This period was, however, extended into hours, in spite of "some drops" being given to hasten matters, without any sign of the child being born. The medical attendant then left, but saw the case that night, and again on the following (Monday) morning, when the patient was, according to her statement and that of her mother, in much the same state as during the previous days, there being strong expulsive pains (or efforts). There had been no discharge or show until after the medical man had made an examination, which hurt her very much; there was a considerable show after this.

Matters went on until the following Friday, when she was seen for the first time since the Monday by her medical attendant, and so continued until the 22nd, when my father first saw the case. On making an examination per vaginam the fœtal head was found presenting, the sutures being plainly made out, but between the head and the finger a membrane was found intervening; the head was completely invested by it. The finger could be passed but a short distance anteriorly before being stopped by the reflection of the enveloping membrane; posteriorly the finger, and even the hand, could be passed much higher, but was finally arrested by a *cul-de-sac*. The os uteri could not be detected. The membrane moved freely over the fœtal head, the bones of which were elastic and compressible. There was not the slightest expulsive effort, but the patient complained of some pain over the abdomen. It being late in the evening, a full opiate was given, and the patient left until the following morning, when my father and I saw the case together.

The patient had passed a good night, free from pain; her expression was good, although somewhat anxious; the tongue clean and moist; pulse quiet. On exposing the abdomen she was seen not to be so large as a woman would ordinarily have been at her full time (later on she was found to measure thirty-six inches). The abdomen was not symmetrical, it being larger and more prominent towards the left side, where there was an increased area of dulness compared with that on the right side. The patient stated that the child always lay, when she was on her back, towards the left side, but by turning towards the right side she could feel the child roll over toward that side: this she demonstrated to our satisfaction. No fœtal heart or placental bruit could be detected, and the patient confirmed this evidence of the fœtus being dead by her statement that she had not felt the child for about a week before being taken with labour-pains. She dates her conception early in April, and says that she quickened some time in August while in the harvest-field. Per vaginam, things were as already described; through the speculum the rugose character of the investing membrane could be plainly seen. A catheter was with difficulty passed into the bladder, which contained a small quantity of urine. After reviewing the case, the diagnosis arrived at was—"extra-uterine fœtation," the fœtus being to the left side of the uterus, and the head pressing down, with the vaginal wall in front of it.

When the nature of the case had been thoroughly explained to the patient, who was an intelligent woman, she became quieted in her mind, which had been sorely tried by protracted hope. There being no urgency in the symptoms, it

(a) Read before the spring meeting of the South Wales and Monmouth Branch of the British Medical Association.

was arranged to have the patient removed to her mother's, who lived nearer us, and one-grain doses of opium were ordered to be given occasionally if in pain. As the efforts of nature to expel the fœtus had ceased, and the patient was now in good spirits and strong, it was deemed advisable to wait until symptoms demanding interference should show themselves, when, in all probability, some suppuration would have taken place, and thereby (as generally held) render operative procedure less hazardous to the woman. She continued very well for about a fortnight, during which time she took opium twice or thrice daily. She then became much distressed by flatus and accumulation of fæcal matter, with retching. These troubles were got rid of by turpentine enemata and hypodermic injections of morphia, but to return once or twice again. Suffice it to say that at the end of a month she became so worn, that it became plain some interference could not much longer be delayed. About this time she had a dark brownish discharge with shreds of mucous membrane, and a bridge consisting of a portion of the vaginal wall could be made out running across the investing membrane over fœtal head. The head had become less prominent—that is, the sutures and bones of the head could not be detected,—but the presenting tumour was more tense and elastic to touch, indicating the probability of suppuration having taken place in the sac. I should mention that during this month of temporising we had frequent opportunities of demonstrating the situation of the fœtus to be on the left side; and the patient stated that the unusual position of the child, together with the ease with which she could lift it across from one side of the abdomen to the other, had attracted her attention, and that she had conferred with her female friends on the matter.

The pelvic region of the fœtus could now be felt at times through the abdominal wall, and the girth of the patient at the umbilicus, when not distended by flatus, was as little as thirty-two or thirty-three inches. After the risks had been laid thoroughly before the patient, she consented to the removal of the fœtus; and, as her surroundings were not good, she was removed into Fishguard on February 27, and on the following day, exactly eight weeks from the onset of labour-pains, I operated, my father giving chloroform.

It was determined, as the presenting tumour occupied the vagina, to attempt the removal of the fœtus per vaginam, and, failing this, to do so by abdominal section. I had little doubt but that the first mode would be successful if the fœtus would hold together. Of this, however, I had my misgivings.

A curved probe-pointed bistoury, which was guarded up to within an inch of its point, was passed into the vagina, and the vaginal wall incised; through the incision the index-finger of the left hand was passed, and the wound enlarged backwards and forwards. The head was found still enveloped by a membrane, and posteriorly and somewhat to the right side the uterus could be felt. The sac was opened, and dark grumous pus was discharged; the hand was then passed in, and the head found to be free; forceps were applied to the head through the incision, and the fœtus extracted entire.

After the head had been extracted, a blunt hook was inserted into the armpit, thereby obviating the risk of the head separating before the trunk was removed, as of course we had no assistance by any expulsive effort, the extraction being entirely performed by traction. No effort was made to extract the placenta, which came away, however, the following day. The fœtus was that of a full-grown male undergoing liquefaction.

It will not be necessary for me, gentlemen, to encroach upon your time by giving a detailed report of the progress of the case, beyond a *résumé* of the treatment. The temperature, which was 100·6° immediately after the operation at 2 p.m., fell that night, and next morning was normal, showing that a cause of irritation had been removed. The principal feature in the after-treatment was that the sac was washed out daily for about three weeks with carbolised or iodine water—principally the former; after several of these washings-out, I noticed a fall of nearly 1° of temperature. The discharge continued free and healthy; and at the end of the fourth week from the operation the patient became unwell.

The position of the wound in the vaginal wall shows that the head came down on the left side. The wound, although originally made well in the mesial line, is now on the left wall of the vagina. The patient has returned home, and the wound is contracting rapidly, it being occasionally touched with nitrate of silver.(b) In connexion with the after-treatment of this case, I wish to notice an instrument which I found of immense service—viz., Messrs. Arnold and Son's vaginal douche; by it I was enabled to syringe out the sac daily without disturbing the patient beyond bringing her to the side of the bed, and without soiling the bed in any way, the effluent water being carried away to a basin on the floor. It is of service not only in those cases confined to bed, but in those where patients are up and about, as it renders the use of vaginal or uterine injections simple and cleanly.

In determining the line of treatment to be followed in this case, we were a good deal influenced by the discussion which took place recently at the Obstetrical Society upon Mr. Jessop's (of Leeds) case. During the discussion, the President, Dr. Priestley, laid it down that interference was much safer to the woman at a later period, after suppuration had taken place, than immediately on the onset of anything like labour-pains. Dr. Edis expressed an opinion that in certain cases extraction through the vaginal wall would be resorted to with a lessened risk to the mother, as the peritoneal cavity would thereby not be opened up.

I do not know whether I am right in saying that this is the first case in which an extra-uterine fœtus has been removed by operation per vaginam, but am inclined to think so. Great stress was also laid, in the discussion already referred to, on the importance of leaving the placenta; but I think in our case we need not have been deterred from removing it at once, as the result proved that the placenta had been separated long before,—consequently there was no risk from hæmorrhage, although, in cases operated on early (whether per vaginam or by abdominal section), the rule would appear good not to remove the placenta, as we have no uterine contractions in these cases to help to prevent hæmorrhage.

Fishguard.

(b) Since the above was written the wound has united thoroughly, and the cicatrix has the os uteri above and to the right of it. I believe at the present date the woman is again pregnant.

THE STRUCTURE AND FUNCTIONS OF THE NERVOUS SYSTEM.

By JAMES ROSS, M.D., M.R.C.P.,
Honorary Physician to the Southern Hospital for Diseases of Children, Manchester.

FUNDAMENTAL PROPERTIES OF NERVOUS TISSUE.

(*Continued from page* 619.)

Conduction.—The property which nerve-fibres possess, of transmitting the state of activity from the one point to the next, is called their conductivity. A particular nerve-fibre usually transmits its activity in one direction only—hence the distinction made between afferent and efferent fibres; but several circumstances might be mentioned, which tend to prove that a nerve-fibre can conduct in both directions. It has been proved by experiment, that if a purely afferent nerve (gustatory) be divided, and its central end be made to unite with the distal end of a divided motor nerve (hypoglossal), irritation of the former after the parts have been healed produces contraction in the muscles supplied by the latter.

Continuity of the nerve-fibre, especially of the axis-cylinder, is necessary for conduction. Lesions of the fibre from section or caustic, or even from a certain amount of pressure, interrupts conduction. The passage of the active condition from one fibre to another never occurs, more especially in the higher evolved fibres which possess a medullary sheath.

The transmission of the active condition from one end of a nerve-fibre to another occupies time. The average rate of conduction in human motor nerves is found by experiment to be 111 feet per second; and in the sensory nerves to be 140 feet per second.

The velocity with which nerve-energy travels may be increased or diminished. The rule is that cold, the condition of an electrotonus, and all conditions which lower the irritability, diminish the velocity; while heat, the condition of catelectrotonus, and all conditions which raise the irritability, increase the velocity of conduction.

Pflüger observed that the effect of stimulating a motor nerve is so much the greater the further removed the point of stimulation is from the muscle. He explained this effect by supposing that the active condition of a nerve accumulates strength in transmission, like the momentum of a falling mass, as an avalanche. It is now considered more probable that this phenomenon depends upon the increased irritability of the more distant parts of the nerve caused by section.

These, then, are some of the more important empirical laws of the functions of nerve-fibres, and of the actions of those agents which evoke their activities. Let us now endeavour to

reduce those laws to some degree of order. On comparing them with one another, the most obvious relationship which exists between them is—that the mechanical, chemical, and thermal agents which act as stimuli when suddenly applied to a nerve, increase the irritability when gradually applied and in a moderate degree of intensity, and destroy it when suddenly applied beyond a certain degree of intensity; and it has just been seen that all conditions which increase the irritability of the nerve also increase the velocity of conduction. Such are the facts which require explanation.

All the functions of nerve-fibres are closely connected with the fundamental property of irritability. We have already seen that irritability depends upon the molecules of the protoplasm being in a condition of unstable equilibrium, and that the energy is rendered actual when the molecules fall to a relatively stable position. There can be little doubt that nerve-irritability depends upon the protoplasm of the axis-cylinder being composed of molecules in unstable positions, and that these are so connected, that the movement or alteration of one leads to the movement or alteration of those in the immediate neighbourhood. The true nature of this movement is not known, but the theory most consistent with facts assumes that it is a chemical change either of the nature called isomeric, or an oxidation such as occurs when a train of gunpowder is ignited at one end. The extreme slowness with which the energy travels from one end of a nerve to another, in comparison with the speed of electrical currents, shows that the two kinds must differ essentially from one another. The agents which act as stimuli set up this chemical change at one end of a nerve, and this is gradually propagated to the other end. When these agents are gradually applied, they act by placing the molecules in more unstable positions without causing them to fall, so that a slighter degree of stimulus will subsequently induce the necessary chemical change; while the same agents, when suddenly applied in high intensity, will produce such a large amount of chemical change as to destroy the irritability. The following illustration may enable us to some extent to realise what occurs in a nerve-fibre during the transmission of its energy. We have seen that when matter possesses potential energy, a certain force called the liberating force is necessary in order to render the energy actual; or, in other words, matter under those conditions offers a certain amount of resistance to change, and the higher the resistance the stronger must be the liberating force. Suppose two books, each a foot in height, to be standing on end on the table, and that the one is half an inch, and the other two inches, in thickness; the slightest tap on the free end of the first will cause it to fall, while it will require a considerable blow to cause the second to fall. The resistance which the latter offers to change is greater than that of the former. And if we arrange two rows of these books placed on end at convenient distances, in such a way that when the first book of a row is made to fall it will strike the second and cause it to fall towards the third, and so on till the row has fallen with the books overlapping each other, it will at once be noticed that the row made up of the thin books will fall much sooner than that made up of the thick books. Each book of the latter row offers a greater resistance to change, and not only is a greater force necessary to initiate the movement in the first book of the row, but the transmission of the movement from one end to the other will be delayed. When the nerve-irritability is depressed, this shows that the molecules occupy relatively stable positions, consequently offering a greater resistance to change, and requiring a stronger liberating force to be applied to them. But not only must the initial liberating force be stronger, but it must be stronger at each point of the conduction—hence the velocity of the conduction will be rendered slower; while the reverse obtains when the irritability is increased.

(To be continued.)

CASE OF DIFFICULT LABOUR.

APPLICATION OF FORCEPS;
PUERPERAL MANIA AND FEVER, TREATED WITH SUBCUTANEOUS INJECTION OF CHLORAL HYDRATE.

By R. EDWARDS, L.R.C.P., M.R.C.S.

On October 7, at 5 a.m., I was summoned to see a lady, aged twenty-eight, in labour with her second child. Her first labour had been tedious, and the child stillborn. On this occasion she had been in labour since early the previous evening, and the pains were severe. On examination, I found that the uterus was very high up; os fully dilated, but the membranes not ruptured; vagina very hot. The plexuses of veins in lower part of vagina and on vulva were remarkedly turgid. I very soon ruptured the membranes, and, after waiting an hour or more, and seeing no progress made—the head feeling immovable and in the antero-posterior diameter at the brim,—I determined to apply the forceps, but failed, partly because the head was so high up, and the parts were very tender and sensitive to the touch. Chloroform was then sent for, which Dr. Hughes kindly administered. At 8.30 a.m. I had succeeded in applying the forceps. Then gentle traction was made, at first only with the pains. This did not seem to succeed, but continuous and gentle traction at last overcame the resistance, and the head began to descend, but very slowly. Altogether, the time from the application of forceps to the birth of the child occupied about two hours. We had some difficulty with the shoulders. Hæmorrhage occurred into the uterus, and large clots came away when the placenta was removed. The uterus, after being well manipulated through the abdominal walls, contracted firmly, but felt larger than it should be. 4 p.m.: The patient has had a slight shivering. Respiration irregular and sighing; pulse 110, bounding, full; temperature 102·2°. Uterus large, somewhat tender; only a slight discharge. Ordered a mixture—℞. Quin. sulph. gr. xij., ext. ergotæ liq. ʒij., aq. ad ʒviij.; ʒj. 4tis horis.

October 8.—Did not sleep much during night; had several shiverings. Uterus very large, reaching midway to umbilicus; not very tender. Bowels very freely opened. Urine passed frequently. Temperature 101·6°; pulse 100, moderately full and firm. Tongue moist, slightly furred.

9th.—Temperature 103°; pulse 110. Discharge slight. Secretion of milk began. Breasts painful.

10th.—Slept at intervals; but on the whole passed a very uncomfortable night. Temperature nearly 103°; pulse 110, softer, but still full. Uterus smaller. Though she expresses herself very well, yet her appearance belies her words, for she looks anxious, with knitted brows and wrinkled forehead; sighing and irregular respiration.

11th.—Morning: Condition similar, but pulse more frequent, 120. At 9 p.m. I was hastily summoned, and found the patient quite delirious, or more properly maniacal, requiring the united efforts of three or four strong men to keep her in bed. She was biting at the bedclothes or at anyone's hand, shouting and groaning; and at intervals there were violent twitchings of the whole body, lasting two or three seconds or even more. She did not know anyone, and refused everything. The pulse too frequent to be counted, remarkably small, and the skin biting hot. I had tried the injection of chloral hydrate in a case of cerebro-spinal meningitis, in which there were convulsions and delirium, with good result, though the patient ultimately died: I determined to try it again in this case, though only as a forlorn hope. Not having the necessaries with me, I hurried back, and sent the pupil (Mr. Williams) with a solution of chloral hydrate, twenty grains in forty minims, and instructed him to inject it into the legs. He first injected ten grains into the right leg; and he says that he observed the twitchings diminishing and stopping in this side of the body first. This was corroborated by the friends of the patient. What explanation to give I do not know. However, she became calm, though still wandering, and took her medicine and nourishment.

12th.—8.30 a.m.: She had a similar attack to that of last night, though not quite so violent. I again injected chloral, which was followed in about an hour and a half by the same result as before. Pulse 132, very small; temperature 103°; great tenderness over the uterus; ordered quin. sulph. gr. iij. every three hours; pil. opii gr. ¾ every two hours, and to take milk, beef-tea, and good port wine. 4 p.m.: Patient very calm; had a quiet sleep; wandering at times, but knows her friends and answers questions rationally; pulse 120, fuller; discharge very offensive, but slight in quantity; there is a hard red swelling, very painful, over the saphenous vein (phlebitis).

13th.—5 am.: Temperature 102·6°; pulse 118, fuller and firmer. 11 a.m.: Temperature 104°; appearance of patient better; pulse same. 7 p.m.: Patient looks much better; has lost her anxious look; is not wandering; the uterus still feels large, and appears quite fixed by inflammatory products, especially in left iliac region; temperature 101·2°; pulse 110, fuller, much firmer; sleeps well.

For the next two or three days there was nothing of importance to note.

16th.—Pulse 80, good strength; temperature 99°; tongue clean and moist, rather raw; there are several spots in the throat like diphtheritic exudation; pain in swallowing. For this a mixture of chlorate of potash and iron was ordered;

puncture points of injection inflamed, and likely to slough; middle joint of right middle finger swollen and tender; there is difficulty in passing urine; abdomen above pubis dull on percussion; the swelling over saphenous vein very red and tender, probably with suppuration.

From this date to November 1, when convalescence was firmly established, it would be tedious to give daily details. The throat was all right in a few days; the puncture-points sloughed, leaving deep but healthy wounds, which rapidly healed; the hardness over the saphenous vein, already mentioned, formed a small abscess, which was opened; the dulness in lower part of abdomen gradually disappeared, and the uterus returned to the normal dimensions.

Remarks.—Having tried the remedy in this form in two cases only, it would be premature on my part to advance any theory as to its *modus operandi*. The two cases were similar in several respects—viz., high temperature, delirium, and more or less violent convulsions. The effect of the remedy in both was the same—viz., a rapid return to consciousness, without, at first, any sleep. Its action in these cases was certainly not like that of chloroform. I am quite convinced that it is a remedy of great value in cases of this nature, in which the patients would otherwise inevitably die. But it must not be used in ordinary cases, on account of its producing extensive sloughs, and patients would be apt to look upon the remedy as worse than the disease.

Bala.

ELEPHANTIASIS GRÆCORUM IN GUERNSEY.

By ROBERT LIVEING, M.D., F.R.C.P.,
Lecturer on Dermatology at the Middlesex Hospital Medical School.

The following short account of a well-marked instance of true leprosy, occurring in a native of Guernsey who had never left the island prior to its development, is not without interest:—

John L., aged twenty, was admitted into Middlesex Hospital, July 12, 1877, and placed under my care by Mr. George Lawson. His father, a native of Birmingham, was a soldier who had served in India, and died aged about fifty-five. His mother was a native of Ireland, and "died of old age." He has several brothers and sisters older than himself, and all healthy. With regard to food, he tells us that he has always had plenty of meat and vegetables, and has not been in any way restricted to a fish diet. The disease began to show itself five years ago, with feverish attacks, swelling of the face, discoloration of the skin, and other symptoms of leprosy. It made rather rapid progress, and a year after its commencement he was advised to try the effect of a sea trip, with a view to the improvement of his health. He therefore made short voyages as a sailor to different parts of the English coast, and once to New York. This mode of life does not, however, appear to have had any effect in checking the progress of the malady. At the present time the disease is fully developed, and he has the very characteristic leonine appearance produced by tuberculated leprosy, together with loss of eyebrows, a harsh and husky voice, enlarged ear and nose, darkened skin, and, though only twenty, the appearance of a middle-aged man. He complains of a feeling of numbness about the little and ring fingers, and also on the inner side and back of both hands, and there is some loss of sensation in the skin of those parts. Brown patches of skin are seen about the elbows and knees; there is a well-marked hard swelling of the left ulnar nerve, just above the elbow-joint, and a corresponding enlargement, less developed, on the right side. In short, he presents altogether a typical example of Elephantiasis Græcorum of the tuberculated variety.

The interesting question is—Is this a case of true leprosy originating spontaneously in Guernsey without assignable cause? I think not. I believe it to be really an hereditary case of the disease, though I admit there is some doubt on this point. We had much difficulty in finding out the cause of his father's death, as our patient himself could give us little information on the subject. We learned, however, from other sources—(1) that his father, when in India, cohabited with a coloured woman; and (2) that he died in Guernsey, and that in his last illness he had sores on his fingers and toes, an enlargement of the nose, and a discoloration of the skin of the face. In short, it seems highly probable that his father contracted leprosy in India, and ultimately died of that disease. It is worth while to remark that if we had depended on the statements of our patient with regard to his father's death we should have entirely lost sight of the true origin of the disease. I cannot help thinking that some other cases of this disease which have been supposed to have originated spontaneously in this country may possibly have been due to untraceable hereditary taint. I will only add that the case has been treated for some months past with Gurjun oil (in drachm doses), and that there is some improvement in the general symptoms, and a marked improvement in the condition of the ulnar nerves. This must be taken for what it is worth.

REPORTS OF HOSPITAL PRACTICE IN MEDICINE AND SURGERY.

CASES OF

HEART DISEASE BEARING ON RELATION OF EMBOLISM TO PYREXIA.

In reckoning up the possible dangers subsequent to heart disease, we are too much in the habit of thinking only of the mechanical results of incompetent valves. But, apart from embolism of the middle cerebral, and the hemiplegia attendant thereupon, which most medical men take cognisance of, the results of embolism in other viscera well deserve consideration.

Given a case of heart disease, if pyrexia be present, and no obvious intercurrent inflammation be discovered, embolism in some of the viscera ought to be thought of. The possibility of splenic embolism should especially be considered, because the spleen may enlarge considerably without the edge being palpable below the ribs. There is no doubt that extensive embolism and pyrexia of hectic type may occur without the endocarditis being necessarily *ulcerative*.

Does the pyrexia depend upon the *mere discharge* of emboli from vegetations into the blood-current, or upon the inflammatory processes set up by these emboli in the tissues where they lodge? Difference in the irritant character of emboli was strongly insisted on by Dr. Goodhart in discussing recently the pathology of cerebral aneurisms caused by embolism. Whatever may be said of the other viscera, there appears reason to believe that splenic embolism, and splenic enlargement consequent thereon, are peculiarly liable to be associated with fever of the hectic type. The following cases should be read in connexion with those reported in this journal of November 17:—

HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET.

Case 1.—*Endocarditis (with history of probable Rheumatism)—Chorea—Pyrexia—Splenic and Renal Embolism—Splenitis and Nephritis—Vascular Changes in Spinal Cord.*

(Under the care of Dr. GEE.)

Helen B., aged eight years and four months, was admitted under the care of Dr. Gee on June 9, 1876. A very imperfect history could be obtained. Both parents were said to have died of consumption; of the three children the two others were healthy. There was no previous history of rheumatism or St. Vitus's dance with regard to this girl, and up to one month ago she is asserted to have been in fair health; but this seems doubtful. About a month ago she complained of pain down the right hip and in the right leg; this made her limp. When she lay in bed her hip was drawn up. She was so for ten days. She was not kept to bed. She did not at that time complain of her other joints or of pain in the chest. There is no information forthcoming as to any fright, but a fortnight ago she began to twitch. She could not hold a teacup, broke a jug, "tossed her head" and "plunged." One week ago her speech was so thick that she could not get her words out. Within the last week she has cried if spoken to. There has been no trouble with swallowing. Has complained of her head for a week. No vomiting, but has felt sick. Possibly this is due to small doses of sulphate of zinc, which she has been taking for one week. She was seen in the out-patient room a few days ago, having mitral disease and slight chorea. To-day, when brought, although the chorea was less, and there were no additional heart-signs, nor indeed any evidence of fresh visceral disease, yet the temperature was 103·4°, and she was on this account admitted into the hospital. She walked pretty steadily upstairs to the ward.

June 12.—The following notes were taken:—Choreic signs: Slight pursing-up of lips; protrudes tongue with a jerk, can't keep it out. Speaks partly in a whisper, partly aloud; hesitates in the middle of a word—*e.g.*, "seven-teen." There is considerable play of corners of mouth, and occasional arching of eyebrows. The pupils are large and sluggish, the left bigger

than the right. She drinks without spluttering; takes a very long time rolling a morsel of bread about in her mouth, but ultimately swallows it. Twitching of fingers and wrists—sometimes alternating in the two hands, sometimes simultaneous. A little shrugging of shoulders and arching of back occasionally, and now and then a little inversion of both ankles, and extension of right big toe. No anæsthesia. Not so lachrymose as on admission. Skin excessively pungent. Tongue slightly furred at the back; lips not dry; pulse 116. The heart's dulness was limited by the third left space, mid-sternum, and left nipple line. Forcible impulse; no thrill. Systolic apex-murmur conducted to base and to axilla. Accentuated pulmonary second sound. No irregularity of heart's action. Pulmonary regions natural. No enlargement of liver and spleen detected. At noon the temperature in rectum was 103·8°; cause of pyrexia not obvious. She was placed in a bath at 90°, which was lowered to 70°. She was kept in for ten minutes, but a few minutes afterwards her temperature was 103·2°. She slept shortly afterwards. During the next two days a cold bath was tried twice a day, but the body temperature increased again shortly after removal from the bath.

19th.—Tongue dry and rather brown; bowels constipated. Cause of pyrexia not yet discovered.

22nd.—The chorea has almost ceased; child very pale, cachectic; tongue creamy; bowels constipated. What is the cause of the pyrexia? There is no evidence of increase of endocarditis—at all events, no change in the heart-signs. There is no abdominal tenderness. The nurse states that during the last three days the child has gone some hours without passing water, and then passed it in great quantities; urine found to contain one-fifth albumen, with middle-sized hyaline casts and swollen epithelia. After standing twenty-four hours, numerous uric acid crystals deposited. There is no œdema.

23rd.—Chorea confined to very slight movements of fingers; has vomited a few times; constipated; pulse 120, full and soft; no pulmonary signs; no œdema; face pale; urine, specific gravity 1020, one-fifth albumen.

24th.—Still vomits; bowels require enemata; pupils large; nothing abnormal to ophthalmoscopic examination. There are purpuric spots on the trunk, and a few on the face; skin very dry; urine, specific gravity 1027, one-fifth albumen; 330 cubic centimetres in twenty-four hours.

26th.—Has retched again to-day. Urine, specific gravity 1020, slightly smoky, one-third albumen; gives faint but distinct reaction for blood with guaiacum and ozonic ether; under microscope, besides blood-discs, there are abundant nucleated cells and some large hyaline casts; 600 cubic centimetres passed in twenty-four hours.

28th.—Has vomited repeatedly; once vomited matter said to be "very dark"; relieved by mustard-plaster to epigastrium; no dropsy. Child complains of pains in ends of left little finger and big toe; no chorea. Pulse 80, not at all "hard." Pulmonary regions natural. Urine, specific gravity 1020, pale, smoky; albumen one half; granular casts and granular epithelia; 580 cubic centimetres in twenty-four hours.

July 10.—For the first time there is slight œdema of face and ankles.

11th.—There is a little dulness at the bases; nothing abnormal to be heard. Urine, nearly one-quarter albumen; many nucleated cells; a few large hyaline and some granular casts; many red corpuscles. During the night, just after taking some brandy, the nurse reports that the child became suddenly pale, foamed at the mouth, and died.

Temperature.

	Morning.	Evening.		Morning.	Evening.

Post-mortem, twelve hours after Death.—Weather hot. Rigor mortis almost gone. Brain: A little blood-stained serum in subarachnoid space. Membranes natural. Spinal Cord: Nothing abnormal on naked-eye inspection. Heart: Weight five ounces and a quarter. Left ventricle hypertrophied. Mitral orifice thickened with old vegetations. One of these hangs from the curtain nearest the aortic orifice, and is remarkably thick and firm. This vegetation can fold back so as to close the aortic orifice. Is it possible that such an occurrence may have caused the sudden death? There is an exceedingly small recent clot in left ventricle, and also one in right ventricle. No clots in pulmonary artery or branches. No disease of valves other than the mitral. Lungs œdematous but to slight extent. One calcified nodule, of the size of a small pea, at the tip of lower lobe of left lung. No infarcts. Bronchial glands natural. Liver enlarged—nutmeg. Spleen considerably enlarged, although *edge does not come below margin*. Weight eleven ounces. Contains about six ounces in bulk of fluid blood. Splenic substance soft. Contains some large infarcts; several of these are soft and recent. Slight adhesion over one of these infarcts of omentum to spleen. Kidneys together weigh eleven ounces and a quarter. Capsule strips easily. Cortex swollen and buff-coloured. There are two large infarcts in each kidney in the cortex—having a very slight depression over them, the infarcts becoming a little pale. Intestines and mesenteric glands present no morbid appearances.

A microscopic examination of portions of the brain and spinal cord, and also of the kidneys, was made by Mr. R. W. Parker, who has furnished the following report:—Brain: Corpora striata and optic thalami were examined; no marked change; vessels full. Cord: On examining thin sections under a low power, the most marked peculiarity is the excessive fulness of the vessels. Neither the white nor the grey substance seems to have undergone any marked changes. If anything, the amount of neuroglia is in excess. Here and there are seen collections of small round cells more deeply stained than the tissue immediately near them. These cell collections are mostly in the neighbourhood of vessels, but some of them are unaccompanied by vessels; in such cases it would seem probable that they belong to the peripheral portion of a cell-proliferation, and that the vessels from which they issue, owing to the thinness of the sections, have not been included. On examining with a higher power, some of the vessels seem to be plugged, and the collections of cells above alluded to prove to be leucocytes which have wandered from the plugged vessels. In one or two sections this condition is very marked. In the centre of the vessel is a dark clot, and radiating from it are leucocytes in large number. There seem to be no secondary changes in the neighbourhood of these plugged vessels. The nerve cells are slightly granular in places, but the change is not very marked nor very constant. These changes are most marked in the cervical portions of the cord. Similar changes (vascular) are observed in the kidney. The kidney tubules are variously changed: some appear but little altered, while others are filled with granular *débris;* the epithelium in these latter being more or less altered, and in some it has disappeared; some tubules contain granular casts.

Note.—From the history it seems probable that the month before admission the child had had an attack of acute rheumatism. The slightness of the joint affection, which did not compel the child to lay up, is quite in keeping with the course of many rheumatic attacks in children. It has been noted that amongst the joints which are affected in rheumatism in children, the hip is by no means unfrequently attacked; so that on one or two occasions the symptoms and signs of early hip-joint disease have been simulated. It was so in this case, if the history given by the friends can be trusted. From the induration of the vegetations (although the heart was not greatly enlarged), it is probable that the child had had endocarditis of older standing than the rheumatism dating one month back would account for. The chorea coming on when the child was recovering from the rheumatism is quite in accordance with the usual appearance of rheumatic chorea, viz., during the convalescence. Although pyrexia does sometimes occur in severe cases of chorea, this child's chorea was so mild in amount that it was strongly believed, when she was seen in the out-patient room, that the pyrexia must depend on some other cause than the chorea. Fresh endocarditis or visceral infarction were suspected; but the spleen could not be felt, and the kidney was not thought of for several days. The discovery of vascular changes in the spinal cord, possibly due to embolism, is of importance in its bearing on the debated pathology of chorea.

LONDON HOSPITAL.

Case 2.—Puerperal Endocarditis (Aortic and Mitral Disease) —Embolism—Cerebral Cortex (?), Brachial Artery, Spleen— Pyrexia.

(Under the care of Dr. SANSOM.)

[Recorded by Mr. B. W. WALKER, House-Physician.]

Elizabeth H., aged twenty-five, was admitted under Dr. Sansom on August 6, 1877.

The patient's family history was good, with the exception of one brother, who was stated to have died of consumption and heart disease. The patient had had excellent health up to the time of her marriage; always able to do her work with ease; no shortness of breath and no unreasonable fatigue. Married four years. Pretty well till her second confinement, in April, 1877. Does not know that there was anything special about it, but has not been right since. Has had "pain in the stomach and small of the back," and her breath has become short and her chest bad. Attending to household duties, and suckling until one week ago, when she took to her bed.

Condition when Admitted.—Pale, anæmic, feeble; dyspnœa easily induced by exertion. Heart's apex beats three inches to left of left edge of sternum; impulse heaving but irregular. Pulse feeble at wrist, compared to strength of heart's impulse. Cardiac dulness to one finger's breadth to right of sternum—upwards slightly into second space, to the left as far as left nipple line. A loud systolic murmur heard over aortic cartilage, and conducted upwards, with a badly defined second sound; down the left of the sternum a blowing diastolic murmur, and at the apex double low-pitched murmur, presystolic and systolic.

August 17.—Urine contains lithates and some albumen; specific gravity 1022.

18th.—Dusky, with a yellowish tint. Great tremor—marked in the lips when she speaks, and in the tongue when she protrudes it. Complains of pain in the left eye, which she does not open so well as the right. The left pupil is smaller than the right.

20th.—There is now undoubted ptosis on left side. Difference of pupils continues. When bright light is brought in front of eyes they contract equally. The tongue protruded points to the left. There is some deafness on the left side.

23rd.—Marked pleural friction on left side.

28th.—Had several convulsive seizures, limited to the left side of the face and body.

31st.—Complains of much pain in the left arm.

September 4.—There is an exceedingly tender swelling in the flexure of the left elbow. The pulse in the left radial is scarcely perceptible. No difference in temperature of the two limbs to be detected.

10th.—Great tenderness in splenic region. Spleen is enlarged. Temperature 102°.

22nd.—Spleen and liver both enlarged. Abdomen distended, and very tender on slightest palpation; bowels relaxed; has passed a small quantity of blood. Patient intensely anæmic; only semi-conscious. Left radial pulse still scarcely to be felt; right radial pulse feeble. Temperature, morning 98°, evening 100·4°.

24th.—Urine acid, specific gravity 1015, nearly one-fourth albumen.

October 1.—Extreme prostration. Pulse too feeble to be counted. Skin feels cold. No change to be found in fundus either of eye, except anæmia.

October 2.—Diarrhœa continues. Blood in motions—dark and clotted.

3rd.—Died. No post-mortem allowed.

During the first month there was pyrexia, the temperature generally being above 100°. The observations that were taken range from 99·8° to 103·6°. From September 10 onwards, when the temperature was taken regularly night and morning, the pyrexia was of the hectic type—morning 100°, evening 102°; morning 97·6°, evening 101·6°, etc.,—but not continuously so. The highest temperature recorded was 103·4°. The last few days the temperature was normal or sub-normal.

Remarks on the Diagnosis, by Dr. Sansom.—There was, no doubt, aortic obstruction and regurgitation, as well as mitral regurgitation. From the physical signs many might have inferred that there was, in addition, mitral stenosis, for a murmur, roaring in character, preceded the first-sound murmur at the apex. In the presence of aortic regurgitation, however, I always hesitate, even when the presystolic murmur seems typical, to make the precise diagnosis of mitral obstruction. There can be no doubt that cases have been recorded in which, though a presystolic murmur has been heard at the apex, yet the disease has been regurgitant aortic, and mitral stenosis has been absent. Indeed, I can realise that the conditions as to the production of the murmur may be nearly identical in the two cases. In the one, a tense and dilated and suddenly distended aorta, causing, immediately after the systole, a sudden reflux through the imperfectly closed aperture into the ventricle; in the other, for "dilated aorta," read dilated, distended, and hypertrophied auricle. In each case the stream of blood—reflex in one case, direct in the other—is urged into the empty ventricle. In this case the cardiograph gave us valuable evidence. We had a sharp and sudden percussion-wave, a sudden fall in the line of descent, a marked rise at the point which indicates the first entry of blood into the ventricle, and, following this, several elevations and depressions, sometimes showing us a vibratory line exactly resembling the tracings in cases of mitral stenosis, accompanied by thrill. It was concluded, therefore, that mitral stenosis existed here with the other lesions. August 23: There was much pain referred to the splenic region and the contiguous chest. At this time there was a doubt whether splenic embolism had occurred, or whether the symptoms were due to pleuritis. There was no rigor nor elevation of temperature; therefore, as there was pleural friction, it was thought that pleuritis alone caused the symptoms. It was quite probable that this was initiated by a pulmonary plug. Dyspnœa was often very urgent afterwards, but there was no cough nor expectoration; in the course of a few days the pleural friction became undiscoverable. September 4: The swelling involved the tissues surrounding the artery at its bifurcation; there was no redness, but great tenderness. At first there was great enfeeblement of radial pulse; but afterwards it was noted that, though the radial pulse continued perceptible, though feeble, pulsations in the ulnar artery were entirely absent. This condition continued. Melæna, probably the result of embolism. No other cause apparent. Note sudden rise of temperature, August 28, 29, 30, coincident with epileptiform attacks, and just preceding the radio-ulnar embolism. Suffering was much controlled by nitrite of amyl. The endocarditis seems to have been puerperal. The French writers seem to recognise this form as peculiarly liable (*a*) to abundant formation of vegetations on the valves (*endocardite végétante*), with sometimes ulceration; (*b*) the accidents of embolism (*Cf.* Lancereaux, "Anatomie Pathologique," page 532).

REMOVAL OF STRONG ODOURS FROM THE HANDS.—The *Schweizerische Wochenschrift für Pharmacie* has a communication from F. Schneider, in which he states that ground mustard is an excellent agent for cleansing the hands after handling odorous substances, such as cod-liver oil, musk, valerianic acid and its salts. Scale-pans and vessels may also be readily freed from odour by the same substance.—*New York Med. Record*, October 27.

DEATH OF MONS. BARTH.—Dr. Barth, one of the most distinguished consulting practitioners in Paris, died on the 3rd inst. at the age of seventy-two, in consequence of a pernicious intermittent which he had contracted during a visit to Rome. The funeral ceremony was attended by a large concourse of the profession. At the request of the deceased, no addresses were delivered at his grave at Bagneux, and the military salute to which he was entitled as a Commander of the Legion of Honour was dispensed with. The Académie de Médecine, of which he was an ex-President, adjourned its sittings out of respect for his memory. The "Traité d'Auscultation," which he wrote in combination with M. Henri Roger, who survives him, and which has achieved a well-deserved reputation, was his only work.

PRESENTATION.—The retirement of Mr. Paul Jackson, of Wimpole-street, has been made the occasion for presenting him with a testimonial consisting of a purse and a "loving-cup" bearing the following inscription:—"This loving-cup, together with a purse containing two hundred and fifty sovereigns, was presented on the 8th day of December, 1877, to Paul Jackson, Esq., M.R.C.S., L.S.A., F.R. Med.-Chi. Soc., etc., etc., on his relinquishing his professional practice, to remind him that he carries with him in his retirement the respect and esteem of his numerous patients and friends, by whom his many estimable social qualities, together with the skill, ability, kindly sympathy, and devotion to his art, which have so eminently distinguished him throughout an active professional career of upwards of forty-two years, have long been recognised and will long be remembered.

SATURDAY, DECEMBER 15, 1877.

HYDROPHOBIA AND TETANUS AT THE ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

The discussion which followed the reading of a paper before the Royal Medical and Chirurgical Society, "On the Relations between Tetanus and Hydrophobia," by Dr. J. Coats, of Glasgow, showed well at once the strength and weakness of the Society as a body. The paper, which was almost purely pathological, and most excellent of its kind, was founded on the careful post-mortem examination and subsequent microscopical investigations of the parts of two dogs the subjects of rabies, and of two patients who had died of hydrophobia. We fear we shall do scanty justice to the author of the paper, for this was neither fully nor perfectly read, and in many points his views were thus most obscurely given; but, upon the whole, perhaps the following may be looked upon as a fair summary.

With essential differences, there may be said to be great analogy between the post-mortem appearances in tetanus and hydrophobia. In both the main changes seem to be situated in and around the vessels in the spinal cord and medulla oblongata, and these consist mainly in the accumulation of exudative or granular matter in the case of tetanus, but of more or less well marked leucocytes in hydrophobia, round about the vessels in the parts named. Dr. Coats had, however, extended his researches farther, and had found similar changes in the cerebral convolutions, in the salivary glands, in the kidneys, and in other organs. From these facts he concluded that, as was certainly the case in hydrophobia, so probably in tetanus, the mischief began by a poison contained in the vessels, thence affecting their walls and contents, and thus producing the evidences seen around them of the important changes as described above.

In the discussion which followed, as it seemed to us, the strength of the Society was exhibited by its many-sidedness, as its weakness was shown by its want of power to keep close to the subject really before the meeting. To the author of a paper which has necessitated long and careful preparation, nothing is more vexatious than inadequate discussion; but side-wind discussions are hardly less unsatisfactory. It is one of the strong points of this Society that when a practical question is before it the question can be illustrated by an unequalled variety of experience; but too often there is a tendency to "follow my leader," to back or attack previous speakers, and to discuss what has not been raised by the paper at all. In the present instance the paper was almost purely pathological; and the discussion on it should have been as much pathological as possible, though for practical outcome a clinical discussion might have been preferable. We are far from disagreeing with the learned President when he rebuked the theorising tendencies of pure morbid anatomists and pathologists, and insisted that clinical facts, when facts, were just as good as any other. Nay, more; we hold he was quite right when he said that the system of hypothesis-building was just as rampant as it was a hundred years ago, only different names were used. We do not admit that these modern terms are more scientific—they only seem to be so. Instances of such quasi-science spring up in our mind by the score. Be that as it may, Dr. Coats and the other speakers added a goodly array of well-set facts to our knowledge, and did good service, though all could not say with old Stoerk, "Non hypotheses condo, non opiniones vendito—quod vidi-scripsi,"—or *dixi*.

But to fall back on what was said in this discussion from the purely pathological point of view. It was affirmed on the one hand that in hydrophobia we have changes, especially in the medulla oblongata and spinal cord, so uniform and so well marked that they could fairly be pronounced characteristic. On the other hand, it was asserted that so little was this the case that the same changes were to be found in chorea, ascending paralysis, and other nervous diseases of totally different types. In point of fact, some affirmed that the microscopic appearances described were simply those of irritation at certain points in the nervous system, producing the migration of white corpuscles, or even local hæmorrhages. Nay, more than one speaker suggested, on good grounds, that inasmuch as the leucocytes, so freely spoken of, were found unusually abundant in nearly all structures in the body, their origin must be sought for rather in unusual conditions of vascular tension than in any other peculiarity of the disease; and it was also hinted that the unusually high temperature sometimes observed was a concomitant not to be overlooked. It is plain that the whole of the phenomena of the two diseases point to the medulla oblongata and the spinal cord as the spots whose lesions are the cause of the palpable outcome of the disease. Changes have been found in both, but whether these changes are part and parcel of the disease—that is to say, the immediate causes of its phenomena,—or whether there is something beyond, as yet remains a mystery.

SOUTHERN HEALTH-RESORTS.

No. V.—Hyères.

(*Concluded from page* 624.)

The accommodation for visitors at Hyères appears to be at present sufficient for their demands, and there is less building going on than at most of the other winter stations of the Riviera. We have already mentioned the villas on the Boulevard d'Orient, some of which, however, are occupied by permanent residents; and other villas are to be met with south and south-west of the Place des Palmiers, and also on the Boulevard National. *Maisons meublées* or furnished apartments are most abundant in the Boulevard National, the western portion of the Route Nationale, near the post-office and the Bureau Télégraphique, and the western corner of the Place des Palmiers. There are several hotels on entering the town from

the west; the Hesperides, and Hôtel des Iles d'Or—the former with a western, and the latter with a south-western aspect, overlooking the Montagnes des Oiseaux—are both good. Their great drawback is their situation in the Boulevard National, which exposes them to the full force of the mistral. The Iles d'Or is the largest and best hotel, all things considered, in Hyères, and is kept in excellent style, and with a good table and attendance. Its rooms are, however, small, the lower ones narrow, and the upper ones narrow and low. This state of things is accounted for (?) by its having originally been built as a hospital, though our modern notions would scarcely admit the excuse as valid. There is a wing, or *dépendance*, at either end. The passages are long and tortuous, and hence draughty, although provided with doors, which no one shuts, to isolate the different parts of the house. Complaints were made last season that imaginary extras were too apt to be inserted in the visitors' bills, and we know of a case where 17 francs had to be struck off for this reason, while the same individual was charged "cork money" for brandy bought privately and used as medicine upstairs. Other persons were charged for the expense of the *calorifère*, or heating apparatus. This sort of hotel management deserves the strongest reprobation, and we allude to it in the interests of the public. The Iles d'Or has excellent gardens, not only behind it on the flank of the Château Hill, but also on the south side of the Boulevard National.

The Hôtel des Ambassadeurs, in the town itself, is perhaps the best situated of all the hotels, and is better adapted for persons of moderate means than the two former. Its aspect is due south, and the windows command a very extensive view. The rooms are excellent, and the attention of Madame Suzanne, the landlady, to her guests deserves the highest commendation. In the Boulevard des Palmiers, the Hôtel du Parc is well spoken of. It has the disadvantage of an open street running down at right angles to it at the back. The Hôtel d'Orient, near the entrance of the Boulevard d'Orient, has a south aspect, but no garden. The Hôtel de l'Europe, in the town near the Ambassadeurs, completes the list.

Prices are perhaps a little lower at Hyères than at Cannes or Mentone, but the difference is not great. The average *pension* would be 12 to 14 francs. Some of the hotels give wine at the *table d'hôte*. Provisions (meat and poultry) are abundant, and vegetables are grown in large quantities in the market gardens which lie to the south and west of the town. The latter, which are generally enclosed with high stone walls, replace the orange groves which, eighteen years ago, as we learn from Dr. Griffith, covered a large portion of the plain. Orange trees are now scarcely to be met with, except in a few gardens, while the peach, the plum, the strawberry, and the artichoke have taken their place. Acres and acres of the small "hautboy" strawberry are grown at Hyères, and supply the Paris market with the earliest pottles, and their cultivation and gathering give employment to a large number of the labouring women. The gardens are in several places protected from the high winds, especially at the entrance of the valley of Hyères, by dense hedges of tall cypresses, which, with their intense dark green foliage, lend a peculiar character to the landscape. Wheat, olives, and vines are largely cultivated round Hyères, on the hill-sides of the Maurettes and elsewhere, and near the Gapeau river, where elm-trees line the roadside; and also, nearer the sea, there are large fields of mowing-grass. The Maurettes are covered on both sides with the picturesque forests of the *chêne-liége*, or cork oak, a tree which does not reach maturity until the age of fifteen years, and which will only bear removal of its bark every seven years. The Montagnes des Oiseaux are clad with pines. The geology at Hyères is in some respects peculiar. The Château Hill consists of mica-schist and clay-slate with quartz, the higher parts of the Montagnes des Oiseaux of limestone, and the southern spur, on which the votive church of the Ermitage stands, of red sandstone, and the latter formation extends over part of the plain of Hyères. Near the town the soil is a product of the disintegration of the clay slate. It is very fertile under proper management, but in consequence of the dryness of the climate requires constant watering by artificial means. Of late years the rainfall has been very scanty, and the inhabitants say that many of the storms seem to avoid Hyères, and to discharge themselves further inland. Possibly this may be due to the high temperature of the air rising from the heated plain, and to the absence of high peaks in the immediate neighbourhood. However, there is a good and abundant water-supply, part of which comes from the limestone hills to the west, and part from a spring near the Gapeau, which is pumped up by a steam-engine. The plain is also watered by means of a canal more than ten miles long, which comes from the hills on the north of Hyères, and which the various proprietors enjoy in rotation. It also supplies the public washhouse and the ponds of the Jardin d'Acclimatation, an ornamental park, with tropical and Australian plants and trees, and a few extra-European birds and animals, a quarter of an hour's walk south-east of the town—a very agreeable promenade on calm days.

The sanitary condition of Hyères is, on the whole, satisfactory. We have already mentioned one or two points which are capable of improvement. Persons taking villas should see carefully to the drains. Typhoid fever is not, as far as we could learn, at all of frequent occurrence, but in May of the present year (1877) two deaths from it took place among the visitors, and there were two other cases which recovered; a mild case was also admitted into the hospital. It seemed clear that one of the deaths arose from water contamination, as the well lay between two open drains. The open drains at the sides of several of the principal roads, *e.g.*, that to the station, and that to the Ermitage, are sometimes extremely offensive, and although they are flushed from time to time, this measure is quite inadequate to clear them of what certainly is nothing less than stagnant sewage.

The inhabitants of Hyères are, as we are informed by Dr. Vidal, the very courteous and skilful director of the hospital, as a rule very healthy. There is no scofula among the children, and phthisis is rare. We saw one case admitted from a distance in the wards of the hospital, whose scanty complement of patients revealed the small amount of pressing sickness among the poorer classes of the neighbourhood. At the cemetery the large number of old people buried there attracted our attention. Within a few yards of one another we noticed ages of ninety, eighty-seven, seventy-five, seventy-four, all dying in the same year, and the sexton told us that the day before they had buried a man of ninety-three, but he added—"The present generation does not promise to be so long-lived as the last, and drunkenness especially cuts off the men." The last two proprietors of the Château Hill may be mentioned as instances of considerable longevity, one having reached eighty-eight, and the other eighty-two years. The Deputy Mayor, M. Suzanne, has kindly furnished us with an extract from the register for 1876, which shows that there were 303 deaths, 206 births, and seventy marriages, the great excess of deaths over births being explained by the deaths of foreign invalids, and of sailors and others connected with the French fleet in the roadstead, being included in the estimate.

A notice of Hyères would be incomplete without some allusion to the valley of Costabelle, which lies to the south west of the Ermitage spur of the Montagnes des Oiseaux, which latter protect it with their fir-clad slopes from the north and north-west winds. The valley is embosomed in pine woods, broken here and there by vineyards and olive orchards, and by the gardens of the few villas which have sprung up there as yet. Near the shore there are large

groves of olive-trees, which are finer than at Hyères itself, and indicate a warmer climate. There is a fair carriage-road through the woods, which reaches the shore about a mile from the Hyères end of the valley, and joins the coast-road to the village of Ceinturon further west. Among the pine woods at some distance from the sea the Duke of Grafton is building a splendid house. The valley of Costabelle is undoubtedly warmer and more sheltered than Hyères itself, and the north-east corner is almost entirely protected from all but southerly winds. Its western portion is rather exposed to easterly winds, owing to the ridge of the Ermitage not extending within half a mile of the shore. With the exception of two or three villas, the only accommodation for visitors in the valley of Costabelle is the Pension Anglaise—a small and very sheltered unpretentious house, which nestles among the pine-trees almost immediately below the Ermitage ridge, and is capable of containing about twenty-two persons. It would be almost sure to succeed if properly managed, but there were great complaints on the latter score among the residents last season. One of the managers who acted as cook is reported to have starved rather than stuffed his customers. A better hotel is needed at Costabelle, the *salon* and *salle à manger* of the present *pension* being small, low, and stuffy, though the bedrooms are tolerably good, but not lofty.

The walks in the valley of Costabelle and on the neighbouring hills are numerous and picturesque, and, even with a strong mistral blowing, there are few days when an invalid cannot get a sheltered walk. We should add that Costabelle is about two miles south-west of Hyères.

The railway, which was until lately nearly an hour's drive from the town, has now been brought within half a mile of it, and there is communication by the same means with the shore. Passengers change carriages at Toulon if coming from Marseilles, or at La Pauline if from the direction of Cannes. No doubt, Hyères will now be visited more frequently by passing travellers than in former years, and it is not unlikely that winter residents will also increase, though probably not in the same proportion as at the more eastern health-resorts, such as Cannes and Mentone. At present there is an average of 300 English visitors each winter, and there are four or five permanent English residents. There is an English church, library, and reading-room, and the English are favourably regarded by the inhabitants. Visitors of other nationalities—the French, of course, excepted—are but feebly represented.

April and May are, with the exception of occasional windy days, extremely pleasant at Hyères, and hence it is a good resting-place on the home journey for invalids who have wintered further east. The botany of the neighbourhood is interesting, and in some respects peculiar; and not only at Hyères, but elsewhere along the coast, those persons who hurry northward with the arrival of April miss one of the most beautiful aspects of the sunny South.

THE WATER-SUPPLY OF LONDON.

There has been another meeting of the Board of Works, at Spring-gardens, at which, this time, every member was present. The subject of discussion was the proposed scheme of water-supply for London. On this occasion several fierce battles were fought, lost, and won; but each of them seemed to bring out some new point in the history of the case. The object of the meeting was to consider, accept, or reject drafts of Bills to go before Parliament—first, for the acquisition of existing waterworks; secondly, for making new ones for a special purpose. The preamble to the Bills is thus stated, and it is singularly insidious:—"Whereas, with a view to the health of the metropolis, it is expedient that a proper supply of pure and wholesome water for drinking and culinary requirements of the inhabitants thereof should be provided and constantly laid on; and whereas, for the purpose of extinguishing fire, and for other public purpose, a supply of water constantly laid on at high pressure would be of great benefit to the metropolis; and whereas, in order that water should be supplied as aforesaid, it is expedient that the Metropolitan Board of Works should be authorised to construct the waterworks and other works in this Act mentioned, and to supply water in the manner by this Act provided." It seems for some particular reason to turn things upside down. There is not a word about the acquisition of existing waterworks—only as regards the construction of new ones. But the cat is let out of the bag by one of the clauses. There is a distinct sop to the House of Commons' Committee, in the shape of the new supply for the purpose of subduing fire, but, according to the wildest calculation, this supply cannot well exceed 16,000,000 gallons daily; and well may we ask, What is this amongst so many? For not only is this to be the source whence fires are to be extinguished without the aid of engines, but it is also to be our supply of potable water. It is not to be the water in which we wash and bathe—not the water used for water-closets and such like—not the water, in fact, used for the daily purposes of life,—it is to be potable and culinary water only. Moreover, we are to have this great advantage: the new supply is to be kept constantly at such a pressure as is represented by 100 feet of fall in all places. This means considerably over 300 in some. Have any of our readers experience of the effects of such a pressure under the continuous supply arrangements. A completely new set of taps and pipes have to be introduced. Should your taps give way or your pipes burst, you have the pleasure of draining the street or district of water. When the water is cut off in any district, every house lacks it. It is, however, quite true that all of these objections are obviated by the double supply. From the old companies we get a trifle of 120,000,000 gallons a day, which would flow in the old manner, but we now know to what vile purposes it is doomed. Of course it would be quite useless to purify water intended for such purposes, and so we shall still be able to enjoy, when the new supply is cut off, a twang of the old nastiness—probably in double volume. Moreover, it will be an interesting thing for the new servant to ascertain which is the pure drinking-tap, which the filthy tap. Little mistakes are likely to arise; let us hope the Board does not think them awkward. The whole scheme seems to us so redolent of self-approbation and confidence, as to beget a feeling of wonder in less gifted mortals than Boardmen—yea, so as to remind us of the story of a benighted king called Nebuchadnezzar.

Moreover, at the last meeting of the Board, one of the silly members, who probably, according to another "honourable"—as they like to call themselves,—would need education, openly declared that nearly every member would have supported the Bill for the purchase of the water companies only; but this does not seem to be what is wanted. So the Board, by a small majority, go to Parliament with a scheme apparently symmetrical, but whose monstrosity will yet be made manifest to the public; and then—— ?

THE WEEK.

TOPICS OF THE DAY.

In the Court of Appeal, last week, the case of Hill *v.* The Managers of the Metropolitan Asylums District was heard. The plaintiff, Sir Rowland Hill, and other gentlemen residing at Hampstead, have brought an action to recover damages for the deterioration of their property, through the proximity and bad management of the Small-pox Hospital at that place. The injury done was alleged to be enormous, and the damage was laid at more than £30,000. Two causes of damage were alleged—direct infection, in consequence of the buildings having been erected too near the plaintiffs' dwellings; and indirect infection

by the passage of patients, nurses, funerals, and infected cabs along the roads leading past the said dwellings, thereby rendering ingress and egress to and from these houses unsafe. Direct infection of small-pox, they said, according to scientific authorities, extends to a distance of thirty-feet; and it was asserted that three consecutive gardeners in a garden adjoining the hospital premises had died of small-pox, and that there had been numerous other cases of death and illness from the infection in the neighbourhood. The defendants denied all the allegations in the plaintiffs' claim, and also pleaded that they were acting in conformity with the terms of their Act of Parliament, and were therefore protected from all liability. To this the plaintiffs replied that they had performed their duties negligently; and to support this allegation they proposed to administer to the defendants thirty interrogatories as to the construction of the hospital buildings, the means used for disinfection, etc. Baron Huddleston had granted leave to administer these interrogatories; but, on the application of the defendants, the Court of Queen's Bench discharged this order, on the terms that the plaintiffs should have full opportunity of inspecting the defendants' premises and books. Against this order of the Queen's Bench Division the plaintiffs now appealed. Finally, their Lordships ordered the appeal to be dismissed, leave being given to the plaintiffs, after the inspection already granted, to deliver further interrogatories if necessary.

It will be remembered that an application was made some time ago to the Chancellor of the Consistorial Court of London on the subject of the disused churchyard of St. Matthew, Bethnal-green. The case involved an important point—whether churchyards closed from interments can be used for public purposes. The incumbent and the churchwardens applied for a faculty to erect a mortuary, a coroner's court, and rooms for post-mortem examinations in the churchyard; and the application was opposed by some of the parishioners, who alleged that the ground had been consecrated, and could not be used for secular purposes. It had been arranged that the case should be heard by *vivâ voce* evidence: but it was subsequently determined that documentary testimony should be given. Mr. Prichard now produced his proofs in support of the application, and called on Mr. Moore, proctor for the objectors, to bring in his evidence. Dr. Tristram made an order that the proofs in opposition should be filed in fourteen days, and remarked that, although he would hear the case on affidavits, he should require some of the deponents to attend the Court for cross-examination.

In accordance with the recent order issued by Colonel Henderson, the police are reported to be capturing stray dogs in the streets of London and the suburbs at the rate of over 200 a day. Of this number about 30 per cent. are claimed and recovered by their owners; and the remainder, with the exception of a few of the most valuable, are destroyed. If prompt measures of this description are carried out all over the country we shall soon cease to hear of hydrophobia except as a very rare occurrence.

At a meeting of the Birmingham Hospital Sunday Committee, held last week, the result of the collections made on October 28 last, in aid of the General Hospital, was announced to have amounted to £5200. Since the establishment of the periodical collections in 1859 the total sum of £83,464 has been contributed on behalf of the local charities as the result of the special appeals on Hospital Sundays. The town of Birmingham must be congratulated on the benevolence and liberality of its inhabitants, this result being, relatively, greatly in excess of the amounts collected in the metropolis for a similar object.

Some further unpleasant revelations affecting our milk-supply were made at Bow-street Police-court last week, where a man had been summoned by his master, a milk-seller, for adding eight quarts of dirty water to thirty gallons of milk, with intent to defraud his employer. The prisoner did not deny the charge, but asked the prosecutor if he had ever given his men instructions to increase the bulk of the milk by adding a mixture. Mr. Hanson, the master, replied that he never told him to put in dirty water. The prisoner then called attention to some white stuff which was kept in the cellar, which, he alleged, was used at the rate of four quarts to sixty-four quarts of water for adulteration purposes, and which was known among his fellow-servants as "the fake." Mr. Hanson explained that the substance referred to was condensed milk, and was only occasionally used when the regular supply ran short. Corroborative evidence was given by the prosecutor's foreman, who denied all knowledge of "the fake." The prisoner said he could call witnesses in support of his statement. Mr. Flowers said his eyes had been somewhat opened by the prisoner's statement; the charge made against his master was very serious, and he should adjourn the case for further evidence. It would appear that to the already long list of abominations with which the London milk-supply is adulterated must now be added dirty water, and "the fake," whatever that may be.

A deputation recently waited upon Mr. Sclater-Booth, at Whitehall, representing the ratepayers of Orsett, to protest against the proposed conversion, by the guardians of eighteen parishes of that district, of the wards of the union into a small-pox hospital. Last June the Guardians of Grays sent into the women's ward of the Orsett Union a non-pauper case of small-pox, which spread to no less than seventy persons, many of whom died. Notwithstanding the experience of the danger of an infectious hospital in close proximity to the workhouse, yet the Guardians had determined on erecting such an institution there, against the wishes of the whole population. It was stated that the infirmary, into which the Guardians admitted the case spoken of, was only eighteen feet from the women's wards, and persons passed it going in and out of the workhouse. The infection had been traced from the workhouse to the village, there being a south-west wind blowing at the time the case was admitted; and within twenty-four hours there were no less than sixteen cases in the village. Despite the protests of the ratepayers, the Guardians were about erecting a new building, at a cost of £1000, on the same spot, adjoining the Union. Mr. Sclater-Booth promised that their representations should be considered in conjunction with the proposals of the Guardians, and care should be taken that the interests of the ratepayers should not be prejudiced in any way.

The *Sanitary Record* says:—"Recent statistics show that the rate of mortality among grocers is as 76 to 100 among the general population at equal ages, while the death-rate among drapers is as 108 to 100 by the same standard. On analysing the cause of this difference between the drapers and the grocers, it is found that it lies in the mode of living. The principal disease which destroys the draper is pulmonary consumption. The explanation is simple: The grocer lives in a shop, the door of which is open the whole day, and he is very active himself in business; the draper, on the other hand, lives in a close place, with the doors of his shop closed, and in a dusty and close atmosphere. No one, whose pleasure or business calls on him to enter the majority of our large drapery emporiums in London, but will feel in a position to testify to the truth of this description. The heat and closeness which are their usual characteristics sufficiently account for the general pallor and unhealthy appearance of the male and female attendants in them."

We are in a position to contradict positively the rumours which have been circulated in several of our contemporaries touching the intended retirement of Sir William Muir, K.C.B., the Director-General of the Army Medical Department. Sir William has recently suffered from a severe and sudden attack

of illness, but he has recovered most satisfactorily, and has once more taken up his duties. On Monday last he inspected the Herbert Hospital at Woolwich. The rumour that he was to be succeeded by Dr. Munro, C.B., the present head of the Medical Branch at Whitehall-yard, is equally without foundation. At the present time Sir William Muir is little more than half-way through his term of office as Director-General; any speculation as to his successor is, therefore, rather premature.

The Vestry of the parish of St. Anne, Westminster, have passed the following resolution on the postponement in the formation of the new street from Charing-cross to Tottenham-court-road:—"This Vestry has heard with great regret that the Metropolitan Board of Works has postponed the formation of the new street from Charing-cross to Tottenham-court-road; that such postponement of a great metropolitan improvement, which has been admitted to be a necessary improvement for upwards of half a century, is attended with great loss and inconvenience to a large body of respectable ratepayers, who are now uncertain when their houses and businesses will be taken from them, and can therefore make no provision for the future. That this Vestry further regrets that the reason alleged for the delay in making the street is stated to be the difficulty the Board finds in providing sites for buildings for the working-classes—a difficulty which could be fairly met by immediately purchasing for the purpose some of the large plots of property comprised within the limits of deviation."

It is reported from Berlin that black plague has broken out at Tiflis, but we have not yet heard any confirmation of this rumour.

We are very sorry to hear that Dr. C. D. F. Phillips is unfortunately one of the sufferers by the collision on the South-Western Railway last Saturday night. He has two broken ribs, and has severely strained his back and neck. On Sunday he suffered very greatly from pains shooting from the spine into both legs, but we are happy to say that, when we last heard, these were passing off.

SENATE AND CONVOCATION OF THE UNIVERSITY OF LONDON.

We regret to hear that the opinion which we expressed on November 17, concerning the unsatisfactory nature of the reply of the Senate of the University of London to the deputation from Convocation, on the subject of the relations of the two Bodies, is likely to prove to be only too correct. We ventured at that time to say that "the deputation should have insisted upon receiving a distinct promise from the Chancellor that the old difficulties should be swept away before new ground was taken up." Instead of doing so, the Annual Committee of Convocation thanked the Senate for having virtually "abandoned" their resolution to proceed with the admission of women under Russell Gurney's Act. In duly noticing this reply, we consented to take a more sanguine view of the state of affairs than we had previously done, and we congratulated the University on this harmonious settlement of the serious difficulty with which it had been beset. But it seems now that our first and less hopeful anticipation was the correct one. We understand that the Senate, at its meeting last week, while acknowledging the thanks of the Annual Committee, distinctly declared that the Senate had made no promise to abandon Russell Gurney's Act, but considered itself free to proceed as it might see fit. It would appear, therefore, that the Senate rejects all the generous advances of Convocation in the direction of reconciliation. At a time when Convocation seems eager to provide for the Senate an honourable retreat from the unfavourable position in which it has landed itself, the Senate rejects the offer, and clings to the position as pertinaciously as ever. The supplemental Charter, which the Senate proposes to introduce to provide for the admission of women into the University, will probably be submitted to Convocation for its approval at the Ordinary meeting in January. But this will not be the first business before the House on that occasion. The report of the Annual Committee will first be read, and the whole question of the treatment of Convocation by the Senate will be thoroughly discussed. Convocation will find that the Senate has distinctly refused to accede to the request "not to take any further action" under Russell Gurney's Act. We venture to say that, after such treatment as this, Convocation will be in no mood to deal with the proposal of a *supplemental* Charter. Convocation will not be content with a supplemental Charter. It will surely take steps at once to obtain a *new* Charter—a Charter in which its privileges will be more definitely stated and more inviolably secured. The reconstitution of the Senate will probably be a prominent feature in the remodelled Charter. When this reform is completed, we may hope to hear of harmony and successful co-operation between the great body of graduates of the University of London and the executive, which at present most unfortunately consists in large proportion of despairing politicians out of place, whose idle hands find a congenial occupation in meddling and muddling.

HOSPITAL REGISTRATION.

The offices of Medical and Surgical Registrars have at present become such well-established appointments, and such important adjuncts to the teaching power of the medical schools, that, as their value is more and more recognised and appreciated, we wonder how our predecessors could have done without them. It was not, therefore, without some surprise that we learned that the London Hospital authorities were considering the possibility or advisability of abolishing these offices, which have been established on their present basis for only about three years. We could not but regret that such a step should be even thought of; and our regret was all the greater when we learned that the motive which induced such a proposition was one of economy. In a large hospital like the London, registration is an important item in the year's expenses. The Committee feel the necessity of the most strict economy, and we can scarcely wonder that, in times of commercial depression such as these, unusual efforts have to be made in order to meet the very heavy expenses of so large an unendowed institution. We are very glad, however, to hear that the Registrars are to be continued. The medical staff strongly opposed any change; and the Committee, sensible of the great value of registration, yielded to suggestions which, apart from questions of expense, were so much in accord with their own wishes and with practical common sense.

It may not be unprofitable, on such an occasion, to point out that there are two sides to this question; for we think that registration (in the now conventional sense of the word) has a lay, as well as a medical, aspect. The medical aspect is well known, but the lay one is not so generally understood. Yet it is clear that anything which conduces to a careful, thorough, and continuous study of the various cases admitted into any hospital will increase the efficiency of its internal administration, as well as the sum of accurate medical knowledge. The more thoroughly cases are taken, the better satisfied will be the patients, and the more exact and genuine the results of treatment—for we shall then learn sooner and with greater certainty the difference between disorder and disease; we shall more quickly rid our hospitals of patients who ought never to have been admitted; and fewer of those who are admitted will be kept in for such indefinitely long periods as is sometimes the case at present. Accurately recorded accounts of the "past history" and of the "present condition" of patients will, moreover, be of the greatest service in years to come, when preventive medicine will occupy a still higher and more assured position than it does at present. So that the lay committees of our hospitals, in providing for

careful registration of their cases, are doing that which is decidedly advantageous in the present, as well as likely to produce large results in the future.

A further advantage, from a lay as well as a medical point of view, of having Registrars is that their presence may be of service to the resident officers. These latter appointments are necessarily of short tenure, and it is obvious that applicants, however capable of holding office, are least capable when they first come on. That to have a friend near at hand, who is able and anxious to help them, would be a clear gain, will be allowed by all who have held such appointments. The advantages, too, of the training which such an office affords is very great, and in our opinion it has, or should have, great weight as a qualification for the higher staff appointments as these become vacant.

We are far from saying that our present system of registration is perfect; on the contrary, we think that it is susceptible of great improvement and of higher development. We do not, however, look to immediate results; in this, as in other matters, there is a seed time as well as a harvest, and those who would reap must first of all sow. We should be pleased, however, to see one uniform system of registration adopted at all hospitals. Some year or two ago, one or two Hospital Registrars endeavoured to bring about such a plan, but the difficulties which presented themselves then seemed insurmountable. The initial step in this direction ought to be taken by the chief medical and executive officers of each hospital; if these gentlemen could be brought to see the advantage and importance of such a combination, and to take active steps to bring it about, the difficulties would soon prove to be surmountable. One or two preliminary and representative meetings would, we think, under proper direction, suffice to put the whole question upon a satisfactory, if not on an absolutely final basis; the annual reports might then be placed in the hands of a skilled statistician; and thus we should have reliable data to work on.

We cannot close our remarks without congratulating the Hospital authorities on their decision. It would have been too retrograde a movement, even when carried out under financial pressure. We hope and believe that the material help which they so much need will not be withheld by those who can give it, and that so the liberal spirit in which the institution is conducted may not be in any way hampered. And we will add that while it is clear that it is the duty of the public to liberally support the hospitals, it is equally clear that the hospital authorities have a duty to perform to the public, not only in curing or relieving patients, but also in furthering in every possible way the advancement of the science and art of medicine.

PATHOLOGICAL SOCIETY OF DUBLIN.

At the meeting of the Society, on Saturday, December 8, the President, Dr. Hamilton, in the chair, Dr. T. E. Little presented a case of dislocation of the spine in a young man, aged eighteen, who died eighty-five days after a fall, down the hold of a ship, on his back and shoulders. Cruveilhier's paralysis occurred before death, which resulted from apnœa owing to the wasting of the intercostal muscles. There was a dislocation of the fifth from the sixth cervical vertebra, the articular processes of the fifth being hitched in front of those of the vertebra below. The spinal canal was narrowed to half its normal lumen, and there was a greyish spot in the anterior columns of the cord. There was inter-muscular wasting. A glazed or glossy appearance of the hands and fingers had been noted during life. Dr. Nixon showed specimens of saccular aneurisms on the right and left middle cerebral arteries of a woman, aged about forty-five, who died of meningeal hæmorrhage. The kidneys were intensely congested, and the lungs also were gorged with blood. There was left hemiplegia. Dr. E. H. Bennett exhibited the head and neck of a femur, removed by excision from a boy aged nine, suffering from morbus coxæ, in the stage of suppuration. He also exhibited the innominate bone and femur of the same patient, removed (post-mortem) seven months after operation. There was caries of the innominate bone and dorsum ilii. The floor of the acetabulum was cribriform, and an intra-pelvic abscess sprang from its perforated floor.

REGISTER OF MEDICAL STUDENTS IN PARIS.

The following "census" of the medical students now registered in Paris, which we have received from a perfectly reliable source, will interest our readers:—

1. *Number of Students Registered on the Books of the Paris Faculty of Medicine, December* 1, 1877.

Male students	4796
Female students	21
Total	4817

2. *Nationality.*

A. Male Students (Foreign).

America	184
Armenia	8
Austria	9
Bavaria	1
Belgium	3
Egypt	10
Great Britain and Ireland	21
Greece	12
Ionian Islands	2
Italy	3
Poland	20
Portugal	2
Prussia	6
Roumania	79
Russia	18
Servia	4
Switzerland	13
Turkey (Asia)	9
„ (Europe)	28
Total number of foreign students	438
French students	4358
Total of male students	4796

B. Female Students.

France	5
Great Britain and Ireland	5
Russia	11
Total of female students	21

3. *Examinations and Degrees conferred, from November* 1, 1876, *to November* 1, 1877.

Number of examinations	6360
Number of M.D.	553
Number of *officiers de santé* or general practitioners	15

REGENERATION OF THE RETINAL PURPLE OUTSIDE THE BODY.

Prof. Kuhne and Dr. A. Ewald (*Centralblatt*, No. 42, 1877) have discovered that solutions of Boll's 'see purple" or "see red," in purified bile which is *absolutey free from ether*, if bleached by exposure to sunlight, recover their colour in a dark room. Similar solutions of the retinal (rodless) epithelium, mechanically freed from insoluble black pigment granules, etc., turn pink in the dark, pale in the light, and pink again if replaced in the dark. The colour of the retinal purple is restored with the greatest intensity in mixed solutions prepared from the epithelium and the retinal rods. It is an interesting fact that if the retina of a frog be bleached in the light before the animal is killed, the colour does not afterwards return under the action of darkness if the epithelium is removed, whereas, in dead frogs, bleaching in the light is followed under identical circumstances by purple regeneration, and the colour can be destroyed and revived several times.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.

THE following resolutions have recently been agreed upon :— "That, in the opinion of the Society, whenever a case of infectious disease occurs in any house or vessel, it should be a legal obligation on the person in charge of the house or vessel, or on the person in charge of the case, to report the fact to the sanitary authority without delay." "That it should be a legal obligation on every medical practitioner in attendance on any such case to give immediate written information respecting its nature to the occupier or other person responsible for reporting it to the sanitary authority."

PROFESSOR LISTER ON LACTIC FERMENTATION.

WE would draw attention to the announcement that at the next meeting of the Pathological Society, on Tuesday evening, the 18th inst., Professor Lister will bring forward a communication upon "Lactic Fermentation and its Bearings upon Pathology."

OPIUM-SMOKING.

DURING the last two years my attention has been frequently given to the question of opium-smoking, as in that period I have treated a considerable number of patients who have been addicted to the use of the drug in this way. My opinion on the subject must go for what it is worth, but as many people who speak and write about it absolutely know nothing whatever about it, the following note of what I have seen of the habit during the last twelve years may not be altogether without value. In this period, then, I have had under my notice, and occasionally under my treatment, several Chinese writers, a good many compradores and small traders, who have all smoked opium more or less. The first thing that struck me in connexion with this habit in the classes I have referred to was, that although they partook of a drug which in my opinion was injurious, it did not, so far as I could see, in more than 10 per cent. distinctly interfere with their general health. All of them have been smoking it for many years, but, with the exception of the 10 per cent. referred to, the amount consumed was not greatly—occasionally not at all—increased from year to year. They were able to attend to their duties, were healthy and active, and enjoyed a good appetite. In reference to these—the 90 per cent.,—the conclusion I have come to is that, while opium, so far as I could see, did them no good, it did not manifestly injure them. I say *manifestly* injure them, because I have a suspicion that eventually the continued daily consumption of even a moderate amount of the drug will be injurious to the health of those using it, and that this in the long run will become apparent. But this is mere suspicion. Of the 10 per cent. who took opium in large quantity—that is, an amount sufficient to interfere with the general health, as indicated by loss of appetite, constant diarrhœa, impaired physical and mental energy, loss of sexual power, etc.,—the condition is as miserable as anyone can well imagine. In their case there is a constant desire that the daily dose should be increased. They find their ordinary business irksome ; and so impaired are their faculties that a slight call for activity of mind or body urgently demands, in the first place, an increased amount of the drug.

I have little knowledge of how opium affects the upper, that is the official and literary, classes, but one would expect that, inasmuch as they have intellectual resources unknown to the trading community, the use of the drug would be to them, if to any, what some have been foolish enough to describe as "a harmless stimulant."

Its use amongst the lower classes, I think, is much more limited than is usually stated. I have taken pains to inquire how many servants in the employ of Europeans here use the drug, and I have found that while many years ago almost every household had several servants who smoked opium, it is a rare thing now to find a single servant who does so, and this in spite of higher wages than the labouring classes generally obtain. Doubtless this is partly due to the determination of foreigners to have nothing to do with servants who smoke opium, but the fact remains that many of the residents have Chinese who have been in their employ for many years in the receipt of high wages, and who have never shown any desire to cultivate the habit.

Many who admit that the use of opium is an evil, contend that it is no more so than that of alcohol. To this I demur. My opinion of opium is, that, except as a medicine, it is never necessary, and for other purposes is seldom, if ever, of any service ; while alcohol is only injurious when taken irregularly and in too large quantities, and to the majority of people who either work with head or hands it is in some shape or other, if not a necessity, a great comfort, and, as a dietetic agent, of very considerable value.

The tendency of those who use opium is to increase the dose. This is by no means universal in the case of those who use alcohol, while a large minority continue to take it in ever-decreasing quantity. Amongst the uneducated and lower classes generally the use of both opium and alcohol, when they can be obtained, is often excessive ; and it is difficult to say which has the more debasing effect when so taken.

The conclusion I have come to from what has been brought under my own notice is, that foreigners have generally exaggerated the amount of evil said to follow the use of opium. I have no doubt in my own mind that opium-smoking is unmistakably an evil. It is a comfort to believe it is not so great an evil as is very generally believed.—*Dr. J. Watson, in the Chinese Customs Gazette.*

OBSTETRIC PRACTICE IN CHINA.

IT would be interesting to ascertain the results of obstetric practice among foreigners in China for purposes of comparison with statistics obtained in other parts of the world. As a contribution, I will analyse the last fifty obstetric cases that have occurred in my practice. Out of these fifty, five were abortions earlier than the third month, and four were miscarriages earlier than the sixth month. There was one case of twins, both females. By the forty-one labours at term there were born twenty-three girls and nineteen boys. Out of the total of fifty, one mother died of puerperal fever of the nervous form, without evidence of septicæmia. This latter case proved fatal within thirty-four hours of the first appearance of excitement. Of the forty-two children born at term, one died of trismus on the fifth day, and one was born dead, having died probably the day before labour set in. In the forty-one cases at term there were forty head presentations, one of the right shoulder, and one of the left shoulder with loop of funis (pulseless). Of these last, the former was rectified by bipolar cephalic version, the labour proceeding naturally afterwards ; the latter was also rectified in the same manner, but, probably on account of the child's death, the head was driven backwards between the shoulders, and the presentation, when fairly lodged in the brim, was found to be one of the face. As the mother was not exhausted, and as the child was known to be dead, time was given, and after two hours it was found possible to extract with the long forceps. Still considering the forty-one cases at term, the forceps was used in twelve cases, of which six were at or above the brim, and six in the cavity. In ten of these cases it was applied in default of uterine action ; one case has been described above, and in the remaining case there had been obliteration of the os, which was represented by little more than a tubercle high up behind the pubes. Incision of the os at three points, followed by steady digital dilatation under chloroform while water-bags were being sent for, produced, by the time these latter arrived, an amount of expansion that barely justified an attempt with the forceps. The difficulty was greatly increased by the excentric position of the os. There were special and urgent reasons which need not be specified for hurrying the birth. The membranes were ruptured, and at the third essay I succeeded in placing the forceps, and delivering a healthy female child. It will thus appear that, out of the fifty cases summarised, there were only two of serious difficulty. In none was there any threat of post-partum hæmorrhage—a fact which may be contrasted with Tilt's representations as to the frequency and formidable character of this accident among European residents in India. But

the marked tendency to inertia is worthy of attention. Of the forty-one mothers delivered at full term, twenty could not nurse at all, two nursed for about four weeks, and fifteen for more than three months; one died, of one I have no information, and the remaining two had nursed on previous occasions; but in one case the child was born dead, and in the other the child died four days after birth. In twenty-nine cases chloroform was administered throughout the entire of the second stage; in the remainder either there was some objection on the patient's part, or labour was terminated so speedily as to render chloroform unnecessary. —*Dr. Jameson, in the Chinese Customs Gazette.*

FROM ABROAD.

Extraction of Cataract.

Dr. Derby communicates to the *Boston Med. and Surg. Journal* (November 1) a paper bearing the title "A Few Practical Suggestions concerning Extraction of Cataract," which he had intended to read to the American Ophthalmological Society, but, owing to the railway riots, its meeting was prevented.

The operation of extraction of senile cataract, he observes, is likely always to remain the capital operation of ophthalmic surgery, and is one about which more interest centres (with the possible exception of iridectomy for glaucoma) than any other. From time to time modifications and improvements have been suggested; and it would be a matter of great interest to have the recorded experience of a candid surgeon, who, after fifteen or twenty years of full practice, would publish a truthful history of his successive changes of opinion, and give his reasons for the course he now pursues. In the present paper Dr. Derby draws attention to only two or three points, concerning which he has been led to materially change the views which he formerly held.

1. *The Use of Mydriatics preparatory to Extraction.*—The usual reasons for dropping in atropia prior to the operation are known to all, and yet many surgeons have long given up its employment. So far from the passage of the knife being rendered more easy, it was found that its point could be more readily directed against a background of iris than when this was wanting; and that wound of the iris was less likely to occur when the pupil was contracted, than when the point of the knife was met by the swollen periphery of a dilated pupil. And mydriasis, returning again after the aqueous humour is resecreted, was found directly to encourage prolapsus of the iris after extraction, and healing-in of the iris in the corners of the wound, when Von Graefe's method had been employed. For these reasons, Dr. Derby has for some years relinquished the use of atropia, and has even employed myotics, dropping into the eye a few drops of a 1 per cent. solution of eserine two or three hours before extracting. At the time of the operation there is then considerable myosis, which interferes in no way with the extraction, and returning, like mydriasis, with the re-establishment of the anterior chamber, exerts on the iris a degree of traction that reduces to a minimum the danger of its healing-in to the corners of the wound, and renders the complication less frequent than heretofore. This contraction of the pupil readily yields to atropia, should it be found desirable to employ it in the after-treatment. Although capsular remains are at first examination found to occupy the area of the pupil, the edge of the iris may generally be made to separate from them with readiness after repeated instillations of atropia. Secondary cataract ought theoretically to more frequently follow when its use is so long postponed; but practically this is not the case. Dr. Derby states that the only eserine fit for use is obtainable at Vée's, 42, Rue du Faubourg St. Denis, Paris.

2. *The Employment of Anæsthetics.*—In Boston, the use of ether in extraction has been for some time past a matter of course; freedom from pain, and the immobility produced, having been regarded as conclusive reasons. Yet the state of anæsthesia is apt to throw appreciable obstacles in the way of successful extraction. The congestion frequently induced encourages hæmorrhage, and the anterior chamber often fills with blood before the division of the capsule, and the patient's will being in abeyance, he is no longer able to render that assistance to the surgeon which is of so much importance. Every needed motion has to be given to the eye by means of the forceps. In profound anæsthesia the muscles are relaxed, the eye loses its tension, and the difficulty of removing cortical fragments is considerably increased. The surgeon is unable, by roughly testing vision, to know whether he has performed his task thoroughly; and the patient loses the moral support of once exercising his newly acquired sight—a support that has cheered many a one through the long, dark days of convalescence. In spite of every precaution, too, the retching and vomiting, which may last for hours, may have an injurious effect upon the eye, and render the patient unable to take nourishment, while his *morale* is lowered. Dr. Derby feels convinced that the superior results which are obtained by some European ophthalmologists, especially Arlt and Wecker, are, after allowing for their dexterity and constant practice, in part due to their not using anæsthetics. For the last year he has followed their example, the patients readily agreeing to dispense with them, and testifying to the little pain caused; and in no case has he had to employ the fixation forceps after the section was completed.

3. *The First Examination of the Eye after the Operation.*—Formerly, Dr. Derby was in the habit of making a hasty examination the day after the operation, and the day after that; but he gradually found that the eye did just as well if left closed for two or three days, changing the dressings daily. Moreover, he came to trace the commencement of inflammatory complications to the first separation of the lids, however carefully and hastily performed; and he was induced to keep prolonging the time during which the eye was allowed to remain unopened, until now he rarely examines until the morning of the seventh day after the operation. Supposing extraction performed in the early morning, he renews the bandage at about five on the same afternoon, bathing the lids with tepid water, and applying fresh lint and bandage. The severe pain which occurs exceptionally a few hours after the operation often yields to a single gentle sponging with iced water. Next morning the bandage is again renewed, and if all is going on well, and there is no swelling, undue secretion, and lachrymation, the bandage is reapplied, and afterwards changed only once a day—the case being allowed to go on thus until the morning of the seventh day, when the lids are opened. It is astonishing to some to observe how little evidence of the operation is then present—a trifling redness close to the wound being sometimes all that is to be seen. Atropia may now be used, if needed; but many cases do not require it all. The eye is now closed, and allowed to remain so for a day or two, a shade being substituted for a bandage, and the room still kept darkened. The redness about the wound, slight at first, will be observed steadily to increase for several days after opening before it begins to disappear. In answer to theoretical objections to this practice, it may be observed that a fair trial of the plan will show that the longer the wound is left undisturbed, in contact with and guarded by the covering provided by nature, thus sealed and protected from any contagion-germs with which the atmosphere may be infected, the greater will be the success in the after-treatment of cataract.

Mortality Returns of the Paris Hospitals.

In his report for the quarter ending in September (*Union Méd.*, November 8 *et seq.*), Dr. E. Besnier states that the mean temperature was 1° C. lower than the mean of the quarter calculated for the period 1806-70, while the humidity was much more considerable than that of the same quarter of preceding years.

1. *Affections of the Respiratory Organs.*—The influence of *normal seasonal conditions* upon the diseases of the respiratory organs is exhibited by the double modification of their number and relative gravity. In the hospitals, in which the number of cases of phthisis (these cases not being excluded from the French general hospitals) is pretty much the same, and to which are brought all patients suffering from grave affections of these organs, the proportion of the seasonal diminution is considerably masked. But still it is exhibited in a very precise manner, not only by the lessening of the number of the patients treated, but also by the absolute and relative diminution of the number of deaths. A table which is furnished allows of the exact comparison not only of the relations of one year to another, but those of one season with another, or with the seasons of the same year or of several different years. The accumulation of a number of documents of this kind, which Dr. Besnier has been making for years, will shortly, he feels confident, enable him to exhibit the exact formula of the

normal course and mean seasonal mortality of pulmonary affections, which are no more exempt than other affections from the true laws, which have to be discovered.

2. *Diphtheritic Affections.*—"Endemo-epidemic diseases, even when undergoing the most excessive annual paroxysms, or while pursuing for years an ascending progress, are none the less subjected, with mathematical regularity, to the influence impressed upon them by vicissitudes of season. In typhoid fever, for example, I have already shown that, however intense may have been the epidemic paroxysm, the disease none the less at the commencement of winter undergoes a diminution, which, in an immutable manner, brings it back to the lowest point of its curve at the end of spring. So for diphtheria: although we are in this very year in the midst of the most violent paroxysm which the disease has ever attained, the decline, which we have (repeatedly) shown to be normal, and regular during the summer period, has none the less been produced. From 728 deaths from diphtheria which took place in the whole of Paris during the first quarter of 1877, the curve descended to 592 in the second, and to 479 in the third or summer quarter, and that in spite of some partial violent explosions which testify to the persistence of the epidemic paroxysm." A table is given, indicating the prevalence of diphtheria in each arrondissement, and it is observed that while the disease was diffused over the entire town, its principal foci were found at the most elevated points, being in complete opposition to what is observed in this respect with regard to typhoid fever. Just as in the case with the other affections of the respiratory organs, not only has the number of cases of diphtheria diminished this quarter, but especially is this the case as to the proportionate mortality. This was 83 per cent. in the past quarter, 79 in the second, and 58 in the third —"enormous modifications entirely unappreciated by observers working in a small circle, and which should ever be borne in mind in estimating the value of therapeutic agents, which, under these circumstances, increases or diminishes according to the variable degree of benignity or malignity of the affection. It is to be hoped that experimenters in therapeutics or statistical therapeutists will bear these remarks in mind." During the quarter there were admitted 188 cases of diphtheria, 109 of which proved fatal, or a mortality of 57·98. M. Bergeron, of the St. Eugénie Children's Hospital, states that the cures of diphtheritic angina, uncomplicated with croup, have been 53 per cent., instead of 47 per cent. in 1876; while the cures after operation for croup have been 22 per cent., instead of 11 per cent. M. Archambault, of the Enfants Malades, states that there were admitted 49 cases of diphtheria (some of them in a hopeless condition), in 31 of which the respiratory passages were affected; and of these 49 cases, 33, or 67 per cent., proved fatal.

3. *Small-pox.*—This has during this quarter exhibited two declining movements—the one seasonal, which is a normal one, the summer quarter furnishing the fewest deaths of all the year; and the other annual, which is very marked. During the quarter there were but 21 deaths from small-pox in the whole of Paris, there having been 76 for the corresponding quarter of 1876, and 74 for that of 1875. Yet the curve is relatively high: it commenced at 0 in 1873, and the figures for 1874 and 1873 were only 12 and 3. The deaths from small-pox in the hospitals this quarter were 8, out of 65 cases admitted.

4. *Typhoid Fever.*—"The laws of the seasonal progress of typhoid fever, which I have deduced from attentive observation of the evolution of the disease in all its phases, are so precise that I was able in my preceding report (*Medical Times and Gazette*, page 343), on the second quarter of 1877, to announce without hesitation that the typhoid curve had reached its annual apogee, and that it was about, at the same time that variola would decline, on the contrary, to rise by a regular, continuous movement definitively decisive in August. The following figures represent this progress, and allow of our tracing the curve for Paris. Thus, while there were in all Paris but 47 deaths from typhoid in June, there were 77 in July, 121 in August, and 128 in September. Without forcing analogies, or instituting misplaced comparisons, I may remark that, considered by years and seasons, epidemic diseases increase and diminish alternately, submit to a true gravitation, pass through curves which are proper to them, and are subjected in their phases to certain laws. Taking the years and seasons as the plane of the evolution of these diseases, exactly in the manner in which astronomers take space as the field of gravitation of the stars, we ought to be able, by attentive and sufficiently prolonged study, and by numerical observations in conformity with scientific procedure, some day to trace the normal map of epidemic diseases, as it is now sought to trace the map of vicissitudes of the atmosphere, and has long since been traced the celestial map. It is useless to object that the complete realisation of this project, of which I only now lay down the positive bases, cannot be effected by an isolated individual, nor in a short period; but when we take into account the clearness and precision of the results which we have already been enabled to partially establish, I entertain no doubt that their realisation will be one day attained." The total deaths of the quarter from typhoid in Paris were a little above the ordinary summer mean, but they amount to less than one-half of the deaths in the same quarter of 1876 —viz., 326, as compared with 655. In the hospitals 488 patients were treated, with a mortality of 128, or 26 per cent. —the same quarter of the eight preceding years having furnished 3265 cases, with 907 deaths, or 27·77 per cent. "The typhoid mortality attains each year its maximum in the second quarter (absolute mortality); but it is in the third quarter that the *relative mortality* rises to the highest level. So that whatever may be the number of deaths, which is always larger in the third than in the fourth quarter, I can affirm that the relative mortality (the mortuary co-efficient) will be lower in October, November, and December, than it was in July, August, and September. As usual, I point out this peculiarity to practitioners who are experimenting on the therapeutics of typhoid fever, and who always omit to inquire the rate of mortality of the disease at the time their experiments are being made."

REVIEWS.

Anatomy, Descriptive and Surgical. By Henry Gray, F.R.S. Edited by Timothy Holmes, M.A. (Cantab.), Surgeon to St. George's Hospital. London: Longmans, Green, and Co. 1877. Eighth Edition. Pp. 800.

The eighth edition of "Gray" is just issued. We have much pleasure in welcoming this new edition, which is improved both in quantity and quality on its predecessors. The chief changes in this issue have been made in the sections on microscopical anatomy and on development—two subjects which are so constantly advancing that they must necessarily be almost rewritten for each edition, if the work is to maintain its present position among students' handbooks. It is undoubtedly "the book" at present, and is the one which we should confidently recommend for all first and second years' students. We must, however, say that many of the old plates ought to be recut, for they are much worn and much less distinct than formerly. Some of them ought to be replaced by more modern ones. We cannot think that Fig. xii. would help anyone to recognise, at the College of Surgeons, costal cartilage from a man seventy-six years of age; at least, we will hope not, for the sake of the microscopic preparations at the College. We have made many microscopic specimens of skin, but we have failed hitherto to produce anything quite like Fig. 50. Indeed, it is so diagrammatic that we should fear it would mislead, rather than aid, students. Could not something better be devised than borrowing from old obsolete German *clichés?* To us it is always a matter of regret that our standard works should borrow and copy plates, rather than have original ones made for themselves. "Gray" is a well-known and firmly established book, and is in the hands of an editor quite able to secure original histological and other drawings; as future editions are called for we sincerely hope that he will do so.

Spinal Disease and Spinal Curvature: their Treatment by Suspension and the Use of the Plaster of Paris Bandage. By Lewis A. Sayre, M.D., Professor of Orthopædic Surgery in New York. London: Smith, Elder, and Co. 1877. Pp. 121.

Dr. Sayre, of New York, with the energy and enthusiasm so characteristic of our Transatlantic brethren, recently undertook a voyage to Europe, in order to introduce and advocate a plan of treating spinal disease which is simple and very inexpensive in its details, easy of application, and—what is more to the point—efficient and satisfactory in its results.

We need not dwell at any length on the very unsatisfactory

result of the treatment of this disease as at present carried out among the poor; each one of our children's hospitals has a long list of spine cases, which drag on month after month, and in which, even should a cure be effected, the results are such permanent deformity that the patients must ever after be classed as cripples, and serve as permanent witnesses of one of the weakest points of our surgical therapeutics.

Profesor Sayre, before proceeding to deal with the treatment, gives a brief summary of his views, "which are somewhat at variance with those of the standard authorities," concerning the nature of *caries* or *Pott's disease* of the spine.

Under the heading of "Pathology," he states that "the deformity of the spine known as Pott's disease, or posterior angular curvature, is a result of slow inflammation and consecutive loss of substance in the bodies of certain vertebræ, and in the corresponding intervertebral discs." This is, no doubt, true as regards the result, but it can scarcely be looked on as the "pathology" of the disease. We must confess to a little disappointment that the subject has not been more fully developed, seeing the very large opportunities which the author of this work seems to have enjoyed. The rest of this paragraph ought to have been merged into the succeeding one on "Ætiology," for it discusses the cause of the disease: "I have for many years held that it (spinal disease) is almost always, if not always, produced through some injury to the bone or cartilage, and that, in common with carious diseases of joints, it is essentially of traumatic origin. The almost constant primary cause, I believe, is some injury sufficient to disturb the nutrition of the bodies of certain vertebræ and the intervertebral cartilages, and to induce inflammatory softening and disintegration of the structure of these organs. (*sic*) I reject altogether the view held by the profession in general, that Pott's disease is above all others one of essentially strumous origin, that it is necessarily dependent upon a tuberculous diathesis, and never met with save when constitutional dyscrasia is present." While we can agree with some of the paragraph we have just quoted, we must join issue as regards the essentially traumatic origin of this disease "in common with carious diseases of other joints." We have known, for instance, of hip-joint disease developing in one joint, while the patient was under treatment in hospital for disease in the other hip-joint, and this although the child had been confined to her bed for six months or more. So, too, with spine disease; it not infrequently shows itself without our being able to trace the slightest traumatism. We cannot accept a traumatic cause, except the effect follow within a reasonable period; neither can we allow to pass unchallenged a statement that children sustain falls and bruises (of which we know nothing), any of which could be rightly regarded as the traumatic source of disease, which only manifests itself after many months' interval. If a child sustain an injury, or fall, or blow, so slight as never to come within the cognisance of its parents, the effects of which, however, months later, show themselves in carious disease of the spine, then we should argue a distinct dyscrasia—a constitution with exceedingly vulnerable tissues; one prone to take on low, chronic forms of inflammation; and one in which, such processes, once started, are exceedingly difficult to stay. This constitution is, in England, expressed by the term "scrofulous." Certainly, if one examines the sum total of cases of spine disease seen in our London hospitals during any given year, it must be admitted that nine-tenths of them occur in this so-called "scrofulous constitution." We nevertheless admit that a certain proportion of cases do follow immediately on a fall, and agree with Dr. Sayre that these must be classed as essentially "traumatic." We think, too, that this justifies the remark that spinal disease "occurs more frequently among boys than among girls, because the former are more exposed to accidents."

The *symptoms* of spinal caries, in its early stages, are sometimes very obscure, and consist mainly in transmitted and reflex nervous disturbances. "The nerves that make their exit from the spinal canal at points corresponding to the seat of the disease become more or less involved, and will manifest such disturbance by symptoms developed at their peripheral extremities." Thus, when the disease affects the cervical spine, the troubles and earliest nerve-manifestations will be referred to the throat and chest—dysphagia and a sense of constriction round the neck, or a troublesome cough, and pain may be the first, and for some time the only symptom. In early diseases of the dorsal spine, dyspeptic symptoms are generally the most marked. If the spinal disease commence still lower down, the symptoms will be referred to either bladder or rectum, or perhaps both. "The chief and earliest complaint is that of a frequent desire to relieve the bladder. The patient suffers occasionally from pains radiating from the pelvis along the thighs. When any of the above-mentioned symptoms are present, and they cannot be explained by the presence of some well-recognised disease, the surgeon should always extend his investigation to the points where the nerves distributed to the seats of pain and uneasiness make their exit from the spinal cord."

Dr. Sayre's method of *examining the spine* is peculiar, but practical. The child should be stripped, "and so placed across the knees of the surgeon that its face looks downwards, its arms resting over one thigh, and its legs over the other. The surgeon, by separating his thighs, is then able to make a gradual extension of the trunk and spine of his little patient." It was the comfort afforded by this extension that first suggested the idea of suspension to Dr. Sayre.

We must pass on to what, after all, is the most noteworthy feature of the book—*the treatment of spinal disease*. "The great object . . is to maintain *rest of the affected parts*, by such means as will not debar the patient from the benefits of fresh air, sunlight, and change of scene." Few will differ from our author on these two points. That rest must be secured is self-evident, and it is equally clear that if fresh air can be obtained at the same time we shall have solved one of the greatest difficulties connected with the treatment of this class of diseases. It does seem to us that Dr. Sayre has shown us how to accomplish this. "The bandages used in the making of this apparatus must consist of some loosely woven material, such as cross-barred muslin, musquito netting, or crinoline. This should be torn into strips three yards long, and from two and a half to three inches wide, according to the size of the patient upon whom it is to be used. Its meshes may be completely filled by drawing the bandage through very fine and freshly ground plaster-of-Paris that has not been long exposed to the air, this plaster at the same time *being rubbed into* the material. Each strip should then be loosely rolled up so as to form an ordinary roller bandage. Several of the bandages thus prepared may be kept ready for use in air-tight tin vessels. When required, they are *set on end* in a basin containing sufficient depth of water to *cover them entirely*. A free escape of bubbles of gas through the water will be observed for a short time; when this has ceased, the bandages are ready for use." The surface of the skin should be protected by an elastic but *closely* skin-fitting shirt, or vest, without armlets, but with tabs to tie over the shoulders, and composed of some soft woven or knitted material. The preliminary arrangements (the vest, and the plaster-filled bandages) being completed, the child is suspended. For this purpose a tripod about nine feet high, provided with a rope and pulley, is the most convenient apparatus. To the pulley is attached an iron cross-beam, and from this the child is suspended by means of an adjustable head and chin collar. The collar fits round the neck in such a way as to grip the occiput behind and the chin in front. Other straps pass beneath the arm-pits. The pulley-rope is now adjusted, and the patient is extended as far as is considered safe; adult patients may extend themselves as long as they feel comfortable. As it is the intention of this "jacket" to restrict thoracic movements, some precautions are necessary with regard to the abdomen and its movements during diaphragmatic respiration (which is, of course, substituted for thoracic), as also for its increased size after meals. For this purpose, the "dinner pad" is employed. It consists of a pad of cotton folded up in a handkerchief, so as to form a wedge-shaped mass, the thin edge being directed downwards. This is placed over the abdomen, between the shirt and the skin. It is important to make it thin where it comes under the lower edge of the jacket, or else the jacket would fit too loosely about the lower part of the abdomen. Any prominent spinous processes must be protected from pressure by little pads of cotton or cloth placed on either side of them. If the patient be a female, especially if she be developing at the time, it will be necessary to apply a pad under the shirt over each breast before the plaster bandage is put on, in order not to interfere with the nipple or breast. These pads, as also the "dinner pad," must be carefully removed just before the plaster completely sets. The plaster bandages are now to be applied, commencing round the smallest part of the body, and gradually working downwards to the crest of the ilium and a little beyond it, and then from below upwards in a spiral direction until the entire trunk from the pelvis to the axillæ has been encased. The bandage must be placed smoothly round the

body, and must *not* be drawn tight; "it should be simply unrolled with one hand, whilst the other follows and brings it into smooth, close contact with all the irregularities of the surface of the trunk. Sufficient bandages must be applied to afford firm support. In order to accomplish this with the least possible weight, Dr. Sayre recommends that strips of tin, roughened like a nutmeg-grater, be inserted between the turns of the bandage. The patient must be kept in the recumbent position until the jacket is dry. If there are sores or abscesses, windows must be cut in the usual manner.

For caries of the cervical region, Dr. Sayre recommends that the head be suspended. The plaster jacket alone is of little, if any, service. For this he has invented what he calls the "jury-mast" apparatus. Our space will not allow of a detailed description; for this and engravings we must refer to the original.

We do not intend to quote any of the cases which are given in the book in support of this plan of treatment. Our own experience bears out, in the main, the truth of Dr. Sayre's assertions. We have seen great benefit result, and we believe that when the necessary mechanical skill in adjusting the jacket shall have been obtained by surgeons, they will have in their hands a means, both simple, economical, and efficacious, of successfully treating a disease which, as seen in the out-patient departments of our metropolitan hospitals, has hitherto almost worn out their patience, and all but defied their efforts for cure.

Dr. Sayre's book is admirably illustrated, and especially by some beautiful photographs, and we would refer the reader to the book itself for information on many points which the limits of our notice forbid us to enter upon.

Ophthalmic and Otic Memoranda. By D. B. St. John Roosa, M.D., and E. T. Ely, M.D. New York: Wood and Co. 1876. Pp. 264.

This neat little book, suitable for the pocket, will be found useful to the student or general practitioner. It does not profess to be a complete treatise, but it nevertheless contains a very great deal of information. It includes the anatomy of the parts, as well as the diseases which are incidental to them. We should think it is likely to be highly appreciated.

The Examiner in Anatomy. By A. T. Norton, F.R.C.S. London: Smith, Elder, and Co. 1877. Pp. 174.

Mr. Norton is doing good work in drawing attention to the necessity of learning how to give *written* answers to *set questions*. We have often adverted in our columns to the utility of this practice; we are not quite sure, however, but that Mr. Norton's book is not as good as it ought to be, coming as it does from a public teacher of anatomy. It lacks, here and there, that precision which the science of anatomy so rigidly demands; and the answers given to his questions are not always as clearly expressed or as concise as they might be. Nevertheless, the book will be useful, if only to encourage students in a class of work which is very essential to those who would do well at examinations.

A Guide to the Examinations at the Royal College of Surgeons of England. By Frederick J. Gant. Third Edition. London: Baillière, Tindall, and Cox. 1877. Pp. 146.

Mr. Gant has collected the examination papers of the College for some years past, and has issued them in the form of a little volume. The mere collection of such papers is of interest, even if it did not serve any other purpose; for it will enable us at a glance to compare the examinations of past years with more recent ones, and so in some measure to gauge the advances which surgery is making both as an art and a science.

An Atlas of Human Anatomy. By Rickman John Godlee, M.S., F.R.C.S. With Explanatory Text. London: J. and A. Churchill. 1877. Part II.

The second part of this beautiful Atlas has just appeared: it fully bears out the favourable opinion which we formed of it as judging by Part I. It contains the dissections to expose the *posterior triangle of the neck*, the *brachial plexus*, and the structures at the back of the neck. The remaining figures illustrate both the superficial and deep parts which are supplied by the branches of the external carotid artery, and also the internal carotid artery in the whole of its course, as well as its relations to the cranial nerves. It is likely to prove as useful to the physician and surgeon as to the anatomist. We are well aware of the labour entailed in the execution of such a work, or otherwise we should wish that it might appear in monthly rather than in bi-monthly parts.

PROVINCIAL CORRESPONDENCE.

MANCHESTER.

December 12.

Notice of the late Mr. Henry Runcorn—Meeting of the Medical Society—Radical Cure of Double Congenital Hernia—Removal of the Whole Tongue with the Scissors—Glycerine of Carbolic Acid as a Dressing after Ovariotomy.

The suffering poor of this city have sustained a severe loss by the death of Mr. Henry Runcorn, the Resident Obstetric Surgeon and House-Surgeon to St. Mary's Hospital. His connexion with the institution commenced thirty-six years ago, when he was appointed House-Apothecary, and continued unbroken to his death. Regardless, almost to a fault, of his own interests and comfort, peculiarly diffident and unobtrusive in manner, he lacked many of the qualities which insure success in private practice. As a resident officer, however, he was very highly esteemed, not only for his faithful and efficient services, but also for his personal worth and his unwearied kindness to the poor. His large experience of difficult midwifery, in connexion with the maternity department of the Hospital, led to his being appointed Resident Obstetric Surgeon when that office was first created, five or six years ago. The arduous and responsible duties which he thereby undertook were fulfilled with praiseworthy devotion and remarkable success. He had been suffering for some days from a severe cold, of which he could not be persuaded to take sufficient care, when he was attacked, on November 24, with symptoms of acute pneumonia. The disease rapidly assumed a very severe character, and he died early on the morning of November 28, aged sixty-five years.

The December meeting of the Manchester Medical Society was almost entirely devoted to surgical topics. I can only allude to one or two of the more interesting communications. Mr. Thomas Jones showed a little boy, two years of age, on whom he had performed the operation for the radical cure of a double congenital inguinal hernia. On July 22 the hernia on the right side descended, and could not be reduced even under chloroform. After symptoms of strangulation had been present for eight hours, the operation of herniotomy was performed antiseptically. The sac having been opened, the stricture divided, and the gut returned into the abdomen, the neck of the sac was isolated from the spermatic cord, and a catgut ligature was passed round it. The wound healed, without a trace of suppuration, in four or five days. On August 1 it was found necessary, for similar reasons, to operate for strangulation of the intestine on the left side, when the opportunity was seized to pass a catgut ligature round the neck of the sac on that side also. In this instance there was a little suppuration; the wound, however, healed satisfactorily, and up to the date of the meeting (December 5) there had been no re-descent of the hernia on either side.

Mr. Walter Whitehead exhibited two patients, in one of whom he had removed a portion of the tongue, and in the other the whole of the tongue, for epithelioma, by means of the scissors alone, without division of the symphysis or submental incision. The latter operation was thus performed:—The patient, a woman of sixty-four, having been placed under the influence of chloroform, a gag was inserted, and the tongue firmly secured by a strong ligature passed through its substance near the tip. The operator, taking firm hold of this ligature with his left hand, divided successively the frænum and the sub-lingual tissues on each side. The tongue being then drawn well forward so that the epiglottis was brought fairly into view, the operation was completed by cutting through the base of the tongue, first on one side and then on the other. Two large vessels were divided: one of these was tied during the operation; the other, after bleeding for a little time, ceased spontaneously. Smart hæmorrhage, however, took place after the removal of the patient, and it was found necessary to have recourse to the thermo-cautery. The operation was not followed by any

constitutional disturbance, and though a fortnight had not yet elapsed, the patient appeared at the meeting perfectly well. The merit of this operation consists in its simplicity. Nearly sixty years ago Boyer described ("Traité des Maladies Chirurgicales," tome vi.; Paris, 1818; page 392) an operation for epithelioma of the tip of the tongue, in which, by means of a pair of straight scissors, he removed a V-shaped portion about an inch in length, and united the flaps by sutures. But, although Mr. Whitehead distinctly repudiates any claim to originality, he is the first, so far as he himself is aware, to have demonstrated the practicability of removing the whole tongue by this simple method. With regard to the hæmorrhage which occurred subsequently, he is quite convinced that this may be prevented in future by taking care to tie both ranine arteries during the operation, whether they give trouble at the time or not.

In the course of a discussion which followed a paper by Mr. Bradley "On Antiseptic Surgery," Dr. Thorburn, the Obstetric Physician to the Royal Infirmary, mentioned a plan of dressing the wound and pedicle after the operation of ovariotomy, which he had recently adopted with marked success. The pedicle having been secured by the carbolised catgut ligature, and divided, the stump and ligature are freely smeared with the glycerine of carbolic acid of the Pharmacopœia, and returned within the abdomen. The edges of the abdominal wound, including the peritoneum, are treated in a similar manner before the wire sutures are tightened, a pad of lint soaked in the carbolised glycerine is placed over the wound and secured by a bandage, and the parts are not disturbed for ten days. Twenty-five cases of ovariotomy have been thus dealt with, and though six of the cases died, in none of the six could the fatal result be attributed, in the least degree, to septicæmia. In no instance had there been any purulent or other discharge, or any inflammatory exudation in the track of the sutures. Dr. Thorburn contended that by thus trusting the wounded parts to the undisturbed influence of the carbolised glycerine for many days, he puts to more practical proof his faith in the antiseptic virtues of carbolic acid than do those operators who examine the condition of the wound so much more frequently.

Dr. E. Lapper, F.C.S., Demonstrator of Chemistry in the College of Surgeons, Dublin, has been appointed to the Chair of Chemistry in the Ledwich School of Medicine, rendered vacant by the death of Dr. W. Handsell Griffiths.

West Kent Medico-Chirurgical Society.—The third meeting of the twenty-second session was held on Friday, December 7, at the Royal Kent Dispensary, Greenwich-road, at 8 p.m.; W. Johnson Smith, F.R.C.S. (President), in the chair. Dr. John Curnow read a paper on "The Diagnosis and Treatment of Acute Diseases induced by Alcohol." The next meeting will be on Friday, January 4, at the same time and place. Dr. J. Milner Fothergill will read a paper "On Diseases which simulate Heart Disease."

London Hospital Medical College.—Since the death of Mr. Kershaw, late Secretary of this College, various changes have been made. When the College Board, consisting of nine members of the House Committee and six members of the staff, with Sir Edmund Currie as chairman, was established, a Secretary was appointed to supervise and co-ordinate the working of the College, and the medical and surgical management of the Hospital. The Secretary, being the officer of the College Board, did not interfere in any way with the functions of the House-Governor, the latter officer being the chief administrator of the Hospital, and the adviser of the House Committee. The College Board, just previous to Mr. Kershaw's death, had resolved to take up this part of their task as the complement to the remodelling of the College, in which they had been very successful. At the recent meeting of the College Board, it was proposed by Dr. Down, and seconded by Rev. J. Kitto—"That a Principal of the College be appointed." It was further proposed by Mr. Couper, and seconded by the Treasurer of the Hospital (Mr. Thomas Fowell Buxton)—"That Dr. Norman Chevers be requested to accept this office." In virtue of this post he will sit at the Board as one of its members, and will also discharge the duties of Medical Secretary. We are sure that this appointment will be satisfactory to all interested in the School, and will serve to enhance its position as an eductional institution.

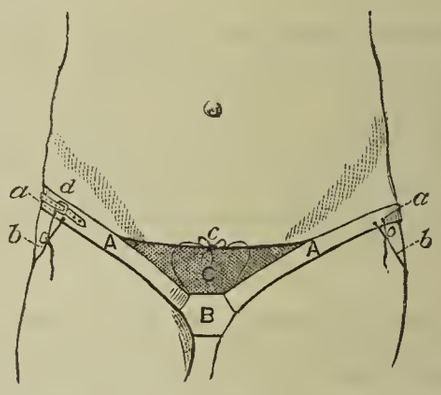
GENERAL CORRESPONDENCE.

NEW FORM OF SUSPENSORY FOR THE TREATMENT OF VARICOCELE BY ELEVATION.

Letter from Mr. W. R. Williams.

[To the Editor of the Medical Times and Gazette.]

Sir,—It is an instructive pathological fact, and one not fully appreciated, that varicocele affects only the lower part of a spermatic vein. The disease, I believe, has never been traced above the external abdominal ring. The reasons for this are obvious. Below the ring the veins are almost destitute of support, yet subject to great fluid pressure; whereas, higher up, the state of affairs is just the converse. This simple explanation clearly foreshadows the treatment. It seems to say—shorten the fluid column, and support the dependent vessels. But how is this to be effected? I answer, by elevation—by raising the scrotum and its contents above the pubes. This arrangement has a double advantage; thus, it directly shortens the fluid column several inches, and at the same time converts it into a hydrostatic syphon. The elevated veins constitute the shorter arm, the contents of which exactly counterpoise a similar height of fluid in the longer arm. In this way the hæmostatic pressure is still further reduced; and the residual strain is transferred from the weakest and most dependent part of the vessels. The suspensory I am about to describe was designed to fulfil these indications. It consists of three parts (see figure):—



1. *The pelvic band*, A, which passes round the pelvis midway between the anterior superior iliac spine and the top of the great trochanter. On either side two loops, *a*, *a*, are attached; to these the gluteal tapes are made fast. When the body is erect, these loops should be in a vertical line with anterior part of the great trochanter. At *d* is a buckle fastening.

2. *The perineal portion*, B, is a triangular tongue, the base of which is forwards at the scrotum; while the apex, to which the gluteal tapes, *b*, *b*, are attached, passes backwards to within about an inch of the anus. The gluteal tapes run along the gluteal folds to the pelvic loops, *a*, *a*.

3. *The scrotal network*, C, supports the scrotum and its contents on the supra-pubic cushion. It should be somewhat bagged above, but contracted below. A small cord, *c*, rove through the upper border, allows the requisite adjustment. Urination is readily effected by depressing the network.

I have not had a sufficiently lengthy experience of this method to enable me to state that it will bring about a radical cure, but its tendencies are in this direction. It does for varicocele what the elastic stocking does for varix of the leg: it enables the patient to undertake an amount of walking exercise that was before impossible, and does not fail to relieve that dragging pain which in ordinary cases is the most distressing symptom. The suspensory is made by Mr. Sillis, of George-street, W.C.

I am, &c.

W. Roger Williams, M.R.C.S.

Mr. John Henry Buxton has been elected Chairman of the House Committee, London Hospital, *vice* Sir Edmund Hay Currie, who has resigned after an active service of ten years. The House Committee purposely chose one of its younger members as Chairman, in the hope that he would have both the time and strength to devote himself actively to the duties of the post.

REPORTS OF SOCIETIES.

THE PATHOLOGICAL SOCIETY.

TUESDAY, DECEMBER 4.

CHARLES MURCHISON, M.D., LL.D., F.R.S., President, in the Chair.

MULTIPLE SARCOMA IN A BOY.

MR. BUTLIN brought forward a boy aged twelve, suffering from multiple sarcoma. He was first seen by Mr. Holden in June, 1875, when a tumour as large as a walnut was removed from the region in front of the left ear. This proved, microscopically, to be a round-celled sarcoma. Four months later two fresh tumours of the same nature were removed from the left frontal region. About twelve months later (in August, 1876) both testicles were found enlarged and indurated, and continued to increase in size under treatment with iodide of potassium and mercury. Since that time other tumours had made their appearance in the following situations:—In the left scapular region, at the back of the left thigh, on the back, over the trochanter, and on the chest-wall. All these growths increased in size and involved the skin and neighbouring structures. The tumour on the thigh sloughed, and the surface granulated and healed completely. The right testicle had certainly been decreasing in size for some months. The boy's general health had never been affected. Mr. Butlin said that the nature of the growths, their mutual relation, the absence of visceral infection, and the sloughing of one of them, were all points of interest in this case. There was no strumous or syphilitic dyscrasia, nor were there any inflammatory characters about the growths except the occurrence of sloughing, which was an occasional event in tumours. He therefore considered the growths as round-celled sarcoma. The right testis alone did not increase in size. There was no evidence that the tumours first removed had been the source of the later tumours by infection, for there was involvement neither of the lymphatics nor of the lungs. The multiple appearance, therefore, probably represented repeated outbreaks of a disease; local irritation being sufficient to determine them in a subject predisposed to their development. He could not offer a prognosis.

The PRESIDENT said that he had a lad under his care at St. Thomas's Hospital with mediastinal tumour, who had had his thigh amputated fifteen months ago for sarcoma.

MULTIPLE TUMOURS OF THE BRAIN.

Dr. PEARSON IRVINE showed this specimen. It was removed from the body of a boy aged seven years, who died in Charing-cross Hospital in November last. He came of a delicate family. In 1876 he had measles, but completely recovered to all appearances, and was well until June of this year. He then had a sense of general illness, with pains in the head. The headache gradually became more severe, persistent, and localised over the left frontal eminence. He began also to suffer from vomiting, restlessness at nights, with moaning in his sleep. In August he was noticed to squint, and complained of double vision and loss of sight. On admission it was found that the boy could walk with precision, but had in walking a slight lateral nodding of the head. He had right internal strabismus; the right lid drooped; the pupils were equal, and dilated; vision was dim. He had a loud systolic murmur all over the cardiac area. There was no retraction of the abdomen. A few days after admission he had severe unilateral convulsions (right), followed by temporary hemiplegia and anæsthesia. Convulsions recurred frequently, and at times were general. By the end of October he was quite blind, the discs being blurred, the veins enlarged, and the arteries buried in "fluffy" exudations. The speech throughout was thick and slow, but memory was perfect. Towards the end the patient had difficulty in swallowing, and took a long time over a small quantity of food. He had no cough, and no regular fever, though for days together at times he had an elevated temperature. After death there was found constriction of the pulmonary orifice, probably congenital; enlargement and caseation of the bronchial glands. One large mass, completely reduced to greenish-yellow pulp, extended over the front of the trachea, beneath the thyroid gland. The upper lobes of both lungs were thickly sown with grey granulations, surrounded by early pneumonic changes; these were less abundant in the lower lobes. They were found also in both kidneys. The cerebral membranes were not adherent; the brain was flattened, and there were six to eight ounces of serous effusion at the base. There were no lymphoid exudations or grey granulations. A tumour the size of a large nut fell from the falx cerebri in the removal of the brain; and at the base of the cerebellum, attached to the pia mater, others were found. In the substance of the brain, and at the bottom of the sulci, several others were found, rounded, and of the size of marbles. Five like bodies were found in the lateral ventricles, falling off easily from the lining membranes. The right half of the cerebellum contained three large masses, and in the left frontal lobe a large mass existed. The pons was healthy. These tumours were all easily enucleated, and had firm fibrous capsules. Some of them were cheesy in the centre, but less so than the bronchial glands. The corpora striata and optic thalami were flattened. The tumours, which microscopically showed the appearances of "tubercular growths," were enucleable possibly because they had ceased to grow and become encapsulated. Dr. Irvine observed that possibly the bronchial mischief was primary (coming on after measles), and that the brain-mischief was secondary to bronchial caseation. There had occurred an acute tuberculisation of the lungs and kidneys. The appearances, at least, indicated that, as regards time, these changes must have been secondary to one another. It was remarkable how few signs of paralysis, or other affection of nerves, showed themselves. The third and sixth cranial nerves were partially affected. It was likely that the unilateral convulsions and the slowness of speech, with subsequent difficulty in deglutition, as also the lateral nodding of the head, were due to the cerebellar tumours, and to compression of the eighth pair of nerves. Dr. Irvine had lately seen two other cases in which tumours limited to this situation had been accompanied by loss of vision on the side affected, and in which symptoms attributed to pressure below the tentorium had led to a diagnosis of the site of the tumours.

CHYLOUS URINE.

Dr. DICKINSON exhibited a specimen of chylous urine, passed by a woman of twenty-one, a patient under his care at St. George's Hospital. The girl, who had never been out of England, had first passed chylous urine two years before her admission; and she had then begun to suffer from debility and emaciation. The urine at first had resembled rich milk, being quite white; and it contained a coagulum: there were no renal casts, but a considerable number of blood-corpuscles. The milkiness increased after meals; albumen was always found in quantity; a molecular base could sometimes be distinguished microscopically. Dr. Dickinson, considering that the chyluria might be due to regurgitation of chyle from the thoracic duct, had applied a tourniquet over the last lumbar vertebra. The immediate effect was most successful; the first specimen of urine passed after the application being normal in appearance, and almost free from chyle; and the subsequent effect was as satisfactory, the amount of chyle being less than one-eighth of what it had been at first, and the patient now weighing nine stone instead of five. Dr. Vandyke Carter, from his experience in India, had contended that the chyle in chyluria was not excreted by the kidney, but mixed mechanically with the urine, inasmuch as the proportions of albumen and fats were preserved in the "urine" as in the chyle, and because the blood was not found chylous when the urine was. The molecules of the chyle, also, were found in the urine; and occasionally even "chylous cells." Dr. Dickinson pointed out, in support of this view, that in cases of superficial chylous discharge the pelvic region or thighs were the ordinary seats of the flow; and it was to these regions and to the mucous membrane of the urinary tract that the chyle would regurgitate in case the thoracic duct were obstructed. Of the few recorded necropsies in chylous urine, in one the kidneys were healthy, in one fatty, and in one tuberculous; while Dr. Lewis had found filariæ in abundance in the kidneys in the chyluria of Bengal. The kidneys, therefore, were not always diseased; besides, renal casts did not occur in chyluria (except in Dr. Ralfe's specimen exhibited at the last meeting, which was probably complicated with intermittent hæmaturia); it was, therefore, improbable that the chyle was excreted by the kidneys. It probably reached the urine in some lower part of the urinary tract.

Dr. ALEXANDER MORISON also exhibited specimens of chylous urine, which had been passed by a woman of fifty-six, a Jewess, born in Algeria, but who had passed the last thirty-one years of her life in Europe. She had been stout; had

borne eight children; and had eaten very freely of oily food. For some time previously she had been a patient of Dr. Leared's. When seen by Dr. Morison she was suffering from debility, dyspepsia, and the passage of milky urine, with lumbar pains; and she was greatly emaciated. The urine varied in quantity, and in colour from a dead white to a simple opalescence; and the specimen of morning urine exhibited was much clearer than the other specimen, which had been passed in the evening. After fasting the clearness had been further increased. The specific gravity varied from 1040 to 1017 before separation of the coagulum which spontaneously formed in it after being passed; and from 1035 to 1013 after coagulation. The urine was faintly acid; and sugar had been frequently found in it, both before and after filtration. Microscopically it contained small refracting particles, leucocytes, and torulæ, but neither casts nor filariæ. Both sugar crystals and crystals of fatty acids had been extracted from it. Dr. Morison said that endemic influence could hardly be at work in this patient, who had been so long out of the tropics. He believed that the chyluria was related to the menopause, and the glycosuria might have preceded or even caused the chyluria.

Dr. Ord exhibited a specimen of fat from chylous urine, which proved to have been obtained from the same woman who was now Dr. Dickinson's patient. She had been under Dr. Ord's care twelve months ago, and the chylous urine had been most carefully examined. To the naked eye, the fluid at that time closely resembled milk; and microscopically it presented a molecular basis, with blood corpuscles (chiefly red), delicate fibrinous coagula, and masses of nucleated protoplasm. There were neither casts, crystals, nor filariæ. Examined chemically, the fluid yielded ordinary albumin, alkali-albumin, and a pellicle on boiling. The pinkish colour disappeared on boiling; nitric acid caused a copious precipitate. No sugar was present. Fat was found to the amount of 0·5 per cent.; but Dr. Thudichum could find only a small quantity of fatty acids, and no lecithin. Altogether, the specimen was composed of olein, palmitin, stearin, and a very small quantity of a fatty acid with a different melting-point, and of alkali-albuminate. The resemblance of the fluid to chyle was very close, and the chylous urine was probably due to admixture. The blood had been examined several times, and found perfectly normal.

Dr. Leared spoke of Dr. Morrison's case, which he had previously seen. At that time no sugar could be obtained after filtration. Chyluria was probably hereditary, and the partiality of the Jews, especially of the Jews in Algeria and Morocco, for olive oil, might account in some measure for the frequency of the disease among them. He also knew of a case of chyluria of some fifteen years' standing, in which the disease had made its appearance shortly after a severe railway accident.

The President asked whether chylous discharges from the surface of the body were invariably associated with chylous urine.

Dr. Dickinson said that chylous urine and chylous discharges were frequently associated, and frequently alternated with each other. In his case neither the blood nor the urine contained filariæ. Certainly chyluria was not invariably due to the presence of filariæ. As yet there was not sufficient evidence to show at which part of the urinary tract the chyle escaped.

Dr. Pye-Smith said that he thought it was generally admitted that chyluria was due to admixture of chyle and urine. Observations seemed to indicate that this mixture occurred by direct passage of chyle from the lymphatics at some point beyond the mesenteric glands into the bloodvessels. Lewis had found lesions in the kidney due to the presence of filariæ; and might not these produce direct openings, and so chyluria? This explanation appeared more simple than that of chyluria by regurgitation.

Dr. Dickinson replied that Prout had regarded chyluria as closely related to albuminuria. The pathology of the disease was still obscure, and further observations were required to test his theory.

Softening Syphiloma of the Liver.

Dr. Wilks showed this specimen, from a woman of thirty-five years without a history of syphilis. For two years before her death she had had abdominal symptoms, commencing with enlargement of the abdomen, jaundice, emaciation, and vomiting: hepatic tenderness and signs of ascites were then discovered. Acute peritonitis supervened, followed by chronic; and enlargement of the right lobe of the liver was ascertained to be present. Post-mortem, a large cavity was found in the right hepatic lobe, containing a yellow bilious fluid, and presenting large hard masses of syphilitic appearance. The liver contained other masses of a similar character. Dr. Wilks said that syphilitic formations usually ended in drying up, cicatrisation, and puckering; the general belief among pathologists being that syphilitic masses did not soften. The characteristics of syphilomata had been exaggerated. Syphilomata did occasionally soften. Dr. Moxon had shown such a specimen in the liver years ago, and had suggested that similar cases in the lung might produce some specimens of vomica. He had himself seen an "abscess" of the liver, with curdy contents, associated with syphilitic lesions; and also instances of softening syphiloma of the brain, and in the mediastinum. Softening nodes were familiar to all. He had once regarded softening of a gumma as a late change, as due to decay of old syphilitic material. But he now inclined to the view that the softening was active, the syphiloma growing like other tumours, and becoming liquid in the centre.

OBSTETRICAL SOCIETY OF LONDON.

Wednesday, December 5.

Charles West, M.D., F.R.C.P., President, in the Chair.

Dr. Roper showed a specimen of Calcified Fibroid Tumour of the Uterus; and a Tumour of the Placenta, believed to be an organised blood-clot, or a growth intermediate between myxoma and fibroma.

Secondary Puerperal Hæmorrhage.

Mr. C. Stewart Redmond said in this case hæmorrhage came on a month after confinement. The woman lost a great amount of blood. A portion of placenta was found in the uterus and removed, and perchloride of iron solution injected. Some febrile disturbance followed, but the patient made a rapid recovery.

General Dropsy in the Fœtus, with Hypertrophy of the Placenta.

Dr. Bassett said that during labour delay had occurred after the birth of the head. It was believed after auscultation of the mother's abdomen that the child was dead. Delivery was effected by drawing down an arm by the blunt hook. The child was greatly œdematous; the placenta large and hypertrophied, weighing three pounds and a half, and in twelve hours it discharged one pound of fluid.

Dr. John Williams said that what we knew of the production of dropsy in the child was the result of our knowledge of the mode of production of it in the adult. Heart disease never caused in the adult uniform general dropsy. That condition was always the result of a blood-state. The effect of central obstruction was to cause œdema of the most distant parts from the heart. In the fœtus the placenta would suffer first; this would interfere with the flow of blood through that organ, and dropsy of the fœtus in consequence. The placenta acted not only as an organ of respiration for the fœtus, but probably also as a renal organ, and anything which interfered with the circulation in it, or increased the thickness of its tissues, would interfere with the elimination of excrementitious products from the blood of the child. This would bring about a blood-condition similar to that met with in Bright's disease, and general anasarca in consequence.

Dr. Edis thought that it ought to have been learned whether or not the child was dead, without the aid of chloroform. The proper treatment was to have brought down an arm at once; the issue might then have been different.

Dr. Roper said that when a head had been born an hour or two without the body, the probability was that the child was dead. The delay is due to disease of the fœtus, ascites, or something else. In that case he would perforate the thorax and deliver.

The President regretted that no reference had been made to the researches of Simpson. New observations should be made, and compared with those made before.

Complete Rupture of the Perineum.

Mr. Charles Robert Thompson said that in this case the arm of a dropsical fœtus appeared through the anus of the mother, and ruptured the perineum completely. Deep sutures

were at once inserted. On the third day they were removed. On the fifth day an aperient was given. The patient was perfectly recovered at the end of a month.

Dr. Hayes was in favour of the use of sutures in laceration of the perineum. He kept them in five days.

Dr. Bantock used silkworm gut.

Dr. Wynn Williams used the first material at hand.

Dr. Murray recommended lateral incisions of the vaginal orifice with a view to prevent rupture.

Dr. Edis thought that the treatment of the bowels was an important point. It was important to insure regular action from the first. He uses silver wire covered with guttapercha.

Meningocele complicating Labour.

Dr. Woodworth Poole related a case as above, in which version was tried by the bipolar method, but ineffectually. The hand was then introduced into the uterus, and version effected by the feet. At the back of the head was a large translucent cyst measuring fourteen metres in circumference.

Double Vagina and Uterus.

Dr. Henry Gervis contributed this case. The patient had been married four years; suffered from dysmenorrhœa and spanæmia sometimes. There were two vaginæ, separated by a septum from one-twelfth to one-eighth of an inch in thickness. The left vagina was larger than the right. At the top of each vagina was a cervix with a small os uteri. A probe could be introduced into the left for half an inch, and into the right for an inch and a half. There were two uteri. The septum between the vaginæ was divided by the galvanic écraseur with a view of relieving the patient's suffering.

Extra-Uterine Pregnancy.

Dr. Henry M. Madge, in a paper entitled "Notes on Extra-Uterine Pregnancy," said that though there are differences of opinion with regard to the varieties of extra-uterine pregnancy, yet most cases may be referred to the tubo-ovarian and tubo-abdominal. The author was of opinion, however, that the placenta may be developed within the ovary, and also when attached to the peritoneum. Mr. Jessop's case was clearly abdominal. In such a case there is no decidua, and there can be no uterine sinuses nor utero-placental vessels—the so-called curling arteries and veins, the size of crowquills, passing from the peritoneum to the placenta; and therefore there must be an absence of what is called the sinus system. The membrane to which the placenta is attached allows of interchange of fluids, and the nourishment of the fœtus is thus provided for. Nothing is known of the structure of extra-uterine placentæ, but it is evident they must be all fœtal. Many questions were raised by such cases as Mr. Jessop's, where the fœtus was not surrounded by membranes—such as, What is the source of the liquor amnii, the origin of vernix caseosa, the disposal of the fœtal urine, etc.?

Removal of Large Uterine Myomata by Abdominal Section.

Mr. Lawson Tait gave particulars of four cases. The first operation was performed on account of recurrent intestinal obstruction due to a myoma; the patient recovered. The next was the removal of a rapidly growing soft myoma reaching nearly to the xiphoid cartilage in a woman aged forty-five. The tumour was freely movable, with but few adhesions. The pedicle was clamped. Patient died on the fifth day after operation. It was found that the uterine cavity entered the tumour for about six inches. The third case was a patient aged forty-one, suffering from a multiple fibroid reaching above the umbilicus. There was no distress, except occasional pressure on the intestines. The author urged her to leave it alone. She determined to have it removed, however, and the operation was performed May 19. The patient died May 22. The last case was a patient suffering from a tumour of somewhat doubtful nature. A medical practitioner tried to tap it, and the tumour then grew rapidly, and the patient's health suffered in consequence. The tumour was removed, the pedicle being clamped. The patient made a good recovery.

Dr. Fancourt Barnes had assisted at an operation for the removal of a fibroid complicating pregnancy. The tumour was in the pelvis. There was great difficulty in removing it. Patient died in five or six hours.

Dr. Playfair said that in two of the patients operated upon the diagnosis was doubtful. In one it was done against Mr. Tait's advice. Why was it done? The course of fibroids is not usually fatal, and abdominal section should not be undertaken for their removal unless life was endangered.

Dr. Routh said the great point in this operation was, how the pedicle could be secured. He had collected cases, and found that death was due to slipping of the ligature or clamp. The pedicle ought to be transfixed. The rule should be, never to listen to what a patient says of the desirability of an operation. Unless there be danger the operation is not justifiable.

Dr. Aveling said that the difficulty he had met with was in dealing with the broad ligament.

Dr. Bantock said the feasibility of the operation depended on the presence of a pedicle. If the fibroid involved the body of the uterus, the operation was contra-indicated. He recommended ligaturing the pedicle in small pieces by transfixion—each ligature linking to its neighbour like the links of a chain.

MEDICAL NEWS.

University of London.—The following candidates have passed the recent B.S. Examination (for Honours) in the First Class:—

Symonds, Charters James (Gold Medal), Guy's Hospital.
Verco, Joseph Cooke, M.D. (Scholarship and Gold Medal), St. Bartholomew's Hospital.

Royal College of Surgeons of England.—At the half-yearly examination for the diploma of Fellowship of this institution, which was brought to a close on the 24th ult., the following Members of the College were reported to have acquitted themselves to the satisfaction of the Court of Examiners, and at a meeting of the Council yesterday, the 13th inst., were admitted Fellows of the College, viz.:—

Amphlett, Edward, M.A. and M.B. Cantab., Leamington, diploma of Membership dated November 17, 1875, student of Guy's Hospital.
Archer, Wm. Gammon, M.A. and M.B. Cantab., Birmingham, January 23, 1877, of St. Bartholomew's Hospital.
Cantlie, James, M.A. and M.B. Aber., Dufftown, Banffshire, May 24, 1877, of the Charing-cross Hospital.
Clarke, Julius St. Thomas, M.B. and L.R.C.P. Lond., Leicester, May 20, 1862, of Guy's Hospital.
Dent, Clinton Thomas, M.A. Cantab., Chesham-street, S.W., January 27, 1875, of St. George's Hospital.
Elliot, Norman Bruce, L.R.C.P. and L.S.A. Lond., Denmark-hill, January 24, 1873, of Guy's Hospital.
Harsant, William Henry, L.S.A., Bristol, July 27, 1874, of Guy's Hospital.
Paley, William Edmund, L.R.C.P. Lond., Peterborough, January 20, 1874, of Guy's Hospital.
Taylor, John William, Birmingham, January 21, 1873, of the Charing-cross Hospital.
Verco, Joseph Cooke, Adelaide, South Australia, November 18, 1874, of St. Bartholomew's Hospital.

Three candidates having failed to acquit themselves to the satisfaction of the Court of Examiners, were referred to their professional studies for one year. At the same meeting of the Council, the following Members of the College were elected Fellows of the College, viz.:—

Donald, John, Army, Wilmslow, diploma of Membership dated September 4, 1835.
Walker, William Newman, Tollington-park, June 23, 1843.

Apothecaries' Hall.—The following gentlemen passed their examination in the Science and Practice of Medicine, and received certificates to practise, on Thursday, December 6:—

Colmer, Ptolemy Samuel Henry, Yeovil, Somerset.
Fox, Joseph Tryelles, Lordship-lane, Stoke Newington.
Hall, John Lees, Porchester-gate, Hyde-park.
Hope, Robert Charles, York-road, Lambeth.

The following gentleman also on the same day passed his Primary Professional Examination:—

William Henry Walter, St. Bartholomew's Hospital.

APPOINTMENTS.

*** The Editor will thank gentlemen to forward to the Publishing-office, as early as possible, information as to any new Appointments that take place.

Bradford, Cordley, M.R.C.S. Eng., L.S.A. Lond., House-Physician to the Queen's Hospital, Birmingham—Surgeon to the Cornwall Works, Birmingham.

Helme, J. Milner, M.B. Edin.—House-Surgeon to the Royal Southern Hospital, Liverpool, *vice* W. Roughton, M.R.C.S., resigned.

NAVAL, MILITARY, &c., APPOINTMENTS.

Admiralty.—Staff Surgeon Joseph Halpin has been placed on the Retired List from the 30th ult.

Militia.—Surgeon-Major Edward Jackson, M.D., 2nd Warwick, resigns his commission; Surgeon William Cullinan, Clare, to be Surgeon-Major.

War Office.—Surgeon-Major Archibald Henry Fraser to be Deputy Surgeon-General, *vice* Vere Webb, retired on half-pay; Surgeon-Major Charles Rattray, M.D., retires upon temporary half-pay; Surgeon-Major William Samuel Chapman retires upon temporary half-pay; Surgeon-Major Charles George Wiche (Bombay Army) to be Deputy Surgeon-General.

BIRTHS.

De Brent.—On December 8, at Church House, Aveley, Essex, the wife of Mortimer de Brent, M.R.C.S. Eng., of a son.

Dyer.—On December 9, at Ringwood, Hants, the wife of H. Geary Dyer, L.R.C.P. Edin., of a daughter.

Fawcett.—On December 4, at Newcastle-on-Tyne, the wife of W. J. Fawcett, M.B., Surgeon A.M.D., of a daughter.

Gowers.—On December 10, at 50, Queen Anne-street, the wife of W. R. Gowers, M.D., of a daughter.

Hill.—On December 9, at 58, West Cromwell-road, S.W., the wife of T. Wood Hill, L.R.C.P. Edin., M.R.C.S. Eng., of a son.

Pitman.—On November 29, at Acacia House, Highgate-hill, N., the wife of Robert Pitman, L.R.C.P., of a son.

Startin.—On December 7, the wife of James Startin, M.R.C.S. Eng., of 17, Sackville-street, of a daughter.

Thomson.—On November 18, at Mogador, Morocco, the wife of H. Richardson Thomson, M.R.C.S., of a son.

MARRIAGES.

Caithness—Westmacott.—On December 11, at St. Saviour's Church, Paddington, James Ernest Caithness, Esq., of Calcutta, to Eugene Sarah Henrietta, fourth daughter of John Guise Westmacott, L.R.C.S. Edin., of 19, St. Mary's-terrace, Paddington.

Goate—Adams.—On December 5, at the Church of the Holy Trinity, Attleborough, W. R. Goate, solicitor, son of C. E. V. Goate, M.D., to Minnie, daughter of J. Adams, Esq.

Harries—Benson.—On December 5, at St. Luke's, Chelsea, Thomas Davies Harries, of Aberystwith, F.R.C.S. Eng., to Annette, youngest daughter of the late S. Benson, Esq., of the Royal-avenue, S.W.

McIntyre—Seymour.—On December 4, at the parish church, Odiham, Hants, William McIntyre, L.R.C.P. L.R.C.S. Edin., of Odiham, to Emma, third daughter of the late John Grove Seymour, Esq., of Odiham.

Symes—Blackman.—On December 11, at Unity Church, Islington, John Edwin Symes, to Elizabeth Florence, eldest daughter of Charles Thomas Blackman, M.R.C.S., of Highbury-grove, London.

DEATHS.

Blakeley, Thomas, M.D., at Brighton, on December 6, aged 54.

Broster, Richard William, M.R.C.S. Eng., L.S.A., late of Beaminster, Dorset, eldest son of William Broster, Esq., of Marland-place, Southampton, at Topsham, Devon, on December 3.

Copeman, Frances, wife of Edward Copeman, M.D., at the Upper Close, Norwich, on December 6, aged 68.

Dean, Peter Thomas, M.D., on December 9, at The Cottage, Upper Norwood, aged 44.

Duncan, Alexander Campbell, M.D., late of H.M. Indian Service, at Wardie-road, Edinburgh, on December 10.

Evans, Herbert Norman, M.D., late of Hampstead, at St. Leonards, on December 10, aged 75.

Gaine, Adele Brydges, wife of Charles Gaine, M.R.C.S., at 8, Edgar-buildings, Bath, on December 7, aged 31.

Lawrence, Leonard Aust, M.R.C.S. Eng., formerly of Southampton, at 154, Adelaide-road, Regent's-park, on December 6, aged 64.

Starling, Thomas John, F.R.C.S., of Higham Ferrers, at Brighton, on December 3, aged 67.

Trench, William Stewart, M.D., Medical Officer of Health for Liverpool, at 107, Bedford-street, Liverpool, on December 5, aged 68.

Wright, Eliza Brewabd, wife of Matthew Hall Wright, M.R.C.S., at The Hollies, Summer-hill, Birmingham, on December 3.

VACANCIES.

In the following list the nature of the office vacant, the qualifications required in the Candidate, the person to whom application should be made and the day of election (as far as known) are stated in succession.

The Guest Hospital, Dudley.—Resident Medical Officer. Candidates must be unmarried, and Fellows or Members of the Royal College of Surgeons of England, Edinburgh, or Dublin, and possess a registered qualification in medicine. Applications, with testimonials and certificate of registration, to the Secretary, on or before January 1.

UNION AND PAROCHIAL MEDICAL SERVICE.

*** The area of each district is stated in acres. The population is computed according to the census of 1871.

RESIGNATIONS.

Huddersfield Union.—The Slaithwate District is vacant; area 4810; population 4409; salary £30 per annum.

Tiverton Union.—Dr. Bothwell has resigned the Eastern and Western Districts; area 17,491; population 10,024; salaries £70 per annum for each District.

Warwick Union.—Mr. Wm. A. Parsons has resigned the Workhouse; salary £64 per annum.

APPOINTMENTS.

Farnham Union.—Alfred J. Atkinson, L.R.C.P. Edin., M.R.C.S. Eng., L.S.A., to the North and Seal Districts, and the Workhouse.

Lampeter Union.—Abel Evans, M.R.C.S. Eng., L.S.A., to the Workhouse.

Richmond (Yorks) Union.—Edward T. Atkinson, M.R.C.S., L.S.A., to the Richmond Rural District.

St. Matthew, Bethnal-green, Parish.—Thos. R. King, M.D. Edin., L.R.C.S. and L.R.C.P. Edin., as Medical Officer of the Workhouse. Patrick Butler, L.R.C.S.I., L.K. & Q.C.P.I., as Assistant Medical Officer.

St. Thomas Union.—Henry W. Furnivall, M.R.C.S. Eng., L.S.A., to the Woodbury District.

Stockport.—Mr. Oswald Wilkinson as Analyst for the Borough for one year.

Tavistock Union.—Richard E. West, M.R.C.S. Eng., L.S.A., to the Tavistock District and the Workhouse.

Thetford Union.—Edwin J. Gurdon, M.R.C.S. Eng., L.R.C.P. Edin., to the Hopton and Hepworth Districts.

Dr. Livingstone.—The bronze statue of this celebrated member of our profession is just completed, and on view at the foundry at Thames Ditton. It is intended for Glasgow.

Marischal College.—A portrait of Dr. John Macrobin, late Dean of the Faculty of Medicine, University of Aberdeen, has been completed by Mr. George Reid, R.S.A., to be presented to the above College by his former pupils.

Iodised Cod-Liver Oil.—Pale cod-liver oil, one hundred grammes; iodoform, one-quarter of a gramme; oil of anise, ten drops. The iodoform removes from the oil its nauseous and disagreeable odour. M. Fonssagrives prescribes this mixture in the same manner as ordinary cod-liver oil, in cases in which it is desired to combine iodine with it.—*Union Méd.*, December 6.

Dr. J. Bell Pettigrew, F.R.S.—This gentleman, formerly assistant in the Museum of the Royal College of Surgeons, Lincoln's-inn-fields, and now Dean of the Medical Faculty and Professor of Anatomy and Medicine in the University of St. Andrews, has been elected by the Universities of Glasgow and St. Andrews as their representative at the General Council of Medical Education and Registration of the United Kingdom.

The statue of the late Dr. Graves is to be unveiled in the hall of the Royal College of Physicians of Ireland, on Wednesday, the 19th inst., at 4.30 p.m. Critics speak warmly of the merits of the statue. It adds to the interest of the occasion that the sculptor, Mr. Albert Bruce Joy, whose colossal statue of Mr. Laird at Birkenhead was lately unveiled, is the son of Dr. Joy, who for many years practised as a physician in Dublin, and wrote several articles for the "Cyclopædia of Practical Medicine," and who is now living in retirement in London.

It is announced that the Victoria Hospital for Children, of which institution her Royal Highness the Princess Louise is the patroness, stands greatly in need of funds at the present time, to enable the work to be carried on efficiently. The hospital is wholly without endowment; yet, since it was established in 1866, relief has been afforded to upwards of 3040 in-patients and 149,000 out-patients. The Convalescent Home at Margate is a branch of this charity, and has been a great boon to poor children; but to support the Home £400 annually is required, whereas the subscriptions and donations have only amounted to a little over £100 per annum.

Diuretic Action of Cafein.—Prof. Gubler related several cases to the Société de Thérapeutique in proof of this. One of these was that of a man with dropsy from disease of the heart, to whom digitalis had been given with but slight result. After the injection of thirty centigrammes of the bromhydrate of cafein, diuresis commenced on the second day, gradually increasing until four litres and a half of urine were passed. When the injections were arrested, the urine again diminished, to increase again after their resumption. Prof. Gubler observed that with cafein the diuresis is abundant and almost instantaneous, while with digitalis the increase of urine only takes place on the second or third day. The citrate or bromhydrate of cafein does not excite any irritation in the cellular tissue. M. Constantin Paul stated that he attached great importance to the state of the pulse in the use of digitalis, and when it fell to sixty he suspended this, as after then, in spite of the continuation of the symptoms, it acts as a poison. Prof. Gubler said that with cafein the pulse diminished only a few beats, and became more regular; but as a "tensor" of the circulation, cafein is inferior to digitalis. Even sixty beats are too low for patients to take digitalis who have disease of the heart. Digitalis should be given only for five days if tincture is employed, but only for three or four days when infusions or macerations are prescribed. Whatever preparation of digitalis be employed, its effect is to determine diuresis, except where there is no dropsical effusion to eliminate, or when there is "imbecility" of the kidney.—*Gaz. Hebdom.*, December 7.

NEW PROCESS OF EMBALMING.—Dr. Lowell, of Brooklyn, has discovered a new process of embalming, which, it is calculated, will save to the city of Brooklyn alone from $75,000 to $100,000 per annum in the one article of ice, now used for the preservation of bodies for transport, besides doing away with much unpleasant and cumbersome material. A solution of chloride of zinc is the fluid used, and this is contained in a porcelain-lined vessel, raised to a convenient height, so that the contents pass into the vessel by gravity. A finely tapered glass tube is tightly fixed in place in the vein, while a glass U-shaped tube acts as a siphon, conducting the fluid from the receptacle, through indiarubber tubing, into the glass tube. The quantity of fluid thus injected will vary, and four or five gallons may be required. Dr. Lowell says that the injection may be made by either artery or vein, but he prefers the brachial artery above the elbow. "The effects are eminently satisfactory. The colour of the integument is improved, even at the points where hypostasis has been at work."—*New York Med. Record*, November 10.

THE following note, taken from our contemporary *Nature*, on the boring of the deepest artesian well at present existing, has some special interest just now in connexion with the new water-supply scheme of the Metropolitan Board of Works:—"The deepest artesian well in the world is being bored at Pesth, and has reached already a depth of 951 metres. The well at Paris, which measures 547 metres, has hitherto been the first. The work is undertaken by the brothers Zsigmondy, partially at the expense of the city, which has granted £40,000 for the purpose, with the intention of obtaining an unlimited supply of warm water for the municipal establishments and public baths. A temperature of 161° Fahr. is shown by the water at present issuing from the well, and the work will be prosecuted until water of 178° is obtained. About 175,000 gallons of warm water stream out daily, rising to a height of thirty-five feet. This amount will not only supply all the wants of the city, but convert the surrounding region into a tropical garden. Since last June the boring has penetrated through 200 feet of dolomite." We learn also that among some of the ingenious engineering devices invented during the course of the boring are especially remarkable the arrangements for driving in nails at the enormous depth mentioned above, for pulling them out (with magnets), for cutting off and pulling up broken tubes, and above all, a mechanica apparatus by means of which the water rising from the well is used as a motive power, driving the drills at a rate of speed double that previously imparted from the mouth of the well.

NOTES, QUERIES, AND REPLIES.

He that questioneth much shall learn much.—*Bacon.*

Dr. Augustus Florance.—Received with thanks.

A Doubter.—Have the kindness to send us a small portion of one of the tumours for further examination.

Dr. Simpson.—"The Signs of Rain" was composed by the celebrated Jenner, and the following lines addressed to a lady upon the recovery of her daughter, and sent with a pair of ducks, afford a fair specimen of his facetious vein:—

> "I've despatched, my dear madam, this scrap of a letter,
> To say that Miss ——— is very much better;
> A regular doctor no longer she lacks,
> And therefore I've sent her a couple of Quacks."

Arts Examination.—You will find the list was published a few weeks ago in this journal.

Sewers.—The Local Board of Hampton Wick obtained an Act of Parliament last year, forming a large district, which comprised Barnes, Kew, Mortlake, Petersham, Richmond, Kingston, Surbiton, the Dittons, the Moulseys, Hampton, Hampton Wick, and Teddington, into a united sewage district, with taxing power, and complete control over the sewerage.

Mountaineering.—One of the main objects of the promoters of Italian Alpine Clubs—the offspring of the English parent of all such associations—has been to give a greater manliness to the character of Italian youths. These clubs have been formed in many cities of Italy and of the Italian Tyrol. The Italian Alpine Club was founded in 1863.

Dairyman.—Yes, there are dairy laboratories in Italy for chemical experiments. The Germans have a mechanical appliance for getting the cream out of the milk by steam power. There is an invention for a special method of lighting dairies to prevent the possible contamination of the milk from the gases in combustion.

Delta.—1. The estimate is—that 1,033,000 acres of the best land in India are devoted to the production of opium. 2. A Commission, appointed by Government, is sitting in Bombay, to decide on a drainage and sewerage scheme for the city.

A Busy Body.—The American's answer was, "Well, sir, I made one thousand dollars, clean cash, *by attending to my own profession*, and I made the other thousand dollars by letting *other folks' business alone!*"

Fidelis.—The lines are those of the poet Crabbe, on "Evils of Quackery to Infants," the conclusions of which are—

> "She (the nurse) gave her powerful sweet without remorse—
> *The sleeping cordial*, she had tried its force,
> Repeating oft: the infant, freed from pain,
> Rejected food, but took the dose again,
> Sinking to sleep; while she her joy exprest
> That her dear charge could sweetly take his rest.
> Soon may she spare her cordial: not a doubt
> Remains, but quickly he will rest without.
>
> "This moves our grief and pity, and we sigh
> To think what numbers from these causes die."

Pranks.—The anecdote is that Sir Astley Cooper, when a boy, having taken two pillows from his mother's bed, carried them up to the spire of Yarmouth Church, at a time when the wind was blowing from the north-east, and as soon as he had ascended as high as he could, he ripped them open, and, shaking out their contents, dispersed them in the air. The feathers were carried away by the wind, and fell far and wide over the surface of the market-place. The timid looked on it as a phenomenon predictive of some calamity; the inquisitive formed a thousand conjectures. It was not long, however, before the difficulty was cleared up in the doctor's house, where it at first gave rise to anything but those expressions of amusement which the explanation when circulated through the town is reported to have excited.

"STINKING FISH."

Eight tons of fish were seized and destroyed by the officers of the Fishmongers' Company, at Billingsgate Market, as unfit for human food, during the past month.

HEALTH OF BOMBAY.

The death-rate in Bombay for the week ending the 17th ult. rose to a very high figure, being 49·38 per 1000 of the population per annum. There were 240 deaths from intermittent fever.

NOTEWORTHY.

By a recent decision of the Vice-Chancellor, the gift of £1000 in railway debentures to the Corporation of Brighton for charitable purposes was void under the provisions of the Mortmain Act.

MORTALITY IN PARIS.

The official returns of deaths in the city of Paris for the week ending the 6th inst., show an increase of 5 over the preceding seven days, the numbers being 888 and 883. Bronchitis increased from 45 to 53; typhoid fever decreased from 25 to 22, and lung diseases from 68 to 63.

PHYSIC AND FEES IN THE RUSSIAN PROVINCES.

A contemporary, in an article on "The Russians of To-day," writes—"A man had better not fall ill while in a Russian country town, for all the doctors outside the large cities are believers in phlebotomy and violent purgatives. They prescribe tea, but drug it without telling you, and the effects are felt for days afterwards. Their fee is anything you like to give; but whatever you may offer, they will be sure to ask more, and must therefore be dealt with as bluntly as tradesmen."

MATERNAL GOVERNMENT.

The Birmingham Board of Guardians, desiring to alter the dietary of the workhouse, by substituting occasionally currant instead of suet puddings for the children in the workhouse, applied to the Local Government Board for their permission for the proposed alteration. The reply received from the Board stated that they "approve of the proposal of the Guardians of the Parish of Birmingham to give the children in the workhouse currant pudding occasionally, instead of suet pudding. With regard, however, to the formula of the currant pudding, the Board are advised that a little sugar should form one of the ingredients of the pudding to make it more palatable."

STREET PERILS.

We are sorry to observe that drunkenness appears to be on the increase among cabmen. Not fewer than four such offences were brought before the London police magistrates in one day quite recently. One had left his horse and cab in the street while he adjourned to a public-house, from which he came out very drunk. Another had also left his horse and cab in the street, and was found by a policeman drunk. The third had, when drunk and driving furiously, smashed another cab. The fourth was seen by a policeman reclining on the top of his cab quite drunk, and driving at a furious pace. The penalties imposed were small fines, with the alternative of short terms of imprisonment. The fines were paid. Surely these offences, imperilling as they so seriously do the public safety, deserve as a punishment something more adequate than a trifling amercement, if drivers of public vehicles are to be made to feel the responsible duties of their calling.

ADULTERATION UNIVERSAL.

According to the annual report of the Local Government Board, in the metropolis in 1876-77 there were 4177 samples of food and 110 samples of drugs submitted for analysis. Of the former there were 515, or about one-eighth of the whole number examined, pronounced adulterated; but of the 110 samples of the latter examined, only 7 were found to be either more or less adulterated. In Manchester sophistication appears to be practised to a serious extent: of 149 samples of food examined, nearly one-half, or 68, were adulterated. In Liverpool more than one-fourth, or 73, out of 219 samples of food were adulterated; of drugs, only 3 samples were analysed, but one of these was found adulterated. In Bristol 58 samples of food out of 180 examined were adulterated. In Birmingham, of 67 samples of food and 25 of drugs, 25 of the former and 9 of the latter were adulterated. In Leeds nearly one-fourth, or 21, out of 95 samples of food were found to be "unduly mixed" with foreign substances.

Nocturnal Literary Work.

It may be of some practical utility to take note of some remarks the *World* makes on the suffering among those who are addicted to nocturnal reading and writing, from the defects of artificial light. The writer says—"A literary friend has lately imparted to me how much his discomforts of this kind have been removed by following the advice of an oculist, who told him to work at night only by the light of Silber burners, consuming either oil or gas. It seems that the light given by these burners, besides being abundant in quantity, is almost exactly like sunlight in its quality, so that it produces the same spectrum when refracted through a prism, and allows even the most delicate shade of colour to be distinguished. The irritating effect of ordinary artificial light is chiefly due to its superabundance of yellow, and from this the Silber lights are free. I impart this information for the benefit of all whom it may concern."

COMMUNICATIONS have been received from—

Dr. Byrom Bramwell, Newcastle; Dr. E. Lapper, Dublin; The Registrar of the University of London; The Registrar of Apothecaries' Hall, London; The Secretary of the Society of Medical Officers of Health, London; The Sanitas Company, London; Mr. Howard Marsh, London; Dr. Sutton, London; Dr. Hughlings-Jackson, London; Mr. J. Knowsley Thornton, London; Mr. Bacon, Seaton; The Secretary of the Obstetrical Society, London; Mr. Spencer Watson, London; Mr. Henry Coright, London; Dr. E. Sparks, Menstone; Mr. W. M. Bywater, London; Dr. J. W. Moore, Dublin; Sir Joseph Fayrer, London; The Secretary of the Harveian Society; The Secretary of the West Kent Medico-Chirurgical Society; Dr. Wm. Duncan, Shetland, N.B.; Dr. C. Theodore Williams, London; Dr. J. Mitchell Bruce, London; Mr. John Chatto, London; Dr. Thomas Barlow, London; Mr. B. R. Wheatley, London; Mr. C. J. Cullingworth, Manchester; Mr. J. Hancocke Wathen, Fishguard, Pembrokeshire; Dr. Graily Hewitt, London; Mr. T. M. Stone, London.

BOOKS AND PAMPHLETS RECEIVED—

Henry Gray, F.R.S., Anatomy, Descriptive and Surgical—I. B. Lyon, F.C.S., Surgeon-Major, Food Tables—Dr. Wilhelm Roth and Dr. Rudolf Lex, Handbuch der Militar-Gesundheitspflege—Transactions of the Medical Society of the State of Pennsylvania, 28th Session—Dr. C. Binz, The Elements of Therapeutics, translated by Edward I. Sparks, M.A., M.B. Oxon.—Isaac Ott, A.M., M.D., The Action of Medicines.

PERIODICALS AND NEWSPAPERS RECEIVED—

APPOINTMENTS FOR THE WEEK.

December 15. *Saturday* (*this day*).

Operations at St. Bartholomew's, 1½ p.m.; King's College, 1½ p.m.; Royal Free, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.

17. *Monday.*

Operations at the Metropolitan Free, 2 p.m.; St. Mark's Hospital for Diseases of the Rectum, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.

Medical Society of London, 8½ p.m. Dr. Andrew Clark, "Prognosis of Certain Forms of Heart Disease."

18. *Tuesday.*

Operations at Guy's, 1½ p.m.; Westminster, 2 p.m.; National Orthopædic, Great Portland-street, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; West London, 3 p.m.

Pathological Society, 8½ p.m. Professor Lister, "On Lactic Fermentation, and its Bearings on Pathology." (Mr. Lister's Specimens will be ready for inspection at 8 p.m.)

19. *Wednesday.*

Operations at University College, 2 p.m.; St. Mary's, 1¼ p.m.; Middlesex; 1 p.m.; London, 2 p.m.; St. Bartholomew's, 1½ p.m.; Great Northern, 2 p.m.; Samaritan, 2½ p.m.; King's College (by Mr. Wood), 1½ p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.; St. Peter's Hospital for Stone, 2 p.m.

20. *Thursday.*

Operations at St. George's, 1 p.m.; Central London Ophthalmic, 1 p.m.; Royal Orthopædic, 2 p.m.; University College, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; Hospital for Diseases of the Throat, 2 p.m.; Hospital for Women, 2 p.m.; Charing-cross, 2 p.m.; St. Thomas's (ophthalmic operations), 4 p.m.

Harveian Society, 8½ p.m. Dr. Graily Hewitt, "On the Mechanical System of Uterine Pathology."

21. *Friday.*

Operations at Central London Ophthalmic, 2 p.m.; Royal London Ophthalmic, 11 a.m.; South London Ophthalmic, 2 p.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. George's (ophthalmic operations), 1¼ p.m.; Guy's, 1½ p.m.

Medical Microscopical Society, 8 p.m. Dr. Urban Pritchard, "On the Cochlea of the Ornithorhynchus." Special Meeting to consider Mr. Golding-Bird's resolution.

VITAL STATISTICS OF LONDON.

Week ending Saturday, December 8, 1877.

BIRTHS.

Births of Boys, 1266; Girls, 1169; Total, 2435.
Average of 10 corresponding years 1867-76, 2228·9.

DEATHS.

At the Royal Observatory, Greenwich, the mean reading of the barometer last week was 29·79 in. The lowest reading was 29·28 in. on Thursday afternoon, and the highest 30·10 in. at the end of the week.

* The figures for the English and Scottish towns are the numbers enumerated in April, 1871, raised to the middle of 1877 by the addition of six years and a quarter's increase, calculated on the rate which prevailed between 1861 and 1871. Salford, however, forms an exception to this rule, as the estimate is based upon the rate of increase of inhabited houses within the borough during the six years ending July 1, 1877. The population of Dublin is taken as stationary at the number enumerated in April, 1871.

ORIGINAL LECTURES.

IS HEBRA'S PRURIGO MET WITH IN ENGLISH PRACTICE?

By JONATHAN HUTCHINSON, F.R.C.S.,
Senior Surgeon to the London Hospital and to the Hospital for Diseases of the Skin, and Surgeon to the Moorfields Ophthalmic Hospital.

PROFESSOR HEBRA'S DESCRIPTION OF PRURIGO—HIS ASSERTION OF FREQUENCY—RARITY IN ENGLAND—RESEMBLANCES AND DIFFERENCES IN ENGLISH CASES—TEST OF TREATMENT—PRIMARY LESION—GROUPS OF PRURIGO CASES—IMPORTANCE OF THE TOPIC.

GENTLEMEN,—In Hebra's work on Skin Diseases you will find a valuable chapter on "Prurigo."(a) As the result of long study of the local causes and clinical history of cases attended by persistent skin irritation, Hebra has arrived at the conclusion that there is a not uncommon form which is wholly distinct from all the rest, and for which he claims the term "Prurigo" to the exclusion of all others. He teaches that this malady has its origin in the nerve-structures of the skin, and that it occurs quite independently of local irritants, beginning spontaneously, and invariably in early life; and that there is nothing in the way of diathesis or health-condition which can be suggested as its cause. He further asserts that although it varies at different periods of the year, and is sometimes much relieved during hot weather, and may also be considerably benefited by local treatment, yet that it is essentially incurable.

He speaks of this malady as if it were tolerably common, and says that he has seen a thousand cases, and his description of it is most graphic and complete. Itching is of course its most prominent symptom, but is always preceded and attended by papules. These papules are sub-epidermic, as big as hempseeds, and differ little if at all from the colour of the skin. They may appear on all sorts of places, with, however, a definite tendency to prefer certain regions, and with the exception that the palms and soles and the flexures are never attacked. The skin is liable, as might be expected, to secondary changes in the later stages of the disease and when the scratching has been long continued. Thus it will become discoloured by pigmentation, eczematous, or thickened by chronic œdema; but these conditions, when they occur, are always secondary to the original malady. The terms in which the incurability of the malady is asserted are very strong. "He may do whatever he pleases, his malady will follow him to the grave. Only those who are unacquainted with this disease in its entire extent can assert that it is with difficulty curable. No, it is not with difficulty curable, for then it might under certain conditions be cured; it is incurable. Hence all that the physician can do is to use means by which the sorely tried sufferer's lot may be rendered more tolerable and he be prevented from falling into utter despair."

Hebra considers that his disease corresponds pretty much to Willan's descriptions of *Prurigo mitis* and *formicans*, and he asserts that it is a disease of the skin itself, and discredits the hypotheses which would associate it with the nervous system or the blood, equally with those which would assign it to local irritation. As I have already said, he insists that the first stage is papular, and states that he would prefer to use the term "pruritus cutaneus" for other conditions in which itching precedes the development of papules. It is, perhaps, needless that I should add that he of course draws the strongest line of demarcation between this disease and the large majority of those which have been described under the name of *Prurigo senilis*, and which are, as a rule, due to the irritation of lice.

We must receive anything which comes from the pen of such an acute observer with the utmost respect and consideration, and if we differ we must do so with great caution. Yet in again bringing before you this summary of Hebra's description of the prurigo which may not improbably in future bear his name, I feel bound to state in the first place that I suspect that some of its features are too sharply drawn. At any rate, it has been a matter of much surprise amongst English observers in dermatology that we meet with exceedingly few cases which at all closely fit with the definition of Hebra's prurigo. In infancy we have a considerable number of patients in whom the malady seems to be threatened, but although they are often very intractable cases, yet we believe that, as a rule, they get well in the end; at any rate, they do not return to us in adult age. Then, on the other hand, we do meet with certain cases which closely correspond in most points to Hebra's description, but which have begun much later in life, and have had perhaps a duration of only a year or two. As a minor matter, I may add that some cases, in other respects the most closely resembling the disease in question which I have ever seen, differed from Hebra's statement as to the influence of season in that they always displayed a strong tendency to improvement in winter. Indeed, I believe I might say, to sum up, that I have scarcely, although carefully on the look-out for many years, seen a single example of severe prurigo in an adult with the history of its having existed from infancy. One of the two cases which I detailed in a former lecture is still uncured, and it is quite possible may prove incurable. Should it do so, it will, I believe, come the nearest to conformity with Hebra's descriptions of any that I have ever observed. But it must be noted that the eruption did not show itself in infancy, but with the first menstruation at the age of eight.

Now, the question of the identity or otherwise of these several maladies seems to me to resolve itself into this: Are they really due to the same cause or class of causes? If they are, we shall find them occurring in the same class of patients, and remediable for the most part by the same methods of treatment. A name is nothing if it does not help us either in prognosis or in treatment. If it merely attaches itself arbitrarily to some one prominent feature which, although indeed very conspicuous, is after all the common property of a number of really different things, it is in danger of becoming an incumbrance rather than a help. I have been told by gentlemen familiar with the practice of the Vienna *clinique* that the cases which I call "winter prurigo" are really the prurigo of Hebra, and that the facts that they do not begin in children, and that they almost invariably get quite well in warm weather, are by no means important. I am told also that cases such as that of P. and of Harriet S., in which the eruption is worse in summer, often gets well in winter, and affects the face by preference, are also, in spite of these discrepancies, well-marked examples of Hebra's prurigo; and lastly, that the very numerous cases of pruriginous lichen in infants are also instances of Hebra's prurigo in its first stage. But if we are to widen the term so much as this, it seems to me that the description to a large extent loses its clinical value. It becomes no longer true that Hebra's prurigo is a disease which always begins in infancy, that it is usually made worse by cold, that it affects the face only secondarily, or that it is incurable. We find, on the contrary, that those examples of it which begin in infancy result in recovery (although admittedly after long periods of treatment); that those which are most intractable (cases of the P. and Harriet S. type), although they sometimes begin in infancy, very usually do not appear till after puberty, are made worse by heat, cured by cold, and usually have the face first affected. The cases have in common the features that the eruption is difficult to treat, very prone to relapse, and for the most part very pruriginous. Here their similarity, in the main, ends, and I am not at all sure that we might not find the solution of the matter in admitting the simple fact that when once the skin has been made very irritable over a long period, by whatever cause, it becomes very liable to take on the same condition again;—*once pruriginous, always pruriginous*, seems to be the thread of connexion which runs through the subject. This seems to me the point for the appreciation of which we are chiefly indebted to Hebra, and it is undoubtedly an important one, although I cannot help thinking that his expressions in respect to it are much too strong.

My remarks as to the differences which exist between the several groups of prurigo cases have thus far had reference chiefly to their clinical history, but if we take also the question of treatment, we shall find my inferences, I think, fully borne out. You cannot prescribe for "prurigo" in one and the same manner if it is to include all these different groups. The cases which result from varicella or other exanthems may be expected to gradually wear themselves out, and, so far as we yet know, the most that the prescriber can do is to alleviate the itching by the use of tar baths and by preventing scratching. They are uninfluenced by weather or climate. The sufferer from winter prurigo will be quite well if you can send him to a warm climate, and he will be very much helped, even

(a) See vol. ii. of the New Sydenham Society's Translation.

through an English winter, if you insist upon his wearing double-thick woollen clothing. The sufferers from the relapsing prurigo which is aggravated in the summer must avoid exposure to heat, and especially protect the face from the sun, and in not a few cases the liability to this form seems to be diminished by the use of arsenic. It would seem, indeed, to be allied in part to the acne of puberty, and in part to the dartrous state. The pruriginous lichen of infants is to be cured by preventing the child from scratching, by the use of the Persian powder to prevent the attacks of fleas, etc., and by spirit or tar lotions. Thus you will see, I think, that the question whether we consider prurigo as a peculiar malady, the cause of which is unknown and the course of which is uninfluenced by treatment, or whether we rather regard pruriginous irritability of skin as a symptom which may be evoked in connexion with several very different causes, is not without its important practical consequences. One is, indeed, almost tempted sometimes to think that it would be more convenient to deny that there is any malady deserving the name of "prurigo," and that we ought rather to think of pruriginous irritation as a symptom which may attend a large number of different skin diseases. If, indeed, we are offered no alternative, if we are not to be allowed to append qualifying adjectives to the word, but are to speak of prurigo as a clinical entity in the same sense as we speak of psoriasis as one, then I unhesitatingly avow my conviction that it would be better to forget it.

We must say just a few words as to the primary skin lesion which attends cases of prurigo, or rather, perhaps we ought to say, the different kinds of lesions which are present in pruriginous cases. Hebra makes it an important point in the description of his disease that there are minute papules which are not developed by scratching, but which precede it. Although, as has been well suggested by Dr. Hilton Fagge, it is almost impossible to feel certain on this point, since we scarcely ever see prurigo cases before the skin has been scratched, yet it is highly probable that this statement is, to some extent at least, true. Very intelligent patients suffering from prurigo will say that they are able to discover on a surface of skin which is quite pale, little, intensely irritable spots, which, when once found, it seems almost a matter of necessity to try to dig out with the nail. The suggestion of Hebra that such spots are really inflamed nerve-papillæ, with possibly a little effusion over their summits, is one which is well worthy of being kept in mind. It is these which, when surmounted by a blood-crust, resemble so exactly the results of bites of lice. But by far the majority of the minute papules which are present in prurigo cases are, I cannot have the least doubt, of the nature of lichen. We have defined lichen to consist of prominent hair-follicles, with more or less of growth—to be, indeed, a morbid aggravation of the physiological state *cutis anserina*. On pruriginous skins at different times, or often at the same time, you will see all gradations from the slightest form of cutis anserina to the most developed lichen. No one can, I think, doubt that there are lichen spots which are irritable, and which, in many instances, induce scratching. Acne is, as we have said, a disease of almost the same structure as lichen, but with more tendency to accumulation of secretion in the sebaceous glands and to inflammatory processes. As might be expected from this fact, we have a distinct form of prurigo which occurs in the acne positions (face and shoulders) and at the acne age (puberty and after), and assumes a decidedly acne type.

You must allow me, then, to repeat that, as the result of careful inquiry extending over many years, I am unable to identify any cases that will fit exactly with the Vienna description of "prurigo." We have, of course, many cases which accord well with different parts of that description, but none to which it applies as a whole. In the first place, we have fortunately none which in the least approach it in degree of severity and in resistance to treatment,—none which are protracted from childhood through the whole life. The cases which most nearly approach this feature are those in which the eruption is benefited by cold weather, and in which the face is always a part principally affected. In this group also the pruriginous element is by no means intense. The cases to which I have given the name of winter prurigo agree with Hebra's description in that they are always worse during cold weather, but they depart from it very widely in the facts that the lower extremities are usually first and most severely affected, that the liability never begins in childhood, and that the patients are not only better, but quite well, in summer. It is very probable that this disease may assume in the cold of a Vienna winter a far more aggravated type, and may thus afford the larger number of the examples to which Hebra's statements apply, but it is remarkable on this supposition that we have no mention of the absolute immunity during hot weather. We have in London practice plenty of cases of intractable prurigo in children (Lichen pruriginosus of authors), but although in many examples of this we are quite unable to boast of having really seen our patients cured, yet we have every reason to believe that they do get ultimately well. At any rate, we do not find these cases return for advice at later periods than those of early childhood.

HARVEIAN LECTURES
ON THE
MECHANICAL SYSTEM OF UTERINE PATHOLOGY.

DELIVERED BEFORE THE MEMBERS OF THE HARVEIAN SOCIETY.

By GRAILY HEWITT, M.D., F.R.C.P.,
Professor of Midwifery and Diseases of Women, University College.

Abstract of Lecture II.

In this lecture the relation of the various uterine symptoms to *alterations of shape* of the uterus was considered.

First, it was pointed out that on *à priori* grounds the best form for the uterus must be that originally given to it. External beauty of form and health are generally conjoined. The preservation of its proper form must be equally necessary for the health of the uterus, and for the carrying on of its various important functions.

Pain is the commonest uterine symptom, and, as a rule, the one most seriously complained of. There is—1. Spontaneous pain, not very common, produced by cancer, tumours, acute inflammation, etc. 2. Pain on motion. This is very common. It has been far too little noticed by pathologists. Formerly the author spoke of it as uterine "lameness." But the designation now proposed is *dyskinesia*. Such a term is required to designate symptoms of this kind. Uterine dyskinesia may be slight or severe; the characteristic is that it is produced by motion, and in not a few cases patients are entirely incapacitated by it, and entirely invalided. These pains are too often regarded as fanciful. They have, as a rule, a real cause. This cause is distortion of the uterus. Two propositions might be given—1. Uterine distortions and displacements invariably give rise to dyskinesia. 2. Dyskinesia (referable to the uterus) is invariably associated with presence of uterine distortion or displacement. Proposition 1 is more nearly true than is generally imagined. Proposition 2 is almost absolutely true. Chassaignac (in 1862) attributed such pains to the jars (*ballottements*) of the displaced uterus. This author evidently appreciated the importance of the "deviations" in this respect. Some writers contend that these distortions and displacements give no discomfort: in fact, cases differ. In pure descent of the uterus, with no flexion, there may be little pain. In cases of slight version and slight flexion conjoined, there may be little pain. But decided distortion is, with very few exceptions, always painful. Sometimes, again, congestion is absent, or the uterus has been long in the distorted condition, and has acquired tolerance of it. Particular positions of the body, exertions, lifting weights, stooping, riding, even sitting, often give rise to this pain, uterine distortion being the provable cause. Why do these movements produce pain? Chassaignac thought them due to the jarring of the uterus. Dr. Graily Hewitt attributes them to temporary aggravation of the flexion produced by the exertion. Observation conclusively proves this to be true. Treatment equally demonstrates its accuracy, for the pain is relieved by whatever prevents aggravation of the flexion. The reason why aggravation of the flexion gives pain is next considered. Compression and condensation of the uterine tissues at the seat of the bend, and the effect of this compression on the nervous fibres at this point, is the probable cause. Such condensation is inevitable (shown by reference to sponge model of the uterus). Increase of the congestion generally also existing in cases of flexion may account partly for the pain. But the compression and condensation theory is the best. Certain sensations as "sinking," "bearing down," are probably due to stretching of the uterine ligaments. Displacement of the ovary—a rare event—occasions dyskinesia to a severe extent.

Undue sensitiveness of the uterus to the touch was next considered. Observation shows that the uterus is almost never painful to the touch unless uterine distortion be present. The more severe distortions, accompanied by congestion, are those in which the tenderness is greatest. In 1868 the author published a paper to show that Dr. Gooch's "irritable uterus" was nothing more than severe chronic retroflexion of the uterus. Subsequent observation confirms this statement, but severe anteflexion may also give rise to exquisite tenderness to the touch, and to a somewhat similar train of symptoms. Acute sensitiveness to the touch is sometimes located at the internal os in chronic flexions, and is found out by use of the sound.

Menstrual Disorders.—The conditions of healthy menstruation were first described. The uterine secretion, fluid, and mucous membrane *débris* have to pass through a small aperture surrounded by dense tissues. This, the smallest part of the uterine tube, is at the middle of the uterus. The escape should be continuous. The capacity of a tube is greatest when circular; flatten it, and it becomes less. Such flattening occurs even to the extinguishing of the tube when the uterus is strongly flexed; and usually the flexion has effect at the middle of the uterus, where the tube is smallest. The condensation of tissues at this spot also renders less easy any dilatation of the tube. (This effect of flexion was illustrated by sponge model of uterus.) Professional opinion has for some time now inclined in favour of the "obstruction" view of dysmenorrhœa. The author, in 1863, expressed these views. Observation conclusively shows that they are correct. The horizontal positions alone—the prone or supine, according to circumstances—have great effect in relieving dysmenorrhœa, because they partly relieve the existing flexion. The pain indicates expulsive effort of the uterus due to the retention; this expulsive effort partly opens the tube, and partial escape of fluid occurs. Scanty discharge of brown fluid means retention, and partial disintegration of the menstrual blood. Further gushes of puriform or watery fluid observed between catamenial periods—purulent leucorrhœa in gushes—are another result of dysmenorrhœal retention. This is a very characteristic symptom of chronic flexion, though not one always present. These cases are commonly called cases of endometritis. But the endometritis results from the irritation of retained products, and it ceases when the canal of exit is made patent by dilatation or straightening of the canal. A further result in many cases is hypertrophy of the body of the uterus, the result, as Dr. John Williams has remarked, of increased muscular action of the uterus.

Another system is *menorrhagia*. In most instances when not due to cancer, fibroid tumour, etc., menorrhagia is due to uterine flexion. First retention, then expansion, then increase of area of uterine cavity, then increased quantity of blood. Clots now and then form, causing great pain in their expulsion. Sometimes the clots break down; hence sanious subsequent leucorrhœa. Attention was directed to the pouch formed by the flexed enlarged uterus, from which, in the upright position of the body, the fluid cannot readily escape. The flexed constricted uterine canal opposes also this escape. The fluid escapes in gushes.

Thus, dysmenorrhœa, leucorrhœa, and menorrhagia are in very many cases associated with flexions; and the effect, in such cases, of treatment of the flexion element is of itself a sufficient proof of the correctness the relationship indicated between the distortion and the symptoms in question.

THE SOCIETY OF MEDICAL OFFICERS OF HEALTH.—The annual report of the Society of Medical Officers of Health for the year 1876-77 shows that fifteen meetings were held by the Society during the year, in the Scottish Corporation Hall, which was kindly placed at their disposal for the purpose. The Society now consists of 156 members—namely, 36 metropolitan, 69 extra-metropolitan, 18 retired medical officers of health, 15 associates, and 18 honorary members. Dr. Buchanan, who has filled the office of President for the last two years with so much advantage to the Society, has intimated his desire not to be again nominated to that position, this step becoming necessary from the pressure of other engagements. The report contains an abstract of the papers read before the Society during the session, but as many of these have already been reported in our columns, it is not necessary to reconsider them now. The Society presented a testimonial in the shape of a silver jug and two goblets to Dr. J. Northcote Vinen, Honorary Secretary, who has held that post for fourteen years to the entire satisfaction of all the members.

ORIGINAL COMMUNICATIONS.

THE STRUCTURE AND FUNCTIONS OF THE NERVOUS SYSTEM.

By JAMES ROSS, M.D., M.R.C.P.,
Honorary Physician to the Southern Hospital for Diseases of Children, Manchester.

(*Continued from page* 643.)

III.—FUNDAMENTAL PROPERTIES OF THE NERVOUS SYSTEM.

In the previous communication the fundamental properties of nervous tissues were briefly sketched; and it was then seen that on ultimate analysis these tissues consist of cells and fibres, having the correlative functions of origination and conduction of molecular motion. The problem which must now be determined is—how are these cells and fibres put together to form a nervous system? The general law of organisation is that unlike functions entail unlike structures; and inversely, that unlike parts assume activities of unlike kinds. On looking at a simple nervous system, the greatest contrast of parts is shown between certain knots termed ganglia and certain cords termed nerves, which connect one ganglion with another, or with different parts of the organism. And since these parts exhibit the widest structural contrast existing in the nervous system, they will also exhibit the widest functional contrast. The ganglia are composed of nerve-cells with thin connecting processes, held together by a fine connective tissue; and the nerves are composed of nerve-fibres arranged side by side in a bundle, also held together by a firm connective tissue, and the whole surrounded by a fibrous sheath. Functionally regarded, the ganglia are originators of motion, and to some extent conductors also, while the nerves are simply conductors.

In the principal nervous centres of the higher animals, however, the ganglia, instead of forming knots, have come by approximation and fusion to form a continuous mass, which from its colour is called the grey substance; and the conducting fibres, instead of forming cords connecting two separate ganglia, also form a continuous mass, which from its colour is called the white substance. But, besides the central organs and the conducting apparatus, we must distinguish in a nervous system the peripheral terminations of the conducting apparatus—terminations which are specially adapted on the one hand for receiving impressions from environing agents and objects, and on the other for transmuting the molecular motions of the nervous system into the molecular motions of the work organs. It is not intended to enter upon even the most general consideration of the peripheral terminations of the conducting apparatus; hence our subsequent remarks will be confined to the consideration of the conducting apparatus itself, and to the central end organs of this apparatus.

The conducting apparatus, as already pointed out, consists of cords called nerves, and continuous masses called the white substance, both of these being composed of nerve-fibres, which remain unbranched in their whole course. Nerve-fibres are grouped into three classes with reference to the direction in which the energy passes through them—(I.) those which convey impressions from the periphery to a nerve-centre, named afferent; (II.) those which convey impulses from a nerve-centre to a work organ, named efferent; and (III.) those which conduct between two nerve-centres, named inter-central.

I. The afferent fibres are further subdivided into—(1) those which minister to reflex action, that is, those in which the disturbances, conveyed by an afferent nerve to a centre, are immediately transferred to efferent nerves; (2) sensory nerves, or those which convey impressions from the periphery destined to reach the highest nervous centre, which we shall subsequently see to be the organ of mind (they are called sensory, because any disturbance of them produces a sensation which the mind always refers to the peripheral extremity of the nerve); and (3) inhibitory nerves, or those which restrain action. It is generally assumed that there are three distinct kinds of nerve-fibres, corresponding to these three functions; but this is an assumption which is by no means proved as yet. The same system of afferent fibres may administer to the sensory and reflex functions, and it may depend upon various other actions, such as the relative resistance which the inter-central fibres concerned in the operation offers to the conduction of the impression, whether the one or other action, or both of of them, will ensue. The balance of evidence, however, appears to be in favour of the view that distinct fibres exist for

these functions. But the existence of inhibitory nerves is very doubtful. No one doubts the existence of an inhibitory function; the only question which arises is, whether the function is simple or compound. If the function is simple, there will be special nerves to minister to it; but if it is compound, it will be a resultant of the action of nerve-fibres, or of nerve-fibres and cells engaged in other operations. For instance, I throw the flexors of my leg and thigh into a state of rigid contraction, yet there is no movement of my leg, because I have at the same time thrown the extensors into contraction. The one action counteracts the other, and the leg is kept in a state of rest; but although the nerves which supply the extensors have been made to perform an inhibitory function, there are no special inhibitory nerve-fibres concerned in the action. But let us take an example from a more purely inhibitory function.

If the central end of the superior laryngeal nerve after section be stimulated by a gentle interrupted current, the respiratory rhythm is rendered slow or stopped altogether in a state of expiration; while, if the central stump of one of the divided vagi be stimulated, the respiration, which from the division of the nerves had become slow, is quickened again. If the nerve has become exhausted by previous stimulation, further stimulation of the main trunk may cause slowing, or even standstill, of the respiration. In accordance with these facts it is generally supposed that the superior laryngeal branch of the vagus contains inhibitory fibres, while the main trunk contains both accelerating and inhibitory fibres, the former of which largely predominate. It is very doubtful, however, whether there is any necessity to assume the existence of any fibres except the afferent fibres engaged in ordinary reflex action. The afferent impulses are first conveyed to an automatic respiratory centre in the medulla oblongata, which centre possesses a rhythmic action whereby it emits complex co-ordinated impulses of inspiration and expiration. The afferent disturbances brought to this centre by the pneumogastrics modify its regulative impulses according to the requirements of the system. When, however, the afferent fibres are stimulated by a faradic current, the rhythm of the molecular disturbances conveyed by them may be so out of relation to the rhythm of the automatic centre, that fibres which usually excite the centre to action may now arrest the action. It is well known that two strings may be arranged in such a manner that each will produce a musical note when made to vibrate separately, while they may under one set of circumstances produce two musical notes, the one of which harmonises with the other; and under slightly different circumstances produce, not a musical note, but a succession of beats with intervening periods of silence. It is quite possible, therefore, that the different effects obtained by stimulating the central ends of the divided vagi and their branches may arise from the altered rhythm of the afferent impulses acting upon an automatic centre already engaged in action.

But the most remarkable instance of inhibition is offered by the heart. It is found that if the peripheral portion of a divided pneumogastric nerve be stimulated for even a short time by a faradic current, the heart is immediately brought to a standstill, with its cavities flaccid and dilated. Here it is assumed that the pneumogastric contains cardio-inhibitory efferent fibres. There are good grounds for believing that the fibres of the pneumogastrics which end in the heart terminate in local automatic ganglia; and hence these fibres must be regarded as inter-central, and not as true efferent fibres. Hence the cardio-inhibitory action of the pneumogastric is susceptible of the same explanation which was given of the respiratory inhibitory action—namely, that the action of the automatic ganglia is arrested by the loss of harmony between the rhythm of their action and the rhythm of the impulses conveyed to them by the artificially stimulated nerve. This explanation is much strengthened by the fact discovered by M. Onimus, that by duly regulating the rhythm of the galvanic shocks passed through the nerve in correspondence with the cardiac rhythm he could increase the number and power of the cardiac beats. The influence of the vaso-motor nerves in causing dilatation of the minute arteries is another striking instance of an inhibitory action. The general law, as discovered by Ludwig and Lovén, is that when an afferent nerve is stimulated there is reflected back to the part along its vaso-motor nerves an influence by which its minute arteries are suddenly dilated; while an influence is sent to every other part of the body, which slightly contracts the arteries supplying them. There are good grounds for believing that arterial tone is maintained by local peripheral nervous mechanisms present in or near the small arteries, which are connected by inter-central fibres with the central mechanism in the cord. The function of these mechanisms, like the functions of the local automatic ganglia of the heart, may be stimulated or arrested according as the rhythm of the impulses conveyed to them from the centres in the cord are in harmony or out of harmony with the rhythm of their own actions. Loss of arterial tone, therefore, does not necessitate us to postulate the existence of special inhibitory fibres. Everyone is conscious of being able by an effort of the will to stop reflex movements; and when the brain of a frog is removed, reflex actions are developed to a much greater degree than in the entire animal. If the optic lobes of a frog from which the cerebral hemispheres have been removed be stimulated by placing upon them a crystal of sodium chloride, it will be found that the generation of reflex impulses in the spinal cord is greatly interfered with—that is, the stimulation of the optic lobes has inhibited the reflex action of the cord. From these experiments it has been assumed that specific inhibitory centres exist in the optic lobes. But this assumption is by no means warranted by the facts. It is quite possible that waves of disturbance conveyed along afferent reflex nerves to certain motor cells, may be met by impulses conveyed down through the ordinary channels connecting these motor cells with the higher nerve-centres, in such a way that the one molecular disturbance will counteract the other. This is rendered more probable since various other instances may be adduced to show that one nervous action interferes with the execution of another, without anyone ever thinking of ascribing such interference to special inhibitory centres or fibres. If the toes of one leg of a brainless frog are dipped into dilute sulphuric acid at a time when the sciatic nerve of the other leg is being powerfully stimulated by a faradic current, it will be found that either the reflex withdrawal of the foot will not take place, or that the period of incubation will be much prolonged. Goltz observed that, in the case of the dog, micturition, set up as a reflex act by sponging the anus, was at once stopped by sharply pinching the skin of the leg. From these, and many other similar examples which might be adduced, it is evident that two sensory impulses, arriving at the same centre by different paths, may interfere with each other in such a way that either the one counteracts the other, or the stronger current caused by the major disturbance drafts off that caused by the minor disturbance, so that the specific effect of the latter does not take place. These considerations therefore tend to show that inhibition is not a simple but a derivative function; and that, although it may be correct to speak of an inhibitory action, this affords no warrant for assuming the existence of distinct inhibitory centres and fibres.

II. The efferent nerves are subdivided into—(1) motor; (2) secretory; (3) trophic nerves. The further consideration of these nerves may be deferred at present, since the function of the motor nerves does not differ from that of the motor fibres already noticed, and the best evidence of the existence of the secretory, and especially of the trophic nerves, is derived from pathological facts.

III. The inter-central fibres may be subdivided into—(1) commissural fibres, or those which unite ganglionic centres of the same order; (2) centripetal fibres, or those which convey impulses from a lower to a higher centre; (3) centrifugal fibres, or those which convey impulses from a higher to a lower centre. A few words of explanation are necessary. I have used the word fibres instead of nerves in speaking of the inter-central channels, because, although we meet both with commissural, centripetal, and centrifugal nerves, yet the most prominent ganglionic centres have become so amalgamated, that the inter-central channels connecting them do not form nerves; but the fibres are packed along with the centres by means of the neuroglia, so as to form the white substance of the cord and brain. The words "centripetal" and "centrifugal" are generally used as synonymous with afferent and efferent; and Mr. Herbert Spencer was the first to use the word "centripetal" in the sense given to it here, and it will conduce to clearness if a corresponding meaning be given to "centrifugal."

Let us now consider the relations which the nervous centres bear to one another, and to the organism at large; or, in other words, the manner in which the nervous tissues and mechanisms are put together to form a nervous system. We have already seen that unlike parts have unlike functions, and for every distinct part of the organism we may expect to find a distinct function, presided over by a distinct nerve-centre. On the other hand, when the parts have become structurally fused, the functions also have become fused, and we may expect to meet with a similar fusion of the nerve-centres. In the development of an organism the first structural contrast arises between the outer and inner surfaces, represented by

the epiblast and hypoblast of the germ-vesicle. The most fundamental structural and functional differences will therefore be found to exist between the outer system of organs which react on environing agencies, and the inner system of organs which carry on sustentation; and we may expect to find the most fundamental structural and functional differences between the nerve-centres which preside over these two systems. The usual classification of the nervous system into cerebro-spinal and sympathetic acknowledges this distinction, since the first presides over the actions of the external, and the second over those of the internal organs.

But a third layer, called from its position the mesoblast, forms between the epiblast and hypoblast, and this layer gives origin to all the parts of the body consisting of connective tissue, muscles, vessels, and nerves, as well as to the urinary and generative organs. The parts derived from this layer serve to connect together the external and internal organs: and, in so far as the intermediate tissues subserve the functions of the external organs, their functions are regulated by the cerebro-spinal centres; and when they subserve the functions of the internal organs, their functions are regulated by the sympathetic: while, in so far as their function is intermediate between the external and internal organs, but partially independent of them, they have an intermediate and partially independent nervous system, termed the vaso-motor.

(*To be continued.*)

ÆGLE MARMELOS OR BAEL.

By Sir J. FAYRER, M.D.

A short notice of Goa powder had the effect not long ago of attracting attention to, and I hope of extending the utility, in this country, of a remedy much used and valued in India in the treatment of certain forms of skin diseases. I should be glad if a similar result were to follow notice of another Indian remedy that would, I think, also be appreciated and valued were it properly tried—I allude to the ægle marmelos or Indian bael fruit. Of course, I know it is now to be found in most English dispensaries, and that it is perfectly well known (by name) to physicians in this country—but this is in the dry form, when it is old and desiccated, the essential oil and aroma dissipated, and all the merits of freshness gone, in which condition it is probably inert,—or in the form of the fluid extract of the Pharmacopœia, of doubtful efficacy.

Steamers come from Bombay in twenty-six days, and there is no reason, that I know of, why they should not bring the bael fruit quite as fresh and fit for use here as in India; and it is only when fresh and nearly ripe that it is of any real value. In this state it would keep for months, and would be useful in a variety of forms of bowel complaint as in India, especially in chronic diarrhœa and dysentery, or in irregular action of the bowels, when it not unfrequently is said to be as beneficial in constipation as in the opposite condition. Given in the form of sherbet it is pleasant and refreshing, soothing and demulcent, from its aromatic and astringent properties, and from the viscous character of the mucilage that surrounds its numerous seeds.

It is hardly necessary to say that the bael is an orange with a ligneous rind in which there is much essential oil; that its pulp is astringent, and contains numerous seeds embedded in the tenacious mucilage. It is common in India, ripens in the autumn, and could be easily brought to England in the imperfectly mature condition. The bael has frequently been described, and is well known to medical men in India as a valuable remedy—not, as sometimes supposed, in the treatment of acute dysentery, but in certain chronic forms of that and other bowel complaints. Martin, Cleghorn, Grant, Waring, Jackson, and others, have spoken of its good effects. Sir R. Martin in the *Lancet* of 1853, and Mr. A. Grant in the *Indian Annals* of 1854, call attention to it. The latter says, "It is useful in habitual constipation, taken early in the morning, and also in the irregularity of the bowels attended by periods of looseness alternating with constipation as is so often seen in certain seasons in India. It has been given with good results in mucous diarrhœa, chronic diarhœa, and dysentery." In fact, many Indian physicians have spoken highly of bael for such purposes, and to a great extent I can confirm their opinion—at all events, quite sufficiently to say that it is a useful and pleasant remedy for some forms of bowel complaint in their chronic conditions; and to express my belief that it would be a valuable addition to our resources in the treatment of similar diseases here.

The preparations of bael are sherbet, and conserve or marmalade—both pleasant to take.

The officinal are the "liq. belæ" liquid of the Pharmacopœia, and the dry fruit. The non-officinal forms are the best.

For further information on the subject I would refer to the *Indian Annals of Medical Science of* 1853, pages 223 to 234; in articles by Dr. Cleghorn and Mr. Grant, giving a full description of the fruit, its preparations, and its properties, and to a paper by the late Sir R. Martin in the *Lancet* of 1853. I think that the facility with which it could, in these days of rapid communication, be imported, may induce some one to try the experiment.

REPORTS OF HOSPITAL PRACTICE IN MEDICINE AND SURGERY.

NEWCASTLE-ON-TYNE INFIRMARY.

ACUTE CANCER OF THE BLADDER AND OTHER ORGANS.

(Under the care of Dr. BYROM BRAMWELL.)

J. B., aged thirty-four, pitman, single, was admitted on December 16, 1875, suffering from swelling of the right leg and thigh.

Previous History.—Five weeks ago a small lump appeared in the right groin. Four weeks ago the right leg and thigh began to swell. He has been off work and confined to bed since. He has rapidly lost flesh. There has been a dull pain in the right groin. Until five weeks ago he was well and at work. He has been an unusually strong, healthy man. He has not had syphilis. The family history is good.

Condition on Admission.—He looks ill: the features are pinched, the conjunctivæ yellow. He is considerably emaciated. The right thigh is enormously swollen and hard. The skin of the right groin and lower part of the abdomen on the right side is thickened and brawny. A few hard purple pimples stud its surface. The abdomen is swollen, and contains some ascitic fluid. The liver is very much enlarged, measuring eight inches and a half in the nipple-line. The lower margin of the liver is hard and sharply defined; no nodules can be felt on its surface, which is decidedly tender to the touch. The bowels are costive. The spleen is slightly increased in size. The urine contains a trace of bile, but is otherwise normal. The thoracic organs seem normal. The pulse is 100, very weak; the temperature 98·6° Fahr. The patient is stupid and drowsy; he cannot be got to answer questions. The optic discs are normal. The blood is normal.

Subsequent Progress of Case.—Patient rapidly got worse. On December 19 he had a series of severe convulsions; both sides of the body were affected, consciousness was lost, and he foamed at the mouth. On December 20, at the time of my visit, he was insensible, and apparently dying. The eyes were turned to the left side; there was some nystagmus. Slight convulsive twitchings occurred every now and again in the right arm; the mouth seemed slightly drawn to the right side; the pulse was 140; the temperature 100° Fahr. On December 21 he was better, quite sensible, and able to answer questions. There was no paresis. The position of the eyeballs was natural; the discs were healthy. The swelling of the right thigh and groin was rapidly increasing. On December 28 the jaundice was very much deeper, and he was in every way worse. The thickening and tubercular appearance had extended over the right side of the abdomen up to the level of the umbilicus. The amount of fluid in the abdomen had increased. On December 30 he vomited a quantity of "coffee-grounds." On January 1 he died.

The *Post-mortem* was made forty-two hours after death. The skin was of a yellowish-green colour; the conjunctivæ were yellow. The right leg and thigh were enormously swollen. The skin of the right groin and of the lower part of the right side of the abdomen was hard and brawny, and was thickly studded with hard nodules, varying in size from a pin's head to a split pea. The abdomen contained a considerable quantity of yellow serum. The termination of the small intestine was firmly bound down to the right iliac fossa. The pelvic cavity was filled with a dense mass of new growth. This mass, which was harder than cartilage, surrounded the urinary bladder and rectum. The walls of the bladder were infiltrated with new growth, and were fully three-quarters of an inch thick; the vessels

going to and from the right lower extremity were pressed upon and partly obstructed. The mass of new growth extended upwards along the front of the spinal column, surrounding on all sides the aorta. Both ureters, in passing through the pelvic mass, were partly obstructed. The left kidney and left supra-renal capsule, pancreas and duodenum, were embedded in the growth. The liver weighed six pounds; its surface was studded with small white nodules, none larger than a pea; a few similar nodules were scattered through the substance of the organ. The walls of the gall-bladder were very much thickened, and contained similar deposits; the gall-bladder contained half an ounce of dark green bile. The spleen weighed six ounces, and was natural; the mesenteric glands were enlarged. The pelvis of the right kidney was considerably dilated; the right ureter, in its upper part, was also dilated—below, as has been already mentioned, it was obstructed. The right kidney weighed eight ounces and a half; its capsule was slightly adherent; on section it was of a dirty yellow colour, the result, apparently, of bile pigmentation; the cortical substance was swollen and congested. The left kidney weighed eight ounces and a half; it presented the same appearances as the right; its pelvis was dilated and studded with numerous small nodules of new growth. The heart weighed fourteen ounces, and was healthy. The pleural surface, especially the visceral layer, was studded with small nodules, identical in every way with those found in the liver and kidney. The right lung weighed one pound fifteen ounces, the left two pounds one ounce; both were œdematous and congested. The bronchial glands were enlarged. The membranes over the surface of the right ascending frontal and ascending parietal convolutions were thickened and adherent to the brain-substance; the adhesions were recent. There was a considerable amount of recent yellowish-green lymph, and numerous small nodules of new growth. These nodules were similar to those found on the surface of the liver, lung, and kidney. The membranes over the left hemisphere and at the base were normal; in the right Sylvian fissure and over the inferior surface of the right frontal lobe there were signs of inflammatory action, but no deposits. The brain was otherwise healthy.

On *Microscopical Examination* the new growth was found to be typically cancerous—a fibrous stroma with loculi containing largely nucleated round and oval cells. The secondary deposits in the liver, kidneys, lung, and brain all presented the same structure. In the skin of the groin and abdomen the division into loculi was not so well seen, but there were multitudes of cells with large oval nuclei infiltrated throughout the brawny tissue.

Remarks.—The case is exceedingly interesting from its very rapid course and from the wide extent of the secondary deposits. The infiltration of the brain, kidneys, lung, and liver in these respects resembled the deposit of miliary tubercle, rather than of carcinoma. The character of the new growth in the pelvis and abdomen was peculiar. I refer especially to the manner in which it had extended along the front of the spinal column, surrounding in a ring of almost stony hardness the aorta and other structures with which it came in contact. I have seen two other cases of a similar character. In one the mass of new growth was more localised, and an abdominal aneurism was closely simulated.

ENLARGEMENT OF THE LIVER AND SPLEEN IN CONGENITAL SYPHILIS.

(Under the care of Dr. BYROM BRAMWELL.)

At the meeting of the Pathological Society of London held on February 6 of the present year, Mr. Hutchinson described some cases of syphilitic enlargement of the liver in the following words:—"In several cases I have witnessed in young persons the subjects of hereditary taint great enlargement of the liver, which has subsequently wholly disappeared. It is difficult to believe that there is any kind of gumma-growth in such cases, and we are obliged rather to fall back upon the hypothesis of mere vascular turgescence. This turgescence may possibly in its turn be due to some disease in the nervous system. I well recollect a lad whose case illustrated what I am saying. He had on more than one occasion such enlargement of the liver that it hung below his navel, and was easily visible as a swelling when he lay on his back in bed. I had had him under observation for many years. He had nodes on almost all his long bones; and his mother, and several of his brothers and sisters, had suffered most severely from syphilis. At length he died. At the post-mortem, which was made by my colleague Dr. Sutton, the liver was found natural, and, excepting some patches of slight thickening of the capsule, showed no changes. . . It seems clear, however, that among the unexpected incidents of constitutional syphilis we meet occasionally with general enlargement of such viscera as the spleen and liver, independent of any of the conditions of new growth, which we recognise as specific and capable of spontaneous resolution."

The following case was apparently an example of this condition:—

B. B., aged twelve, was admitted on October 26, 1876, suffering from enlargement of the liver.

Previous History.—He has always been delicate. Four years ago he was laid up for some weeks with "gatherings" in various parts of his body. A cicatrix, the result of one of these abscesses, is to be seen in the left groin. For some time past he has been under the care of my friend Dr. Drummond, who recommended him to me. The enlargement of the liver has been noticed for several months, and remains stationary.

Family History.—His mother is dead. His father is a dissipated, drunken fellow. He had one brother and one sister; they both died young.

Condition on Admission.—He is small for his age. The forehead is square; the nose shrunken; the teeth somewhat peg-shaped. The nose used to be sore, and it "mattered" for a long time. There is a small cicatrix at the left angle of the mouth. The corneæ are clear. There are no nodes. He is thin and pale; the tongue is clean; the appetite good. The abdomen is very large-looking in its upper half. On palpation the swelling is found to be due to an enlargement of the liver. The inferior border is sharp and well defined; it reaches the umbilicus. Superiorly the liver dulness extends as high as the fourth rib. To the left it can be traced to a point drawn downwards in the line of the left nipple. The surface is quite smooth; the organ seems uniformly enlarged, and can be freely handled without causing any uneasiness. The spleen is also enlarged; its anterior border can be grasped between the finger and thumb when pressure is made with the other hand from behind. The blood is quite normal. The other organs are healthy.

The *Treatment* consisted in the application of the tincture of iodine and of the biniodide of mercury ointment externally; the administration of the syrup of the iodide of iron, iodide of potassium, and cod-liver oil internally, together with a generous diet.

Progress of the Case.—The patient's general condition quickly improved. The enlargement of the liver decreased somewhat; at the time of his discharge (December 28, 1876) the inferior border was an inch above the umbilicus. The lad has been under observation since his discharge. The liver enlargement still continues, but is less than at the time of his discharge.

Remarks.—I was at first doubtful whether the liver and splenic enlargement might not be "waxy." The healthy condition of the urine, the absence of diarrhœa, and the improvement under treatment, were against this supposition. The evidence of hereditary syphilis was not, perhaps, so strong as it might have been; still it was, I think, sufficient to justify the diagnosis.

BORAX LOTIONS.—1. Borate of soda 50 grammes (℥xij.), water 500 grammes (℥cxxij.); four tablespoonfuls to be added to a quart of warm water. 2. Borate of soda ℥j. to ℥jss.; emulsion of sweet almonds ℥xxxij. These lotions are useful in pruritus of the vulva, in aphtha of the genital organs of little girls, and in parts attacked by chilblains.—*Union Méd.*, December 1.

FECUNDITY OF WOMEN IN SOUTH AMERICA.—Dr. Posado-Arango, writing from Antioquia, in Columbia, South America, observes that the occupation of wet-nurse does not exist here, as every woman, rich or poor, suckles her own child until signs of a new pregnancy are apparent, which is usually the case in the ninth month—so that every child is eighteen months older than the one which succeeds it. There are, however, many women who produce children who are in good condition every eleven months. Thus suckling is nowise in opposition to procreation. Every marriage gives rise usually to from ten to thirteen children, and there is a lady here who has thirty (some of them twins) living children. A man, also, who has married three times, has had fifty-one children; and as his last wife is still young, he may perhaps reach his sixtieth child. Women marry early, from thirteen to sixteen years of age, and begin menstruating at thirteen or fourteen. The nature of their nutriment certainly contributes to this great fecundity. Maize forms the principal basis of this; and its influence is also observable with respect to hens and sows.—*Union Méd.*, December 4.

SATURDAY, DECEMBER 22, 1877.

THE SEWAGE AND THE THAMES.

The question of the disposal of our metropolitan sewage, which has for some years lain comparatively quiescent, bids fair to become again one of the most prominent, as it is one of the most difficult, of our social problems. It is now twenty-five years since the first great attempt was made to grapple with the gigantic evils that had arisen from the *laissez aller* policy of former generations. And the attempt was made manfully—no half-measures were used; the enemy was looked straight in the face; and the plan of action, when once decided on, was carried out vigorously, notwithstanding the great financial and engineering difficulties inseparable from an undertaking of such magnitude. For result we have the great main drainage system of Bazalgette—an engineering work of which London may well be proud. But no sooner have we settled quietly down in the belief that our exertions have been crowned with success, and that we have solved once for all the problem of the ultimate disposal of our sewage, than we are told that we have only been preparing a fool's paradise for ourselves; and that while we have been remedying one evil, we have brought upon ourselves another little less formidable. The main object of our endeavours hitherto has been to rid ourselves of noxious refuse, without such refuse becoming a nuisance elsewhere. Even in this, it is said, we have not been entirely successful; and we are now asked to believe that our refuse is becoming a serious impediment to the navigation of Father Thames.

Very soon after the opening of the main drainage system in 1863 it was found that changes were taking place in the bed of the Thames, which in places was gradually becoming filled up by deposits of mud, and that near the southern opening of the drainage works the depth of the water had decreased from seventeen to seven feet, and the bottom was found to consist of mud instead of gravel as heretofore. This discovery gave rise to some consternation, for it was immediately supposed that what was taking place rapidly near the outfalls would be going on less rapidly over the whole bed of the river for some distance above and below those points—that a gradual process of damming-up the river had been begun, which must end in disastrous results.

In 1867 an inquiry into this matter was set on foot, and directions were given that periodical surveys of the river-bed should be made. It was then stated, as the result of the inquiry, that the shallowing process which had taken place was not due to the accumulation of sewage-matter, but to the opening up of a new channel by extensive dredging operations undertaken some time previously, and which, by altering the course of the stream, had deprived the old channel of its wonted scour, and so led to its gradual filling up with mud. The periodical surveys have shown that although the Thames, instead of decreasing, has gradually increased in depth near the sewer-outlets during the past sixteen years, yet the rate of increase has been only half what it was during the previous thirty years. It has been found also that mud taken from the bed as high as Woolwich Reach is largely contaminated by organic matter. These results were embodied in a report presented to the Thames Conservators by Captain Calver, F.R.S., of the Royal Navy. This gentleman appears to doubt that the dredging can have been the cause, or at any rate the sole cause, of decrease in the river's depth. He considers that the surveys show that there is a gradual deposit going on in the river-bed, which, on account of the presence of sewage-matter in it, he regards as mainly due to sewage discharge. If this interpretation of the facts be correct, we cannot consider our sewage question as settled, nor, indeed, as much nearer to a solution than it was five-and-twenty years ago.

How does it happen that sewage thrown into a tidal river is not at once carried out to sea, but hangs about, and finally leaves behind as deposit the solids which it held in suspension?

It would appear that, discharged as it is many miles from the mouth of the Thames, even though the discharge takes place during the early part of the ebb tide only, the sewage does not arrive at the mouth so as to be mingled with and lost in the sea before the tide turns. It is thus carried up the river again, and, oscillating in this way with the tide, its actual rate of progression towards the sea amounts to no more than five miles in a fortnight. It has also been calculated that any given portion of sewage is only finally disposed of at the end of twenty-two days. During the whole of this period the suspended matters are gradually sinking and being deposited in the river-bed.

Granted that such is the case, we must not suppose that these solids are entirely or even mainly composed of fæcal or other organic matters. In London, with its soot and dirt, large quantities of insoluble inorganic material must be carried into the drains by the rain and by other means, and these will for the most part be very much heavier than the insoluble organic materials, many of which will be little, if at all, heavier than water. Hence the deposit will be composed largely of these heavy and, in themselves, harmless substances, which, however, carry along with them some organic particles. Such being the case, it is obvious that the silting-up question is a separate one from that of the disposal of our excrementitious matter; for, were the latter to be withheld altogether from our sewers, there would still be a mud deposit, differing only from that which now exists in so far as it would contain a smaller proportion of organic substances.

We will first deal briefly with the mud question. It is, we suppose, incontestable that the river is the only possible receptacle for our rain and other waste waters. If the evil to which Captain Calver has called our attention be a real one, how are we to avoid it? To us there appear to be but three possible solutions of the problem—either to leave things as they are, trusting to the dredging-machine to keep the bed of the river free; or to filter the sewage before throwing it into

the river (an arrangement which would necessitate the construction of large filtering-beds near the present outfalls); or, lastly, to carry the sewage for such a distance farther down the river before discharging it as to allow of its much more complete admixture with the sea before the turn of the tide stops its progress. The second and last alternatives would involve great outlay, and the probability is that the evil might be successfully combated by the dredge.

The other question—viz., that of the contamination of the river and of the river-mud by excrementitious matter—is by far the more important of the two from the medical standpoint, if we are to believe that this contamination is really going on in any appreciable degree. Captain Calver lays great stress on this point, but his statement is denied by Sir Joseph Bazalgette, who, trusting to the great dilution of the sewage, and the oxidising power of water, considers that the contamination is not enough to be dangerous, and that it can scarcely even be looked upon as a nuisance. Captain Calver, however, adduces one very telling fact, namely, that the river below bridges has of late years become much more fatal to fish than previously—so much so, indeed, that the Dutch fishermen, who twenty-five years ago towed their cargoes of live fish as high as Erith, now seldom come higher up the river than Hole Haven, some twenty miles below. Here we have to deal with the old problem, how to dispose safely of excrementitious matter: to which is now added the question, Can we not utilise it for manure, and thus turn to profit what hitherto has been treated as waste?

The possible solutions to these questions are, roughly, three: either to preserve the excrement in an undiluted form, and thus make use of it—in other words, to adopt the *dry* method of removal; or, secondly, to remove it by water as at present, and to separate it before discharging the water into the Thames, the residue being used for manure; or, finally, without attempting to utilise the sewage in any way, to disinfect it before its discharge.

The dry system, of which the best representative is Moule's plan of disinfection with dry earth, though excellent in small communities and in agricultural districts, may be at once set aside as regards London, for to carry it out it would be necessary to supply not less than 40,000 tons per week of prepared earth. It is needless to dwell upon the impracticability of such a plan.

As regards the other systems, we are afraid it is useless to wait until some financially successful plan shall have been discovered for utilising our sewage. We must be content if we can prevent the pollution of our river; and, considering the importance of doing so, we ought not to complain if we have to pay, even somewhat heavily, to secure this boon. Various schemes have been proposed for accomplishing this end—some with a view to the utilisation of the products, some aiming simply at disinfection—but space will not allow us to treat of these in detail. Suffice it to say that no system of preparation for the purposes of manure has hitherto been found, when applied on a large scale, to yield a financial success. Without wishing to prejudge the question too dogmatically, we cannot but think that our endeavours should be directed, in the immediate future, to the simple disinfection of our sewage; and that, far from expecting to find in it a source of gain, we must be prepared to incur an annual loss, and must be well satisfied if, by paying down a periodical sum, we can free ourselves from an incubus which is one of the worst impediments in the way of our national health.

THE ACTION OF ANÆSTHETICS.

Professor Ranke, of Munich, has published in the *Centralblatt Med. Wiss.*, No. 34, 1877, an account of some experiments he has made on the effect of injecting various anæsthetics into the blood of rabbits and frogs. He was led to the investigation by observing that a 10 per cent. solution of chloral hydrate injected into a rabbit's femoral artery caused well-marked rigidity (Starre) in the muscles which this artery supplied. It is well known that even small quantities of chloroform excite muscular rigidity if injected into the corresponding artery; and, on experimenting further, Professor Ranke found that other anæsthetics besides chloral and chloroform—namely, ether, amylene, bromoform, and bromal hydrate—have the same property of coagulating myosin in the living muscle, and producing rigidity, after a preliminary stage of powerful fibrillary twitchings. He also found that iodoform (which has hitherto not been credited with general anæsthetic properties, although it is said that it relieves *local* pain), if dissolved in ether and injected into an artery, causes rigidity, exactly as does chloroform; such rigidity being much more rapid in its appearance, and more intense, than if ether alone were injected. Hence Ranke concludes that the anæsthetic properties of iodoform are, probably, ordinarily masked by its insolubility. The interesting point about this research is this: that while muscular rigidity is excited by true anæsthetics, a number of powerful astringent substances—namely, tannin, sulphate of copper, corrosive sublimate, sulphate of iron, as well as other bodies like alcohol, trichlor-acetic acid, and distilled water—have no such effect. The only substance among those just enumerated which caused anything approaching to rigidity was sulphate of copper in a 10 per cent. solution; but the appearance of the muscles was different from that produced by the injection of the anæsthetics. Ranke therefore believes that the latter exert a sort of specific influence on muscular fibres.

These experiments are further of interest from the fact that Professor Binz, of Bonn, has lately asserted that the narcotics of the Pharmacopœia possess the property of causing a kind of coagulation of the cortical substance of the brain, which so affects its tissue-changes as to render it incapable (for the time) of exercising the functions which are associated with wakefulness. Now, although Professor Ranke has failed to successfully repeat Binz's experiments as described in the *Archiv fur Exper. Pathol.*, Bd. vi., and therefore refuses to admit that morphia (the particular drug experimented with) owes its effect to a "process of coagulation," he is willing to assume that the general effect of anæsthetics is similar to what Binz believes, and that the various consecutive phenomena of narcotism—loss of consciousness, cessation of irritability, first in the motor nerves and then in the muscles, and lastly muscular rigidity—are to be explained "by a gradually intensifying action on the albuminous molecules of the nerve and muscle fibres." If this be true, the muscular rigidity, with which Ranke's experiments chiefly deal, would, as he remarks, be the most conspicuous terminal link of a chain of connected processes.

That coagulation of protoplasmatic matter may be an essential feature in a nervous phenomenon is shown by the remarkable discovery made by Darwin, that the transmission of the stimulus which causes inflection of the tentacles of the *Droseraceæ* and other insectivorous plants is accompanied by the formation of minute granules in the cells of the glands (in *Drosera*), which gradually aggregate into larger and larger spheres, or into "oval, club-headed, thread, or necklace-like masses of protoplasm," and that such coagulation extends from above downwards through the cells of the tentacles. Now, after a time the coagulated material is redissolved, and the cell-contents become once more clear: and this is the point to which we wish to call special attention, because one of Ranke's objections (*loc. cit.*) to the idea of coagulation as an element in anæsthesia is that such coagulation must be *permanent*. The analogy of *Drosera*—not, of course, an exactly

parallel case, but still one bearing on the question—shows that temporary coagulation may occur in living protoplasm in connexion with a nervous process; so that so far Ranke's objection falls to the ground.

The idea of coagulation as an element in nervous phenomena may be a fruitful one by giving a definite direction to research. Any idea is better than that involved, or not involved, in the old explanation of the narcotic effects of morphia—namely, that it so acted "owing to its property of causing sleep"!

THE WEEK.

TOPICS OF THE DAY.

It is instructive to watch how the necessities of modern civilisation seize upon the most incongruous methods to supply the demand for out-of-the-way adjuncts to personal appearance. A little time ago agents travelled the whole of Europe to negotiate the purchase of human hair from the living and the dead. Now it appears that the price of a human jaw at the seat of the war in Bulgaria is 10 fr., more or less. It varies according to the regularity, soundness, and whiteness of the teeth. In Paris the quotation is 50 per cent. greater at wholesale prices. This extraordinary commodity is conveyed in cases containing 500, and the teeth are extracted after their arrival at the city to which the jaws are consigned. The business on the spot must be exceedingly brisk, otherwise it is fair to assume that the teeth would be extracted before transit.

It would appear that the river Thames is beginning to suffer somewhat severely from the large and continuous discharges of sewage from the outfalls at Barking and Crossness. In the summer of this year the Conservators requested Captain Calver, R.N., F.R.S., to report upon the changes which have occurred in the bed of the river since the main drainage scheme was carried out, his attention being also directed to the analyses by Dr. Letheby and Dr. Williamson of the soil of the river-bed at several points near the main sewer outfalls and Woolwich Reach. Captain Calver's report has recently been issued, and from this it is to be gathered that foul and offensive accretions have recently formed within the channel of the Thames; that a material portion of these accumulations is in the immediate neighbourhood of the metropolitan sewage outfalls, and that they have formed since the outfalls came into operation; that the sewage discharged contains matter in sufficient quantity to account for the mass of the new formations; and that some statements connected with the current action and the purification of the sewage after discharge, brought forward in support of the system of sewage discharge at the metropolitan outfalls, are not tenable. Captain Calver recommends that the Metropolitan Board of Works be called upon at once to dredge away such portions of the accreted matter as interfere with the navigation of the river, and that they be requested to adopt such other arrangements as may be calculated to prevent similar accumulations in the future.

In a recent report the British Consul-General at Bagdad (Mr. Nixon) states that in another outbreak of plague this year in that city there were 1549 deaths registered between April 4 and June 1; but this was a lower mortality than in the last year, owing chiefly to Surgeon-Major Colvill having influenced the Jewish community to quit the city of Bagdad, and to their exodus being followed by that of the Christians and the Mohammedans. The disease scarcely appeared in any other locality, and where it did it was apparently carried from Bagdad.

The annual report of the Local Government Board, in dealing with the working of the Sale of Food and Drugs Act, records that the Act has been found to work well in many parts of the country, although the results of the different analyses show that comparative freedom from adulteration is only to be found in a few counties and boroughs. In most localities many of the samples of food and drugs submitted to the analysts were reported to contain deleterious and foreign substances. In the metropolitan districts, out of 4177 samples of food, 515 were adulterated; and out of 110 drugs, 7 were adulterated. In Staffordshire, 25 per cent. of the foods, and nearly 50 per cent. of the drugs, subjected to analysis were not up to the standard; in the county of Somerset, out of 800 samples of food, 164 were adulterated; in Gloucestershire, 37 out of 605 samples were condemned; in Surrey, out of 502 samples of food and 3 of drugs, 56 and 2 respectively were adulterated. In some of the manufacturing districts the proportion of the adulterated samples was especially large—in Lancashire 142 out of 303, and in Salford 33 out of 85. Similar results were elicited in Hampshire, Bedford, Durham, Warwickshire, Sussex, Liverpool, Leeds, Bradford, Brighton, Southampton, Wolverhampton, Nottingham, Sheffield, and other places. Proceedings were not instituted in the majority of these cases, as the extent of the adulteration did not seem to require the prosecution of the sellers.

In a letter to the *Times*, Dr. Leonard, of Upper Norwood, makes a suggestion which should not be lost sight of. He says:—"While we are receiving many tons of dead meat from the other side of the Atlantic in the most perfect state of preservation, we read with astonishment that eight tons of fish were last week destroyed at Billingsgate Market, being unfit for human food; and we ask the Fishmongers' Company how it is that so much excellent food, caught at our own doors, is allowed to go to waste. Is no effort ever to be made to have chilled cells for the conveyance of so much valuable food from our prolific fishing-grounds to market? On March 20 last, the Bremen Geographical Society gave a dinner of fish from the river Ob in Siberia. The fish had been packed in ice, and forwarded from Tobolsk, and arrived in perfect condition after a journey of 3060 miles, though eighty-three days on the road. A moderate amount of energy and proper appliance seems to be all that is necessary to bring our fresh fish to market from any part of the German Ocean and coast of Ireland."

At a meeting of the Lower Thames Valley Main Sewerage Board, held last week at Kingston, an application from the Heston and Isleworth Local Board to be included in the United District was considered, and it was agreed to express disapproval of the inclusion unless one-half of the cost of making the communication between the sewers of Heston and Isleworth and the main sewer or sewers of the joint Board was borne by the Local Board of Heston and Isleworth. Notice was also received from the Chertsey Rural Sanitary Authority that application had been made to the Local Government Board to include Oatlands, Hersham, and Weybridge in the United District.

General Sir Arthur Cotton last week read a paper at a meeting convened by the East India Association, on the "Prevention and Counteraction of Indian Famines." Famine, he said, had not been prevented, though vast sums had been spent on railways, irrigation, and navigation works; nor had we prevented millions from dying of want. We had failed both in producing food and in bringing it to the starving. In the provision of artificial irrigation and improved transit the way to escape from future famines would be found. It might be confidently concluded that all the great lines of India through the populous points might be opened by steamboat-canals at practicable cost; that all the multitude of old works might be greatly improved and extended; that every district in India might be to some considerable extent irrigated; and that innumerable sites existed for storing water on the grandest scale, as had been done at Poona and Sholapoor. In the discussion which followed the address of General Cotton, his views were for the most part warmly approved of.

At Sheffield, last week, Mr. Wightman, the Coroner, resumed the inquiry on the bodies of two children who had

died, it was alleged, from the effects of vaccination. The children, as well as a third, since dead, were vaccinated at Ottercliffe Provident Dispensary by William Taylor, an unqualified surgeon. Erysipelas and inflammation intervened, and the children died. The Coroner advised the jury that if an unqualified person performed an operation from which death resulted, no matter whether properly performed or not, he was guilty of manslaughter. The jury adopted this view, and returned a verdict of manslaughter against Taylor, who was committed to the assizes for trial. We shall wait for the clear evidence in these cases before commenting on the alleged connexion between the vaccination and erysipelas.

Mr. Rawlinson, C.B., who is superintending the sanitary improvements being carried out at Marlborough House, reports that "all old drains and all tainted subsoil are being removed from the basement of the residence; all drains are being removed, and new drains are being constructed externally; all sink-pipes pass into external traps externally ventilated; all timber floors are being taken up, and the ground surface examined, cleansed, and covered by three inches of Portland lime concrete. These floors will be free from any refuse underneath, and will be fully ventilated. Where the old drains have been removed, new clean gravel is substituted, and the surface is then concreted. The entire basement is, in fact, being examined, freed from tainted material, and is also being concreted. No pains or expense are being spared by the Office of Works to free Marlborough House from a suspicion of sewage taint; and when it is again handed over to his Royal Highness, it will, presumably, be as complete in all sanitary works as such a house can be made."

Another death from typhus fever has occurred in the County Gaol, Salop. An inquest was held last week upon the body of Herbert Hartland, aged seventeen, who was committed at the last Michaelmas sessions for felony at Chetton. The prisoner died the day preceding the inquest. The jury, after a thorough investigation into the cause of the death, returned a verdict that deceased died from typhus fever, and expressed a wish that the attention of the justices should be called to the water-supply of the prison. This is the fifth case of typhus fever which has happened in the gaol this year.

At the monthly meeting of the Town Council of Carlisle, held last week, Dr. Elliot was re-appointed Medical Officer of Health. This post would appear to be by no means a sinecure in Carlisle, for at the same meeting it was reported that Dr. Prescot had called attention to overcrowding in dwellings, and had stated that in several parts of the town he found that overcrowding existed to a considerable extent, and the sanitary laws were seriously transgressed. The members of the Council were reminded what a serious epidemic occurred in Carlisle only a few years ago, and they were recommended to keep this subject before them and see what could be done. The matter was accordingly referred to the Health Committee to be thoroughly dealt with.

Communications from the Local Government Board were read at the meeting of the Metropolitan Asylums Board on Saturday last, one of them approving generally of the views of the managers as to the erection of additional buildings on the site of the schools at Darenth, for imbeciles who have proved incurable while under school treatment; and the other enclosing a highly satisfactory report of the Lunacy Commissioners relative to visits to the Leavesden Asylum. The number of inmates of this Asylum is at present 2048—879 males, and 1169 females.

An Order in Council recently published in the *London Gazette* signifies the approval of the Lords of the Privy Council of a resolution agreed to by the Council of the Pharmaceutical Society, declaring that chloral hydrate and its preparations ought to be deemed poisons within the meaning of the Pharmacy Act, 1868.

THE ACTION OF GLYCERINE.

This subject has recently been investigated by Dr. A. Catillon (*Arch. de Physiologie*, 1877, page 83, and *Gazette des Hôpitaux*, 1877, No. 19), chiefly in relation to nutrition. He found that the addition of 0·5 gramme glycerine to the ordinary green food of guinea-pigs caused an increase of *one-tenth to one-fifth* in their body-weight in a month; whereas a number of the same animals, similarly fed, but without glycerine, remained *in statu quo*, but on the addition of the latter drug gained an equal amount of flesh in the same period of time. The increase appears to depend partly on a development of fat, and partly on diminished destruction of nitrogenised tissues. The excretion of urea is reduced by the use of glycerine. Catillon found that in six days, *without* glycerine, he passed a mean of 23·55 grammes per diem; and in the next six days, with similar diet and thirty grammes glycerine, 17·10 grammes. The effect was not increased by larger doses than 30 grammes—in fact, it was rather diminished by them, and they gave rise to diarrhœa and other signs of disordered digestion. Experiments on dogs did not reveal the presence of retained urea in the blood (*i.e.*, the blood during the use of glycerine is not abnormally rich in urea). No appreciable quantities of the drug can be detected in the blood, and the same is true of the sweat and fæces. The blood of dogs which have had large doses for a very long time appear to contain less than the normal quantity of glucose. As soon as the dose exceeds 20 grammes daily (in dogs), part of the glycerine passes into the urine about an hour after ingestion, and can be detected there for about four hours. Neither albumen nor sugar were ever present in the urine. The temperature of the animals rose from a few tenths of a degree to 1·5° Cent. In moderate doses, not exceeding 30 grammes per diem, which should be taken all as once, diluted with about *ten* times the quantity of water, Catillon affirms that glycerine improves the appetite and the digestion, and acts gently on the bowels. He does not recommend a larger dose, but we may mention that Harnack, in an article on the Treatment of Diabetes by Glycerine, published in 1874 (*Archiv f. Klin. Med.*), gave diabetic patients as much as 180 to 360 grammes daily, in association with animal food, and found a marked improvement in their general condition, and a reduction in the quantity of urine sugar, and urea excreted, the latter two results agreeing with those obtained by Catillon in his experiments on dogs and on himself. It is important to notice that glycerine is a poison in large doses. Fifteen grammes to each kilogramme of body-weight will kill a dog if administered in one dose. This subject has been more fully investigated by Drs. Dujardin-Beaumetz and Andijé (*Union Médicale*, 1876), and they found that subcutaneous injections of eight to ten grammes per kilogramme of body-weight would kill a dog in twenty-four hours. They were followed by hæmaturia and vomiting, and later on by dryness of the mucous membranes and severe thirst, by great muscular weakness, sopor, moderate depression of temperature, and death. Tetanic spasms occur after doses of fourteen grammes per kilogramme, and the temperature rises above the normal. Post-mortem examination showed marked hyperæmia of the liver, kidneys, lungs, and intestinal mucous membrane. How glycerine exerts its poisonous action is as yet unknown.

CHARGE OF AN ATTEMPT TO PROCURE ABORTION.

We are sorry to learn from a Manchester paper that Mr. J. C. White, Senior House-Surgeon to the Ardwick and Ancoats Dispensary, has been committed to take his trial at the next Manchester Assizes on a charge of attempting to procure abortion. It appeared, from the evidence given before the magistrates, that a domestic servant, twenty years of age, became pregnant by her master, a married man with several

children. Before it became necessary for her to leave her situation she had taken savin-tea, a morning draught of gin and Epsom salts, and other popular emmenagogues, supplied to her by her master. These measures failing of their intended effect, her master provided lodgings for her, and in three or four days after she had gone there to reside, he called to say he was going to bring a doctor who would make her all right in forty-eight hours. Accordingly, the same afternoon, he brought Mr. White to see her. Immediately on his arrival the girl was requested to go upstairs with the landlady and undress. She was then about four months pregnant. Mr. White introduced a "sponge," and said the girl was to lie in bed until his next visit. He also left a small bottle of medicine and a measure-glass, with instructions that sixty minims by measure were to be administered in water every four hours. During the next five weeks Mr. White called about a dozen times at varying intervals. On each occasion he passed either a "sponge" or a "little wooden tube." When these had not slipped out of themselves he removed them at his next visit. He also left fresh supplies of medicine from time to time. On December 10 some information was received at the detective office which led to the divisional police surgeon being requested to visit the girl and report upon her condition. This gentleman found the girl lying in bed. She was about six months pregnant of a living child. Four sea-tangle tents, each two inches and a half in length, were found tied together in a bundle, and lying loosely in the vagina. On a chair by the bedside were a two-ounce bottle, about one-third filled with a liquid preparation of ergot, and a minim measure-glass. A pair of forceps, shaped like a pair of large pliers, and an ordinary pocket midwifery case, were lying on the dressing-table. There were no signs of labour, and on the following day (December 11) the girl was able to attend at the magistrates' court and give evidence. The police-surgeon stated, in answer to a question from the Bench, that he saw nothing to justify the induction of premature labour; the girl was well-formed and in good health. On the application of the solicitor for the accused, who said there was a very good defence to the charge, the magistrate said he would accept bail, either in two sureties of £500, or in three of £350. The girl's master was afterwards arrested on a charge of aiding and abetting, and has since been committed for trial.

THE EFFECT OF ACIDS ON THE ANIMAL ORGANISM.

Experiments made by Fr. Walter, in Prof. Schmiedeberg's laboratory, show (*Archiv für Exp. Path.*, vii., 148) that the blood of rabbits is differently affected by the injection of considerable quantities of dilute acid (hydrochloric) from that of dogs. In rabbits the volume of carbonic acid dissolved in the blood is enormously diminished owing to the alkaline bases with which it was previously combined being appropriated by the stronger acid. In one case the volume of carbonic acid fell to 2·07 per cent., whereas the mean of four experiments on healthy animals was 25·81 per cent. The loss of so much carbonic acid was fatal to the rabbits—not, however, *per se*, but because of the abstraction of alkali from the blood by the stronger acid. This was proved by the negative results of the post-mortem examination of the dead rabbits, and by the fact that if acid were injected into a rabbit's stomach, and simultaneously a solution of carbonate of soda were injected under its skin, the animal remained completely uninjured; and further, by the possibility of restoring animals in the last agony, or even after apparent death, to life by the injection of the carbonate. The chief symptom of poisoning by acids is dyspnœa with deep and laboured inspirations. The blood pressure is not materially affected, except by the influence of the respiration on it. The respiratory centre appears to be first stimulated and then paralysed by an excess of acid, and the early restoration of the balance of alkaline power arrests the stage of paralysis at its commencement. In dogs, the amount of alkali which is withdrawn from the blood by combination with a stronger acid than the carbonic is very slight, and it appears that the greater part of the stronger acid serves either to increase the acidity of the urine, or to combine with organic bases and form salts, which can be excreted by the kidneys. The ammonia was found by Walter to be decidedly increased on those days on which acid was administered, an average of 3·671 grammes more than the normal amount being excreted on five consecutive days, or enough to saturate 72·2 per cent. of the acid injected. The reason of the different behaviour of rabbits and dogs, under the influence of acids, is still unexplained, but it is well to remember that the former animals are adapted for vegetable, and the latter for animal food, and it is possible that the excess of acid may, in the case of the dog, be primarily diverted to the gastric secretion, and so prevented from concentrating itself in the blood.

PATHOLOGICAL SOCIETY OF DUBLIN.

At the meeting of this Society held on Saturday, December 15, Dr. E. Hamilton, President, in the chair, Dr. J. W. Moore showed an example of white softening of the brain from embolism of the middle cerebral arteries. Ten weeks before death, the patient, a hitherto healthy woman aged fifty-four, was seized with an apoplectic attack followed by complete left hemiplegia. The heart-sounds were normal and free from murmur, but she had suffered from rheumatic fever twenty-seven years before. There was marked flushing of the left side of the face. No consecutive fever occurred, and for a time she progressed favourably. Symptoms of insanity set in, and she sank into an imbecile state which ended in death. Unfortunately the heart was not examined. The middle and posterior cerebral lobes on the right side, and the posterior cerebral lobe on the left side, were reduced to a pulpy consistence. The cerebral arteries were extensively atheromatous, and the right middle cerebral was plugged by an embolic mass or thrombus. Dr. Lyons made a preliminary communication on the disease termed "black quarter," in the calf. He promised to show at the next meeting the post-mortem appearances in a young bull calf which had died of the disease in the country the previous day after three hours' illness. He regarded the affection as probably dependent on some lesion of the lower part of the spinal cord. Dr. R. J. Harvey brought up a report on the pathological appearances in cases laid before the Society at recent meetings by Drs Banks and Lyons. In Dr. Banks' case, peculiar nodules on the surface and in the substance of the liver of a lad aged ten, the subject of ascites, were simply a caseous degeneration of previous tubercular deposits. Miliary tubercle was found near the caseous masses and in the healthy liver-tissue. In Dr. Lyons' case of "hydronephrosis," the affected kidney showed remains of healthy cortical substance, and lacunæ observed in the medullary portion proved to be dilated straight tubes. A connexion between the kidneys—horse-shoe kidney—consisted largely of true renal tissue, numerous Malpighian corpuscles being found in it. The other kidney was in a state of advanced fatty degeneration. The liver was for the most part quite healthy, although the patient had been very intemperate, and the subject of extreme ascites at one time. The spleen showed hyperplasia of its connective tissue.

PAYING WARDS TO PUBLIC HOSPITALS IN MELBOURNE.

The question of adding paying wards to public hospitals has been engaging the attention of the profession in Melbourne, and Dr. John Blair, F.R.C.S., Surgeon to the Alfred Hospital in that city, has drawn up a report on the subject, which has been published. He is decidedly in favour of setting apart a

special ward or wing of the Alfred Hospital for the reception of a class of patients who are able and willing to pay for their accommodation, who are not able to be nursed and attended to in their hotels and boarding-houses, but who are equally unable to apply to hospitals for gratuitous relief. Dr. Blair states that the Massachusetts Hospital at Boston is conducted on the principle of charging patients who are able to pay. It has four classes—(1) Free beds, but not many; (2) beds free in general, but on which certain persons who have given moneys have a claim for their friends; (3) the beds, constituting the great majority, for which a charge is made of one dollar a day, but part or all of which is sometimes remitted at the discretion of the governor, who is one of the acting medical officers. (No difference is made in the privileges of these three classes, nor is any asked for by the patients.) (4) Some private rooms at five or six dollars a day. Dr. Blair is of opinion that the introduction of such a system would tend to diminish the abuse of gratuitous relief, which is now largely practised by people well able to pay for medical assistance, and in this view he is, no doubt, correct; but in this country, up to the present time, the admixture of paying and non-paying patients in the same hospital has not been found to answer, and the scheme which is already afoot to open separate hospitals for the well-to-do, will, we think, prove the correct solution of the question. In all large cities there are numbers who can get along very well so long as they are in health, but who suffer from want of the commonest attention if sickness or disease attack them: for this numerous class a paying hospital would be an inestimable boon; and if in Melbourne they can add paying wards to the public hospitals without interfering with their utility, the introduction will, no doubt, be financially and philanthropically a great success.

SULPHOCYANIDES IN THE URINE.

According to the recent independent experiments of Gscheidlen and Munk, the urine of man and other mammals constantly contains sulphocyanic acid, which gives with ferric chloride, in urine previously acidified with hydrochloric acid, a reddish colouration. The precipitate which nitrate of silver throws down in ordinary urine is a mixture of chloride and sulphocyanide of silver, and if it be suspended in water decomposed with sulphuretted hydrogen, and filtered, the filtrate gives the ferric chloride reaction distinctly, even if only 200 cubic centimetres of urine be analysed. Human urine contains about 0·0225 sulphocyanic acid in 1000 cubic centimetres in the form of a sodium salt, and 0·0211 NaCNS was found in the same quantity of rabbit's urine (Gscheidlen). Munk estimates that one litre of human urine contains 0·11 NaCNS. The source of the sulphocyanide appears to be the saliva, which always contains sulphocyanide of potassium, and Gscheidlen could detect none in the urine of a dog whose salivary secretions had all been prevented from entering the digestive tract by means of external fistulæ. It is a remarkable fact, observed by Munk, that, in spite of the great solubility of the sulphocyanides, the urine contains sulphocyanic acid in abundance seven or eight days after a dose of sulphocyanide of ammonium. Dr. Thudichum has endeavoured to prove that Gscheidlen's method of extracting sulphocyanogen from the urine in combination with lead (*Pflüger's Archiv*, xiv., s. 401), is faulty; but it appears, from Gscheidlen's reply to his criticisms, that Thudichum did not observe the necessary caution in repeating the former's experiments, and that there is no reason to doubt their accuracy.

ROYAL COLLEGE OF PHYSICIANS.

At a meeting of the Royal College of Physicians of London, held on Monday last, the President informed the College that he had been in communication with a gentleman who wished to offer one hundred guineas for the best essay on rabies and hydrophobia, their etiology, and their treatment, preventive and curative; and this gentleman hoped the College of Physicians would undertake to regulate the conditions under which the prize should be offered, so as to make it most likely to be of real use, and that the College would also appoint three learned and discreet men to adjudge the prize. The College decided to accept the offer of the generous unknown, and referred the subject to the Council to consider the best mode of obtaining the benefits hoped for by the donor, and to report to the College thereon. The President of the College (Dr. Risdon Bennett) and the Treasurer (Dr. Pitman) were, on the nomination of the Council, elected the representatives of the College on the Committee of Reference, and it was resolved that each of the representatives should be paid five guineas for each sitting of the Committee. Dr. Barclay and Sir Alexander Armstrong were elected on the Council of the College, instead of Dr. Fincham and Dr. Barnes, who are now Censors. Twenty-four candidates had presented themselves for the final examination for the College licence, and twenty, whose names will be found elsewhere, had passed, and received their licences. Three candidates had undergone the primary examination, not one of whom was successful. Dr. Michael C. Grabham, residing in Madeira, was admitted a Fellow of the College *in absentiâ*. The President reported that Surgeon-Major J. R. Deane had presented a valuable collection of urinary calculi, with histories of the cases, to the Museum of the College. A report from the Council on the Recommendations of the General Medical Council was read; and the College agreed to act on the Recommendation that "any cases in which decided ignorance in the subjects of general education has been displayed by candidates" during the professional examination, "with the name of the board or boards before which the preliminary examinations have been passed," should be reported to the Registrar of the General Medical Council; it being understood that the names of such candidates are not to be given. With regard to the Recommendation "That it is desirable that the examination in general education be left to the Universities," etc., the Council directed that the attention of the General Medical Council be called to the fact that the College already fulfils the Recommendation; and as to Recommendation 27—"That there be in future three professional examinations"—the College agreed that the consideration of that might be left to the coming Conjoint Board. The College received, with great regret, the news of the death of Dr. Francis Hawkins, and directed that a letter should be written to his family, expressing the heartfelt sympathy of the College on the great loss they and the College had sustained.

ROYAL COLLEGE OF SURGEONS.

At the ordinary meeting of the Council of the Royal College of Surgeons of England, held on the 13th inst., all the members of the Board of Examiners, with the exception of Mr. Birkett (who had resigned), were re-elected; and Mr. W. W. Wagstaffe, of St. Thomas's Hospital, was elected in place of Mr. Birkett. Mr. Simon's motion, to rescind the regulation that all Examiners in Anatomy and Physiology shall be Fellows of the College, was rejected by a very large majority. The Dental Practitioners Bill, which provides for placing on a register, separate from the Medical Register, but by means of the machinery of the Medical Council, all dentists, irrespective of any qualification, with the exception of being engaged, *bonâ fide*, in the practice of dentistry before and when the Bill shall be passed, was approved after much discussion. The Bill takes much the same ground as to qualification, it will be observed, as was taken by the Apothecaries Act of 1815. A letter was received from Dr. Burder, the Secretary of the Faculty of the Bristol Medical School, explanatory of certain difficulties that had arisen in the way of the affiliation of the School with the Bristol University College; and the Council resolved that Dr. Burder

be informed that they adhered to their former resolution, though they regretted that "the 'amalgamation,' or rather 'affiliation,' of the Bristol Medical School with University College—as the latter now appears to be the more correct definition of the intention of the authorities of the Medical School—should be in any way delayed by their resolution of October 18 last, inasmuch as the Council hoped that the said 'affiliation' would bring about an improvement in the accommodation for teaching in the School, which the Faculty seem to admit is not now adequate to the just requirements of students." Mr. Hancock's motion for doing away with the students' registration at the College had to be postponed from want of time for its consideration: but we believe that there is little doubt that it will eventually be agreed to.

A SIMPLE PLAN OF EMPTYING THE PLEURAL CAVITY.

Simplicity is a merit even in surgery, and hence the method of evacuating pleuritic effusions recommended by Dr. Girgensohn, of Riga (*Berlin. Klin. Woch.*, No. 48, 1877), deserves notice. He taps the chest with an ordinary canula and trocar, withdraws the latter, and slips over the end of the canula a caoutchouc tube three to six feet long, and of a suitable diameter, closed at the lower end with a clip or a small stop-cock, and filled with a 1 to 2 per cent. solution of carbolic acid. The tap is then opened under the surface of a solution of carbolic acid in a large vessel placed at a lower level than the opening in the chest, so that the tube is converted into a syphon. A serous effusion of six to eight pounds weight can be in this way evacuated in a quarter of an hour. If the stream stops from any cause, the tube can be alternately compressed and allowed to expand, so us to exert a pumping action on the fluid higher up. Where it is absolutely essential to prevent air entering the chest, Girgensohn recommends the trocar to be passed through the wall of the caoutchouc tube, into the upper end of which the canula is tied; the tube is then filled with carbolic solution from a funnel inserted into the raised lower end, so as to completely expel all air. The trocar is inserted with the canula into the chest, and withdrawn gradually until the necessary communication between the chest and the tube is established, and then completely withdrawn, and the tube slipped forward over the canula and tied, so as to close any opening left by the trocar. The fluid is then drawn off siphon-fashion as before. The author claims for his method the advantages of simplicity, of avoiding the continued presence of a sharp instrument in the chest during the operation; of being uniform in its action and easily regulated; and, lastly, of permitting the whole apparatus used to be cleansed and kept in order without the slightest tronble.

THE PATHOLOGICAL SOCIETY.

Members of the Pathological Society will observe that the next meeting will be held on Friday, January 4, instead of on Tuesday, January 1. This change of arrangement was agreed to at the very full gathering on Tuesday evening, and was made on account of the small attendance on previous years when a meeting fell upon the first days of January.

ROYAL INSTITUTION OF GREAT BRITAIN.

A course of six lectures (adapted to a juvenile auditory), on Heat, Visible and Invisible, will be delivered by Professor Tyndall, D.C.L., LL.D., F.R.S., on the following days, at three o'clock:—Lecture 1, Thursday, December 27, 1877; 2, Saturday, 29th; 3, Tuesday, January 1, 1878; 4, Thursday, 3rd; 5, Saturday, 5th; 6, Tuesday, 8th. The following are the probable subjects of the course:—Heat produced by friction. Heat produced by combustion. Heat produced by electricity. Heat of rusting metals. Animal heat. Heat of the sun. Ice and water. Boiling and evaporation. Cold of liquefaction. Cold of vaporisation. Heat of solidification. Heat of condensation. Expansion of bodies by heat. The force of heat. The propagation of heat—*a*, by convection; *b*, by conduction; *c*, by radiation. The production of wind, rain, snow, dew, and hoar-frost, by heat and cold. Passage of heat through transparent and opaque bodies. Invisible heat. Ebullition, incandescence, and combustion at invisible focus. Invisible heat images. The condition of heat in stellar space. Inner meaning of heat.

MURDER OF A POLISH PROFESSOR OF SURGERY.

The town of Warsaw was thrown into great commotion on November 15, by the news of a murderous assault on Dr. Girsztowt, Professor of Surgery, and a man universally respected by all classes of society, He was the founder and editor of one of the Polish medical journals, and the publisher at a printing-office under his own management of a number of medical works in the Polish language. The jealousy of a journeyman printer in his employ led the latter to attack Dr. Girsztowt with a knife at the door of his consulting-room, and he inflicted a severe wound in his left thigh, dividing the profunda femoris, and giving rise to tremendous bleeding, which was with difficulty checked. The wounded man died of gangrene of the left leg on the eighth day. The general expression of grief and regret which his death has elicited shows clearly how great a loss medical science has sustained in Poland.

UNVEILING OF THE STATUE OF THE LATE DR. GRAVES AT THE COLLEGE OF PHYSICIANS, IRELAND.

Of this interesting event, which took place on the afternoon of last Wednesday, in the presence of his Grace the Lord Lieutenant and a large assemblage, we hope to give a detailed account next week.

For some time past a difficulty has been experienced by the Borough Coroner at Wolverhampton in holding inquests on persons who have died in the Wolverhampton Hospital, owing to the refusal of the Hospital authorities to direct their officials to attend as witnesses. Last week, in consequence of a similar refusal, the Deputy Coroner was compelled to issue summonses against the Matron, House-Surgeon, and one of the nurses, before he could secure their attendance.

Subcutaneous Injections of Chloroform.—In a note addressed to the Société de Thérapeutique (*Gaz. des Hôp.*, Dec. 14), M. E. Besnier details the results of numerous trials which he has made at the St. Louis, of the hypodermic injection of chloroform, first practised by Dr. Roberts Bartholow in 1874. There has been, he observed, but little published upon the subject, probably because these injections have been used only for a limited purpose (the treatment of neuralgia), instead of employing them for the relief of every kind of pain. Their great advantage, he considers, consists in the fact that they may be employed in this manner, and thus supersede morphia with its consequent inconveniences. No ill effect whatever, local or general, follows these injections, and yet they are efficacious. But the mode in which they are made is of importance, for, inefficiently performed (which is very commonly the case), they may give rise to local phlegmasia. They should always be practised in two stages, the needle being first separated and introduced alone, so that if it happen to penetrate a vein this may be made known by the issue of a droplet of blood. When the syringe has been reapplied, in order to prevent local irritation being caused, the injection should be propelled *into* the hypodermis (*i.e.*, the subcutaneous cellulo-adipose layer, which varies in thickness in different regions and individuals), which not only possesses a special tolerance and insensibility, but a very active absorbent power. If the point of the needle be very fine and sharp, it may be passed through the skin into this tissue without appreciable pain, which, however, will be felt if it be carried too far, so as to reach the muscles, etc. The needle is manœuvred with the greatest facility as soon as it has passed the dermis, its point being easily guided to any part of the hypoderm. This done, the syringe may be adapted, and the injection made with the greatest security.

THE SICK AND WOUNDED IN THE RUSSO-TURKISH WAR.

We have received from the Stafford House Committee the following abstracts of Reports from their Surgeons to Mr. Barrington Kennett, Special Commissioner to the Stafford House Committee. The demands on our space unfortunately make it impossible to publish the Reports more fully:—

Dr. Stiven (Rustchuk), November 10, 1877, writes:—"During this past week we have admitted into the hospital three other patients, thus bringing the total number of patients treated up to 151. From this number three patients have died, two of whom had perforating wounds of chest and lungs, and the third was wounded in the leg, but succumbed, not from his wound, but from a severe attack of typhoid fever. The patients discharged and fit for duty have been eight, thus leaving a total of 140 patients at present in hospital under treatment. A separate ward of ten beds is being prepared for the reception of officers, but the actual number of beds from 200 has not been increased. There not being sufficient room in the *fabrique* buildings for all the *infirmiers* to occupy one room and be always near the ward, I have formed a 'Zimlick,' or mud-house, for their accommodation. A second will also be formed for the cook and kitchen servants, as they at present occupy a tent, which will not be sufficient protection during the winter."

On November 18:—"The beginning of this week saw 140 wounded still under treatment in this hospital, and this number was not increased by any new arrivals. Twenty patients have been discharged to their battalions fit for service. We had three deaths this week—one a case of severe wound of the knee-joint; one a case where the ball entered the shoulder-joint, death being caused by an attack of acute bronchitis; and the third a case of wound in the leg, death being caused by pyæmia. Beyond these deaths everything continues satisfactory. The total number of patients under treatment is at present 117."

And on November 20:—"We are now as hard at work as we can possibly be. Our hospital contains 180 patients, and I expect the other empty beds to be filled to-morrow, as forty-four wounded are at present lying at Kadikeni, in the Turkish hospital, ready to be passed on to us. The cases we have received this time are serious, and require a great deal of attention to insure good results. Yesterday we had a grand battle in this neighbourhood, extending from Pyrgos to Popkoi. The firing was continuous, and lasted all day. The Russians got thrashed, as usual. Lake and I went out towards Pyrgos, but were too late to be of service there, so we went on to Kadikeni, where the fighting was recommencing. I left Dr. Lake there with the Turkish doctors to assist in dressing the wounded, and I returned to hospital to receive others there. I found Dr. Beresford with Mehemed Effendi, hard at work upon the wounded sent in from Pyrgos. We got them all safely into bed about 5.30 p.m.—sixty four in number, leaving only sixteen beds empty; and as two have died and two have been sent to their battalions, we have now twenty beds ready for new comers. I am making other ten beds for officers on account of this fighting, which will continue if this weather lasts, and they will not add much to the expense. Try and send us some good amputation cases: we want them more than ever."

Dr. Pinkerton (Erzeroum) writes thus on November 14:—"Denniston and I arrived here on Sunday, November 4, the day of the battle of Deve-Bouyonon. Next day we went to the hospital, and helped Fetherstonhaugh and Guppy to dress their cases; a number of new men had come in from the battle of the day before. We went on quietly dressing till Friday, when we were awakened about 4.30 a.m. by the sound of guns; the Russians had attacked Erzeroum. We got everything ready, and were at work dressing the wounded in the field at 7 a.m. We remained at this place till 1 a.m., and then, as the number of the wounded coming in had diminished very considerably, we elected to go right into the fortifications. Besides we four, there were two Turkish surgeons, and an English surgeon in the Turkish service. We calculate that we four passed pretty nearly 1000 wounded through our hands. At the fortifications we were directed to go to a barrack; there we saw about 150 more wounded, a few more cases were dressed in the trenches, and then about 3 p.m. we left, as there was no more work to do. The transport service from where the wounded were dressed was fairly well done, as they were dressed rapidly and roughly, taken to the different hospitals. Next we went to our hospital, when we found about 150 new cases, a great number of whom had to lie on the floor, as their number far exceeded that of our beds, but we did everything we could to make them comfortable, distributing blankets, tobacco, and water; besides, every new case had a hypodermic of morphia. We made inquiries also, and found that they had all had ood. Next morning we discharged every patient we could, to give us as much room as possible; we have discharged about seventy, about forty have died, and at present we have about 130 in the hospital. We have amputated three legs, four arms, and a large number of fingers, all the results of Friday's fighting; quite as many men remain to be done; and a number have died who refused to submit to operation. As the fighting was at very close quarters, most of the bullets went right through the part of the body struck; consequently, we have not extracted a great many. We have lately adopted a new plan in order to persuade men to submit to operation. A Kurd, whose arm Fetherstonhaugh amputated, is sent to any man who refuses to submit to operation; he argues the point with them, and in many cases is successful. On Monday night (November 12), about 8 p.m., the Russians attacked again, but we got no fresh cases; in fact, we have given notice that we can receive no fresh cases at present. Three days ago Mr. Zohrab sent a telegram for lint and guttapercha tissue; these are urgently needed. If you could also manage to send me by post a couple of pairs of artery forceps, I should be greatly obliged. Weiss has forgotten to put one in my amputating case, and the pair in my pocket-case I found broken when I opened it. Meantime Fetherstonhaugh has lent me a pair."

Dr. Fetherstonhaugh, writing also from Erzeroum on Nov. 14, says:—"I am sorry to have to acquaint you with the illness of Dr. Guppy. He was with us at the hospital on Monday morning, when he had to leave, and has been ever since feverish, with a severe headache, and very weak. We have had a busy time since last Friday, when at 4.30 a.m. the Russians attacked the eastern forts, got into one of them, but were driven out at the point of the bayonet, and finally repulsed. We were all at work by daylight at a bridge close to the town, over which most of the wounded should come. In a couple of hours we were joined by two Turkish surgeons, who worked well; and at about 11 a.m. by Dr. Hughes, T. O. Army, and Mr. Cole, American missionary. At 1 p.m., as we saw the wounded were not coming so thickly, we went up to the forts and dressed a number of cases which could not be moved till they were looked to. We had finished there by 3 p.m., when we went to our hospital and found the place crammed full, every available spot having a man in it. We distributed blankets, beef-tea, tobacco, and morphia injections, etc., and had the poor fellows fairly comfortable by 8.30, when, thoroughly worn out, we came home. At the bridge and forts nearly 1000 had their wounds attended to, and about 150 were admitted to our hospital; nineteen of those died during the night, some few others next day. On Saturday we discharged every case fit to be moved, and so made room for the new men, most of whose wounds were very severe. We have extracted a number of bullets, amputated three legs, four arms, and a number of fingers since, and have as many more to do. Drs. Pinkerton and Denniston arrived just at the right time, and without their aid I should never have been able to get on. Mr. Zohrab telegraphed to you for lint, charpie, and guttapercha tissue, as we are sure to have another attack soon, when the calls upon our stores will be very large. The latter, even the largest case, is nearly used up. On Saturday we were at work from before 9 a.m. till 7 p.m., on Sunday from 9 to 6.30, Monday from 9 to 5, yesterday from 8.30, and to-day from before 9 to 4.30. Nothing can exceed the gratefulness of the wounded, and numbers of the townspeople came to the hospital to have their wounds dressed, as they have lately been armed by the Government, and as soon as the firing began went out to fight. The transport from the bridge where the wounds were dressed was fairly good, a number of waggons being told off for the purpose. They were not comfortable, but got the men quickly to the different hospitals. Nothing has yet been heard of Drs. Casson and Buckby, but no doubt, if well, they are kept as busy as ourselves. Reginald Zohrab assists us at the hospital, and Mr. Zohrab is always ready to render us aid with his presence and advice, and every day sends us luncheon to the hospital."

Mr. Zohrab (Erzeroum), on November 18, says:—"I re-

quested Mr. Layard by telegraph yesterday to communicate to you the sad intelligence of Dr. Guppy's death. He was ill for five or six days, but till the night before last we did not think him in any danger. He had typhoid. Perforation of the bowel took place early in the morning yesterday, and he then sank rapidly, dying at 7.10 a.m. The very exceptional circumstances we are placed in obliged me to order the funeral for yesterday afternoon. It was attended by the medical body, and a guard of honour consisting of a company of infantry escorted the body to the grave, which is in the cemetery belonging to the American missionaries. This sad event has cast a deep gloom on our little circle. I received your telegram announcing the departure of surgeons and stores. I wait more detailed information to organise a second hospital, which the authorities here are very anxious to see opened. Mukhtar Pasha has, at my request, telegraphed to the Valy of Trebizond to send on the surgeons and stores with the least possible delay. I have written to Dr. Casson to try and return here with Dr. Buckby. My letter was sent by Mukhtar Pasha to the Russian lines. I hope to get an answer in a few days. We await with deep anxiety a development of the Russian plans. Since the 9th they have not moved, beyond throwing out vedettes in various directions. Whether we are to be bombarded, blockaded, or left alone, remains yet to be seen."

Dr. McIvor, Adrianople, reports, November 10:—"Patients admitted during the week, 134; in hospital beginning of week, 176—total, 310; discharged during week, cured, 97; died, 5—total, 102; remaining in hospital at end of week, 208."

Report for week ending November 17, 1877.

"Patients in hospital, November 10, 208; admitted during week, 49—total, 257; patients discharged during week, *nil;* died, 6; remaining in hospital, 251. I may again report that the wounded who arrived here from Sophia were in a most miserable condition, both as regards their clothing and the state of their wounds. Amongst them were several cases of erysipelas, and many of diarrhœa. I have also to report that during the past week we have increased the number of beds in one hospital by sixty-three. These also contain most severe cases. During the past week we have performed three capital operations. We also operated on a case of fistula in the person of an officer who had twice before been operated on by Turkish doctors, but without any beneficial effect, and during the past fortnight forty minor operations have been performed in our wards, which include incising abscesses, removing dead bone and parts of fingers and toes, and extraction of bullets."

And on November 24: "Patients remaining in hospital, November 17, 251; admitted during week, 3;—total, 254; died during week, 2; discharged, 18—total, 20; remaining in hospital, 234; number of empty beds, 40; major operations performed, 2; minor ditto, 10. Received stores, also an ambulance waggon fitted up with necessary appliances for the comfortable carriage of wounded."

Dr. Barker (Roumelian Railway Ambulance), reports for the week ending November 19:—"I left Stamboul by the post train with my waggon and two waggons with beds, and arrived the same evening (Monday, the 12th inst.) at Adrianople. On the road I met Dr. MacKellar, who informed me that there were no wounded ready for transport at Bazardjick or Philippopolis just then, so I stayed the three following days at Adrianople, in the hope of getting wounded from there, during which time I took the opportunity of having my stove put up, and the cupboards made more secure to the walls of the van. On Friday, the 16th inst., having learnt by telegram that there were 160 wounded to start from Philippopolis, the next evening I proceeded there, and found the men ready seated beside the line. I picked up the worst cases, and put them in the beds, many of them being in a very feeble state, the greater part of them being sick, and some seriously so. We were supposed to start in an hour's time after my arrival—viz., at 6 p.m.,—but, owing to some bridge requiring mending, we were kept at Philippopolis station till 1 o'clock a.m. At 4.30 a.m. we arrived at Tirnova-Semenly, where soup was ready, and awaiting our arrival. Each man also received bread and tobacco, for which they were extremely grateful. Between Tirnova and Adrianople, at which place we arrived at 11 a.m., I was able, with the assistance of a Turkish dresser, to attend to all the wounded. On arriving at Adrianople the wounded were placed in the Government barrack erected beside the line, where I was informed that each received a piece of bread. At 4 p.m. we left Adrianople with 465 wounded, etc. We travelled very slowly, only arriving at Tchorlou the following day at 4 a.m., where soup, tobacco, and bread was again served out. Two men, who were in a very exhausted state, died on the way, notwithstanding that every care was taken of them. A third, who was also very low, I succeeded in saving by the judicious administration of stimulants and food. At Kabadjia I was able, owing to a long stoppage, to dress many of the wounded, and during the day I managed to get all dressed by passing from carriage to carriage. In this I was assisted by some Turkish dressers who accompanied the wounded. These men were sick, not wounded, and, like many others, in my opinion ought not to have been moved from Philippopolis or Adrianople, as the case may be, being hardly able to crawl out of their carriages. With regard to the Stafford House soup kitchens at Tirnova and Tchorlou, I think it is one of the best undertakings we have, and that many Turkish soldiers could say, 'We owe our life to British generosity in feeding us during our return from the front'; those from Philippopolis only having received loaves of bread for rations from the Government during forty-eight hours. I would wish to ask the Committee, if possible, to obtain a change of the system of sending wounded by luggage trains in place of special ones, the former taking twice as much time as the latter to get over the same distance. I believe the railway company would be willing, and it would be an act of humanity to the men. I have to thank the railway officials for kind assistance as dragomans, etc."

ADDITIONAL NOTES ON PONGO'S POST-MORTEM.

The following lines supplement the brief account of Pongo's post-mortem which appeared in our issue of December 8. Before the body was opened, careful casts were taken of the head, trunk, and extremities, with a view to the reproduction of exact models of the external form of the gorilla. The brain, the muscles, and the vascular system were reserved for detailed and careful examination, at leisure, by Professor Hartmann. The interior of the skull, after removal of the brain, presented a remarkable resemblance to that of a child, except in greater depression of the ethmoid bone, and greater prominence of the roof of the orbit as seen from above.

On opening the abdomen, the very fat omentum was found adherent at several places to the anterior and lateral parts of the abdominal wall, evidently owing to slight former attacks of peritonitis. The most striking superficial difference from the abdominal cavity of a child was the greater space occupied by the large and small intestines, and the retraction of the liver and spleen. The signs of intestinal catarrh met with on opening the bowel were identical with those in an infant dying of catarrhal diarrhœa; the glove-button and the needle found in the cæcum had probably not the slightest share in exciting the fatal illness. The liver, spleen, and other abdominal organs, were perfectly healthy. The chest was opened through the diaphragm in the interest of comparative anatomy, and the lungs were found *absolutely healthy*. The pericardium was firmly adherent at certain places to the heart, and it seems probable that the inflammation which gave rise to the adhesions took place about two months after the gorilla was brought to Europe, when Dr. Falkenstein, his medical attendant, found him for a short time very scant of breath. The interesting point about Pongo's death is that he should not have been carried off by tuberculosis of the lungs, the ordinary disease of monkeys in Europe, but by the scourge of young children. Intestinal catarrh is, however, a recognised cause of death in these animals, and two other monkeys in the Berlin Aquarium have succumbed to the same disease. Dr. Boehr, in his article in the *Berlin. Klin. Wochenschrift*, No. 48, 1877, does not say whether Pongo suffered from diarrhœa. In a human infant intestinal catarrh would scarcely kill without giving sufficient external manifestation of its presence to admit of a diagnosis being arrived at; and if, as we infer from Dr. Boehr's remarks, the cause of death was only discovered in Pongo's case at the post-mortem, this would be an interesting proof of the greater susceptibility of his system generally to digestive disturbances.

FROM ABROAD.

Dr. Fordyce Barker on Tarnier's Forceps.

At a meeting of the New York Academy of Medicine (*New York Medical Record*, October 27), Dr. Barker gave a demonstration of the action of Tarnier's forceps, prefacing it with some observations on the changes of opinion which have taken place with respect to the employment of the forceps since the early part of the present century. Formerly, it was always taught that it should not be used except when delivery could not be accomplished without instrumental aid. The forceps, in fact, was regarded as a dangerous instrument to be used as seldom as possible. There were three reasons why the celebrated men who operated at the early part of this century regarded it with such horror:—1. They were entirely ignorant of the mechanism of labour. 2. While they greatly exaggerated the dangers, both to mother and child, from the use of the forceps, they did not recognise the danger which results to both from prolonged labour. 3. They confounded the difficulty and skill demanded in the use of the forceps in the comparatively few cases in which it was required, when the head of the child was at or above the superior strait, with the very many cases in which we now use it when the head is in the cavity or at the outlet of the pelvis.

The plain, practical question to be settled in every case, Dr. Barker remarked, is, which is safer for mother and child—to use the forceps, or permit further delay in the completion of labour. The danger in the use of the forceps may be considered—*first*, while the head is in the cavity or at the outlet. In the hands of an obstetrician who thoroughly understands the mechanism of labour, who has proper instruments, and who operates only in appropriate cases—when there is no disproportion between the fœtal head and the pelvis—there can be no danger in the use of the forceps. Danger can only arise when disproportion exists, requiring such compression to be used as may injure the fœtal cranium or the soft parts of the mother. A word may be said, however, on the delivery of the head, in order to prevent laceration of the perineum. In Dr. Barker's opinion, the forceps, when properly used, is more likely to prevent than to produce such laceration. His own practice is, when the vulva becomes fully dilated, to remove the forceps, and introduce the fingers into the rectum, pull the head forward, and deliver. He never completes delivery by rapid removal of the head through the outlet. During an experience of twenty-five years he has never had laceration occur to an extent calling for surgical interference. *Secondly*, as to danger when the head is above the superior strait, the question is, whether the safety of the mother and child is not greatly increased by early delivery, rather than by following the teaching of the older writers, who never used the long forceps, but always resorted to craniotomy. In these cases it is to be observed—1. The operator should thoroughly comprehend the cause rendering the operation necessary. 2. The mechanism overcoming that cause should also be thoroughly understood; and the relations of the diameters of the head and of the pelvis must be well known, so as to be able to adapt and change the direction of the traction. 3. The operation should be performed slowly, half an hour being the least time required for bringing the head down from the superior strait. 4. Very much depends upon the instrument employed. Dr. Barker ordinarily employs Simpson's. He rarely uses the short forceps. In cases in which simply a slight increase of force is required, the short forceps is sometimes used to save the woman two or three hours' suffering, and is applied without change of position, and often without the patient having been aware that it has been used.

Speaking of Tarnier's forceps, Dr. Barker observed that its inventor claimed for it—1. It enabled the operator always to make traction in the direction of the axes of the different straits. 2. It allowed the fœtal head such mobility that it might take the direction it would normally take in passing through the cavity. 3. It furnished a guide which showed the operator in what direction traction should be made to correspond to the axis of the pelvis. The theory of the instrument is as follows:—When the head of the child is at or above the superior strait, it is impossible to make traction with the forceps in ordinary use, in the exact axis of that strait, because of the resistance offered by the perineum. It is necessary to make traction in a line somewhat forward of the exact axis, and a certain amount of force is wasted against the posterior surface of the symphysis pubis. In Tarnier's instrument this is obviated by a curve in the handle, which permits traction to be effected without making undue pressure backwards on the soft parts. Traction is made by means of independent rods, which are attached to the posterior border of the blades, terminating in a cross-bar just beyond the handles. The instrument is adjusted in the ordinary manner, and the blades locked and fastened; and the handle contains a mechanical arrangement for regulating the amount of compression to be brought to bear on the head of the child. (To this Dr. Barker objected, believing that the degree of compression should always be under the immediate control of an intelligent hand.) When the instrument is applied, traction is first made backwards and downwards, but as the head approaches the cavity of the pelvis the handle of the forceps begins to rise, thus indicating in what direction traction should be made to correspond to the axis of the pelvis, through which the fœtal head is passing. As the handles rise, the tractor is brought up to them, forming thus an automatic indicator, which gives *direction* to the force of the operator. The instrument is strong—which is to be regarded as an argument in its favour, for it is claimed as an axiom that, in the obstetric forceps, power is safety, and feebleness is danger.

In the discussion which followed Dr. Barker's demonstration, Prof. White, of Buffalo, expressed his opinion that the reason why the forceps had been used less, and the perforator more, in the British dominions than on the Continent, is because the operators of the latter use the long double-curved instruments. He believes that it should be used much more frequently than it is, but only by those who were thoroughly familiar with the mechanism of labour, and had sufficient mechanical knowledge to handle it properly. He was unable to see the utility of Tarnier's instrument, and believed it to be a substitute of mechanical device for skill. He maintained that the perineum could be pushed back sufficiently far to allow traction to be mixed in the axis of the superior strait by means of instruments now employed, and that a finger, guided by intelligence, is a sufficient indication as to the direction in which traction should be made. If a thorough knowledge of the mechanism of labour taught the operator in what direction his traction should be made, why be troubled with a mechanical indicator? He predicted that twenty years hence Tarnier's forceps would be found among the obstetric curiosities. Professor Lusk was not prepared to accept Tarnier's instrument as being any more desirable, or even as desirable, as many forceps now in common use. The objection to the old instruments, because the operator was not able to make traction in the exact axis of the superior strait, he did not believe to be warranted, for there was no danger of inflicting injury upon the perineum by depressing the handles of the forceps, so as to make traction in the proper direction. When the head had been brought into the cavity of the pelvis it could be easily delivered with the ordinary forceps; and it was to be noted that, in so doing, as the traction intermitted, the handles would rise, and consequently there was no need whatever of an extra indicator. Again, the new instrument was objectionable when used at the upper strait, because in such cases there is very commonly contraction of the pelvis in its antero-posterior diameter. The consequence was that the head of the child did not engage in the oblique diameter nearly so often as in a somewhat transverse diameter. The result was that, when the forceps was applied, one blade rested over the occiput and the other over the frontal region; and although the tissues against the pubes might be saved from pressure by Tarnier's instrument, the operator ran the risk of injuring the tissues between the head of the child and the promontory of the sacrum. Prof. Lusk was in favour of the straight forceps used by Prof. Taylor when the head was at the superior strait; and after it had been brought into the cavity the main difficulty was overcome, because the double-curved forceps could be used with comparative ease. Prof. Isaac Taylor observed that the straight forceps which he used was Pitkin's instrument. He believed that by this new instrument we should set aside what nature taught us, and he was unable to see any advantage whatever that could be derived from its use.

REVIEWS.

Traité d'Hygiène Publique et Privée. Par A. Proust, Agrégé libre de la Faculté de Médecine de Paris, Médecin de l'Hôpital Lariboisière.

The comprehensive work on Hygiene by M. Proust which has recently appeared is one that is eminently calculated to increase the knowledge of the profession at large on this important subject, even though there may not be much fresh information of that detailed description requisite for an active medical officer of health. The book is well arranged, well written, and eminently readable, and, as such, we know of no work which would be of greater service to the average student or practitioner, who, without aiming at making a scientific study of hygiene, wishes to obtain a fair working knowledge of the subject for general use. The book contains throughout a vast number of most interesting facts, gathered from various countries and innumerable authorities, and in certain parts many new facts have been adduced by the author himself; but the very vastness of the ground which he has attempted to cover has prevented him from going very fully into detail in most of the subdivisions of his subject, and we observe that those parts of the science which he has chosen for more thorough treatment are such as have a clinical rather than a chemical or economic aspect: thus, the three subjects to which he has given proportionally the greatest space are—the diseases excited by mode of occupation; climatology, including the geographical distribution of disease; and the etiology and prophylaxis of the acute specific diseases.

By far the most remarkable of these is the division devoted to the Diseases arising from Occupation, which is very full and complete. He first describes the occupation—the different processes of manufacture, etc.—indicates wherein lies the unhealthy influence, gives an account of the clinical history and pathology of the induced affection, and finally refers to any measures which have been suggested or employed to lessen the tendency to the production of disease. His description of lung diseases and of the varieties of poisoning, lead or other, met with in workmen, is especially good; but one of the most interesting sections in this part of the work is that in which the author investigates the influence of close study upon the sight. He believes that myopia is produced artificially on an enormous scale in children at school, and he explains its occurrence in this way: the statistics of Erisman have shown that the vast majority of children under the age of seven are hypermetropic, and to see to read clearly at the usual distance they make great efforts of accommodation. The contraction of the ciliary muscle, thus produced, causes increase in the intra-ocular tension, and as this is kept up for long periods at a time, the coats of the eye eventually give way in the direction of least resistance, *i.e.*, posteriorly: the antero-posterior axis of the eyeball is lengthened, a posterior staphyloma produced, and myopia eventually results. The myopia is increased by the fact that the ciliary muscle being kept in a state of strong contraction for so long, at last becomes hypertrophied, and the curvature of the lens becomes permanently greater. The statistics of Cohn prove how frequently myopia is thus produced; for he found that in the first (or lowest) grade schools in Germany the proportion of myopic scholars was 6·7 per cent.; in the second grade schools it was 10·3 per cent.: in the third grade 19·7 per cent.; whilst in schools of the highest grade the proportion was as high as 26·2 per cent.; and in the top class of these schools more than half the students were myopic. M. Proust lays special stress upon the importance of plenty of open-air exercise as a preventive against this condition, the accommodation being then practically at rest. As myopia, when once established, is liable to become hereditary, it is of great importance that bodies which, like the School Board in England and the Ministry of Public Instruction in France, are undertaking the training of children by the hundred thousand, should pay special attention to this point, if the advance of education is not to be accompanied, *pari passu*, by increased impairment of sight in the race at large.

In that part of his work which deals with Climatology, M. Proust first gives a full account of the different elements which enter into the constitution of climates, and this is followed by a chapter treating shortly of the climates of the chief countries of the world, and of the diseases most prevalent in them; and the section is closed by a chapter of considerable length on acclimatisation.

In the section on the Cause and Prevention of Miasmatic and other Diseases the author gives a comprehensive summing up of all that is known on the subject, without adding much fresh information to aid in the settlement of the many vexed questions involved. In the case of typhoid fever M. Proust expresses an opinion in favour of its spontaneous origin, agreeing in this with Murchison, Trousseau, and Griesinger; but he admits that it is far more frequently transmitted from one patient to another by means of the stools, and therefore, in common with all other hygienists, gives careful instruction for disinfection in this disease.

This brings us to the subject of Sewers and Disposal of the Sewage, and here we find a great deficiency in M. Proust's account; he is much too brief in his description of the construction of sewers. In his recommendations as to the amount of fall necessary, as to ventilation, trapping, etc., he confines himself much too exclusively to generalities, and leaves almost untouched the details of inventions and processes employed for these purposes. He gives but little information which could help in the investigation of suspected defects in sewers, such as any medical man may be called upon to undertake when an outbreak of typhoid takes place in his neighbourhood. He is rather fuller in his account of the various systems of closets, and he condemns—much too strongly, as we think—the system of water-closets in England; whilst, on the contrary, he upholds the system of cesspools, so prevalent in Paris. Without wishing to attach too much importance to our own system, we think M. Proust has failed in mastering it sufficiently to allow him to form a trustworthy judgment on the question; and he scarcely mentions many of its really good points, which might with advantage be adopted in France. He gives but a few lines to the whole question of traps, upon which, since they are practically unknown in France, he ought, as a reforming hygienist, to have laid special stress. He blames—and justly—the pollution of our rivers with sewage, and our failure to apply it to agricultural purposes, but he is evidently not well acquainted with our present method of disposing of our metropolitan sewage; and, so far as the Paris system is concerned, he only succeeds in showing how difficult, and often dangerous, it is to carry out. It is, of course, impossible to lay down any absolute rule for all towns; and what might answer our purpose in London, with a tidal river at hand, obviously cannot be applied to Paris, hundreds of miles from the river's mouth: but at present Paris is suffering from the disagreeables of all the systems, for so much fæcal matter still finds its way into the sewers that the river is polluted by it. M. Proust himself complains that the cesspools have so much liquid thrown into them as seriously to interfere with the utility of their contents as manure, and the places where their contents are converted into a useful form are nuisances in the neighbourhoods where they are situated.

M. Proust devotes a long and very interesting chapter to the subject of Hospital Hygiene, but the interest is derived from the historical side, rather than from the consideration of details of construction, etc. M. Proust gives us the idea here, as in other parts of the book, that he is a clinician rather than a scientific hygienist; for after giving a long account of the Hôtel Dieu in past times, and after quoting many authorities to prove how bad has been the condition of Paris hitherto, when he comes to the practical point of giving advice for our future guidance, he confines himself to quoting a few general recommendations drawn up by the Société de Chirurgie of Paris, but which, though very well as general suggestions, would be of small service to anyone who had to plan out in detail sanitary works for a hospital. Referring to the maternity hospitals, the author quotes statistics, showing that the mortality in them in the last ten years has been about thirteen times greater than in the case of women confined at their own homes; and he describes an admirable system of isolation recently adopted at La Maternité, by which each woman has a separate room, and can be at any moment completely isolated from the others. The only difficulty will be to provide accommodation of this kind on a sufficiently large scale to make any perceptible difference in the mortality in a town where between 5000 and 6000 women annually are confined in hospitals.

In his section on Food, we find the same want of detailed instruction for the practical hygienist as in other parts of the book. Adulterating substances are often mentioned one after the other, without comment and without indications for distinguishing them from one another; and the instructions given for conducting the chemical analysis of water and other

substances are far from sufficient. In speaking of Liebig's extract of meat, M. Proust is unqualified in his condemnation, looking upon it as not only useless, but positively harmful. We think M. Proust does injustice to a substance which, though it may not quite take the place of meat, has, in our opinion, established its position as a valuable adjuvant in the sick-room.

Space will not allow us to speak with further detail of M. Proust's work. Notwithstanding the extensive research shown in it, and the large amount of information it contains, we consider it, as a whole, more adapted as a text-book for the student than as a book of reference for the professed hygienist; but in the former capacity it is perhaps the most interesting book we have yet met with on Hygiene. Each topic is treated historically as well as practically; the style is not too condensed, and facts are presented in a way which enables the reader to assimilate them easily. M. Proust has written a book which will unquestionably prove of great utility, and we heartily wish success to the work.

GENERAL CORRESPONDENCE.

THE PENGE CASE.

LETTER FROM DR. J. F. PAYNE.

[To the Editor of the Medical Times and Gazette.]

SIR,—As you have devoted so much space to Professor Virchow's article on the Penge case, I will ask you to allow me, though tardily, to make one or two brief remarks upon it.

I do not dwell upon Professor Virchow's strictures on the English methods of conducting post-mortem examinations for legal purposes, nor with those on the terminology and conclusions of the reporters of the post-mortem examination; all I wish to point out is, that his whole article proceeds upon a premise which was not in any way a part of the foundation upon which Dr. Greenfield and I based our arguments. The Professor seems to suppose that the two accounts of the post-mortem appearances of the brain, which he calls Dr. Longrigg's and Dr. Wilkinson's respectively, both formed part of the evidence given at the trial. These statements Professor Virchow very naturally characterises as "utterly irreconcileable"; and he also very reasonably urges that no medical expert ought to assert that he could form a judgment in a case where the evidence is so conflicting. With this, as a general principle, I at least entirely agree. From irreconcileable statements as to a matter of fact, where further research is impossible, no sound conclusion can be drawn, and even the value of the particulars in which two such accounts agree is impaired by their wide divergence on other points. But this divergence in evidence did not exist at the trial. The only notes of the autopsy furnished were those which Professor Virchow calls Mr. Longrigg's, and with that gentleman's evidence the other witnesses stated, in general terms, their concurrence. On the basis of Mr. Longrigg's account, Professor Virchow admits, if I understand rightly, the *possibility* that death may have taken place from tuberculosis of the meninges, but he asks, Can we decide whether Mr. Longrigg or Dr. Wilkinson was in the right? Most certainly we cannot decide, and, had such a decision been necessary, I do not think there would have been, even on this side of the Channel, any lack of that "wise reserve" which Professor Virchow desiderates. But neither Dr. Greenfield, Dr. Bristowe, nor I myself, ever saw Dr. Wilkinson's notes, or knew that such notes were in existence.

Now that the matter is entirely decided, and has been very fully discussed, it seems to me hardly worth while to consider what our opinion might have been had the premises been different.

One other point I must briefly notice. There seems to be a disposition in some quarters to quote Professor Virchow as supporting the opinion that the evidence proved that death took place from starvation. I cannot see that this is anywhere implied in his article; and one does not see why the Professor should not have expressed this opinion had he held it. What he says is, that it is not proved whether or not tubercular meningitis was the cause of death, that it is difficult to account for such extreme emaciation by tubercular disease alone; and there always remains the possibility that Mrs. Staunton was not supplied with food. No one can, I suppose, question this possibility, for of course a person afflicted with any disease whatever might be inadequately, or not at all, supplied with food. What was asserted for the prosecution was, that the post-mortem appearances proved starvation—which we deny. Further, we contend that the symptoms were such as simple inanition or privation of food could not have produced. These positions, which, as you know, sir, have received the assent of a very large proportion of the most competent members of the profession, I do not see that Professor Virchow in any way impugns. In fact, he does not refer to the symptoms at all.

It is not perfectly clear, when the Professor says the verdict should be "*non liquet*," whether he means that the diagnosis of death from tubercular meningitis was not proved, or whether that the charge of murder was not proved.

If the former, it is plain that this is a very different thing from saying that death must have been caused by starvation, and does not at all imply such a belief. If the latter, then it is equally clear that, had the court adopted Professor Virchow's view, the prisoners ought to have been acquitted. On either hypothesis there is little or nothing to support the view of the prosecution. It is the high respect and esteem—I might say the reverence, in which I hold Professor Virchow's utterances on any pathological subject, which alone leads me to make any reply to his observations; and I can only express the regret that the English colleague who invoked this distinguished authority did not more completely inform him with respect to the circumstances of the case.

I am, &c.,

78, Wimpole-street, December 18. J. F. PAYNE.

MR. WATHEN'S CASE OF EXTRA-UTERINE FŒTATION.

LETTER FROM MR. W. B. WALL.

To the Editor of the Medical Times and Gazette.]

SIR,—Being the medical man referred to by Mr. J. H. Wathen in the report of his case of extra-uterine fœtation in your paper of to-day, and as the history given is not quite correct, will you allow me to rectify it.

The woman had not one labour-pain on either of the occasions that I saw her. I gave an opiate to allay colic, and did not expect it "to hasten matters." The fœtal head was low down, with the anterior part of the cervix uteri over it. The os could be felt posteriorly. There was no complaint of pain on examination, or any "show."

My opinion, as expressed to the husband, was that she had not reached her full time, and might go on for another month. I had not the slightest doubt about the fœtus being in the uterus; and as it does not appear from report that the uterus was found to be distinct from the "sac," or that it was even examined, I do not see sufficient reason to alter my opinion.

I attended the woman in her previous labour, which was quite natural. I am, &c., WM. BARROW WALL.

Neyland, Pembrokeshire, December 15.

PRESERVATION OF VACCINE VIRUS.—Dr. Colinet, speaking from an experience of forty-five years, states that he has always been able to preserve this in an efficient state, not only for weeks and months, but for two or more years. The virus speedily undergoes change from contact with light or air, from cold, heat, humidity, or electricity, and the object is to guard against the action of such agents. His procedure is as follows:—He chooses some children of good constitution and healthy parentage (which is easy to do in a country practice where he knows everybody). These children, who have been vaccinated seven, or at most eight days before, assemble at his house early in the morning, before the light has become too vivid, he having prepared already very dry vaccine tubes, a lighted taper, some sealing-wax, and a test-tube of blue glass. The pustules are opened in the arm of one child at a time, and when the droplets of virus appear, quite free of blood, the tubes are *completely* filled, sealed, and placed in the test-tube, this last being hermetically closed, after a paper containing the name of the child and the date of the tubes has been put in. This is immediately placed in the darkest corner of the wine-cellar, where it remains exempt from the influences which damage the virus, that then retains its efficacy for weeks, months, or even a year or two.—*Union Méd.*, December 15.

REPORTS OF SOCIETIES.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

TUESDAY, DECEMBER 11.

CHARLES WEST, M.D., President, in the Chair.

ON THE PATHOLOGY OF TETANUS AND HYDROPHOBIA.

Dr. JOSEPH COATS read a paper as above. The author first described the lesions met with. In *tetanus* the central nervous system showed hyperæmia, and certain appearances in the neighbourhood of the bloodvessels. In the cord and medulla oblongata, pons, corpora quadrigemina, and corpus striatum, but chiefly in the two first named, there was a granular material around the vessels, probably an exudation. In the medulla oblongata it was noted that a longitudinal vessel in the posterior parts was particularly affected, and that there, as well as in other parts, there were occasional hæmorrhages. In the convolutions there was an exudation of a yellow fluid outside the smaller vessels, the medium-sized ones (which are those affected in the cord and medulla oblongata) having mostly escaped. In *hydrophobia* there was in the central nervous system an aggregation of leucocytes around the bloodvessels. In the cord, medulla oblongata, pons, and corpora quadrigemina, it was the medium-sized vessels which were so affected; in the convolutions it was those of small or capillary size. The salivary glands were infiltrated with leucocytes, which have special relations with the bloodvessels. The mucous glands of the larynx were similarly affected, though much less intensely. The kidneys were hyperæmic, with aggregation of white blood-corpuscles within them. The pathology of these two diseases was then discussed, and it was pointed out that there is a great similarity in the distribution of the lesions in the central nervous system, as well as a certain analogy in the kind of lesion. The special distribution of the lesion was compared to the localisation of the tubercles in tubercular meningitis, and was ascribed to physiological and anatomical peculiarities of the circulation. Attention was also drawn to the fact that in hydrophobia the lesions are not confined to the central nervous system; while in tetanus facts are deficient in that regard, but a parenchymatous affection of the liver, kidney, etc., was asserted by one author. The special localisation of the symptoms in both diseases, in the tongue, throat, and neck, was associated with the special prevalence of the lesions in the medulla oblongata, and especially in the neighbourhood of the nuclei of the nerves in the floor of the fourth ventricle, etc., it being pointed out that the principal nutrient vessel of the medulla was specially related to these nuclei of grey matter. It was concluded that in tetanus and hydrophobia we seemed to have two different poisons, each of which, circulating in the blood, attacked the central nervous system. These agents irritated the nervous system, but, as they were different in nature, so the kind of irritation they produced was different. There was, however, a remarkable similarity in the localities affected by them, and these seemed to be specially the spinal cord, medulla oblongata, and corpora quadrigemina, and to a lesser degree the cerebral convolutions. The irritation seemed to centre in the medulla oblongata, and in a particular region of it, this localisation being probably determined by the anatomical and physiological relations of the nutrient vessels. The high temperature met with in hydrophobia, and sometimes in tetanus, was regarded by the author as not inconsistent with these views.

Dr. ALTHAUS thought it exceedingly interesting that pathological changes should have been found in the medulla oblongata, though they had not been discovered even by such an able observer as Dr. Lockhart Clarke. Were these changes, however, essential in their character? He also asked whether the cervical ganglia had been examined, as then, in all probability, changes would have been found. The third cervical ganglion had been found diseased, but this was before the days of exact microscopic research. On the whole, he did not think the appearances pathognomonic, for similar appearances had been found by Dr. Lockhart Clarke in paralysis as in tetanus, especially in the kind called ascending paralysis. He did not believe that there was a poison in tetanus; there could be no doubt of its existence in hydrophobia. He had seen actual experiments of inoculation from one animal to another; in some the poison did not take till after a time. There was no such transmission of tetanus. Though there might be much in common between tetanus and hydrophobia, there was no real identity; even the kind of spasm was different. Moreover, the one was only dangerous to the individual, the other to the community at large.

Dr. DICKINSON said he had seen Dr. Coats' preparations by daylight, and he would observe with regard to them that in many nerve diseases the first changes observable were alterations between the bloodvessels and nerve-substance. There were signs of hyperæmia, and escape of blood corpuscles from the vessels. There was really a great similarity in the morbid appearances of many of these diseases, and they must consequently look for something more. He was inclined to think both hydrophobia and tetanus were blood diseases, for in tetanus there was almost always an open wound, and a very definite period elapsed between the time of the wound and the appearance of the symptoms.

Dr. GOWERS thought both the preparations and the facts adduced constituted valuable additions to our knowledge, particularly as directing attention to other organs besides the nervous system, especially the salivary glands and kidneys. Again, they showed the similarity between the lesions in the dog and man, and moreover, that both tetanus and hydrophobia had characteristic lesions. In five out of six cases of hydrophobia he had examined, the lesions were so similar that they might have been called characteristic. In each of those five there was infiltration of leucocytes, especially in the tissues of the medulla oblongata. There was much less of this in the spinal cord. Some very small vessels were affected, but they having no distinct perivascular sheath, the changes were more diffuse. In tetanus the changes were similar, but less intense in the medulla. He thought that probably the paroxysms of arrested respiration had something to do with the escape from the vessels. The perivascular spaces were really the only vacant spaces where matter could aggregate outside the vessels. He did not think Dr. Coats' specimens inconsistent with ordinary views. There was really a local inflammation of nerve in many instances, but no poison was really necessary in the case of tetanus. Hydrophobia, the result of a special poison, might give rise to a more important vascular lesion.

Dr. TURNER said they might get grouping of leucocytes in the walls of the stomach as the result of an ordinary congestion. In a case of hydrophobia examined by him, leucocytes were found in all organs, but especially in the spinal cord. Vessels of all sizes were affected. The consistence of certain parts of the spinal cord was greatly altered. There was some hæmorrhage in the cervical portions of the cord, and there was also a good deal of granular matter to be seen. In the brain there was nothing particular. There were many leucocytes in the liver and kidneys, in the former especially round about the fœtal canals. In another case fewer leucocytes but more exudation material was to be found.

Sir J. FAYRER said he had come to the meeting in hopes of hearing something of the two diseases themselves; but though he had heard much that was interesting and instructive, there was nothing about the phenomena of the diseases, nor of what could be done for them. He had seen a good deal of both, and of hydrophobia his experience was unfavourable; that of tetanus was better. He was quite sure he had seen tetanus endemic where there was absolutely no wound to give rise to it. That form was amenable to treatment; probably the other was so also; but he would like to hear more on the subject.

Dr. BUZZARD remarked, with regard to the statement that arteries of various sizes were differently affected, that we had a similar affinity or selection-power in the case of many poisons. Perhaps more minute chemical examination was now wanted, rather than microscopical investigation.

Mr. CURLING thought the clinical history did not agree well with the alleged pathological facts. If there was so much change in the spinal cord as had been described, they would expect paralysis rather than spasm; but there was nothing of the kind in tetanus, even up to the turn of life. The patients seemed to die of exhaustion, or sudden cessation of respiration. It was difficult to explain the period of incubation: in tetanus it was a few days; in hydrophobia six weeks or two or three months. If tetanus was really a blood disease, why did section of the irritated nerve early in the malady arrest it?

Sir J. FAYRER said he had often seen tetanus thus arrested, even when the disease had been fully developed.

Mr. HOWSE thought that tetanus was most apt to occur in

the case of wounds where dirt had been so completely ground into the tissues that it could not be removed; and he narrated certain instances illustrative of this. He thought idiopathic tetanus quite a different thing from the traumatic disease, and suggested that in the latter case absorption might take place by the inflamed nerve.

A Gentleman present said that tetanus was not uncommon among horses, and that veterinary surgeons used for it successfully hypodermic injections of conia. This, however, had failed in the case of his own horse.

Dr. Greenfield thought Dr. Coats' researches tended to confirm former observations, though the changes in the cerebral convolutions were something new. Our views of the pathology of the disease were, he thought, biased. The changes seemed to be strangely variable in different cases. Were they not rather due to local irritation than to the disease itself? In reality, similar changes were found in diseases widely different—as in tetanus, hydrophobia, chorea, etc. It would be interesting to know how far they occurred in other diseases accompanied by high temperature. The changes in the glands and similar organs were surely due to irritation. On the whole, he thought that the changes were not due to the disease itself, but to over-vascularity.

Dr. J. Harley said it was an interesting fact that by means of aconite all the symptoms of tetanus could be produced.

Mr. Wood asked if the scar had been examined for any signs of irritation. This might throw light on the period of incubation.

The President drew attention to the form of tetanus occurring among new-born children, and how it had been got rid of by good sanitation. He remarked strongly on the tendency to abandon clinical investigation for purely pathological observation. Pathological facts were not more certain than those observed at the bedside. The vaunted accuracy of observation did not, he found, put a stop to the wildest theorising. It was just the same a hundred years ago, only men used what seemed to be a more scientific nomenclature nowadays. After all, their function was not so much to observe as to cure disease if possible.

Dr. Coats, in reply, said that had his paper been read in full many of the comments would have been rendered unnecessary. Above all, he did not assert that these lesions were the disease, but only the result of an irritant, probably a poison. What the poison may be we know not. The two diseases referred to were only analogous, not identical, but perhaps both were due to a morbid poison. As regards the leucocytes found in the walls of the stomach, they were a part of the normal texture. The lesions found were not so considerable as to produce paralysis. As regards the incubation of hydrophobia we had something similar in an infective tuberculosis from long-standing scrofulous glands. In one case he had found signs of irritation in the cicatrix after a long time had elapsed.

THE PATHOLOGICAL SOCIETY.

Tuesday, December 18.

Charles Murchison, M.D., LL.D., F.R.S., President, in the Chair.

Lactic Fermentation and its Bearings on Pathology.

Mr. Lister brought forward a communication upon this subject, and demonstrated his method of experimentation. He said that a few years ago it would have seemed improbable that the souring of milk should have any bearing upon human pathology. But there was evidence that the essential changes in fermentation occupied a foremost place in the mind of the pathologist of to-day. On reading the report of discussions on kindred subjects—*e.g.*, the discussion on Pyæmia at the Pathological Society—it had seemed to Mr. Lister that medical men had begun from a clinical rather than from a pathological point. It seemed to him that if sure steps were to be taken towards the knowledge of presumably fermentative diseases, it was necessary that we should have a clear knowledge of the simplest forms of fermentation, which could be investigated in the laboratory. Some might reply that Pasteur and other workers had done enough in this direction. But this opinion was not universal. There were still high authorities who said that though organisms were present in putrefaction, they were present merely accidentally. Some time ago, Mr. Lister continued, he had made an attempt by investigating the process of lactic acid fermentation to satisfy himself upon this point. And he had succeeded, and he thought that it might be interesting to the Pathological Society to see samples of the preparations on which his conclusions had been based. He would not have presumed to bring this subject forward if he had not had more to exhibit and tell than he had already shown. He would to-night bring forward some new points not yet published. And, first, he would speak of the *method* of experimentation. The method that he followed depended on the fact, which had been verified by experience, that if we have a glass, pure of anything living, covered by a pure glass cap, and both by a glass shade, the whole reposing on a plate of glass, any organic liquid contained in the apparatus, and free from organisms, will remain free from organisms. The cap and the shade might not fit accurately, the air might enter, yet the result would be the same, if the atmospheric dust were excluded; no organisms would occur in the liquid. The glasses were obtained pure by exposure to a temperature of 300° Fahr. for two hours. All life was then destroyed. The air that entered during the cooling of the glasses must also be filtered, and this was obtained by making the air pass through a layer of cotton-wool fastened between the door and the walls of the iron box in which the glasses were heated. The box was uniformly heated in every part by means of a simple arrangement. Into such a box a dozen of glasses were put, while a thermometer at the top of the box indicated the temperature. After two hours of 300°, the flame was extinguished, and the whole allowed to cool, and then the glasses were removed. The next point to consider was, how organic liquids should be introduced into such a glass. He had arranged a much simpler method of decantation than his previous method. A flask was provided with a neck large at its commencement and comparatively narrow at its termination. When a liquid was poured from such a flask, and the flask was then erected, the nozzle of the neck was valved by a drop of the liquid, and regurgitation of air never could occur through such a nozzle. The mouth of the flask was plugged with cotton-wool, and this filtered the air that entered above the fluid. The guarding drop in the nozzle preventing regurgitation of air for the moment, a piece of lint steeped in carbolic acid was then applied to the nozzle; the guarding drop of liquid was absorbed; and the cotton-wool, taking its place externally, was tied on as a permanent protection. Then came the question, how was the glass to be protected during charging? The carbolised cap was removed from the nozzle of the flask, and instantly replaced by a bit of india-rubber ball which had been impregnated with carbolic acid, and thus rendered thoroughly antiseptic. The glass cap upon the glass was now removed, and the indiarubber being held over the glass, the liquid was quickly poured from the flask; and the glass having been sufficiently charged, the glass cap was placed upon it. This method had been uniformly successful in Mr. Lister's hands. The next question came to be, how was the charging-flask to be obtained pure and filled with a pure liquid? The flask itself was purified by heat as before. A pure organic liquid was to be found in urine unboiled. The glans penis and meatus having been smeared with a solution of carbolic acid, the urine was passed into the opening of the flask, and the latter instantly plugged. Urine thus introduced might be kept pure, mucus and all, for any length of time, without a trace of the decomposition which was perhaps universally associated with standing urine! But if milk were to be used it must be purified by heat. In Edinburgh Mr. Lister had found that no organism resisted 210° for half an hour in the moist state. No liquid continued fertile after such treatment. He said 210°, and not 212°, because he immersed the flask in boiling water, and the temperature of the flask never reached the boiling-point. There was thus no frothing of the liquid, and this was a great convenience. What had to be done was to introduce the liquid into the bottom of the flask without touching the upper part, otherwise the heat would not reach it uniformly. Mr. Lister's plan was as follows:—A rag dipped in carbolic acid lotion was used to purify the outside of a funnel, and the funnel was then passed down into the flask to be charged. The fluid was then carefully poured in, and the mouth closed with cotton-wool, when the flask was ready for immersion in water in a saucepan for the purpose of heating. Success uniformly attended this method of proceeding when the fluid used was Pasteur's fluid or vegetable infusions; but with milk the method as uniformly failed. Some authorities would have concluded from this result that there were complex organic

molecules in milk, which developed into organisms; but Mr. Lister could not consent to this conclusion, and had been convinced that the result was due to faulty experimentation. It occurred to him that the air necessarily introduced through the funnel, and appearing as bubbles, carried dust with it; and milk was a pabulum that supported all bacteria, except, perhaps, one form; he therefore repeated the experiments, substituting a syphon for a funnel. The syphon was composed partly of glass tubing, and partly of indiarubber tubing, fitted with a stopcock; the lower end of one limb of the syphon was wrapped round with a carbolised rag, and through this rag it was passed into the flask; when sufficient milk had been admitted, the syphon was carefully withdrawn, and the mouth of the flask plugged. Since he had adopted this improved method, Mr. Lister had never failed with milk; and he was able to show a specimen of milk to the Society, which had kept without putrefaction from last August. He believed that this failure and correction of failure were most instructive, showing as they did how faults and defects in manipulation were sufficient to explain many appearances that would otherwise be misleading. Having concluded his description of the method pursued, Mr. Lister next passed on to an account of the *facts* that had been obtained by it. He had selected the lactic fermentation for special study for several reasons—namely, first, because the lactic fermentation was conspicuous by its souring effect and by its products; and, secondly, because the ferment was rare, so that any accidental defect in manipulation would not be so likely to allow of its introduction. He called the lactic acid ferment rare in the world generally, but it was very abundant in dairies. Now, if many glasses were charged with milk and exposed, there was sure to be a development of organisms in them, but not necessarily lactic fermentation nor its organism, the *Bacterium lactis* (Lister). The bacterium lactis was a motionless bacterium, usually found in pairs, or in threes or fours, as leptothrix-chains. If milk were taken, as Mr. Lister had taken it, fresh from a cow standing in an orchard near a dairy, and kept unboiled in purified glasses, every specimen would probably be found to contain organisms, as his specimens had been. In spite of great care, organisms had entered in these experiments,—but in not one was there lactic fermentation. Many of the organisms developed were of the most brilliant colours; but the bacterium lactis was never found. The experiment was therefore repeated, but with more rigorous care, and in the majority of the glasses no organism could be found. The conclusion was that pure milk from the cow contains no organism capable of causing the lactic fermentation. The next series of experiments consisted in boiling the milk and adding common water to the glasses. The water was admitted through a graduated pipette, by means of which one one-hundredth of a minim of water could be added at pleasure. When this was done to ten glasses of milk the result was that organisms appeared in some of the glasses, and also fermentation, but not the lactic fermentation. And, further, different ferments were found in different glasses, and some of the glasses escaped altogether. These results proved that the fermentative agency in water was not dissolved in the water, but consisted of suspended particles; otherwise every drop would have been infective. If the cream were thick on the surface of the milk, the spot of inoculation might be seen of various colours, and the colour on examination would prove to be due to innumerable bacteria. Still, various as the forms of fermentation were, the lactic fermentation was not among them. The conclusion was that the souring of milk, instead of being something inherent in the milk, required the introduction of something from without, and this something was scarce in water and in the air generally—except in dairies. And even in a dairy Mr. Lister had exposed a glass of milk for a quarter of an hour, and got no lactic fermentation—only the development of a filamentous fungus, and another bacterium. In this experiment he got a most remarkable viscidity in the milk, which could be drawn up on the end of a needle for thirty-eight inches; yet there was no lactic fermentation. All these results indicated that the lactic fermentation was a form of fermentation favourable for experiment. And now Mr. Lister said he had to make a confession. Next to the promulgation of new truth, he considered that the best thing was the recantation of published error. Some years ago he had published in the *Microscopical Journal* an account of the behaviour of the bacterium lactis in various liquids. In urine, for example, a very different organism had been developed when the urine was inoculated from milk. Instead of a bacterium of $\frac{1}{60000}$th of an inch in breadth, there appeared an organism comparatively large, spirilla-like, but still motionless. A second urine-glass gave the same result; Pasteur's fluid on inoculation produced a different bacterium, which was very active in its movements. From this product there were obtained, by secondary inoculation, coiled organisms; and from this third product the lactic ferment was derived. Mr. Lister believed at the time that he could trace all these stages into each other. Lately he had occasion to mention these results to an eminent authority, who had not previously agreed with his views, and this eminent authority had confessed that such results could not be accidental. But Mr. Lister had felt that he ought to confirm these results if possible. He therefore inoculated urine and Pasteur's fluid, as before, using great precaution. This time he obtained exactly the reverse result—the urine produced an active bacterium; while the Pasteur's fluid, either directly or indirectly inoculated, produced a motionless bacterium. He saw that he had been in error, and had contaminated his fluids. He set about to get rid of the sources of contamination; and in the following way:—He diluted milk with pure water to such a degree that only a single bacterium should be present in each drop of the inoculating mixture. As the bacterium lactis was proportionately the most abundant in milk, it was probable that the bacterium lactis alone would occur always after inoculation, and that the others would be excluded from some of the glasses. The bacteria were counted in a drop of souring milk; the milk was diluted one million times; and five glasses of pure milk were inoculated with the mixture. One of the five glasses produced bacteria. With this he inoculated urine, presumably pure; the bacterium grew, but was very scarce in some specimens, and very slow in development. He then inoculated Pasteur's solution, using in the manipulation a tube of peculiar design to insure a successful result. No change appeared, neither was there any change after direct inoculation of the Pasteur's fluid. The conclusion was that Pasteur's fluid will not grow the bacterium lactis, though it will not actually destroy it. Mr. Lister said that he must have been wrong, therefore, in his first experiments, the baeteria being accidental. The conclusion from all these results, Mr. Lister continued, was that a variety of organisms infest milk. Having obtained by the preceding method the pure bacterium lactis, he estimated the number of bacteria in a given amount of milk, calculated the amount of water that should be added in order that each drop of the fluid for inoculation should contain one bacterium, and inoculated ten glasses with the mixture. Some of the glasses only presented an effect, and, very curiously, exactly five out of ten. These experiments were performed months ago, and at this moment there were no bacteria in any of the five glasses named. A pure white was visible, but no other alteration, such as penicillium, or the butyric acid fermentation. The sour odour of souring milk occurred under the influence of a pure bacterium, and the question was, What was the cause of the odour? Lactic acid was absolutely odourless. The common sour odour of souring milk was butyric. What was the cause of the odour in pure lactic fermentation? Mr. Lister had distilled the products, and obtained a pure liquid with a more pungent odour, but destitute both of acid taste and acid reaction with litmus. Probably, though a sour-smelling substance, it was not an acid, but an ether. With respect to the nature of the lactic ferment, its particles were in suspension in water, and not in solution, as was proved by the previous experiments, for of glasses inoculated with equal drops of fluid, only one-half of the number were affected. What were these particles? Let it be granted, for the sake of argument, that they were mere chemical particles destitute of life, and that could not be observed undergoing subdivision. Suppose these particles capable of developing by self-multiplication. It would be perfectly inconceivable that, if the bacteria were merely accidental in the fermentation process, they should be present in the drops where fermentation occurred, and not in the others, and that the two influences should go in pairs. But whenever the fermentation occurred, there the organisms were found. The conclusion was that this particular bacterium was indispensable to the lactic fermentation. Turning next to the consideration of the characters of the bacterium lactis, Mr. Lister said that the particles were near the *minimum visib le*. The circumstances of their appearance and their grouping had to be considered in recognising them. The *torula cerevisiæ* was enormous compared with the bacterium lactis, the

granules contained in the torula being themselves larger than the whole bacterium lactis. Let but other organisms be conceived, as much smaller than the bacterium lactis as the bacterium lactis was smaller than the torula, and we might thus reach ultra-microscopic structures, which might occur in erysipelas and similar diseases. When milk was diluted 1200 times with water, a puny progeny of bacteria was produced in three days. This result confirmed a previous experiment of Mr. Lister's. He introduced tap-water into a purified flask, and at the end of forty-eight hours he could just discern a bluish-white film by examining the flask with a light in a darkened room. This film consisted of many minute motionless bacteria. How many more must there be in running water! And so, on subdividing water into one one-hundredths of a minim, and examining such a quantity microscopically, one would search for days in vain, and not find the bacterium on the slide. All this showed how vain it was to conclude that there were no bacteria in given fluids, because none could be seen. It had been asserted that *germs* of bacteria had been seen. But there was no evidence that there were germs of bacteria beyond microscopic power. Bacteria were mere reproductive bodies. Their scarcity and their minuteness were alone sufficient to account for their not being seen, without speculating on germs. The needless mystery of germs might therefore be set aside.

At the conclusion of his address it was announced that Mr. Lister had been unanimously elected a member of the Pathological Society.

The PRESIDENT, in making this announcement, said that in some societies it was the custom for new Fellows to deposit with the Society a specimen of their art. Mr. Lister had that evening deposited in their annals, on the occasion of his election, a memorial of his work which was truly worthy of his name. He invited discussion on the subject of the address.

Dr. BASTIAN, after expressing his thanks to Mr. Lister for his communication, said that he had himself no similar experiments to record. But in the main the experiments dealt with fluids preserved from contamination, and the assumption underlay them that in the body there were no such organisms. Now, there were several facts bearing on this that ought to be stated. The subject of fermentation and putrefaction was broad, and the results seemed wholly discordant. Mr. Lister's experiments seemed to be quite convincing, and a flaw was difficult to find in his conclusions. But the question remained, whether observations made under other conditions would give the same results. There were two or three points to be noticed. The first of these was the fact that if we took a healthy animal and suddenly killed it, and allowed it to remain, in summer weather putrefaction would occur. Organisms occurred in abundance in the alimentary canal, and some authorities believed that contamination took place from this source. But the circulation had ceased, the movement of the particles was not progressive, and organs at a distance were infected. Even in the interior of the brain, swarms of organisms were found. To Dr. Bastian this seemed a fact worthy of attention. Again, organisms might be made to appear at will in any organ of an animal. Dr. Sanderson had said that boiled caustic ammonia, introduced with every precaution into the subcutaneous tissues or peritoneal cavity of a rabbit, led to the appearance of swarms of bacteria in the parts. There was another way of producing the same result. Lewis and Cunningham had caused artificial failure of nutrition locally; they tied one renal artery in a dog, and killed the animal in twenty-four hours. The corresponding kidney contained swarms of organisms; and he had himself made an approximation to a verification of this result. Last September a boy died in University College Hospital of disease of the heart and kidneys, with multiple embolism. Examination a few hours after death revealed embolic patches in the spleen and kidneys, of all ages; blood was carefully taken from the right ventricle and from the freshly-cut surface of the lung, and urine from the bladder, but no organisms were found; but the embolic patches contained long vibrionic organisms, distinctly visible, while none could be found in the parts at a distance. Dr. Bastian would, therefore, hesitate before drawing conclusions from Mr. Lister's facts, until they had been compared with others obtained under different circumstances.

Dr. BURDON-SANDERSON expressed his agreement with the conclusions at which Mr. Lister had arrived. He said he was gratified to find that Mr. Lister was in agreement with himself respecting the absence of morphological proof of the existence of germs of bacteria. Professor Tyndall had defined a germ as anything that germinates, without reference to visibility or anatomical characters. He had himself thought that, putting aside the question of possession of structure or not, we might call this a germ; but this did not prejudice the question as to the existence of germs as seeds of bacteria. The facts of splenic fever seemed opposed to this view, but the spores of the organisms in splenic fever were larger than any of the organisms that had been described to-night.

A vote of thanks was then passed to Mr. Lister with acclamation.

OBITUARY.

JAMES FURNESS MARSON, F.R.C.S.

WE are indebted for the following notice of the late Mr. Marson to an account of him given at the meeting of the North London Medical Society, held December 11.

Dr. Kesteven, referring to the loss that the Society had sustained by the death of the late J. F. Marson, took occasion to dwell upon the obligations under which Mr. Marson had laid the profession at large by his exact statistics of the cases admitted into the London Small-pox Hospital while under his charge, extending, it should be stated, over a period of forty-one years. To his industry we owe the history of several epidemics of small-pox in London. The logical conclusions deduced, and closely reasoned out, from the data of admissions, and published in the thirtieth and thirty-sixth volumes of the *Medico-Chirurgical Transactions*, have formed the basis of subsequent legislation upon public vaccination, as well as of our clearer views of the protective powers of vaccination, and still more so of revaccination; while, at the same time, the sources of failure in protection were so distinctly pointed out that the rules of practice thence inferred have not since been successfully disputed. In those papers, and in the essay on Small-pox in Dr. Russell Reynolds' "System of Medicine," Mr. Marson performed good solid work, and has left a model of precise and logical observation after the true Jennerian type.

For several years past the deceased had held the appointment of Examiner in and Teacher of Vaccination under the Privy Council. From its first formation Mr. Marson was also one of the active members of the Epidemiological Society; he was also a member of other medical societies, and an honorary member of the Metropolitan Association of Medical Officers of Health. Mr. Marson received his medical education at St. Bartholomew's Hospital, became a Member of the Royal College of Surgeons in 1834, and Fellow in 1862. For the last few years of his life he had suffered from stone in the bladder, with chronic cystitis, under the effects of which he succumbed at Worthing on November 15, a few months only after his failing health had compelled the resignation of his appointments. It may with truth be affirmed of Mr. Marson, that in the discharge of the duties of his office he had rendered a strict account of his stewardship; and that of the vast amount of material furnished by a large metropolitan hospital, little indeed was allowed by him to run to waste, but, on the contrary, much was, at his hands, laid up in the common store-house of medical science.

FRANCIS HAWKINS, M.D. OXON.

WE regret to have to record the death of Dr. Francis Hawkins, one of the oldest Fellows of the Royal College of Physicians of London, who died at his residence, Ashley-place, Victoria-street, on the 13th inst., in his eighty-fourth year.

Dr. Hawkins came of a family of whom he might well be proud, and whose fair fame he well maintained; his father, the Rev. Edward Hawkins, was the youngest son of Sir Cæsar Hawkins, Serjeant-Surgeon to the Sovereign, and Surgeon to St. George's Hospital. Dr. Hawkins went to St. John's College, Oxford, from Merchant Taylors' School in 1812—an institution at which many distinguished members of the learned professions have been educated. In 1813 young Hawkins carried off the "Newdigate Prize"; and took honours in both the schools, being in the second class both in classics and mathematics. After this successful "preliminary education," he entered on the study of the medical profession at St. George's Hospital, and graduated M.D. Oxon. in 1823. The following year he was admitted a Fellow

of the Royal College of Physicians of London, soon after which he was elected Physician to the Middlesex Hospital, in the vacancy occasioned by the migration of Dr. Peter Mere Latham to St. Bartholomew's Hospital; his great-uncle, Mr. Pennell Hawkins, another Serjeant-Surgeon, had previously been Surgeon to the Middlesex Hospital. In 1829 he was appointed Registrar of the Royal College of Physicians, which office he held until the establishment of the General Medical Council in 1858, when he was happily selected to be Registrar to that body—an office which he retained till the end of 1876. He was also one of the "Elects" of the Royal College of Physicians—the body who formerly elected the President of the College. He delivered the Lumleian and Croonian Lectures, and the Harveian Oration, and served the office of Censor. As Censor he was, we believe, a Trustee of the Hunterian Collection of the sister College, in which he always took a deep interest.

When King's College was established he received the appointment of Professor of Principles and Practice of Medicine in that institution, which he held until 1836, and on his resignation was succeeded by Sir Thomas Watson, Bart. As he was the first to hold that chair, so of all who have held it he is the first to die. He was Physician to the Household of William IV. and of her present Majesty, and as physician to the late Duke of Cambridge and the Duchess of Gloucester he was much and deservedly appreciated by their Royal Highnesses. He was an excellent classical scholar, as his admirable Harveian Oration testified. He had not contributed much to the advancement of medical science; a volume on Rheumatism and Diseases of the Heart, published in 1826, was well received. He was well known in our profession, and highly appreciated for the high tone of thought and feeling that marked every part of his life. In all the affairs of the College of Physicians he took an active and most useful part.

Dr. Hawkins married a daughter of Sir John Vaughan (a brother of Sir Henry Halford, so long the President of the College of Physicians), and leaves three sons—one an eminent member of the Chancery Bar, and two who are clergymen. His surviving brothers are the Provost of Oriel College, Oxford, and Mr. Cæsar H. Hawkins, the Senior Serjeant-Surgeon to the Queen, and twice President of the Royal College of Surgeons.

JOSEPH ROBERT BAYLIS, M.R.C.S. Eng., L.S.A.

We regret to announce the death, aged eighty-four, of Mr. Joseph Robert Baylis, which occurred after a short illness, at the residence of his son, Mr. T. Whitmore Baylis, F.R.S.L., the Waterfall House, Lower Tooting, Surrey, on November 25. The late Mr. Baylis was one of the few remaining veteran members of our profession, and we observe his diplomas for the College and Hall bear date as long back as 1819 and 1825. He formerly practised in the City of Gloucester, but retired comparatively early in life from the profession. Mr. Baylis was a pupil of the great Abernethy with the late Mr. F. C. Skey, F.R.S. The late Mr. Baylis, when studying for his degree in a Gloucestershire village, was a successor of Dr. Jenner, who had once resided there as a pupil, and whose rooms he occupied for several years. Mr. Baylis was an only brother of Mr. Thomas Baylis, F.S.A., the well-known antiquarian, also a member of our profession, who died about two years since, some of whose works of art have now places in our Royal and National collections.

King and Queen's College of Physicians in Ireland.—The arrangements for the second annual course of scientific lectures, to be delivered in February and March, 1878, were completed at the last monthly meeting of the College. The names of the lecturers, and the subjects upon which they will lecture, are as follows:—Dr. T. W. Grimshaw, two lectures on the "Present State of our Knowledge of the Intimate Pathology of Contagion, and its Relation to the Prevention and Treatment of Zymotic Diseases"; Dr. Walter G. Smith, two lectures on the "Principles of Electro-Therapeutics"; and Dr. J. M. Purser, King's Professor of Institutes of Medicine, two lectures on "Some of the Physiological Bases for Diagnosis in Spinal Disease." Dr. Grimshaw is to lecture early in February, Dr. Smith in the second half of that month, and Dr. Purser in March.

MEDICAL NEWS.

University of London.—The following gentleman has passed the examination in subjects relating to Public Health:—

Taaffe, Richard P. Burke, M.D., M.S., student of St. Bartholomew's Hospital.

University of Dublin.—School of Physic in Ireland.—At the Michaelmas Term examination for the degree of Bachelor of Medicine, held on Monday and Tuesday, December 3 and 4, the successful candidates passed in the following order of merit:—

Doodroffe, John F.	Thompson, R. Norman.
Powell, Blacker C.	Fogarty, Thomas F.
White, Edward W. W.	McCullagh, James A.
Casement, Brabazon.	Galbraith, John.
O'Donnell, Joseph F.	Taylor, Rogers.

Cox, Henry L.

At the examination for the degree of Bachelor in Surgery, held on Monday and Tuesday, December 10 and 11, the following was the order of merit in which the successful candidates passed:—

Doodroffe, John F.	O'Donnell, Joseph F.
Hurford, Cedric H.	Manning, George H.

Arthur Annesley West, M.D. Univ. Dub., also obtained the degree of Master of Surgery at this examination. At the examination for the diploma in State Medicine, held on Thursday, December 13, and following days, the qualification was granted to—

Goode, William Henry, M.D. Univ. Dub.

Royal College of Physicians of London.—The following gentlemen were admitted Licentiates on December 17:—

Ashworth, John Wallwork, Heaton Moor, Stockport.
Blake, William Farewell, 25, Grafton-street East, W.C.
Cones, George Augustus, 6, Devonshire-terrace, Kensington, W.
Cressey, George Henry, St. Bartholomew's Hospital, E.C.
Cripps, Edward Charles, 39, Charlwood-street, S.W.
Davies, Francis Joseph, 190, Stanhope-street, N.W.
Deane, John Richard, 9, St. Mary's-road, W.
Dingle, William Alfred, Millbrook, Southampton.
Flint, Arthur, Park-hill, Croydon.
Hayman, Sidney Arthur, Epping.
Husband, Walter Edward, St. Bartholomew's Hospital, E.C.
Judson, Thomas Robert, 16, Wynell-road, S.E.
Meek, John William, 70, Stockwell-park-road, S.E.
O'Grady, William Fitzwilliam, Workhouse Hospital, Manchester.
Pain, Alfred, Coultings, Bridgwater.
Parker, George Roger, 35, Granville-square, W.C.
Poynder, John Leopold, St. Luke's Hospital, E.C.
Proffitt, William John Walthew, Burton-on-Trent.
Smith, Ferdinand Clarence, 18, Albert-street, N.W.
Sworder, Horace, Luton.
Wise, Alfred Thomas Tucker, M.D. Brus., 82, Sutherland-gardens, W.

The following gentleman at the same time was admitted a Fellow:—

Grabham, Michael Comport, M.D. Aberd., Madeira.

King and Queen's College of Physicians in Ireland.—At the ordinary monthly examination meetings of the College, held on Tuesday, Wednesday, and Thursday, December 11, 12, and 13, the following candidates were successful:—

For the licence to practise Medicine—

Previous Examination.
Mahony, John Dennis.

Final Examination.

Dodd, Henry Francis.	Marques, Laurenço Pereira.
Drury, Maurice O'Connor.	O'Sullivan, Daniel.
Flanagan, John Wm. Henry.	White, Thomas George.

For the licence to practise Midwifery—

Dodd, Henry Francis.	Marques, Laurenço Pereira.
Drury, Maurice O'Connor.	MacNeece, James Gaussen.
Flanagan, John Wm. Henry.	O'Sullivan, Daniel.

White, Thomas George.

For the licence as a Midwife and Nursetender—

Parkinson, Ellen.

Apothecaries' Hall.—The following gentlemen passed their examination in the Science and Practice of Medicine, and received certificates to practise, on Thursday, December 13:—

Allinson, Henry Calthrop, Lynn, Norfolk.
Brown, John Alexander, 61, Lyndhurst-road.

Candler, William John, Harleston, Norfolk.
Clitherow, Robert Edward, Horncastle.
Damania, Phirozsha Jamsetjee, Bombay.
Reynolds, Lewis William, Park-villas, Poplar, E.
Small, Morton Alfred, 165, Edgware-road.
Thorpe, Henry Stanley, Hertford.
Wilson, Joseph Henry, Oundle.

The following gentleman also on the same day passed his Primary Professional Examination:—

Brookes, Frederick, Charing-cross Hospital.

APPOINTMENTS.

*** The Editor will thank gentlemen to forward to the Publishing-office, as early as possible, information as to any new Appointments that take place.

Browne, Lennox, F.R.C.S. Edin.—Honorary Surgeon to the National Training School for Music.

Hemming, W. Douglas, M.R.C.S.—Assistant-Surgeon to the Central London Throat and Ear Hospital.

Murray, James, L.K.Q.C.P.I., M.R.C.S.—Chloroformist to the Central London Throat and Ear Hospital.

Steele, George R., M.R.C.S., L.S.A.—Assistant-Surgeon to the Central London Throat and Ear Hospital.

NAVAL, MILITARY, &c., APPOINTMENTS.

Royal Dublin City Militia.—Surgeon George William Owens resigns his commission.

War Office.—Surgeon-Major Thomas George Fitzgerald retires on half-pay with the honorary rank of Deputy Surgeon-General; Surgeon-Major Charles Henry Leete, half-pay, resigns his commission; Surgeon-Major Curtiss Martin, from half-pay to be Surgeon Major; Surgeon-Major Walter Crisp, from half-pay to be Surgeon-Major.

BIRTHS.

Murray.—On December 14, at Meadowside, Upper Richmond-road, Putney, the wife of G. Stanley Murray, M.D., of a son.

Roberts.—On December 14, at 24, Upper Rathmines, Dublin, the wife of Browne Roberts, L.K.Q.C.P.I., of a son.

Will.—On December 5, at 40, George-street, Portman-square, the wife of George Elmsby Will, L.R.C.P. Edin., Surgeon-Major Army Medical Department, prematurely, of a son.

MARRIAGES.

Lucey—Harding.—On December 18, at St. Stephen's Church, Kirkstall, William Cubitt Lucey, M.D., of Ben-Rhydding, Wharfedale, to Eleonor Anne, second daughter of T. R. Harding, Esq., J.P., of St. Ann's Tower, Headingley, Leeds.

Tomkins—Tomkins.—On November 22, at the British Consulate, Santos, Brazil, Charles Capper, second son of Charles Joseph Tomkins, M.R.C.S., of Teddington, to Mary Ann Amelia, fifth daughter of Frederick James Tomkins, M.A., D.C.L., barrister-at-law, of Lincoln's-inn.

DEATHS.

Hawkins, Francis, M.D., Physician to her Majesty's Household, at 16, Ashley-place, on December 13, in his 84th year.

Hyde, Rachel, wife of Edward Hyde, M.R.C.S. Eng., at Bloxam, Oxon, on December 16, aged 69.

Macartney, John Park, M.D., late of Mexico, at Pelham-crescent, South Kensington, on December 12, aged 70.

Simpson, Alexander Rudolf Virchow, son of Alex. Russell Simpson, M.D., F.R.C.P. Edin., etc., at 52, Queen-street, Edinburgh, on December 13, aged 5 months.

Whitchurch, Nathaniel, M.R.C.S. Eng., of Melton Mowbray, at Great Barford, Beds, on December 12.

Williamson, George, M.D., Surgeon-Major Madras Native Infantry, at 30, Cambridge-gardens, Notting-hill, on December 16, of aneurism.

VACANCIES.

In the following list the nature of the office vacant, the qualifications required in the Candidate, the person to whom application should be made and the day of election (as far as known) are stated in succession.

The Guest Hospital, Dudley.—Resident Medical Officer. Candidates must be unmarried, and Fellows or Members of the Royal College of Surgeons of England, Edinburgh, or Dublin, and possess a registered qualification in medicine. Applications, with testimonials and certificate of registration, to the Secretary, on or before January 1.

UNION AND PAROCHIAL MEDICAL SERVICE.

*** The area of each district is stated in acres. The population is computed according to the census of 1871.

RESIGNATIONS.

Melksham Union.—Mr. Lewis Miller has resigned the First District; area 1970; population 6256; salary £55 per annum.

Thingoe Union.—The Eighth District is vacant; area 2390; population 578; salary £18 per annum.

Warminster Union.—Mr. Robert L. Willcox has resigned the Longbridge Deverill District; area 13,420; population 3681; salary £98 per annum.

APPOINTMENTS.

Beaminster Union.—Arthur Butler, L.R.C.S. Ire., L.K.& Q.C.P. Ire., to the Evershot District.

Clitheroe Union.—Joseph J. Smithies, L.F.P. & S. Glasg., L.R.C.P. Edin., to the Clitheroe District.

Rochford Union.—Wm. A. Raper, M.D. Lond., M.R.C.S., L.S.A., to the Great Wakering District.

The Library of the Royal Medical and Chirurgical Society will be closed on Monday, Tuesday, and Wednesday, December 24-26.

St. Mark's Ophthalmic Hospital, Dublin.—At a meeting of the governors of this institution, held on Monday, December 17, Dr. John Benjamin Story was elected Junior Surgeon, in the room of Dr. Rainsford, chosen Senior Surgeon after the lamented death of Mr. Henry Wilson in June last. Dr. Story is a distinguished graduate of medicine of the University of Dublin. He took his degrees in 1876, and has since then studied on the Continent and in St. Mark's Hospital.

Treatment of Epistaxis.—Dr. Blondeau relates a case of epistaxis in which a large quantity of blood had been lost, and which, not yielding to other means, he succeeded in rapidly arresting by the application of a tape tightly around the middle part of the thigh. As the bleeding did not recur, this was removed next day, when the hæmorrhage reappeared soon after. A new application of the ligature was made, and was again promptly successful, the bleeding again returning, when it was removed. At last, after a series of these alternations, the hæmorrhage ceased entirely.—*Union Méd.*, Dec. 8.

Ergot in Hæmorrhoids.—Dr. Lansing states that he has found this very useful in four cases. He employed four grains of ergotine as a suppository, night and morning at first, and then only at night. The first effect was the production of pain for half an hour or more. After the use of three or four doses, neither this or other unpleasant effect occurred, the hæmorrhage ceasing, and the congested state of the parts disappearing—the slight tumefaction remaining suggesting interstitial fibrinous exudation, or cellular hyperplasia.—*Philadelphia Med. Times*, October 13.

The Journey to the South of France.—Since December 1 the Mann boudoir sleeping cars, which are identical with the well-known Pullman's cars, run over the whole distance between Paris and Mentone, on the Paris, Lyon, and Méditerranée Railway. The extra cost of a place beyond the price of a first-class ticket is forty-six francs to Mentone, or thirty-six francs to Marseilles, and ten francs on. Tickets can be also taken to the intermediate stations of Cannes, Nice, Antibes, etc. To secure places early application is necessary, as their number is limited, and only eight places can be guaranteed between Marseilles and Mentone. The cars are attached to the 7.15 p.m. express from Paris, and to the return train leaving Mentone at 9 a.m.

Discharge of Ascarides through the Abdomen.—Dr. Anrep relates the case of a robust soldier, aged twenty-eight, in whom appeared, amidst symptoms of partial peritonitis, an abscess the size of a goose's egg in the right inguinal region. This opened spontaneously, discharging a considerable quantity of greenish-yellow pus, accompanied by a yellow stinking fluid containing particles of fæces and two large ascarides. During the next two days two other worms were also discharged. The finger could be passed considerably upwards without inducing pain, and the wound healed speedily. On account of the slight degree of peritonitis, and the small amount of fæcal matters discharged, the author believes that the processus vermiformis was perforated, the ascarides having been accidentally detained therein.—*St. Petersburg Med. Woch.*, December 1.

Death of Dr. Elie Gintrac.—This veteran of medical science has just been carried off by a sudden stroke of apoplexy, in the eighty-fourth year of his age. Associate of the Academy of Medicine, and Honorary Director of the Bordeaux School of Medicine, "M. Gintrac," M. Dechambre observes (*Gazette Hebdomadaire*, December 14), "was beyond contradiction, by his talent, his constant ardour for work, and the dignity of his character, one of the most remarkable figures of the contemporary medical body. He commenced his career with remarkable effect, for his inaugural thesis of 1814 became the point of departure of all that has been since written upon a pathological condition that the works of Sénac, Corvisart, and Caillot had made only imperfectly known—we speak of cyanosis. This thesis became in the hands of its author a true monograph on that affection in 1824. We owe to him also a considerable number of memoirs relating to affections of the chest, various observations in clinical medicine and pathological anatomy, on heredity, and on the treatment of various diseases. But M. Gintrac's great title to renown is his "Cours Théorique et Clinique de Pathologie Interne et de Thérapie

Médicale," which has reached its ninth volume, and the termination of which it is to be feared and regretted will now never be seen. It is one of those works teeming with erudition, good sense, and clinical wealth, which it is rare to find springing up in the departmental schools, even those of the first rank. In fact, if the Bordeaux Ecole de Médecine occupies the high position we see it in, and which has rendered it worthy of being promoted to the rank of a Faculty, it owes this in great part to M. Gintrac, who, by his enlightened direction, and still more by the noble example which he himself offered to emulation, was enabled to increase, fortify, and stimulate this scientific centre, once so languishing. It suffices to say that during his period of office the number of pupils increased gradually from about forty to more than 400."

INCREASED FREQUENCY OF RESPIRATION IN PHTHISIS AND BRONCHITIS.—It is an important clinical fact that frequency of respiration bears no such relation to bronchitis as it does to phthisis. A great amount of bronchitis may be present, and yet not be accompanied by any increased frequency of respiration. A greater length of time is required for the air to make its entrance and exit in bronchitis than in phthisis, because of the want of elasticity in the expiration, and usually there is more or less obstruction to inspiration; the patient perhaps labours for breath. Increased frequency of respiration is to be regarded as one of the earliest symptoms of phthisis—the disease, although limited in extent, giving rise to more frequent respiration than is seen in a bronchitic patient, with lungs over which all kinds of auscultatory signs can be heard.—*New York Med. Record*, October 27.

JUVENILE DEPRAVITY.—It would appear that at least some of the public-houses in Poplar require strict police watching, if such assemblies of drunken boys and girls as that recently discovered at the house of William Miller, a publican in that district, are to be stopped. A police-sergeant, at eleven o'clock on a Saturday night, found in the "club-room" of Miller's house about forty boys and girls, of ages ranging between fourteen and twenty years. The girls had neither bonnets nor shawls on, and were very disorderly and uproarious in their conduct. Miller told the sergeant "it was a juvenile lead—he couldn't help it." One of the girls was lying on the seat drunk, and apparently in a fit. The sergeant tried to rouse her, when she opened her eyes, and exclaimed: "This girl is drunk!" Two boys, about sixteen years old, were sitting on a table with a pot of beer between them. Miller was summoned before the magistrate for permitting drunkenness on his premises, and fined £5, the conviction being ordered to be endorsed on his licence.

NOTES, QUERIES, AND REPLIES.

He that questioneth much shall learn much.—*Bacon.*

Dr. West.—We cannot say, but believe that Dr. William Farr, F.R.S., has been connected with the General Register Office as Superintendent of Statistics since its establishment. The salary which he ably and fully earns appears as £1100 per annum.

Dr. Campbell.—Unable to answer your inquiry last week; cannot find that a photograph has been published of Mr. Prescott Hewett. Perhaps when his portrait, which is now being painted by Mr. Owless, for exhibition at the Royal Academy, is finished, the subscribers may be presented with an engraving, as in the case of the late Sir William Fergusson.

Anatomist, Exeter.—The widow of Sir Charles Bell died in November, 1876, aged ninety years.

Mr. Williams.—The late Sir William Fergusson was created a baronet in 1866; Sir James Paget in 1871.

Mr. Cooper.—Mr. F. T. Buckland, the Government Inspector of Salmon Fisheries in England and Wales, is a member of our profession, his diploma of Membership of the College of Surgeons bearing date 1851. The salary attached to the above office is £700 per annum.

Geologist, Falmouth.—Professor Huxley holds other appointments besides that of Naturalist in the "Geological Survey of the United Kingdom," the salary of which appears as £600 per annum. As Professor in the Royal School of Mines he receives £200 per annum. He is a Member of the Royal College of Surgeons.

Sanitary Work.—The inquiry was held at Croydon last week by Lieutenant-Colonel Ponsonby Cox, one of the inspectors of the Local Government, as to the application of the Rural Sanitary Authority of that Union to borrow £77,070 for works of sewerage and sewage-disposal for Beddington, Merton, Mitcham, Morden, and Wallington.

Charity.—The Hospital Sunday collection made at Melbourne this year amounted to £3371.

Cato.—According to a report presented to the Parliament of Queensland, and published under authority, the birth-rate for the year 1876 was 3·74 and the mortality 1·88 per cent. of the population.

Reading Hard.—No; what Miss Fenwick Miller said, when lecturing on the human brain and its functions, was, that a full amount of sleep was a *necessity*; and her conviction was, "that the idea of 'saving time' by taking an extremely short allowance of sleep was a dangerous physiological delusion."

Scrutator.—The German Universities receive about £500,000 a year from the Imperial Government. This sum was considerably exceeded in 1875, when Strasburg alone was apportioned nearly £200,000. There are other German Universities, situated beyond the confines of the Empire; and altogether there are twenty-eight of them in Europe. The number of professors paid by the German Empire is 1300, and that of the *Privat-docenten* 1050. The Medical Faculty is the only one in which it is imperative on the student to take the degree of doctor. In the other faculties, admission to the privileges and honours of a profession is obtained solely by passing the so-called State or Government examination.

Naval Pension.—The Greenwich Hospital pension of £50 a year, vacated by the death of Staff-Surgeon Tarn, has been awarded to James Vaughan, Deputy Inspector of Hospitals and Fleets.

Sybil.—Yes; we understand a number of chemists have organised an association under the title of "The Institute of Chemistry of Great Britain and Ireland." It is stated that its objects are the promotion and encouragement of a thorough study of chemistry and the allied branches of science, and for the purpose also of taking necessary steps for the maintenance of the dignity of the chemical profession. 2. The students of Owens College, Manchester, have formed the Owens College Chemical Society.

A Surgeon, Yorkshire.—The paper about which you inquire was communicated by Mr. Galton to the Statistical Society in 1873. He stated he had carefully analysed and discussed the census returns of 1000 families of factory operatives in Coventry, and of the same number of agricultural labourers in the neighbouring small rural parishes of Warwickshire, and found that the former had little more than half as many adult grandchildren as the latter. They had fewer offspring, and of these few a smaller proportion reach adult life, while the two classes marry with about equal frequency, and at about the same ages.

JOHN HUNTER, F.R.S.

We are again indebted to Mr. Stone, of the College of Surgeons, for permission to publish the following very interesting document, described on the envelope by Jenner, to whom it is directed, as a "Letter of Importance from the late John Hunter":—

"Dear Jenner,—I thank you for your last letter. I want you to pursue the enquiry considerably further; and to give you an idea of what I mean, I'll first premise that there are in Nature but three Colours—viz., Red, Blue, and Yellow, all the others being combinations of these three.

"First present him with these colours singly, and see what he calls them; then altogether (not mixed), and see how far they correspond with his first ideas of them. When that is ascertained, then begin to mix them; for instance, a Blue and Yellow (which makes a Green)—see what he calls that; then a Yellow and Red (which makes a Scarlet); next a Blue and Red (which makes a Purple).

"Now to explain the intention of these experiments:—Suppose he has a perfect idea only of one colour; and although you mix that colour ever so much, yet he sees none of the other, but only that colour in the mixture. Suppose all three colours, when seen singly or unmixed (with Him), are Blue; mix Blue with Red (making a Purple), he will only see the Blue, the Red not being visible to him; and so on of the others, according as he sees them. Suppose that a simple colour makes no impression, but a compound does—viz., Green (which is composed of Blue and Yellow); then mix Blue and Red in all proportions to see what the colour is; then mix Yellow and Red in all proportions and see what colour these are; if he sees no green in any of them, then mix all the three colours in various proportions, and see what colours those make. When all the Colours are mixed in various proportions, and the whole is a Green, perhaps of different shades, according to the quantity of blue and yellow, then you may fairly conclude that it is the mixture of the Blue and the Yellow which produces it, the Red never making any impression. If there is any other simple compound that he sees, as *Scarlet*, which is Yellow, and the *Modena* Red, or a Purple, which is Blue and Red, see if, when those two are predominant in the mixture (although there are all the three colours in the Mixture), that the compound becomes the visible colour.

"The drawing of the scull has been made ever since you desired it, but I had forgot it. I have a cast for you of the aneurismal varix described by Dr. Hunter. How shall I send both? Let me know.

"Ever your much obliged JOHN HUNTER."

There is no date to this letter. It was written probably in November, 1783 (he died 1793), the date of the following letter (also from the same collection), relating incidentally to the same subject:—

"Dear Jenner,—I received yours with the experiments on Heat and Colours, but have not had time to pay sufficient attention to the colours. I also received your little publication with the Tart. Emet. I have a great deal to say about it. First, do you have to take out a Patent? Do you have to advertise it? Or do you have to let it takes its chance? I aprove (*sic*) of it much, and will do all in my power to promote the sale; but I would advise you to give it new a name expressive either of the composition or of its virtues in the body—viz., sal. antim., or sal. sudorif., or sal. antim. sudorif. I would also desire you to burn your Book, for you will have all the world making it. Let me have your answer to all this.

"Ever yours, JOHN HUNTER."

PARISH RELIEF.

The Conference of Poor-law Guardians last week resulted in a resolution to request the Central Committee to take such steps as they may deem expedient to urge on boards of guardians generally the adoption of the principle that outdoor relief should be the exception, and indoor the rule.

HEROIC.

Mr. Blackburn, a practitioner in Barnsley, at great personal risk captured a dangerous lunatic named Birkinshaw, who was at large a few days ago. The latter had pursued several children with a carving-knife, and, advancing towards Mr. Blackburn, threatened him with death, presenting a revolver, which the doctor fortunately sharply knocked out of the lunatic's hand, and then seized him. He was subsequently lodged in the padded room of the workhouse.

COMMUNICATIONS have been received from—

Mr. J. KNOWSLEY THORNTON, London; Mr. BACOT, Seaton; THE SECRETARY OF THE OBSTETRICAL SOCIETY, London; Mr. SPENCER WATSON, London; Mr. HENRY WRIGHT, London; Dr. E. SPARKS, Mentone; Mr. W. M. BYWATER, London; Dr. J. W. MOORE, Dublin; Mr. JONATHAN HUTCHINSON, London; Dr. CARTER, Melbourne; Dr. HUSSEY, Oxford; Dr. KESTEVEN, London; THE REGISTRAR OF THE APOTHECARIES' HALL, London; THE REGISTRAR OF THE UNIVERSITY, London; Dr. W. APPOINTMENTS FOR THE WEEK.

December 22. *Saturday* (*this day*).

Operations at St. Bartholomew's, 1½ p.m.; King's College, 1½ p.m.; Royal Free, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.

24. *Monday*.

Operations at the Metropolitan Free, 2 p.m.; St. Mark's Hospital for Diseases of the Rectum, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.

25. *Tuesday*.

Operations at Guy's, 1½ p.m.; Westminster, 2 p.m.; National Orthopædic, Great Portland-street, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; West London, 3 p.m.

26. *Wednesday*.

Operations at University College, 2 p.m.; St. Mary's, 1¼ p.m.; Middlesex; 1 p.m.; London, 2 p.m.; St. Bartholomew's, 1½ p.m.; Great Northern, 2 p.m.; Samaritan, 2½ p.m.; King's College (by Mr. Wood), 1½ p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.; St. Peter's Hospital for Stone, 2 p.m.

27. *Thursday*.

Operations at St. George's, 1 p.m.; Central London Ophthalmic, 1 p.m.; Royal Orthopædic, 2 p.m.; University College, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; Hospital for Diseases of the Throat, 2 p.m.; Hospital for Women, 2 p.m.; Charing-cross, 2 p.m.; St. Thomas's (ophthalmic operations), 4 p.m.

28. *Friday*.

Operations at Central London Ophthalmic, 2 p.m.; Royal London Ophthalmic, 11 a.m.; South London Ophthalmic, 2 p.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. George's (ophthalmic operations), 1¼ p.m.; Guy's, 1½ p.m.

QUEKETT MICROSCOPICAL CLUB, 8 p.m. Mr. Marcus M. Hartog, "On the Investigation of Floral Development."

VITAL STATISTICS OF LONDON.

Week ending Saturday, December 15, 1877.

BIRTHS.

At the Royal Observatory, Greenwich, the mean reading of the barometer last week was 29·93 in. The lowest reading was 29·57 in. on Wednesday morning, and the highest 30·31 in. on Saturday morning.

* The figures for the English and Scottish towns are the numbers enumerated in April, 1871, raised to the middle of 1877 by the addition of six years and a quarter's increase, calculated on the rate which prevailed between 1861 and 1871. Salford, however, forms an exception to this rule, as the estimate is based upon the rate of increase of inhabited houses within the borough during the six years ending July 1, 1877. The population of Dublin is taken as stationary at the number enumerated in April, 1871.

ORIGINAL LECTURES.

IS HEBRA'S PRURIGO MET WITH IN ENGLISH PRACTICE?

By JONATHAN HUTCHINSON, F.R.C.S.,
Senior Surgeon to the London Hospital and to the Hospital for Diseases of the Skin, and Surgeon to the Moorfields Ophthalmic Hospital.

(*Concluded from page* 666.)

The following may, perhaps, be found a fairly accurate grouping of the cases of prurigo as met with in English practice. Of course I put wholly aside the numerous cases in which the irritation of the skin is due directly to the presence of parasites—scabies, and morbus pediculosus. Although I have little doubt that attacks of these maladies do sometimes lay the foundation of chronic and persistent prurigo—of cutaneous irritability which may persist for years after the cause has been removed—and which may then deserve a change of name and take position under that of the disease which we are investigating; yet it would be extremely inconvenient to confuse them so long as their phenomena are in direct relation with a special cause of this nature. After, however, we have relegated all forms of pedicularia (comprising almost all that were formerly known as *Prurigo senilis*) to their proper position, there will still remain a considerable number of cases of prurigo proper, or prurigo without parasitic cause, and these I would propose to group as follows:—

Group I. *Cases in Young Children or Infants which have resulted from Varicella, Vaccinia, or Measles.*—These cases are tolerably common, and are severe. They may be diagnosed by their history, and by the existence of small bullæ and pus-crusts and the formation of vesicles on the palms and soles. They are very intractable, but get well in the end.

Group II. *Cases of Severely Pruriginous Lichen in Infants and Young Children.*—These are yet more common than the preceding, and every out-patient clinic affords abundant examples of children covered over back and loins, and often on extremities also, with itching lichen-spots which have been scratched and abraded. These also are difficult of cure, but are usually very much benefited by treatment. They are almost always worse during summer (the flea season), and there is often reason to suspect that the eruption is, in large part, due to the bites of insects—fleas, bugs, or gnats. These cases might be supposed to supply examples of Hebra's prurigo in its earliest stage, but we have no reason to believe that any considerable proportion of them are protracted into adult life.

Leaving the period of childhood, we find that young adolescents are liable to a peculiar form of prurigo, which in some features resembles acne, and which is almost invariably liable to exacerbation in summer; of these cases we constitute—

Group III. *Prurigo of Adolescents and Adults, Relapsing in Summer.*—This eruption affects the face and arms, and although it may extend over the whole surface of the limbs and trunk, it is always most severe on face, arms, and shoulders. Its pimples are but slightly developed, and erythematous congestion of the skin is always conspicuous. It does not usually itch excessively, but it is always more or less scratched, and always leaves scars. Although more common about the period of puberty, it may begin in childhood or in adult age. Some of these cases approach very closely to Hebra's type, but the summer aggravation, the severity with which the face is affected, and the seldomness with which it begins in infancy, are important differences.

Next we have, as constituting—

Group IV. *Winter Prurigo*, comprising cases in which the skin is made pruriginous by cold. These patients are always well in summer; they are usually thin and of feeble circulation and very prone to cutis anserina on exposure. The eruption never affects the face, and almost always begins on the lower extremities. It is seldom or never seen in the very young.

Very closely allied to the winter prurigo group we have another, which may be suitably known as the—

Group V. *Persistent Prurigo of Adults and Aged.*—This differs in nothing from Hebra's type excepting in that it is rarely a very severe malady, and that it does not begin until past middle life. It is for the most part a disease of the aged. The following case may be cited to illustrate this form:—

The Rev. C. M. consulted me because I had been fortunate enough to cure of a most troublesome prurigo an elderly lady with whom he was acquainted. His case, although by no means a severe one, presents some interesting features. He is about sixty years of age, an inheritor of gout, from which he has suffered mildly; thin, and of rather feeble circulation. When a boy he had eczema intertrigo behind the knees, and a troublesome itching rash on the shins, but it got well, and he did not again suffer until three years ago. He once had something like nettle rash from drinking beer, but is not liable to much irritation from the bites of fleas. His present inconvenience consists in a general irritability of skin, which is worst on his legs. There are no spots, but he says that when he begins to scratch he always succeeds in finding little itching points which afterwards develope into papules. These often bleed from his scratching. He insists after deliberate argument that the scratching really gives him great relief, and that it would be useless to attempt to abstain. The prurigo is not very severe, and it never keeps him awake at night. He has not observed that articles of diet influence it, or that fire-heat makes it worse. It has persisted now for three years, being worst in winter, but by no means absent in summer. There is some irritation of the scrotum, but no actual eczema.

I may observe that in several other cases of this type I have obtained the history of eczema of the popliteal spaces in childhood, and in some of more or less of skin irritation generally, thus more nearly completing the picture which Hebra has given. In none, however, had the symptoms in childhood been in any degree severe, and in all they had been soon cured, and a long interval had occurred before the senile attack.

In the case of an officer in the army, who was sent to me by Dr. Meadows, the prurigo was rather severe, and had lasted several years, but there was no history whatever of symptoms in boyhood.

In the following we seem to have a connecting link between constitutional or dartrous eczema and Hebra's prurigo:—

Sarah H., aged forty-nine, was admitted in April, 1869, and gave the history of having suffered from itching eczema in the flexures in childhood. At the age of fifteen she got rid of it, and had no skin disease until her present trouble began three years ago. On the backs of her hands, and on both legs just above the ankles, and thence upwards to the thighs, were patches of eczema, which itched excessively. Between the patches the skin was harsh and pigmented. The nails were roughened. Boils had occurred and had left scars. She had sometimes been confined to bed by it, and during the whole three years it had never been quite well. The case is, perhaps, rather pruriginous eczema than prurigo proper, but it is interesting to note that it affects the prurigo positions rather than those usually attacked in eczema.

The following case—one of the very few in which, with a history extending over many years, lice were discovered—may suitably raise the question whether the parasites ought to be considered as more than an accidental complication. It will be seen that the eruption occurred on the face, and to some extent on the arms—parts which do not usually suffer from the irritation of lice. Yet it is quite possible that in some cases a general pruriginous state of skin may be set up by their presence, which may involve parts not actually infested. This theory is, I think, by no means improbable as the true explanation of a certain number of the cases of relapsing prurigo.

Hannah C., aged eighteen, admitted July, 1872. Had been liable to relapsing prurigo since the age of two years. It had been very changeable, but never got quite well. It affected the extensor surfaces of the upper and lower extremities, and the face and back; a few spots occurred on the fingers. Lice were found on her head and in her clothes.

Richard M., aged twelve, has been liable to prurigo every summer for four years. It is slight on the body, and worst on the arms and legs. It was a mixed papular and pustular eruption, and very much scratched. It was stated to have begun between the fingers. The skin of the outer surfaces of his thighs and arms was thickened and dry. There were lice in abundance on the head, but none were found on the clothest The suggestion made in the preceding case as to persisten. irritation from lice may here possibly apply to that of scabies

Thus, then, under one or other of these five headings—(1) Varicella prurigo; (2) lichen-prurigo of infants; (3) relapsing or summer prurigo of young persons; (4) winter prurigo; (5)

persistent prurigo of adults—I think we should be able to group pretty easily all the cases occurring in English practice in which prurigo is a disease of the cutaneous surface generally. I have left aside for the present those in which it is a local malady, as, for instance, the prurigo pudendi and prurigo of the anus. Although, put together, we have in these several groups of cases all the features which Hebra enumerates, yet I must protest that they are clinically very different from each other, and that we do not observe any in which they are combined in the same patient.

Before concluding, I have to remark that although these groups include, I think, the chief maladies which deserve the distinctive epithet of prurigo, yet that a pruriginous element must be expected in many other maladies which do not obtain or deserve that name. Eczema-lichen, lichen ruber, acne, and even psoriasis itself, may be each in turn more or less pruriginous. When they are so, the primary eruption at once receives important modifications, and special measures of treatment are required. I have recently had under care a most terrible case of pruriginous eczema, in which it would be hardly too much to assert that the man scratched himself to death. He used to tear his skin incessantly, and had produced by doing so lines of scar and great indurated wheals of an almost keloid character. Yet his skin was also universally eczematous, and he had been seen by almost every dermatologist in London with that diagnosis. The disease had begun rather suddenly in middle life, and had been attended by intense prurigo from the first, which lasted without abatement till the time of his death, three or four years later. His sister, older than himself, suffered also from winter prurigo, and was constantly scratching, but had no eczema. In many cases of eczema in children the itching which attends the eruption becomes an important cause of its aggravation.

I have lastly to express a hope that I shall not be considered to have indulged unduly, in the present lecture, a controversial spirit. No one admires more than I do the vigorous powers of observation and zest for the discovery of truth which are displayed in the writings of Professor Hebra. If I have seemed to address myself to an attempt to rectify his descriptions, it has been chiefly because I found his graphic chapter on prurigo a very convenient text from which to start. I cannot, however, conceal my belief—indeed, I have already expressed it—that the chapter in question is not applicable to English experience. Instead of admitting that there exists a causeless and incurable malady, to be known as PRURIGO, which is for the most part unconnected with other skin diseases, my endeavour has been to show that there are certain definite causes of skin irritation to which these maladies are attributable, and that it is more consistent with clinical truth to break up the group of maladies described under this name into several smaller ones, each associated with something peculiar as regards cause or concomitant conditions. How far I have succeeded in my attempt I must leave to you to judge. The classification at which I have arrived is, it must be asserted, by no means unimportant in practice, for the different groups of cases require very different methods of treatment. Nor is prurigo, although fortunately in its severe forms a rare disease, in any degree to be regarded as unworthy of detailed study. It may easily spoil the happiness and mar the usefulness of a large part of a life, and if we can succeed in any degree in increasing our knowledge of its causes and the modes of its prevention, neither our time nor our trouble ought to be grudged.

ORIGINAL COMMUNICATIONS.

NOTES OF A CASE OF

DISSEMINATED SCLEROSIS OF THE BRAIN AND SPINAL CORD IN A CHILD.

By E. I. SPARKS, M.A., M.B. Oxon., M.R.C.P. Lond.,
Late Physician to the Skin Department of the Charing-cross Hospital, etc.

THE publication of a case of cerebro-spinal sclerosis in a young child, by my friend Dr. Humphreys, of Manchester, in the *Medical Times and Gazette* of November 3, page 491, induces me to send the following, I fear imperfect, account of a parallel case which has been under my own observation for now more than four years. It will be noticed that the child was about three months older than Dr. Humphrey's patient when the disease is supposed to have commenced:—

J. C., aged three years and four months, came under my care at the North-West London Dispensary for Sick Children, at which I was one of the physicians, on April 28, 1873, for an attack of whooping-cough, and was treated with ipecacuanha mixture for a few days, and afterwards with vin. ferri ʒij. and oleum morrhuæ ʒij. t. d. s. during the greater part of May, with considerable improvement of his general health. On May 29 it was first noticed that there was marked external squint and dilated pupil in the left eye, which his mother stated to date from May 23. There was also slight paralysis of the inferior rectus. At the same time attention was first called to the condition of other parts of the body, and to the fact that the child could not stand or walk without help, but staggered about like an ataxic patient when put on his legs. He could raise both arms above his head; but if made to hold any object he could not raise them so far as when empty-handed, and the left arm was involuntarily shaken about in an irregular and convulsive manner.

These symptoms led to an inquiry into the child's earlier history, the details of which, though they scarcely throw much light on the case, are as follows:—

J. C. was much weakened by hæmorrhage from the navel soon after birth; but he was fairly healthy until February, 1873, when he had an attack of shingles (herpes zoster) on the left side of the head and neck, extending up behind the ear. From this illness, which left him very weak, his mother dates the beginning of the motor disturbances and loss of power in the legs; for previously he could walk well for a child of his age, and he had been able to attend the infant-school in the summer of 1872. The child had never had a fit, a blow on the head, or a severe fall, and had never suffered from otorrhœa or worms. He used to lie and beat his head at one time, probably in consequence of headache. The family history also fails to elucidate the case. The father and mother are healthy and strong, and no relatives have ever been similarly affected. The mother had scarlet fever at the time of the boy's birth, and her confinement is said to have been brought on by it. Later on she was laid up with rheumatic fever. J. C. was her fourth child. The eldest is alive and well; the second and third died of bronchitis. None of the children, including J. C., ever had sores on them; and the mother never had sore throat except at the time of the scarlet fever. Since J. C., three children have been born, viz., a boy in 1873—a fine healthy child according to the most recent accounts (November, 1877); a girl in 1875, "a small but very healthy child"; and a boy in February, 1877, which lived four months and a half, and died of hydrocephalus. The mother writes that she was told that if the last baby had lived it must have grown up an idiot.

On June 12 my friend Dr. Gowers saw J. C. with me, and kindly examined his eyes with the ophthalmoscope, and reported that "he has no optic neuritis; the edge of the disc is clear; the veins are a little larger than normal; there is slight redness of the disc, but no swelling; sight is good." The following note was also taken:—"There is no marked alteration in the sensibility of the legs; there is no facial paralysis; the tongue is protruded straight. He has ptosis to-day, but not complete. He eats pretty well, and can talk when at home. He can hear well, and has no headache. Both legs are rather inclined to waste. Ordered—℞. Potass. iodidi gr. iij, syrupi ferri iodidi ℥xv. t. d. s., hydrarg. c. cretâ gr. ¾, nocte maneque sum."

June 28.—"Complains of much headache in the last few days, and has asked his mother to hold his head. The appearance of the optic discs is the same (Dr. Gowers); the ptosis of left eyelid is, if anything, more marked. The unsteadiness of the left arm and ataxy of the legs is unimproved; in fact, his mother thinks he shakes more than he did. He cannot walk without support, and if held and made to walk, swings his right leg down, instead of bending it in the ordinary way."

July 7.—"He is in much the same condition as before; if anything, he walks worse, throwing the legs outwards and jerking them down. He eats very greedily, his mother says."

12th.—"His whooping-cough, which still continues, is very troublesome, and he has from twenty to thirty paroxysms in the twenty-four hours. He perspires very much about the head; has no headache now. Dr. Gowers again saw him, and reported 'a small patch of atrophy in the right eye.'"

He was not now seen again until October 25, when it was noted that "the child walks, when slightly supported, like a blind man groping his way; he sways the body, and puts the legs out far and very deliberately. There seems to be slight paralysis of the superior rectus muscle of the *right* eye. The

squint and dilated pupil on the left side are no better. The child generally looks to the right. There is rather less shaking of the left arm, but the right is a little affected now, and there is some incoördination of the jaw and the tongue. There is no complaint of pain in the body or limbs, but he occasionally suffers from headache. He is cleanly in his habits, and passes his water well. He has a good appetite, and is fatter than he was in June. He has lost his cough, and has gained colour." Just before this note was taken the child was an in-patient at the Great Ormond-street Hospital for three weeks, as his mother was expecting her confinement. He did not attend as an out-patient, and his mother does not know what medicine he took while in the hospital. After this he was lost sight of until August 30, 1875, when Dr. Gowers again saw him with me. We then noted that "the left arm and hand shake even when no voluntary movement is attempted. If he tries to grasp something held before him—*e.g.*, a stethoscope,—he takes several seconds with outstretched palm and extended fingers to seize it. The jactitation is thus much worse than it was. The left pupil is dilated out of proportion to the paralysis of rectus, but there is considerable divergence of the eye outwards. There is no nystagmus. The right hand is almost quite steady. The child cannot walk at all without support. He can stand alone, but shakes from side to side. He can also stand with the eyes shut. He has been treated with an orthopædic apparatus for the last four months, but cannot walk any better for it, and it merely supports him. He shakes about very much when the irons are taken off. He has a good memory, but cannot read or spell. His speech is slow and syllabic. He can count numbers up to twelve, but omits a figure occasionally. His general health is good, and he sleeps well. He is remarkably fat for his age."

Since 1875 I have not, unfortunately, had an opportunity of seeing the boy myself, but, in answer to my inquiries, his mother, who is a very intelligent woman, has sent me the following particulars, with the date November 7, 1877. She says—"I am happy to say he enjoys most excellent health; his appetite is good, and he sleeps well, but the shaking is just the same, and mostly on the left side as it always was. He never uses his left hand. He can (now) manage to walk across the room *without* support, but very slowly indeed, as the shaking seems worse then, and makes him fall very much (? often), but we hope that he will be able soon to use a crutch. His hearing and sight are quite good. The pupil of the left eye is just the same as when you saw him. He has never had any fit, nor yet a day's illness since August, 1875. He does not wear any supports (orthopædic irons) now, nor has he done so for eighteen months, as they appeared to be useless after a year and a half's trial. I think, if anything, his speech is a little better, and he has a wonderful memory. He never complains of pain in the head or elsewhere. He has never taken any medicine since you saw him, and, in fact, I think I may say that he is in just the same state as he was then. The only improvement I notice is in his speech, and that is very slight."

On November 16 she wrote that "J. C. is suffering from rather a sharp attack of bronchitis, which seems to affect every nerve, but I hope that he will soon recover with care."

Remarks.—In this case there is clear evidence of pathological lesions in the brain and spinal cord, affecting the co-ordination of various muscles, and paralysing the functions of the third nerve on the left side, and possibly to a slight extent on the right. These facts, and the co-existence of tremor on voluntary movement, point almost certainly to cerebro-spinal sclerosis as their cause, and the case is interesting from the early age at which the disease commenced—viz., three years and six months. Syphilis could be excluded with considerable certainty, and treatment directed against its possible presence was without appreciable effect. Tubercle also was scarcely to be thought of, considering the symptoms, the family history, and the state of the child's nutrition throughout. None of the ordinary supposed exciting causes of cerebro-spinal sclerosis were present in this case. The scarlet fever from which the mother suffered at the child's birth is scarcely likely to have affected him; and whooping-cough attacks thousands of children without any nervous sequelæ like the above; moreover, the greater part of the motor incoördination seems to have preceded the whooping-cough, though the paralysis of the third nerve certainly arose during the course of that disease. That there was some connexion between the attack of herpes, from which the nervous symptoms are alleged to date, is more probable, though I should regard the herpes rather as an effect of the incipient sclerosis than as its cause. I have seen herpes of the ilio-inguinal nerve associated with "infantile" paralysis of the opposite leg. Treatment had no appreciable effect in improving the symptoms; whether it helped to arrest the progress of the sclerosis is an open question. Iodide of potassium and grey powder were given for several weeks while the child was under my care, and he was also treated with cod-liver oil and iron; but as his general health was latterly excellent, there was no special indication for the continuance of these remedies after the subsidence of the whooping-cough for which he first attended. I rather regret that chloride of barium, as recommended by Hammond, was not tried at the onset of the sclerosis.

The disease appears to be for the present arrested, but there can be no hope of a cure of the existing symptoms, and the child is, and must always remain, a cripple.

SATURDAY, DECEMBER 29, 1877.

ANNUS MEDICUS 1877.

Notwithstanding the epidemic of small-pox, which had gradually increased in severity till it attained to a very grave magnitude and character, the state of the public health in 1877 was generally satisfactory, the death-rate having been throughout the year, in London and in the country, very low.

The fatal cases of small-pox registered in London had been 97 and 75 in the last two weeks of 1876, but rose to 116 in the week ending January 6, 1877, the highest weekly number that had been registered during the epidemic. During the same week, small-pox caused 22 deaths in Liverpool, and 8 in Manchester and Salford, but none in any of the sixteen other largest towns. After this the epidemic gradually declined much in severity during some weeks, and then increased again, till, in the week ending March 17, the deaths from small-pox in London had risen to 100. They then declined, till, in the week ending June 23, they were only 44, the lowest number returned in any week since November, 1876. After this date the deaths continued to decrease in number, and, in the first week of September, were reduced to 8 only. Towards the end of the year small-pox again became more prevalent in London, in the four weeks of November the deaths registered as occurring from the disease being 25, 14, 27, and 31

respectively; but it remained unusually quiescent in all the others of the twenty largest towns, during the last fourteen days of November only 2 fatal cases of it being registered in the nineteen provincial towns, namely, one in Liverpool, and one in Birmingham.

The number of cases of small-pox admitted into the Metropolitan Asylums Board Hospital during the year ending in October, 1877, was 7333.

Hydrophobia has occurred during the year with very remarkable and, happily, unusual frequency; but no advance was made in our scientific knowledge of the disease or of its treatment, and all the cases in England died. Three or four cases have, however, been reported from Germany and America, in which patients who were believed by qualified and skilled medical men to be labouring under genuine hydrophobia were cured by, or recovered under, treatment by the hypodermic exhibition of curare. It may, of course, be questioned, or very greatly doubted, if the cases were correctly diagnosed; but, at any rate, the special power that the drug is known to possess over the muscular system renders its remedial action in hydrophobia not incredible, and it must therefore be scientifically and carefully tried.

The two Houses of Legislature met for business on February 8, and the session was again opened by her gracious Majesty in person. But this happy act was the only feature of the opening of the session of the Parliament of the fortieth year of Queen Victoria that gave any special satisfaction to the medical profession; for her Majesty's Speech—or, to use a more strictly accurate phrase, the Speech from the Throne,—though long, contained no reference whatever to any sanitary measure, or to any measure having even a distant connexion with sanitary legislation. The profession is very far from wishing for anything like fussy, meddlesome, incessant legislation on matters relating to the public health, but several subjects of very grave and pressing interest demanded the attention of the Legislature, as the provision of an abundant and pure water supply, the reform of the coroner's court, and the state of the lunacy laws; and faith had not yet been lost in the Prime Minister who had more than once declared that the health of the people ought to be the first and the greatest object of a statesman's care and attention. And this year the disappointment caused by the conspicuous absence of the mention of public health measures from the Speech from the Throne was not lessened, as it was in 1876, by any allusion to such subjects in the speeches on the Address to her Majesty. Some private members of the House of Commons indeed endeavoured to make up in some degree for the neglect of the Government. Sir Trevor Lawrence asked the President of the Local Government Board whether, having regard to the severity of the existing epidemic of small-pox, the urgent necessity of more perfectly universal and efficient vaccination, and the prejudices prevailing in some minds against the use of humanised lymph, he would take steps to provide a supply of vaccine lymph from the calf. But the reply was most unsatisfactory, and nothing has been done by Government to meet in this way either any occasion of extraordinary demand for vaccine lymph, or the not altogether unfounded scruples of those who, dreading the danger that may possibly attend arm-to-arm vaccination, openly resist, or evade the vaccination laws. The subject was again, late in the session, brought before the House by a motion made by Earl Percy for a Committee to inquire into the working of the vaccination laws. The motion was unsuccessful, and rightly so, for the appointment of such a Committee would, in all probability, lead many people to suppose that there is some real doubt as to the value of vaccination. But the subject will, unquestionably, turn up again; and when it does, it will be the duty of Government to be prepared on three points, viz., the animal-lymph alternative, the advisability of providing for the compulsory vaccination of infants and children when their parents obstinately refuse to have them vaccinated, and the question of revaccination. Mr. Dillwyn called the attention of the Government to the lunacy laws, and obtained the appointment of a Select Committee to inquire into its operation as regards the security afforded against the violation of personal liberty. At the end of the session a Parliamentary Blue-book of nearly 600 folio pages was issued, containing the evidence given before the Committee, but no report; the Committee stating only that they had resolved "to report the evidence to the House, and to express an opinion that the Committee should be re-appointed next session for the purpose of agreeing upon a report to be presented to the House." Considering what a voluminous mass of evidence—much of it of the most contradictory character—was taken, no one can wonder that the Committee felt quite unable to digest it, so as to form any clear judgment upon it, without a large extension of time. Their report next year will be looked for with much interest, and more curiosity, for some of the evidence given is so crotchety and one-sided that the Committee cannot but feel considerable difficulty in estimating its value. We may try to hope, but can hardly expect, that solid benefit will be gained by the inquiry. Several important measures relating to public health were indeed introduced during the session, but all but one were, at the end, among the "massacred." Of these were—the Factory Acts Bill, a consolidation measure; the Sale of Food and Drugs Act Amendment Bill; the Habitual Drunkards Bill; three Medical Acts Amendment Bills; the Public Health (Metropolis) Bill; and the Public Health (Ireland) Bill. The Bill to consolidate and amend the law relating to Public Health in the Metropolis, which was introduced on June 4 by the President and the Parliamentary Secretary of the Local Government Board, was not generally thought to be a satisfactory and well-considered measure, either as to the consolidation clauses or the amendments proposed to be made; and it was regarded with much disfavour both by the Metropolitan Local Authorities and by the Metropolitan Asylums Board. It was withdrawn in the end by Mr. Sclater-Booth, who intimated that he should introduce, in a future session, a stronger and more comprehensive measure. The Bill to consolidate and amend the Acts relating to Public Health in Ireland, introduced by the Chief Secretary (Sir Michael Hicks Beach) and the Attorney-General for Ireland, passed through a Select Committee, receiving there several important amendments, chiefly owing to representations and exertions made by the King and Queen's College of Physicians, and the Royal College of Surgeons of Ireland, and by the Irish Medical Association; but it failed, through the opposition of the Irish obstructives, to get into Committee of the House of Commons. It will appear again, when we hope it will be still further improved, and meet with a happier fate. The one sanitary measure which did become law was the "Canal-Boats Act, 1877." It is a short Act of seventeen sections, and provides for the registration and sanitary regulation of all canal-boats used as dwellings; and its most important sections are those which give powers to sanitary authorities for the inspection of canal-boats, and for the prevention of the spread of infectious diseases by them. The Bill contains also provisions as to education; a child living in a canal-boat, barge, or flat being made subject to the compulsory clauses of the Education Act in force at the place which the boat is registered as belonging to. The Act comes into operation on January 1, but will not be enforced till before January, 1879. It is not in any way a strong measure, but probably a stronger one would not have been passed, and this one gives powers for good if wisely and well carried out. Some provisional orders were made and confirmed in connexion with the operations of the Artisans'

Dwellings Act; and a local Act, the Bolton Improvement Bill, was passed, which contains important provisions for the compulsory registration of all cases of infectious sickness occurring within the borough. An Act, which may prove a very useful one, was also passed, giving to landowners of limited interests, in England, Wales, and Ireland, powers to charge their estates with the expense of constructing reservoirs for the storage of water. It recites that in many places it would conduce greatly to the establishment of a plentiful supply of pure water to the inhabitants of villages and towns, and for the industrial requirements of localities, if facilities were given to landowners of limited interests to charge their estates, subject to the Inclosure Commissioners, with sums expended by them in constructing reservoirs and other works for the supply of water; and the sections of the Act provide for the way of carrying its object. The Act is 40 and 41 Victoria, c. 31. The total result of the labours of Parliament, as regards matters of special interest to the medical profession, was therefore painfully meagre; but we cannot complain very much of this, for the session was singularly remarkable for barrenness in legislation of any kind, owing, in at least a very large measure, to the tactics of the Irish obstructives; and the session of Parliament of 1877 will be most memorable for the unprecedentedly long continuous sitting of twenty-six hours, by which Government at last met and overcome, though all too late for any legislative purposes, the persistent and reckless opposition offered to all progress by a very small band of Irish Home Rulers.

The General Council of Medical Education and Registration met for the session of 1877 on Thursday, May 10, when the President, Dr. Acland, delivered the usual address, reporting to the members the business of any special importance that had been before the Executive Committee during the recess, and telling them of the various subjects which they would have to consider during the session. The debating power and the weight and influence of the Council had been strengthened by the election of Sir James Paget as the representative of the Royal College of Surgeons of England; but, on the other hand, the President had to inform the members that they were to lose the valuable services of Dr. Stokes, who had been the Crown nominee for Ireland ever since the Council was first formed. The Council sat for thirteen days, the longest session on record. We wish we could add that the real work done—the gain to the great object of the establishment of the system of medical education—was at all proportionate to the length of the session; but it is simply impossible to deny that time was woefully wasted in discussions on verbal amendments, and on matters of very secondary importance. Three resolutions of importance, respecting changes in the system of education of students, and of value, supposing them to be acted on by the licensing bodies, were passed. A "recommendation" that there shall be an examination at the end of the first year, was agreed to; and this, with the very laudable and necessary object of stimulating and testing both teachers and students, of preventing idleness during the first year of study, and so of lessening the proportion of rejections at the first professional examination. The Council also recommended that students shall be required to produce evidence of having had six months' experience in the charge and treatment of patients in a hospital, dispensary, or elsewhere; and that no student shall be required to attend more than one course of lectures on the same subject. The first of these two recommendations ought to bear good fruit in increasing the clinical, practical knowledge of students, and may supply in some measure the loss suffered by the abolition of the old system of apprenticeship; while the second may excite teachers to greater efforts to make their lectures instructive and interesting, for students will always be willing to attend lectures which they find really helpful. Some other "recommendations," having also for their object the improvement of medical education, were agreed to, as, on the order and sequence of examinations, and of subjects in each examination, and for the limitation of the area examined on in some subjects. These few resolutions cannot be looked upon as a satisfactory result of a large expenditure of work-time, but they are the only real outcome of days of discussion; and they are only "recommendations." But, as our readers will remember, time was wasted day after day on minute verbal criticism of sentences in the "recommendations," amendments were proposed in such profusion and fought over with such persistence that it might have been thought that the real object was *not* to agree to anything, and on several occasions a resolution was passed, was reversed, and was passed again—sometimes, but not always, on one and the same day. A very large amount of time was given by the Council to the consideration of the Report of the Medical Acts Amendment Committee, and it was agreed to recommend that medical qualifications granted under legal authority in any part of her Majesty's dominions outside the United Kingdom shall be registrable under the Medical Act, but "in a separate alphabetically arranged section of the Register"; and, further, that the Council shall have authority to establish in the Register a distinct alphabetical section for "foreigners practising in the United Kingdom, with qualifications granted in foreign countries, and entitling to practise in those countries respectively," when the qualifications are judged by the Council to be sufficient guarantee of the possession of the requisite knowledge and skill for the efficient practice of the profession. The Council disapproved of the penal clause in the Medical Acts Amendment Bill of the East London Medical Defence Association, and recommended that the introduction of more stringent penal clauses into the Medical Acts be postponed "till such time as these Acts shall have received all legislative amendments in the provisions relating to the profession itself"—a "good time," which we fear will be very long in coming. The Council declined to institute a visitation of the medical schools; they expressed their regret at the way in which the Cruelty to Animals Act (1876) had been administered, and authorised the Executive Committee to remonstrate with the Home Secretary on the subject, should they think fit to do so; they erased two names from the Medical Register, re-admitted three names, and declined to admit other two; and they discussed for a long time a communication from the Queen's University in Ireland respecting the non-registration of honorary degrees in medicine granted by that University—a question involving the whole subject of the registration or non-registration of honorary degrees,—and at last discovered that it was a question for high legal opinion, and resolved to take it. The opinion of the law officers of the Crown for England was taken, and, as it supported that of the Irish law officers of the Crown, the degrees in question have been registered. The Council could not afford time for the discussion of one of the most important sections of the Medical Act Committee, that regarding the education and examination of midwives, but resolved "That means under legal sanction should be provided for giving credentials of qualification to competent midwives," and "that the lives of women in labour should, so far as practicable, be protected from the incompetent," and directed that these resolutions should be communicated to the Lord President of her Majesty's Privy Council. The great questions of the efficiency of the present methods of professional teaching, and of the causes of the great number of rejections at the professional examinations, were not gone into, nor were the opinions obtained from the licensing bodies on the latter subject considered. After various changes of opinion and prolonged discussion, the Council agreed that "it is desirable that the examination in general education be left to the universities, and such other bodies engaged in general education and

examination as may from time to time be approved by this Council," and that the Executive Committee should communicate with the licensing bodies on the subject. It may be mentioned also that the Council received from the Registrar-General the assurance that if a clear case should be reported to him "of an unqualified medical man forging for his own purpose the name of a qualified registered medical practitioner," in hope of obtaining a conviction he would take the opinion of the legal authorities serving under the Lords of the Treasury whether legal proceedings should not be instituted; and it will be seen elsewhere that a man has been successfully proceeded against for this offence.

One of the most, if not *the* most, memorable events of the medical year 1877 is the final settlement of a Scheme for a Conjoint Examining Board for England. It may be remembered that at the close of 1876 two of the co-operating medical authorities still objected to the amended scheme then before them. The Royal College of Pnysicians, London, had approved of the Scheme, "provided that the original principle of each body abstaining from the exercise of its independent privilege of giving admission to the Medical Register be adhered to"; this proviso being added because the first clause of the Scheme had been altered after naming the co-operating bodies, and reserving to them liberty to confer, as they think fit, their honorary distinctions and degrees, so as to run thus—"Each of them will abstain, *so far as allowed by law*, from the exercise of its independent privilege," etc. The words we have italicised, and to which the College of Physicians objected, had been inserted to meet a difficulty felt by the Royal College of Surgeons with regard to the admission of women, and especially with regard to its midwifery licence; and this difficulty, it was believed, could only be removed by a legislative measure. It was more than doubtful whether such a measure could be obtained, and the College of Physicians did not, in the end, insist upon its objection. The University of Cambridge proposed two changes in and one addition to the Scheme, viz.—"That the Committee of Reference consist of two representatives from each of the medical corporations and universities," instead of requiring each of the universities to send one representative of medicine and one of surgery, while each of the corporations sent simply "two representatives"; that "on each occasion double the number," instead of "not less than twice the number," of examiners to be appointed be nominated by the Committee of Reference; and that the following new clause be added:—"That the Scheme of Conjoint Examinations terminate at the end of ten years from the date of its sanction by the General Medical Council, and do then cease unless renewed." At first the University proposed that the Scheme should terminate at the end of *five* years unless renewed, but after a time consented to enlarge the time to ten years; and in this form the proposed new clause, as well as the alterations, was accepted by the Conference, and the re-amended Scheme was sent in March to the co-operating authorities for consideration. The proposed alterations were accepted, and the new clause rejected by the threo medical corporations and by the Universities of Oxford, Durham, and London. The University of Cambridge then withdrew its opposition, and the Scheme as finally amended was presented to the General Medical Council on May 24, and received their sanction. Thus, seven ycars after the Council had sent to all the licensing bodies in the United Kingdom a message strongly pressing on their notice the desirability of a Conjoint Examining Board for cach division of the kingdom, a perfected Scheme for England was presented; and since the meeting of the Council the co-operating authorities havc severally elected their representatives on the Committee of Reference. The experiment of one Conjoint Examining Board will therefore be tried in England; and its success is endangered by the fact that it is to be tried in that division only of the kingdom, all attempts at forming a Scheme for Scotland or Ireland having totally failed hitherto. But unless the English Board proves to be a failure, a like Board will undoubtedly be formed, voluntarily or under compulsion, in the other divisions.

A very serious dispute has arisen, unhappily, between the Senate of the University of London and Convocation. In February tho Senate decided by, it was said, a majority of fourteen votes to seven, to take advantage of Mr. Russell Gurney's Act, 1876, and admit women to examination for its medical degrees. This had been done without any communication to or consultation with Convocation. And it appeared afterwards that the resolution had been brought forward in the Senate also without any previous notice of motion, and that those members of the Senate who were opposed to such a resolution were taken by surprise. Such a mode of proceeding was not illegal, for, strangely enough, no regulation to the contrary existed in the University; but the Senate expressed as strongly as possible its disapproval of the course, by passing, on March 28, a resolution preventing the possibility of such a thing happening again. A Committee appointed by the Senate, to consider the regulations for carrying out the resolution for the admission of women, presented their report on March 28, and recommended that women-candidates should have gone through the same course of study and should pass the same examinations as men—the examinations being separately conducted; but they also recommended that women who had begun or finished their medical studies should be exempted from passing the matriculation examination, and that foreign certificates of study should be received as well as, or in place of, English. Meanwhile the medical graduates of the University presented to the Senate a memorial, bearing over 230 signatures, praying them to "reconsider their decision," and the Senate, recognising the weight of the memorial, consented to suspend further action in the matter for the present. Soon afterwards a "whip" for the approaching meeting of Convocation was sent out in the shape of a circular signed by three members of the *Senate* (not by members only of Convocation) stating that a notice of motion had been given in the Senate to rescind the resolution of February 28, and urging all graduates who approved of the policy adopted by the majority of the Senate to attend the meeting of Convocation, at which a resolution would be proposed thanking the Senate for their resolution of February 28. The meeting of Convocation, held on May 8, was a very large one. Two leading members of the Faculty of Arts brought forward the motion—"That Convocation thanks the Senate for their resolution to admit women to degrees in medicine," which, on the proposal of Dr. Buchanan, they amended by the insertion of the words "desiring that women should be admitted to degrees in all the faculties" after the word "Convocation." Mr. Savory, in a very eloquent speech, then moved the following amendment:—"That this House is of opinion that it is undesirable for this University to admit women to degrees in medicine before it shall have considered the advisability of admitting women to degrees in all the faculties." This was ably seconded and supported by Drs. Barnes, Quain, Wilks, Wilson Fox, and Sir William Jenner, while not one medical graduate spoke in support of the original motion. On division, 142 voted for the amendment, and 129 against it; and when the amendment was then put as a substantive motion, it was carried by 144 to 116. On June 23 the Senate of the University met, and by a vote of 16 to 11 decided to pursue the course they had determined upon in February; thus disregarding the memorial of the medical graduates and the clearly expressed opinion of Convocation. This decision was received by the medical graduates with very great regret, for, as it would have been impossible for the Senate to make the change determined on without consulting Convocation and obtaining an amendment of the charter, had it not been for Mr. Russell Gurney's Permissive

Act, it was felt that they ought to have given special weight to so decisively expressed an opinion on the subject as was the resolution passed in Convocation. The situation was further aggravated by its becoming known that, at the same meeting of the Senate, Sir James Paget asserted that it would be impossible to examine women in the same way as men for the degree in medicine; it was known also that more than one of the examiners for the medical degrees of the University had stated that they would not, and could not, examine a female candidate on the same range of subjects as male candidates had to submit to: though on Presentation-day the Chancellor of the University and Mr. Lowe had declared that no modification of the examinations was intended. Thus, it appeared, the University was threatened with a loss of some of its most distinguished examiners, and a deterioration in the value of its medical degrees, should the Senate carry out their determination. The next step in the dispute was that the Annual Committee of Convocation decided, in July, to test the question whether or not the privileges of Convocation had been infringed by the action of the Senate; and they requested the chairman to summon an extraordinary meeting of Convocation, "with a view of considering how far the constitutional privileges of Convocation had been superseded by the Senate in adopting a permissive Act of Parliament, by which the constitution of the University would be materially altered, without consultation with Convocation." Thus the original question in dispute between the Senate and Convocation—the question of the admission of women to degrees—was merged in the larger and much more important question of the privileges of Convocation; and the step now taken marked as strongly as possible the gravity of the difference between the Senate and Convocation, for it was the first time since its creation, more than twenty years previously, that Convocation had been summoned to meet upon special and urgent business. The meeting was held on July 27; and the result was a complete triumph for the cause of constitutional freedom. In a house of 225 members, and after an exhaustive discussion, Convocation by a large majority condemned the adoption by the Senate of a permissive Act of Parliament without reference to Convocation. The chief resolution—"That this house, regrets that the Senate has, by adopting a permissive Act of Parliament (Act 39 and 40 Vic., cap. 41), without reference to or consultation with Convocation, materially altered the constitution of the University, and has thus practically superseded the privileges of Convocation"—was moved, in an able, eloquent, and temperate speech, by Dr. Tilbury Fox. One of his most effective points was a legal opinion given by Mr. Farrer Herschell, Q.C., who was unavoidably absent. Mr. Herschell, who had gone fully into the case, had shown that the Senate had changed the constitution of the University contrary to the spirit of the charter; and, further, that, contrary to the opinion of the Senate, women, if admitted to degrees in medicine by Russell Gurney's Act, could claim by their degree a right to sit in Convocation. With regard to the latter point, Dr. Fox showed that the law officers of the Crown had, indeed, said that "women admitted to degrees in medicine or surgery would become members of Convocation in the same way as men, but under the proviso contained in section 1 of 39 and 40 Vict., cap. 41, they would be under a special statutory disability, which would prevent them from taking any part in the government, management, or proceedings of the University"; but they added, "the proviso just referred to enacts that 'no person, who but for this Act would not have been entitled to be registered, shall by reason of such registration be entitled to take any part in the government,'" etc. And they continued, "it is obvious there has been a slip in the words of the proviso. It ought, we think, to be construed as if the words 'qualification for such registration' had been used, instead of the words 'such registration.'" And Dr. Fox then stated that he had written to Mr. Russell Gurney on this point, and Mr. Russell Gurney had replied that the proviso had been given to him as the condition on which the Bill would be allowed to pass; and had added, "I wish it had been worded differently." Dr. Fox admitted that the Senate had a *legal* right to admit women to medical degrees under the permissive Act of Mr. Russell Gurney, without reference to Convocation; but proved that in so doing they had done that which was *morally* and *equitably* wrong. Dr. Fox was ably seconded by Dr. Curnow; and the view that the Senate had acted unconstitutionally, and that *morally* they were in the wrong, was supported by some of the graduates in the Faculties of Law and of Arts. In the end Dr. Fox's resolution was carried by 114 votes to 71—that is, by a majority of 43; and a second resolution, empowering the Annual Committee to confer with the Senate on the subject, and to ask them not to take any further action under Mr. Russell Gurney's Act, was also carried by 88 votes to 52—majority, 36. On October 12 the Annual Committee resolved to request the Senate to grant an audience to a deputation from the Committee upon the subject of the resolution of Convocation; and the Senate, on November 14, received this deputation, who laid before them a memorandum containing the gist of the arguments advanced at the extraordinary meeting of Convocation against the action of the Senate: to the memorandum an appendix being added, containing the opinions given by Mr. Farrer Herschell, Q.C., M.P., and by Mr. Montague Cookson, Q.C. The Chancellor of the University returned a reply which had been previously approved of by the Senate, stating that the Senate was willing to apply for a supplemental charter, which should admit women to degrees in all faculties; and hoping that this proposal would meet the wishes of Convocation, and that Convocation would co-operate with the Senate in carrying the proposal into effect The deputation replied that they had no power and no right to pledge Convocation to any particular line of action—which fact the Senate at once admitted; and then the deputation withdrew.

We pointed out at the time that the reply contained no expression of regret that the Senate had forgotten or disregarded the constitution of the University, and had set at nought the expressed wish of Convocation on the subject of the admission of women to degrees in medicine; and that no definite promise had been given to abstain from proceeding under Russell Gurney's Act; but when the Annual Committee of Convocation met, on November 16, they accepted the reply as a satisfactory one, considering that the Senate had, in giving it, virtually abandoned their resolution to proceed under the permissive Act; and the Committee expressed their willingness to co-operate with the Senate in procuring a supplemental charter. We expressed our fear that the Annual Committee had taken too sanguine a view of matters, but, hoping that they rather than we ourselves were right, we rejoiced over the prospect of a restoration of that harmony of feeling and action between the Senate and Convocation which is so absolutely necessary for the well working and prosperity of the University. This dream of settled difficulties was, however, soon rudely dispelled. When the Senate met, on December 7, a message was received from the Annual Committee of Convocation, thanking the Senate "for acceding to the request of Convocation by abandoning their proposed action under the Russell Gurney Act, and by submitting the intended important change in the constitution of the University to the judgment of Convocation by a new charter, which will apply to all the faculties." To which the Senate replied that they received with pleasure the expression of the opinion of the Annual Committee "that the objects desired in common by the Senate and by Convocation may be obtained in a manner to which

neither party objects, by a new supplemental charter in place of the existing one for the admission of women to all degrees, with the requisite limitation in regard to the admission of women to Convocation; but at the same time feel it necessary to point out that they have not taken any resolution as to their future course." The Annual Committee, generously perhaps, but not wisely, assumed that the Senate had abandoned action under the Russell Gurney Act, and the Senate of course declined being thanked for what they had not done; but they, in their reply, assumed much more than the Annual Committee had done. The Annual Committee had sent a simple message, expressing no opinion, and the Senate should have made a simple reply, but neither on this occasion, nor when they received the deputation, have they spoken generously or frankly. At the next meeting of the Senate the Chairman of Convocation drew attention to the wording of the above reply, and pointed out that neither directly nor indirectly had he expressed himself in the sense assumed; and the Senate, recognising their mistake, amended their reply, so as to thank the Annual Committee for their "courteous expression," and to express their trust "that the objects desired in common by the Senate and by Convocation may be obtained in a manner to which neither party objects"; but stating again that they "had not pledged themselves to any future course of action."

The Royal College of Physicians, London, again elected Dr. Risdon Bennett to be their President for the ensuing year. The College, having been asked by the General Medical Council whether and under what conditions they would be disposed to admit foreign graduates to examination, passed the following new by-law:—"That any candidate for the College licence who shall have obtained a degree in medicine or surgery at a British, colonial, or foreign university recognised by the College, after a course of study and an examination satisfactory to the College, shall be exempt from re-examination on such subjects as shall in each case be considered unnecessary." The Baly Medal of the College was awarded, on the recommendation of the Council, to Professor Carl Ludwig, M.D. A new edition of the Roll of the College is to be prepared by Dr. Munk, the learned editor of the former edition. The new edition will be in three, instead of two, volumes, and will bring the Roll of the Fellows down to 1824. A new and revised edition of the "Nomenclature of Diseases" is also to be prepared, and a Committee has been appointed for that purpose. The first edition occupied twelve years in its preparation, and but few copies of it remain unsold. During the year the College received, from the Colonial Office and the India Office, several important communications on leprosy, which were severally reported on by the Leprosy Committee. In one of their reports the Committee expressed the opinion that "in many cases in which medicines have been used with *apparent* good effect, the favourable result has really been due in great measure, if not entirely, to the improved general hygienic conditions in which the lepers had been placed"; and the Committee recommended that the College should strongly urge that the attention of the Government should be especially directed to this consideration; and "decidedly recommend that lepers should be placed under the immediate charge of the Government in hospitals or asylums properly provided for that purpose," where every attention to hygienic conditions should be observed, and where "the real value of any system of treatment might be submitted to careful investigation under the observance of competent medical men." The reports were forwarded by the College to the Colonial Office and the India Office. At their last meeting, the College resolved to accept and carry out the recommendation of the General Medical Council, that any cases in which decided ignorance in the subjects of general education has been displayed by candidates at the professional examinations, with the name of the board or boards before which the preliminary examinations have been passed, shall be reported to the Registrar of the Medical Council.

One of the most noteworthy events in the year's history of the Royal College of Surgeons of England was the remarkable and eloquent Hunterian Oration which was delivered by Sir James Paget. It was in every way worthy of the orator, and was a most interesting and able study of the life and character of Hunter, the greatest physiologist, pathologist, anatomist, and surgeon of his day, and the founder of comparative anatomy. The Oration was graced by the presence of the Prince of Wales, and the College afterwards entertained his Royal Highness at a banquet in their library. The Council at their quarterly meeting, on January 11, formally adopted some alterations in the regulations relating to the education and examination of candidates for the Fellowship, which had for a very long time been under consideration. But as the proposed alterations became known they excited great dissatisfaction, and in March, before the resolution of the Council was confirmed, a strongly worded memorial, signed by 300 Fellows, was presented to the Council, objecting especially to the section of the new regulations relating to "candidates, members of the College of not less than ten years' standing," and pointing out that the alteration proposed by that section would materially impair the value of the Fellowship diploma, and would be an act of injustice to a large number of existing Fellows; and that there was no adequate ground for it. This memorial was read at the meeting of the Council on March 8, when the resolution to adopt the formulæ for altering the Fellowship regulations came on for confirmation, and after a lengthened discussion, an extraordinary meeting of the Council was ordered for the reconsideration of the subject. This meeting was held on March 22, and resulted in a resolution to annul Section 6 of the new regulatitns, and to alter Section 5 in conformity therewith. The proposod alterations in the by-laws relating to the Fellowship were published at the time in our columns, and it will be recollected that other of the proposed changes besides those contained in Section 6 were very objectionable, but after the decision of the Council at their extraordinary meeting the matter need not be more fully spoken of here. The Jacksonian Prize of the College was awarded to Mr. Harrison Cripps, one of the surgeons of the Great Northern Hospital, for the best essay "On the Treatment of Cancer of the Rectum, particularly as regards the possibility of curing or relieving the patient by excision of the part affected." On the proposal of Mr. Marshall, the Council agreed to give effect to Section 5 of the Charter, 15th Vict., with respect to the election each year of two members, of twenty years' standing, to the fellowship, subject to certain conditions. At the annual election of Fellows into the Council of the College, three vacancies had to be filled up, created by the death of Sir William Fergusson and by the retirement, in the prescribed order, of Messrs. John Gay and J. E. Erichsen. Mr. Gay and Mr. Erichsen presented themselves for re-election, and Messrs. William Adams, W. S. Savory, and Timothy Holmes were also candidates. The choice of the Fellows fell on Messrs. Erichsen, Savory, and Holmes.

On October 18 the Council of the College had under consideration the condition of the Bristol Medical School, incited thereto by a communication from some of the staff of the Bristol Royal Infirmary, and by the very large proportion of the students from that School that have of late been rejected at the College examinations. The Council resolved—"That, in consideration of the transitional state in which the Bristol School of Medicine has recently been, owing to its proposed amalgamation with the University College, Bristol, it is not expedient that at present any action should be taken with a view to inspecting the School in the manner suggested by the Faculty of the Bristol Royal Infirmary," but that at the end

of the present winter session the Faculty of the School should report very fully to the Council on the condition of the School and on all the arrangements made for teaching and examining the students; and the Council would then determine "whether or not to take further steps in the matter, and as to the future recognition or non-recognition of the School." Later in the year the Council received from the Secretary of the Faculty of the School a communication as to certain difficulties that had arisen in carrying out the "affiliation" of the School with the Bristol University College; but the Council, while regretting that their use of the expression "amalgamation" instead of "affiliation" appeared to have had something to do with the reported difficulty, decided to adhere to their former resolution, and to wait for the returns they had required before taking any further steps in the matter.

The Council had before them for a long time the consideration of what qualification should be required to be held by lecturers and teachers in dentistry. One body of dentists—the Association of Surgeons Practising Dental Surgery—petitioned the Council to refuse to receive certificates of attendance on lectures and dental hospital practice respectively, from any lecturer on dental physiology, dental anatomy, or dental surgery, or from any surgeon to a dental hospital or the dental department of a recognised hospital, who does not hold a registrable qualification in surgery, such as that of Member or Fellow of the Royal College of Surgeons; and this recommendation, with the additional requirement that the lecturer or teacher should possess also the College licence in dental surgery, was approved of by the Dental Board of the College. Another party among the dentists insisted, on the contrary, that the dental licence of the College ought to be held to be sufficient, and should be required. The Council appointed a committee to consider "certain questions relating to the diploma in dental surgery"; and this Committee recommended that the dental diploma should, in itself, be sufficient to enable the holder of it to undertake the appointments above mentioned; that the dental diploma should be required to be held by the lecturers and teachers in addition to any other qualification they might possess; and that the Dental Board should gradually increase the severity of the examination for the dental diploma, so as to give it greater value and importance. This view of the whole question was eventually adopted by the Council, and, on the whole, we think rightly adopted. The Council did not, we believe, take the opportunity thus offered of reconsidering the advisability of granting a dental diploma at all, which is very doubtful, unless indeed as supplemental to the membership of the College—and the propriety of that, even, might be questioned; but so long as the College does confer a licence in dental surgery, to be obtained after a curriculum not greatly differing from the curriculum for the membership, and a special examination, we do not see how it is to be declared that the licence is not sufficient to qualify its holder to teach dental surgery—unless, indeed, the Council admit that the examination for the licence is a pretentious sham.

The various Medical Societies of the metropolis have, as usual, been active, and have, one and all, done good work for the advancement of the science and art of medicine. One of the most interesting discussions at the Royal Medical and Chirurgical Society was that on the pathology of tetanus and hydrophobia, but it was not productive of any real addition to our knowledge. No really new pathological appearances were described, and of those described we do not *know* that any are peculiar to either hydrophobia or tetanus; nor whether or not any or all of them are results or causes of disease.

At the Pathological Society the chief subject taken up was the pathology of visceral syphilis; and here the boundaries of our knowledge were decidedly enlarged, much new and important information being given as to the morbid changes caused by the syphilitic infection, whether congenital or acquired. For a summary of the discussion we must refer to our pages, as we have not space at our command to give here the pathological gains of the year in this or in other directions. For the same reason we must be content to refer to our reports of the Clinical Society, and to various scientific editorial articles, for the principal therapeutical results of the year.

Women can now obtain a full medical education in England, and can obtain a registrable diploma in Great Britain, entitling them to practise the medical profession. Mr. Russell Gurney's Act of 1876, permitting any licensing body to admit to examination for its degrees or diplomas any persons, without regard to sex, was, early in this year, accepted and acted on by the King and Queen's College of Physicians in Ireland, and several female candidates have since passed the examination of that body. The Senate of the University of London also decided to admit women to examination for its medical degrees, though, as we have elsewhere recorded, difficulties of a very serious nature have as yet prevented that decision from being carried into effect. But there remained for a time the grave obstacle that female medical students could not anywhere in Great Britain or Ireland obtain the hospital practice required by our licensing bodies. This last remaining difficulty also has been overcome. The Royal Free Hospital has been affiliated to the London School of Medicine for Women as a clinical school for female students; and at the beginning of the present winter session its wards were formally opened to the students of the School of Medicine for Women, with the object of providing them with the necessary hospital practice and clinical instruction. Women have thus, with great energy and perseverance, triumphed over all the difficulties that beset their determination to enter and practise the medical profession; and it remains to be seen whether their determination will be justified, or whether the profession were not right in holding that they were making a great and grievous mistake.

When we wrote at the end of last year, the profession and the public at large had been greatly moved by the fact that the Arctic Expedition had been obliged to return to England without attaining the great object of the Expedition; that their return had been caused by a severe and disastrous outbreak of scurvy among the sledging parties; and that the sledging parties had been sent out practically without lime-juice; and when we wrote, no explanation of this had been given by the Admiralty. Early in the present year an Admiralty Committee was appointed to inquire into the cause of the outbreak of scurvy, into the adequacy of the provision made in the way of food and medicine, and into the propriety of the orders for provisioning the sledge parties. At the end of February the Admiralty received from the Committee a preliminary report, the substance of which was made known to the public; and in May the full report was published. The Committee took the evidence of the Commander of the Expedition, Sir George Nares, of the principal officers, and certain of the inferior officers and men, of officers and men who had taken part in previous Arctic voyages, and of the Director-General of the Navy; and, after communication with the Royal Colleges of Physicians and Surgeons, they took also the evidence of the most eminent medical authorities of the day on the subject of scurvy. The inquiry was thus a very exhaustive one, and it is to be noted that the First Lord of the Admiralty stated in the House of Commons that the Committee was a "judicial one." The judgment delivered was full and decided. The Committee stated—"We attribute the early outbreak of scurvy in the spring sledging parties to the absence of lime-juice from the sledge dietaries," though they considered that the long winter, extending over 142 days, and the confinement to a comparatively vitiated and somewhat damp atmosphere, with exposure to changes of temperature and the

deprivation of fresh meat, had predisposed the officers and men to scurvy; they found that "the provision made in the way of food, medicine, and medical comforts" was in every respect adequate, and "more complete than that made for any previous expedition which had proceeded on Arctic service"; and they found that "the orders of the Commander of the Expedition for provisioning the three extended and principal spring sledge parties did not include lime-juice"; that this was a deviation from the memorandum of recommendations and suggestions furnished for his information by the Medical Director-General, and that "the reasons assigned for this deviation being insufficient, the said orders were not proper." The report is a very valuable one, affording a complete vindication of the scientific opinion regarding scurvy, and the value of lime-juice as a trustworthy preventive of that disease. The evidence taken clearly confirmed "the fully established value of lime-juice, and that the conveniences attending its use render it greatly superior to all other suggested antiscorbutic remedies." It was also shown that the remedy was not injured by being frozen; and in a "Paper on Scurvy," written by the medical members of the Committee, which was spoken of in the highest terms by the First Lord of the Admiralty, it was recommended that a thorough and careful trial should be made of certain concentrated preparations of lime-juice suggested by some of the witnesses. After the close of the Admiralty inquiry, Fleet-Surgeon Thomas Colan, M.D., the Senior Medical Officer of the Expedition, was promoted to the rank of Deputy Inspector-General of Hospitals and Fleets, for his services in connexion with it. It was officially stated that the delay in promoting him had not been due to any want of recognition of his services, but only to the fact that there was no vacancy in the superior grade at an earlier date. He might, however, have been at once made a Supernumerary Deputy Inspector; and no delay had been allowed before bestowing promotion and honours on the Commander of the Expedition. It may be added, the Admiralty Committee fully exonerated Dr. Colan from any responsibility in the non-issue of lime-juice to the sledge parties.

During the year some very important and praiseworthy reforms have been made in the Army Medical Department. A long-standing grievance has been removed by the publication of a General Order providing that army medical officers doing duty with regiments shall not in future be called upon to contribute to mess and band funds. A new Army Hospital Corps Warrant was issued, providing, for the first time in this country, a full and carefully considered organisation for field medical service, and placing the Army Hospital Corps directly under the command and control of medical officers. The Director-General is to have administrative charge of the Army Hospital Corps, and is to be assisted by a staff officer, a member of the corps, who will be appointed on his recommendation. The officers of the Army Medical Department will, subject to the local military commanding officer, exercise command over the medical officers, all ranks of the Hospital Army Medical Corps, all patients in hospital, and all such non-commissioned officers and men as may be attached thereto, without their own officers, for duty. The principal medical officer, subject to the general officer commanding the district, will have supreme authority in all matters of discipline affecting the Army Medical Department, including the Army Hospital Corps in his district. The medical officer in charge of each general, station, and field hospital will have disciplinary control over the medical officers, the Army Hospital Corps, and all soldiers in or attached to the hospital; but is to refer to the local military authority such cases as require to be dealt with by court-martial. The officers and non-commissioned officers of the Army Hospital Corps will, under the medical officers, command the men of their own corps, the patients in hospital, and all non-commissioned officers and men attached, without their own officers, for hospital duty. And on active service the "bearer companies" will be under the command of the senior medical officer present with each; the officer of orderlies under him only taking command of the company in his absence. The officers of the Army Hospital Corps will perform such pay and clothing duties as are performed by captains in line regiments; and the duties connected with the equipment and dieting of hospitals, and all duties formerly performed by the Purveyor's Department, are in future to be carried out by the officers of the Army Hospital Corps, under the supervision of the medical officers. The Warrant effects a vast improvement in the field medical service, and makes a most important change in the position of army medical officers, investing them with disciplinary power over all persons connected with military hospitals and with medical service in the field, and with real and complete authority in their own department; and it relieves them from the pressure of some administrative details.

Such reforms as these, provided men can feel tolerably sure that a newer Warrant may not soon nullify them, will go some way towards making the service again an attractive one, which Mr. Hardy's short-service Warrant has certainly not done. He is, as our readers know, a very courageous and very sanguine Minister. He had, or he took, occasion three or four times during the late session of Parliament to defend the condition of the Army Medical Department, and always spoke of it in the most cheery and hopeful manner. Mr. Dunbar drew attention to the very small number of candidates for commissions in the service. Dr. Lush on one occasion pointed out the disabilities under which the officers of the Army Medical Department labour as to leave of absence, as to allowances for forage, as to the right of exchanging, and as to compensation for any grievances of which they might think themselves entitled to complain; and Colonel North declared that while in his day the medical officers were always treated with attention and respect, and were the friends of the officers and the men, there are now "no medical officers who do not find fault with the treatment of the Department by the War Office." But Mr. Hardy said that everything had been done that was possible to make the Medical Department a happy and contented one, and made out that the state of things in general was very satisfactory. At the examination for entrance into the service in February, however, only twenty-three candidates presented themselves to "compete for fifty appointments; and of the twenty-three only seventeen were successful. At the examination held in August things were a little better, as thirty-three candidates came forward for the fifty vacancies then again advertised, and thirty were accepted. But while the vacancies in the Department thus always exceed in number even the candidates, it is easy to understand why Mr. Hardy "does not see how it is possible to meet the demand for exchanges." The Indian Medical Service continues to be popular. At the examination in February forty-six candidates competed for twenty-seven commissions in it, and all were reported as qualified for the service; and at the August examination twenty-five candidates appeared for nineteen vacancies. That service, however, has a "reform" hanging over it, and its popularity may therefore quickly be stamped out.

Some new Regulations have been issued for the medical officers of the Auxiliary Forces. They are published on page 550 of our current volume. Officers now holding appointments as assistant-surgeons and acting assistant-surgeons in the Auxiliary Forces are in future to be styled surgeons and acting surgeons respectively. A "Volunteer Sick-Bearers' Association" has been formed, under the sanction of the War Office, with the object of providing for the reserve forces a medical or ambulance department of their own, and for regularly training

and instructing the medical officers and two or three men per company in the duties of attending to the sick and wounded during active service.

The forty-fifth annual meeting of the British Medical Association was held in Manchester, and was in every way a very successful one. Some 1300 members inscribed their names in the roll of the members present at it; Dr. Eason Wilkinson, the Senior Physician to the Manchester Royal Infirmary, was the President; the three addresses-in-chief were delivered by Dr. William Roberts, of Manchester, and Mr. Spencer Wells and Dr. Robert Barnes, of London; and the five sections were presided over by Sir William Jenner, Mr. E. Lund, Dr. Priestley, Surgeon-Major F. S. B. De Chaumont, M.D., Dr. Arthur Gamgee, and Dr. J. C. Bucknill. The President, in his address, spoke chiefly on the question of hospital defects and their remedies, and on the subject of hospitals and their connexion with medical education, taking as his texts the history of the Manchester Royal Infirmary and the history of the Manchester School of Medicine. As is well known, and has been fully noticed in our pages, Manchester has been much agitated on the question of rebuilding the Infirmary on its present site, or on a new site, larger and more open, removed from the noise, bustle, dirt, and smoke of the city, and more convenient for the students of the School. About the necessity of rebuilding there can be no doubt, as the present structure has been thoroughly condemned in a very able report by Mr. Netten Radcliffe, of the Local Government Board, and Mr. Field, an engineer of acknowledged eminence in sanitary matters, as well as by the prevalence of erysipelas and other diseases of blood-poisoning among the patients, in spite of all medical care. But the removal of the Infirmary is still a vexed question, and one which has to be regarded from many points of view; and at present, as Dr. Wilkinson observed, the hope of removal has been checked, "while means are being taken to patch up still further the building already patched to death." The School of Medicine is now a department of Owens College, and is the best appointed and most important medical school in the provinces. Dr. W. Roberts, who gave the Address in Medicine, selected as his subject one of the foremost questions of the day—"The Doctrine of Contagium Vivum, and its Applications to Medicine." He devoted himself chiefly to the consideration of the nature of the means or the mechanism by which infective fevers are produced. He claimed to prove the experiments and arguments which he brought forward—(1.) "That organic matter has no inherent power of generating bacteria, and no inherent power of passing into decomposition;" (2.) "That bacteria are the actual agents of decomposition;" and (3.) "That the organisms which appear as if spontaneously in decomposing fluids owe their origin exclusively to parent germs derived from the surrounding media;" and he adduced some new and forcible arguments in support of these propositions. As we pointed out at the time, we cannot hold that the last word has yet been said on these points; but no one will fail to appreciate the masterly manner in which Dr. Roberts dealt with his subject. His address was singularly lucid and able, and well merited the praise given it by Sir William Jenner when he stated he believed it would form a new starting-point for advances in our knowledge of certain classes of diseases. The Address in Surgery, by Mr. Spencer Wells, was on "The Past, Present, and Future of Scientific Surgery," and was, as was to be expected, very able and interesting. He spoke of surgery as it was in the days of Queen Elizabeth, and as it is in the days of Queen Victoria, and pointed out how enormously it has advanced as a science and art during the life of the British Medical Association. He spoke of anæsthesia and anæsthetics, of the radical cure of hernia, of electricity as a therapeutical agent, of bloodless surgery, and with honest pride of ovariotomy; and he well declared that those who are to become the conservative surgeons of the future "must not be content with saving limbs only; it is life that must be saved." Dr. Barnes, in the Address on Obstetric Medicine, took for his theme the scientific and political relations of obstetrics to medical science and the organisation of the profession. He protested against "the rapidly growing tendency to split up the study of the healing art into sections," tending "to the study of medicine in disjointed bits, to the neglect of those grander lights which can only be caught by a well-balanced study of all in their mutual relations"; and the principle so stated he forcibly illustrated from his own speciality, summing up his argument in the proposition—"As pregnancy is the test of soundness in the individual, it may be of all her blood relations too, so is pregnancy often a crucial test of the soundness of pathological doctrines." And from this he passed to his political corollary—viz., "A philosophic comprehensive science of medicine or surgery cannot be built up without an earnest study of obstetrics." He attacked the Royal College of Surgeons for licensing men to practice who have, so far as they know, no knowledge of obstetrics, and for their proposal to licence, to practise upon women, persons whose knowledge in the larger branches had not been tested; and the Senate of the University of London for entertaining the proposal to demand from women-practitioners a lower standard of acquirements than they demand from men. The drift of the address was contained in one sentence at the end:—"The political error which mars the usefulness of some of our medical institutions flows from the scientific fault—a want of due appreciation of the place which obstetric science and practice should hold." The Addresses by the Presidents of Sections were also very good, and especially noteworthy were Sir William Jenner's Address on "The Objects and Uses of Association in the Medical Profession"—a model of wisdom and brevity; Mr. Lund's, on "The After-History of Surgical Cases"; that of Dr. De Chaumont on "Scientific Research in relation to Sanitary Progress"; and that of Dr. Arthur Gamgee on "Recent Advances in Physiology." In the sections there was an ample abundance of papers, and good discussions, and, in most, special subjects were selected for discussion, one of which at least—that on "The Treatment of Pleuritic Effusion"—was separately noticed in our pages at the time. Altogether the meeting was, as we have already said, a very good one; and the Association may be congratulated on their increasing prosperity and success.

The British Association for the Advancement of Science met in Plymouth on August 15, and will be remembered especially for the valuable address delivered by the President, Dr. Allen Thomson, one of the most distinguished of living embryologists. He took embryology as the subject of his address, and it must suffice here to say that he stated his conviction that the investigations of the last seven years have been unfavourable to the doctrine of spontaneous generation; and he declared, though with some caution of phrase, his belief in the evolution theory. With regard to the former of the two subjects, he observed that "no development of organism, even of the most simple kind, has been satisfactorily observed to occur in circumstances which entirely excluded the possibility of their being descended from germs or equivalent formative particles belonging to pre-existing bodies of a similar kind"; and with reference to the latter he said, "I consider it impossible, therefore, for anyone to be a faithful student of embryology in the present state of science, without at the same time becoming an evolutionist. . . . There can be little doubt remaining in the mind of any unprejudiced student of embryology that it is only by the employment of such an hypothesis as that of evolution that further investigation in these several departments will be promoted, so as to bring us to a fuller comprehension of the most general law which regulates the adaptation of structure to function in the universe." During the meeting, two important papers, which we may name without

inferring in any way that other valuable papers were not also produced, were read, in the section of Economic Science and Vital Statistics, bearing on public health—viz., one by Dr. William Farr, "On Certain Laws of Population," arguing against the doctrines of Malthus and others, teaching the necessity of limiting the great increase of the population, and one by Mr. Bramwell, on "The Water-Supply of London," giving an account of the scheme of Sir Joseph Bazalgette, Mr. Easton, and himself, for improving and increasing the water-supply of the metropolis.

The Annual Congress of the National Association for the Promotion of Social Science was held in Aberdeen, and was opened on September 19 by an address from Lord Aberdeen, who had very fittingly been elected the President for the year. The Department of Public Health was still more appropriately presided over by Mr. Edwin Chadwick, C.B., who delivered an instructive, interesting, and able, but soberly-toned address on Public Health, which, he said, was about to emerge from the empirical into the scientific stage. In this department or section papers were read, and discussions held, on several of the vexed questions of the day. Dr. William Hardwicke read a paper on "What is the Best Method of providing Suitable Accommodation for the Labouring Classes, and of utilising Open Spaces in Towns?" Dr. Stevenson Macadam, of Edinburgh, dealt with the Air-Spaces, Water-Supply, and Drainage that ought to be provided in cottages, and with the Ventilation of Drains and Sewers; Mr. E. J. Watherston, of London, read a paper "On the Laundry as a Centre of Contagion," in which he dwelt on the mischief that arises from washing being done in dirty and unhealthy places, and suggested the establishment of proper washing establishments, and that it should be made a punishable offence for householders or occupiers to send washing to any washerwoman or laundry without previous notice, in the case of there being illness in the house; and Dr. Cornelius Fox contributed a paper "On the Mode of Registering Sickness," in which he argued that no reason existed for the continuance of the present system, and that an efficient system will never become *un fait accompli* in this country until the people demand it of the Legislature. On the latter point we are disposed to agree with Dr. Fox, but we may say that we were not aware that anything that can be called *a system* of registering sickness exists already in England.

The Sanitary Institute of Great Britain commenced its first provincial meeting at Leamington, on October 4, under the Presidency of Dr. B. W. Richardson, who opened the proceedings by an address, which, whatever may be thought of it, was certainly anything but commonplace. He is an entire disbeliever in the evil agency of germs, if he believes in their existence at all; and in the place of the so-called "germ theory" he proposed, for a second time, and much more fully than before, a "glandular theory" of contagia, and, further, a theory of the nervous origin of contagious diseases, and a third, of their heredity; and his address may at least be called "highly suggestive." On the second day of the meeting, Dr. George Wilson, Medical Officer of Health for Mid-Warwickshire, gave a very instructive and encouraging address on "The Past History and Future Prospects of Sanitary Science." He described the "insanitary" mode of living of our forefathers, and pointed out how, as a better condition of life had obtained, and cleanliness of the person and in the house had been more and more generally adopted, the death-rate for England and Wales had improved; and, taking the death-rate in London as an illustration, he showed that it had decreased from 80 per 1000 in the seventeenth century to 24 per 1000 in the present day, and might and ought to be lower still. For, he said, "if the death-rate of the whole country were reduced to the low average death-rate of a town like Leamington, 17 per 1000,—and such a reduction was quite within the possibilities of sanitary science—then, as the Registrar-General's returns proved, there would be an annual saving of 115,000 human lives in England and Wales." On the third day, Mr. R. Brudenell Carter delivered an eloquent speech on the "Present Possibilities of Sanitary Legislation," or on the inquiry, "What amendments of the law, in the interests of public health, are practicable in the existing state of enlightenment and of opinion?" He began with the postulate that a law to be useful must command the willing assent of the majority of those who live under its provisions; but that, also, legislation may with propriety be a little in advance of prevailing practice, so as to exert, in some measure, an educational influence. He considered why it is that laws in the interests of public health are required at all, and what purpose they are intended to fulfil, illustrating his teaching in the most forcible manner by a description of the ravages committed by filth-diseases; and in speaking of these he justified the use, for the present, of the word "zymotic," and objected to the present employment of the word "germ," as tending to impose a hypothesis upon us for a truth. He dwelt upon the ways in which the Legislature or the local government may, and ought now, to protect and help and teach the public; and the way and degree in which they fail to do so; and he concluded his most brilliant speech by expressing in a few eloquent words the wish that, "if such a transformation is possible, some professional politician of the day may undergo development into a statesman, and may thus become able to perceive the opportunity for the highest statesmanship which would invite him to enter upon a comparatively untrodden career." Many papers of considerable interest and value were read during the Congress, of which we must be content to mention here one by Archdeacon Dennison, on the "Supply and Storage of Water at East Brent"; one by Dr. J. Sinclair Holden, on "The Law of Caprice in Contagion"; one by Dr. Horace Sweete, the borough analyst, on "The New Artesian Water-Supply of Leamington"; and one by Surgeon-Major De Chaumont, on "The Effects of Climate on Health," of which it may be noted that the first of the conclusions stated was, "that with proper hygienic precautions there is hardly a place on earth where man may not enjoy good health," and that "where this is not found possible it is from the existence of malaria."

The case of Tebbs *v.* Jones, tried in November in the Queen's Bench Division of the High Court of Justice, before the Lord Chief Justice and Mr. Justice Mellor, is of importance as recording, a second time, the very clear and decided opinion of the Court, that if an order for the vaccination of a child is disobeyed, the offending party may be proceeded against again and again: "It was evidently intended that the penalties should be inflicted as often as the offence was committed—that was, as often as there was a refusal to have the child vaccinated."

Several trials of importance to medical jurists, or in some way of special interest to the profession, have occurred during the year, some of which may be mentioned here. A man named Treadaway was tried for and convicted of murder. He was an epileptic, and a plea of epileptic insanity was suggested in his defence, but broke down, and the convict was sentenced to death. But the judge who tried the case expressed an opinion that the murderer, being an epileptic, might be supposed to possess less power of resisting an impulse to crime than a healthy criminal, and was in favour of a merciful consideration of the case; and strong remonstrances were addressed to the Home Secretary against the carrying out of the sentence. Mr. Cross consulted, of course, the judge, but he also called to his aid the President of the Royal College of Physicians, Dr. Risdon Bennett, a representative of general medicine; and Dr. Crichton Browne, an alienist physician, and one of the Lord Chancellor's Visitors of Lunatics—whom he appointed to

examine and report upon the mental condition of the condemned man. The report of the physicians was not made public, but in the end the sentence was commuted from death to penal servitude. Mr. Cross, in answer to a question put to him in the House of Commons, stated that the mercy thus shown was not extended to the criminal on the ground of "insanity"; and it may be supposed that, looking at the condition of the murderer, and all the circumstances of the case, it was considered to be one of "murder, with extenuating circumstances."

On April 27 a case of great interest and importance to the public, from the sanitary point of view, was tried in the Exchequer Division of the High Court of Justice, before the Lord Chief Baron and Barons Pollock and Huddleston. Lady Winchelsea had taken a furnished house in the West-end of London for three months, but when she came to take possession the house smelt so strongly throughout of sewer gases that she declined to inhabit it. It was also inspected by Dr. Corfield, Professor of Hygiene, University College, and pronounced uninhabitable. On examination an old cesspool was discovered near the kitchen, and the drain was found to be an old brick one, and in a very foul state. The lessee directed repairs, which were completed in about nineteen days; but Lady Winchelsea still declined to complete the bargain, and an action was brought against her to recover the rent. The case was first tried in March, 1876, before the late Mr. Justice Quain, and the jury having found that the house was not in a habitable condition, on account of the drains having been out of order when the defendant came to take possession, the judge directed a verdict to be entered for the defendant, leave being reserved to the plaintiff to appeal. In May, 1876, the case was argued before Barons Bramwell and Cleasby, but a rehearing before these judges was ordered, and hence the trial of which we now speak. The three judges decided unanimously in favour of the defendant. They held that there was a condition precedent implied, that a house so let for immediate occupation should be reasonably fit for such occupation. This condition had wholly failed here, and the defendant, had she entered, would not have really got what she bargained for, and what it was clearly the intention of the parties should be given and paid for. The contract was for use and occupation of a reasonably comfortable house; and the ruling of the judge at the first trial was correct—the defendant was not compellable to enter.

The case of Carpenter *v.* Hamilton, also tried in the Exchequer Division, before Baron Cleasby and Mr. Justice Hawkins, is of importance to the profession and the public. The case was an appeal from the decision of Mr. Knox, the police magistrate, who had declined to convict the defendant under Section 40 of the Medical Act, 1858, for wilfully and falsely pretending to be, or taking or using the name or title of a physician, doctor of medicine, etc. The defendant exhibited in his shop, in Oxford-street, a large diploma, purporting to be of the Metropolitan Medical College of New York, bearing date 1862, but of the validity of which, beyond the production, he gave no proof. He styled himself also to a witness, and substantially to the public at large, as Dr. John Hamilton, Doctor of Medicine of the aforesaid Medical College. His name did not appear on the Medical Register. It was contended that no person can practise in this country unless he is registered, and that by using the above title the respondent falsely pretended that his name was on the Register. On the part of the respondent it was argued that the section of the Medical Act quoted was not prohibitory of practice, but only imposed disabilities in the shape of non-recovery of fees. Some practitioners voluntarily refused to be registered, and these could not recover their fees; and some could not be registered—those, namely, who possessed only foreign qualifications, and had not been in practice in England before 1858. And thus it was a question of fact for the magistrate, whose decision should not be disturbed. The Court held that the decision of the magistrate was conclusive on the question of fact, and dismissed the appeal. It may be added, however, that Mr. Justice Hawkins desired to express no opinion as to what might happen if a fresh summons were taken out.

At the end of July, William M'Irvine, an unqualified practitioner, was successfully prosecuted, at the Leeds Assizes, for having wilfully made and forged a certificate, purporting to be the certificate of one John Shearwood Roberts, as to the cause of death of one Harriet Haigh, contrary to the Births and Deaths Registration Act. Two other charges of a like nature were made, and twenty-three other certificates put in by the prosecution. M'Irvine was a medical student, who had been assistant to a qualified practitioner in Sheffield; and on leaving him had applied to Dr. J. S. Roberts for employment. Dr. Roberts altogether declined his services; but he nevertheless proceeded to practise, and filled up in Dr. Roberts's name death certificates, which the Registrar thought were the certificates of Dr. Roberts. The accused was found guilty, and sentenced to one year's imprisonment with hard labour, the judge justly observing that the offence committed was a most serious one, and unattended with any mitigating circumstances. The case is one of special importance, because the prosecution was conducted by the Treasury at the instance of the Registrar-General.

The "Bradlaugh Trial" does not call for much notice here, as it did not concern the medical profession especially, excepting through the fact that the accused put forward several medical works as a part of their defence. Mr. Bradlaugh and Mrs. Annie Besant were convicted, after a trial which lasted rather more than three days, of publishing a pamphlet "calculated to deprave public morals." The work in question was entitled "Fruits of Philosophy: an Essay on the Population Question," and advocated the prevention of over-population by the use of "scientific checks to conception." It taught and advocated openly the indulgence of the sexual passion, with a "scientific" safeguard against the natural consequences. We need not add that no support of such teaching could be found in medical works.

The Medical Defence Association did good service to the public in obtaining a warrant to search the house of a man named Matthew Allison Orr, who sold (claiming that he did so as the agent of a "Dr. Bruce") a work recommending the employment of a "pessary," intended to prevent the natural result of the intercourse of the sexes. On search being made, 1700 copies of a pamphlet on over-population, one hundredweight of a pamphlet entitled "England to the Rescue," and 750 copies of a book giving instructions for the use of the preventive pessary, were seized; and, on application to one of the police magistrates, the whole of the works were condemned to be destroyed, as being obscene.

The Penge case will be remembered, not only for the particularly revolting circumstances connected with and surrounding the crime of which the accused four prisoners were found guilty, and for which sentence of death was passed upon them, but also on account of the very imperfect and incomplete character of the medical evidence brought forward by the prosecution. It is unnecessary to go into details in this record, for the case is perfectly well known and has been largely commented on: a bare outline of the medical points will be sufficient. The deceased woman, Harriet Staunton, who had always been a person of weak mind, had, not very long after her marriage to Louis Staunton, been placed by him under the care of his brother and sister-in-law, Patrick and Elizabeth Staunton, while her place in her husband's house and bed had been taken by Alice Rhodes, the sister of Elizabeth Staunton. Harriet Staunton was kept under restraint, and after some months was suddenly removed in a

state of great weakness to Penge. There medical aid was, for the first time, provided for her. Mr. Longrigg had been engaged to attend her, but though she became rapidly worse on her arrival, and he was twice sent for, he did not see her till the next morning, when he found her insensible, with stertorous breathing, rigidity of the arms, and inequality of the pupils. She died the same day, and Mr. Longrigg gave a certificate that death arose from cerebral disease and apoplexy. Circumstances were communicated to him afterwards, that led to the withdrawal of his certificate, and, six days after death, to a post-mortem examination. Six medical men were present at the autopsy, and on their report, together with other evidence, the Crown prosecuted the other three Stauntons and Alice Rhodes for wilful murder of the deceased by starvation. The defence made was that the deceased died from disease; and that, at any rate, the post-mortem appearances did not prove death from starvation. It was urged that points of the most essential importance, as to the condition of some organs of the body, were not noted, as the condition of the œsophagus, nor the absence of some diseases, as diabetes, proved; that the incomplete and imperfect manner in which the facts observed were recorded made it almost impossible to form any decided opinion as to their true nature; and that the length of time after death before the examination was made was not taken duly into account; while the admitted existence of tubercle in the membranes of the brain or on the brain, "small patches of rough millet-seed-like deposit in the meshes of the pia mater, probably tubercular," with some adhesions of the membranes, and the presence of tubercle in one of the lungs, taken together with the symptoms observed by Mr. Longrigg when he first saw the deceased, and her history, all pointed to the possibility, if not the great probability, that death was due to disease; and certainly neither entirely nor mainly to starvation. The judge's charge, however, was very strongly against the accused; the jury found them all guilty of murder, though they recommended the two women to mercy, and all four were sentenced to death. The case for the defence had the support of such eminent and skilled pathologists as Dr. Bristowe, Dr. Payne, and Dr. Greenfield, though the evidence of the latter gentleman was not received at the trial, as he had not been present in court when the medical evidence for the prosecution was given. After the trial their view received the powerful support of one of the Physicians of Guy's Hospital, a high authority, who, in a letter to the *Times*, stated that he was ready to aver his belief "that the facts sworn to by the doctors at the trial absolutely proved that Harriet Staunton died of tubercular meningitis"; and there was such a strong and widely spread feeling in the profession that there had been a miscarriage of justice, that memorials, largely and influentially signed, were addressed to the Home Secretary, representing that the verdict was not justified by the medical evidence. In the end the Home Secretary, after consultation with the judge who had presided at the time, and with Sir William Jenner, recommended her Majesty to grant a free pardon to Alice Rhodes, and to alter the sentence on the three Stauntons to penal servitude for life. The medical aspect of the case was not improved by the strange fact that after the trial a paper called "Report of Post-mortem Examination, and the Cause of Death of Harriet Staunton," and signed by five of the medical men who made the examination, was published by one of them, and was stated that "there were one or two small and recent patches, which together would be covered by a fourpenny-piece, upon the surface of the arachnoid membrane, on the upper surface of the left hemisphere"; but added, "there was no deposit on the pia mater, and the arachnoid and pia mater were not adherent." The whole case illustrates in the most forcible manner the urgent necessity of a thorough reform in the present system of obtaining the evidence of medical experts in trials at law, and of conducting post-mortem examinations for coroners' inquests.

Some progress has been made in the provision and in the application of sanitary measures. We have elsewhere spoken of what was done in this way by the Legislature; but two or three other things must be mentioned here. Proceedings have been taken in some cases under the Rivers' Pollution Act. Mr. C. Woollam, of St. Albans, has instituted proceedings against the Corporation of that city for the pollution of the river Var; the Commissioners of Sewers for East Kent have obtained an inquiry into the pollution of the Stour; and an inquiry has also been commenced under the Act into the state of the Avon, in Wilts. Of the thirty-nine vestries or district boards which constitute the sanitary authorities within "Registration" London, all but three—the Vestries of Clerkenwell and the District Boards of Holborn and of St. George's, Hanover-square—now supply their medical officers of health with weekly returns of all the registered particulars of the deaths in their respective districts; and the Vestry of St. George's, though not yet giving their medical officer of health the returns as to all registered deaths, do supply him with immediate information of all registered deaths from infectious diseases.

The first buildings of the Metropolitan Artisans' and Labourers' Dwellings Association were opened at the end of June. Each of the tenements has a constant water-supply, a coal-bunker, and a dust-shoot. The blocks of buildings are so arranged, and isolated by intervening open-air spaces, as to reduce to a minimum the danger of the spread of any infectious disease that may occur in them; the drains are arranged so as to prevent the escape of foul air from the sewers into the dwellings; and care has been taken to supply them with all the best proved sanitary appliances. Lord Beaconsfield opened the buildings, and took the opportunity of enlarging on the importance of "the home as the unit of civilisation"; and had the courage to again publicly express his conviction that "the health of the people is the first duty of the statesman."

The Corporation of Manchester have decided on a plan for providing the town with a new and ample water-supply by purchasing the Thirlmere Lake, erecting a large dam across the lower end of it, so as to make the area of it 700 acres, instead of 335, as it is at present, and bringing the water to Manchester; and they have ordered a Bill to be prepared for getting from Parliament the powers necessary for carrying out the scheme. The Bill will, however, be most vigorously opposed, as it is said the plan would entirely destroy the beauty of one of the most lovely of our lakes, is unnecessary, and would not be unattended with danger. The scheme adopted by the Metropolitan Board of Works for taking under their control the water-supply of London will also meet with very determined opposition, as, besides proposing to buy out the existing water companies and to take their works, the Board have appended to this a plan, prepared by Sir Joseph Bazalgette and Messrs. Bramwell and Easton, for obtaining an additional and purer supply of water from the water-bearing strata round London; and the success of this part of the scheme is thought to be very doubtful, while the attendant expense would be enormous.

At the annual meeting of the Royal Albert Hospital, held at Devonport, it was shown that the working of the Contagious Diseases Acts during the past year has been very satisfactory, with respect to both their medical and their reformatory bearings. Mr. E. St. Aubyn pointed out that in Plymouth and Devonport the number of soldiers incapacitated by the diseases dealt with by the Acts had fallen from 76 per 1000 in 1867 (the year in which the Acts were introduced), to 29 per 1000 in 1875; whilst in districts to which the Acts had not been applied, such as London, the ratio had only

fallen from 163 to 146. As to the reformatory working of the Acts, the results were also very gratifying, the chaplain's report stating that eighteen women had been admitted to, and still remained in, homes and penitentiaries; thirty-seven had returned to their friends, gone into service, or married, from all of whom good accounts had been received; and seventeen only had fallen back into their former mode of life. Admiral Willes, C.B., and several other influential speakers, all bore testimony, from their own personal observations, to the excellent results of the working of the Acts. And Mr. Tremayne, member of Parliament for East Cornwall, who presided at the meeting, had the courage to say that "no person could dispassionately and accurately examine and weigh the evidence which public returns supplied without coming to the conclusion that those Acts, although looked upon as a horrible necessity, yet indeed were a necessity, and were in their way beneficial," and ought to be applied to all populous places. He observed also that the great difficulty people laboured under in working the Acts was, that though they could stamp out disease in their own districts, the Acts could not prevent the importation of disease from outside the area of their operations.

An important Parliamentary return, called for by Sir J. Harcourt Johnstone, has also been recently published, showing the effect of the Acts upon the prevalence of venereal diseases in the Royal Navy. The return shows "the number of cases of venereal disease in her Majesty's ships and vessels stationed at five home ports at which the Contagious Diseases Acts have been and are in operation, and the number of cases in her Majesty's ships and vessels at five home ports at which the Acts have never been applied, from the year 1860 to the year 1875 inclusive, together with the ratios per thousand of force for each year at each port, and the total ratios for the ports under the Acts, and the ports not under the Acts." The five ports under the Acts dealt with are Plymouth, Portsmouth, Southampton, Queenstown (Cork), and Dartmouth. The ports not under the Acts are Liverpool, Hull, Kingstown (Dublin), Greenock, and Leith. The period of sixteen years dealt with by the return includes the four years 1860-63, which preceded the passing of the first Act in 1864, two years when that Act was partially in force, and the two succeeding periods of five years during which the Acts of 1866 and 1869 were in force. In the five ports brought under the Acts, the average ratio of cases of venereal disease per 1000 of the force declined from 75·0 in 1860-63 to 43·6 in 1871-75, equal to a decrease of 42 per cent.; while in the five ports not brought under the Acts, the average ratio of cases increased from 70·1 in 1860-63 to 96·4 in 1871-75, showing an increase of 37·6 per cent. In 1860-63, before the Acts were passed, the ratio of disease was somewhat lower in the five ports never brought under the Acts than it was in the five subsequently brought under their operation; but in 1870-75 the ratio of disease was only 43·6 in the five ports under the Acts, while it was 96·4 in the five which had not been brought under the Acts. There had been a considerable increase in the cases of gonorrhœa in all the ports, whether under the Acts or not; and with regard to this the Director-General of the Navy remarks that "it may be attributed to the greater number of cases of gonorrhœa recorded, rather than to any real increase of disease," as, since the passing of the Acts, a large number of cases have been brought under the notice of the medical officers which previously would not have been reported.

We have had the pleasure of putting on record many very gratifying recognitions of various kinds of faithful and valuable service rendered by individual members of the profession, but we can mention here only distinctions conferred by her Majesty. After the death of Sir William Fergusson, Sir James Paget, who was Serjeant-Surgeon Extraordinary to the Queen, was made one of her Majesty's Serjeant-Surgeons in Ordinary; Mr. Prescott Hewett, then President of the Royal College of Surgeons, was appointed Serjeant-Surgeon Extraordinary, and Mr. Erichsen was made one of the Surgeons Extraordinary to the Queen. Professor Lister's removal to London made it, of course, necessary that he should resign the appointment of Surgeon to the Queen in Scotland; and the vacated honour was conferred on Professor George Macleod, of Glasgow.

The death-roll of the year would demand a sadly large amount of the space at our command were we to attempt to give it at all fully, and we shall mention comparatively but a few of those whom the profession and the public have had to mourn. First and foremost among these is the great operative surgeon, and apostle of conservative surgery, Sir William Fergusson. Having recovered to an unhoped-for degree from the long and severe illness of last year, he had returned to London, and to some extent resumed work, when he again, very early in this year, was attacked by a return of his former malady, and in February died, at the age of 68, crowned with fame and honours. Many well and widely known men, or men of more local eminence, who have died during the year attained or exceeded the age of three score and ten. Dr. E. L. Meryon lived to be 96; Dr. Herbert Taylor, of Uttoxeter, and Mr. J. Foster Reeve, died at 87; Dr. John Mollan, of Dublin, and Dr. S. F. Bridge, of Wellington, at 86; Dr. J. Butter, of Plymouth, and Mr. W. S. Ward, of Ollerton, at 85; Dr. Robert Lee, Dr. William Morris, of Stourbridge, and Mr. George Cooper, of Brentford, at 84; Dr. Francis Hawkins, Mr. J. Wickham Barnes, of Bath, and Mr. Edward Coupland, of Boston, at 83; Dr. Zachariah Sillar, of Sydenham, and Mr. John Elliot, at 81; Dr. John Manley, of Barkham, at 80; Dr. Silvester, of Clapham, Dr. J. D. Macready, of Dublin, and Mr. Robert Dunn, at 78; Mr. John Whipple, of Plymouth, at 77; Mr. William Coulson, and Dr. Thomas Heberden, at 75; Mr. R. G. Whitfield, of St. Thomas's Hospital, at 76; Dr. W. Murphy and Inspector-General Dr. Scott, C.B., at 74; and Dr. W. R. Basham and Dr. F. A. B. Bonney, at 73; and Mr. John Adams was 71 when he died; and Mr. Thomas Stone, 70. Of those who died early in the fight we will name only a very few:—Mr. John Douglas Laurie, of Bradford, died at the age of 34; Dr. Handsel Griffiths, of Dublin, at 31; Mr. Henry Wilson, also of Dublin, at 39; Dr. Henry Lawson, at 37; Dr. Charles Mayo, at 40; and Dr. Bathurst Woodman also died at a comparatively very early age. And death came to very many who were in the thick of the battle of life, and apparently still in full strength and vigour:—Mr. A. Williams, Secretary to the Veterinary Department of the Privy Council, died at 48; Dr. A. Mackay fell a victim to the insanitary condition of one of our public offices, at the age of 55; Mr. Alfred Smee, and Mr. G. Morley Harrison, of Manchester, died at 58; Dr. Henry Davies, of Brighton, at 62; Dr. T. Snow Beck, and Dr. William Carr, of Blackheath, at 63; Dr. S. Scott Allison, at 64; Dr. W. Swayne Little, Ireland, and Dr. Daldy, at 65; Dr. Duke, of Rugby, and Mr. F. Ticehurst, of Hastings, at 67; and Dr. Lawson Cape, at 69. We had very lately to record also the death of Dr. Stewart Trench; he had been for fifteen years the Medical Officer of Health for Liverpool, in which capacity he showed remarkable ability and knowledge, with untiring energy and perseverance; and we must mention the death of Mr. Marson, who was for forty-one years Resident Surgeon to the Small-pox and Vaccination Hospital, for so many years situated near King's-cross, and afterwards, and now, at Upper Holloway.

Turning now to speak with more detail of the contents of our own volumes for the year, we mention in the foremost place the Lectures that we have been enabled to give our readers. First among these we have concluded a series of very valuable and practical "Select Lectures on Medical Juriprudence," by Dr. Ogston, Professor of Medical Logic and Medical Jurispru-

dence in the University of Aberdeen. We have recorded recently our opinion of the special excellence of these lectures, and of the weight and authority that attaches to Dr. Ogston's reputation and experience as a teacher, so that we need not now do more than mention his lectures. We have also had the satisfaction of publishing Mr. R. Brudenell Carter's very able and instructive Hunterian Lectures, delivered at the Royal College of Surgeons, on "Defects of Vision which are Remediable by Optical Appliances"; and, among other papers on affections of the eye, we have given Dr. Hughlings-Jackson's Oration, before the Medical Society of London, on "Ophthalmology in its Relations to General Medicine," Clinical Lectures by Dr. C. Bell Taylor "On a Case of Squint," by Mr. Jonathan Hutchinson "On Progressive Choroiditis in connexion with Acquired Syphilis," and some "Lectures on Ophthalmology" by Mr. C. Higgens. Mr. Timothy Holmes enabled us to publish his Clinical Lectures on "Amputation," on "Dislocation of the Hip into the Obturator Foramen," and on "The Results of the Operation of Excision of the Hip." We have given "Clinical Lectures" or "Lectures" by Dr. J. Headlam Greenhow, on "Croup and Diphtheria"; by Mr. J. W. Hulke, "On a Case of Intracranial Sarcoma," and "On Cases of Exostosis upon the First Rib"; by Mr. J. Hutchinson, "On the Extension of Syphilis from a Mother to her Fœtus," "On Syphilitic Phagedæna," and "On Hebra's Prurigo"; three Lectures on "The Clinical Aspects of Chorea, as affording a Key to its Pathology," by Dr. Octavius Sturges; Dr. Henry Thompson's Clinical Lecture on "A Case of Multiple Aneurisms in the Heart, the Lungs, and the Cavity of the Cranium"; Dr. Byrom Bramwell's Lecture "On a Case of Progressive Pernicious Anæmia cured by Arsenic"; Dr. Cayley's Clinical Lecture on "A Case of Ulcerative or Infecting Endocarditis, simulating Typhoid Fever"; a very opportune Lecture by Dr. W. B. Cheadle, "On the Pathology of Hydrophobia"; and an abstract of some remarkable Lectures by Professor Volkmann, "On the Antiseptic Treatment of Compound Fractures"; and Professor Jaccoud's Clinical Lectures on "The Lymphogenic Diathesis."

We have also published abstracts of Dr. Braxton Hicks' Croonian Lectures, "On the Difference between the Sexes in regard to the Aspect and Treatment of Disease"; and of Dr. George Johnson's Lumleian Lectures on "The Muscular Arterioles, their Structure and Function in Health, and in certain Morbid States." We gave our readers Sir James Paget's Hunterian Oration, delivered at the Royal College of Surgeons; Dr. Moxon's Annual Oration before the Hunterian Society, on "The Biologist and the Physician"; the Harveian Oration, by Dr. Sieveking; and we gladly found room in our pages for the Address delivered before the Clinical Society by Mr. Callender, that delivered by Dr. C. West before the Obstetrical Society, and Mr. R. Brudenell Carter's Address (elsewhere spoken of in these columns) at the Congress of the Sanitary Institute of Great Britain.

Under the heading "Original Communications," we have, as usual, placed before the profession many able and valuable papers, most of them of specially practical character, and several on subjects that have during the year attracted particular interest and attention. Among these we may mention a paper by Dr. E. A. Sansom, on "Croup and Diphtheria—a Contrast"; one with the same title, by Mr. R. B. Searle; one by Dr. W. R. Macdonald, of Ayr, on "The Treatment of Diphtheria"; and one by Dr. A. Sceligmüller, of Halle, on "Chlorate of Potash in Saturated Solution—a Specific in Diphtheria"; Dr. Gavin Milroy's papers on "Yaws, and some Allied Skin Diseases," and on the question, "Is Leprosy Contagious?"—in which he comes to the conclusion that the weight of evidence is decidedly against its being so; Dr. Balmanno Squire's paper on "Goa Powder as a Remedy in Skin Diseases; and one on "Acne Rosacea treated by Chrysophanic Acid"; Mr. C. T. Fox's "Fatal Case of Pemphigus (Foliaceus)"; and Dr. James Russell's "History of a Case of Pemphigus (extending over seven years), intermixed with attacks of Erysipelas, and with the appearance of Epilepsy"; and from the last-named well-known physician we gave other papers, as remarks on "Unusual Slowness of the Pulse," and "Abscess in the Left Frontal Lobe of the Brain, Distension of the Lateral Ventricle, Persistent State of Imperception." We have given papers, by the late Dr. Henry Lawson, on "The Subcutaneous Injection of Morphia, etc., in Sciatica"; by Surgeon-General C. B. Francis, M.B., on "Large Doses of Antiperiodics in Neuralgia"; and by Dr. S. Marlett Boddy on "The Treatment of Neuralgia"; by Surgeon J. D. Gunning, Fyzabad, on "A Large Abscess treated chiefly by Aspiration—Recovery," and on "A Case of Hydrophobia"; by Dr. James McCraith, Smyrna, on "The Practice of Physic in Smyrna," including "A Case of Hydrophobia from the Scratch of a Cat"; and from Dr. Dudgeon, Pekin, on "Hydrophobia in China," besides papers on "The Chinese Knowledge of Cod-Liver Oil and Iodine," "Chinese Treatment of Ague," and on "Early Anæsthetics"; from Dr. T. Stretch Dowse, "On a Case of Aneurism of the Cœliac Axis—Rupture and Hæmorrhage into the Peritoneum"; from Mr. T. M. Dolan on "Some Cases of Thoracic Aneurism"; from Mr. E. L. Hussey on "A Case of Popliteal Aneurism in the Left Leg, cured by Pressure, four years after a like affection in the right leg"; and from Dr. T. Barlow, a "Note on Cerebral Aneurisms, subsequent to Emboli," besides a paper on "A Case of Hysteria, with Hemianæsthesia, and Ovarian Hyperæsthesia of the Opposite Side"; from Dr. A. E. Longhurst, "Observations on Scarlet Fever"; from our friend "Mucor," "On Measles"; and from Mr. Charles A. Fox, on "The Present and the Last Epidemic of Small-pox"; Mr. J. Knowsley Thornton contributed a paper on "Removal of a large Fibroid Uterus with Outgrowths, and both Ovaries—Recovery," and "Cases illustrating the various Results of Rotation of the Ovaries"; Mr. F. Ensor, South Africa, "A Case of Double Ovarian Disease, Removal of both Ovaries—Death"; and Dr. J. Marion Sims, one on "Normal Ovariotomy," for which he suggests the name "Oophorotomy," but thinks it ought to be known as "Battey's operation." And we have published papers, by Dr. James Barr, on "Reduplication of the Cardiac Sounds"; by Mr. E. Nettleship, on "Cases illustrating some of the less frequent forms of Keratitis and Cyclitis"; by Mr. C. F. Maunder, "On Lumbar Colotomy"; by Mr. S. Messenger Bradley, "Clinical Notes on Precision in the Use of Topical Remedies"; by Dr. J. Sullivan, on the question, "Does the Poison of Malaria really Exist?" by Dr. C. Handfield Jones, on "Two Cases of Fever with Hyperpyrexia," and on "Two Cases of Idiopathic Tetanus," both treated by physostigma, one ending in recovery, and one in death; by Dr. John Day, of Geelong, Australia, "On the Use of Peroxide of Hydrogen for the Prevention of the Spread of Scarlet Fever and Small-pox"; by Dr. A. Yule, "On the Relation of Germs to Infectious and Contagious Diseases"; and by Dr. A. Wallace, of Colchester, "A Therapeutic Proposition"—viz., the exhibition of volatile antiseptic agents by inhalation in diseases having the characters of blood-poisoning; by Dr. Hughlings-Jackson, "On Nervous Symptoms with Ear Disease"; by Dr. A. E. Aust-Lawrence, "On the Treatment of Pain in Carcinoma Uteri," and "On the Diagnosis and Treatment of Miscarriages"; by Dr. A. H. Newth, "On a Case of Poisoning by Cyanide of Potassium"; by Dr. James Andrew, "On Pernicious Anæmia"; by Dr. Thomas Peacock, "On a Case of Stenosis of the Orifice of the Pulmonary Artery from Valvular Disease, probably Congenital"; by Dr. Stephen Mackenzie, "On Retinal Hæmorrhages and Melanæmia as Symptoms of Ague"; by Dr. B. Walker,

of Derby, "On a Case of Gangrene of the Lung—Recovery with Turpentine Vapour Bath and Full Doses of Quinine"; by Mr. S. Fullom Conolly, "On a Case of Diabetes Mellitus in an Infant"; by Dr. F. Irving de Lisle, New Zealand, "On Scurvy: its Cause, Prevention, and Antidotes"; by Dr. G. M. Beard, New York, "On the Nerve Theory of Hay Fever"; and by Mr. Lowndes, "On the Coroner's Court in England." Also communications from Dr. Julius Althaus, "On Syphilitic Affections of the Nervous System"; from Dr. James Ross, "On the Structure and Functions of the Nervous System"; and from Sir Joseph Fayrer, "On Elephantiasis Arabum," and on "Ægle Marmelos or Bael"; Dr. W. R. Gower's "Remarks on Two Cases of Writers' Cramp"; Mr. A. De Watteville's paper "On the Nature and Therapeutical Value of Electrical Tension"; Dr. T. Whipham's "Clinical Remarks on Catarrhal Laryngitis"; Dr. Eugene Dupuy's "Critical Review of the Prevailing Theories concerning the Physiology and Pathology of the Brain," especially with regard to "Localisation of Functions, and the Mode of producing Symptoms"; and Dr. James Dunlop's "Second Contribution to Antiseptic Surgery—Cases treated in the Glasgow Infirmary." Many instructive papers have also been contributed by other old friends and supporters, as Mr. Henry Morris, Dr. R. Shingleton Smith, Dr. R. Smith (of Sheffield), Dr. Brinsley Nicholson, Dr. R. Liveing, and Mr. Hancocke Wathen.

A glance at a list of our Editorial Articles during the year will give a very fair idea of the subjects which have particularly concerned and interested the profession, and of those that, while more directly affecting the public, have had also a professional interest. Among these, sanitary matters have held a very prominent place. We have had occasion to write on "Model Dwelling-Houses," on "The Metropolitan Artisans' and Labourers' Dwellings Association," whose first buildings were opened in June; and on some of the schemes of improvement adopted under the Artisans' and Labourers' Dwellings Improvement Act; on the "Sanitary Difficulties in Country Towns," on "Watering-Places and Summer Resorts," on "Seaside Sanitation," on "The Air of Cities," on "The Sanitary Condition of the War Office," and on "Uninhabitable Houses"; on "Infant Mortality in an Orphanage"; on "False Certificates of Death"; on "Germs and the Germ Theory," and on "Professor Tyndall's Lectures on Germs"; on "Safeguards against Small-Pox," on "Vaccination and Erysipelas," and, besides others on "Vaccination," one especially on "Vaccine Virus," giving some account of the very large experience of Dr. Henry Martin, of Boston, U.S., in the employment of animal lymph; on "Poisoning by Chloral"; and on "Water-Supply." We have commented on some other subjects also of general interest, as on "The Madras Famine"; on "The Outbreak of Scurvy in the Arctic Expedition"; on "The Rescued Miners"—the sufferings and deliverance of the miners imprisoned by explosion in the Pontypridd Coal-Mine; on "Philanthropy in War"; on "The Bradlaugh Trial"; on "The Penge Case"; on "Hydrophobia and Rabies"; and on "The Sewage and the River Thames."

As regards questions and occurrences directly affecting the profession, the subjects we have had to deal with may be conveniently classed under the headings of The Services—Medical Policy and Education—Medical Science and Art. As regards The Services, we have commented on the state of "The Army Medical Department"; and have described and discussed "The New Organisation" of the Department; and "The New Army Hospital Corps Warrant and the Army Medical Department"; and we have also, in the interest of the soldier, criticised the present system of "Hospital Stoppages," and the wretched position of the family of the soldier who has "Married without Leave." As touching Medical Politics and Medical Education, we have had editorial articles on "The French Government and Foreign Medical Men," and on "English Doctors in France"; on "Professional Remuneration," and on "Hospital Elections," and on "Hospital Reports and Hospitals"; on the proceedings of the General Medical Council, on "The Conjoint Examining Board for England"; on "Clinical Teaching"; and on the Dispute between the Senate and the University of London.

We will besides, in this summary, direct attention to the valuable series of papers on Hyères, Bordighera, San Remo, Alassio, Cornigliano, Nervi, and Rapallo, as health-resorts—papers the more instructive and useful in that they are written by a very able and accomplished young physician, who had occasion to study them from an invalid's as well as from a physician's point of view.

In conclusion, we wish all our professional brethren a Happy New Year, assuring them that we have, for the best possible reasons, full confidence in being able to make the journal worthy of the profession through the coming year, while at the same time we invite their continued help towards that object.

EXCRETION OF INDICAN IN THE URINE.

We recently called attention to Professor Senator's researches on the above subject (*Medical Times and Gazette*, September 22, 1877), but we omitted to make any mention of the equally interesting and important experiments of Professor Max Jaffe, of Königsberg, by some of which, indeed, Professor Senator was led to undertake his own independent investigation. The method also which the latter adopts is but slightly modified from that first suggested by Jaffe, and described in full in *Pflüger's Archiv* for 1870. The chief difference between the two methods is this: that, after converting the indican in the urine under examination into indigo, by concentrated hydrochloric acid, and the careful addition of a strong solution of chloride of calcium drop by drop from a pipette until the depth of the blue tint ceases to increase, Senator merely shakes up the indigo with chloroform, and (always using the same volume of the latter) estimates the indigo quantitatively by comparing the amount of sediment with that of the supernatant fluid; whereas Jaffe (*Virchow's Archiv*, Band 70, Heft 1, s. 74) collects the precipitated indigo on a weighed filter, washes it with cold and hot water, and finally with hot ammonia, and then dries and weighs it. Jaffe's process is hence by far the more accurate, but involves a large expenditure of time and labour to carry out, and is therefore not well suited for the coarser exigencies of clinical observation.

So much as to the method. We may now briefly state what Jaffe has made out about indican. He has not ranged over so wide a field as Senator, but has mainly restricted himself to endeavouring to elucidate the curious phenomenon of increased indican excretion in *intestinal obstruction*, to which his attention was accidentally directed by a case of ileus, in which the urine was tested and revealed enormous quantities of indigo. Senator, in his paper in the *Centralblatt Med. Wiss.*, referred to in our former article, makes the observation that intestinal obstruction due to mechanical causes, or to intussusception, appears (in the absence of cancer or diffuse peritouitis) *not* to cause much excretion of indican; but since Jaffe's paper was published he has modified this statement (*Berliner Klin. Wochenschrift*, No. 40, 1877, s. 584), and has observed a case of strangulated hernia, with fæcal vomiting, where the amount of indican was increased *fifteen* to *twenty* fold above the normal amount for the same individual.

By careful experiments on animals (dogs), Jaffe found that ligature of the *small* intestine invariably caused a great increase in the indigo precipitated from their urine by hydrochloric acid and chloride of calcium, provided they had been largely fed on nitrogenous food for a few days previously; whereas

ligature of the *large* intestine, whether in the ascending, transverse, or descending colon, caused either no increase in the indican excretion, a relatively slight increase, or more often an actual diminution. To explain this difference in the behaviour of the two intestines was at first difficult, especially as the two sets of experiments were carried out precisely in the same manner, and the animals fed, the urine collected and analysed, etc., precisely in the same way in both. Professor Jaffe, after proving by numerous experiments that the quantity of indigo in the urine is, under ordinary circumstances, nearly directly proportional to the amount of nitrogen supplied in the food, goes on to show that this indigo, or the indican from which it is formed by oxidation, is the product of a body named indol (C_8H_7N), which probably takes origin, in part, from the decomposing albuminates present in the intestinal canal during the later stages of pancreatic digestion. Now, in a normal permeable bowel the greater part of these albuminates—*e.g.*, peptone, leucin, and tyrosin—are probably, Jaffe believes, quickly absorbed, so that very little indol can be produced from them; whereas, if the bowel is obstructed, stagnation of its contents occurs above the seat of stricture, and the decomposition on which indol depends is able to take place, provided the obstruction is not too quickly removed. On the other hand, the reason why obstruction of the *large* intestine is not followed by any material increase in the excretion of indican, is theoretically, according to Jaffe, because in men and carnivores the digestive process is almost entirely completed in the small intestine, and the albuminous bodies from which indol is formed are absorbed in the latter, leaving almost nothing but indigestible waste matter to enter the colon as fæces.

Although admitting that Jaffe is correct in his facts with regard to the increase of indican in intestinal obstruction, and also in diffuse peritonitis, Senator does not accept his theory of the way in which the different results of obstruction of the small and large intestine are brought about. He justly points out that patients with acute peritonitis not only take in very little nourishment, but vomit the greater part of what they ingest, until at last only bile-tinged green mucus returns; and the same is true of those with obstruction of the small intestine, especially if the stricture is high up in the bowel. A true explanation of the above phenomena seems, therefore, at present to fail, unless Salkowski's discovery (*Bericht der deutsch. Chem. Gesellschaft*, 1876), that in *states of inanition* the amount of indican excreted is even greater than when an abundance of *non*-nitrogenous food is supplied, gives us a clue, and points to the formation of the indol, not in the bowel, but in the muscles, and, as Jaffe remarks, "perhaps in most of the organs of the body." Possibly it may eventually be found that the source of the indol, which appears as indican in the urine after ligature of the small intestine in animals which have been largely fed on nitrogenous food (for otherwise the experiment is not certain to succeed), is different from that of the indol which is excreted as indican in natural pathological conditions; or the latter indican may even not be derived from indol at all, although it is certain from Jaffe's careful experiments that the subcutaneous injection of this substance immediately increases the excretion of indican by the kidneys. It is evident from all this that there is still open a wide field for investigation with regard to indican.

Clinical observations on the effect of stricture of the *large* intestine in the human subject are much wanted, with a view to determine whether what Jaffe has made out in animals as to the excretion of indican in this condition applies to man, and can be made use of for diagnostic purposes. In conclusion, we should state that the normal amount of indican, as indigo, in healthy human urine varies between five to twenty milligrammes *pro die*, and that hence anything beyond thirty milligrammes indigo in twenty-four hours deserves notice, while *fifty* milligrammes should be regarded as a considerable increase. According to Jaffe, in severe cases of ileus fifty to 100 or even 150 milligrammes indigo are ordinarily passed; and the same is true of diffuse peritonitis.

THE WEEK.

TOPICS OF THE DAY.

The annual general meeting of the Committee of the Hospital Sunday Fund was held last week at the Mansion House. The Lord Mayor being unable to be present, the chair was taken by Alderman Sir Sydney Waterlow, M.P. The report of the Council on the operations of the Fund during the year, already published, was taken as read. The chairman, who said he was instructed by the Lord Mayor to express his regret at not being able to be present, remarked that he regarded the growth of the Fund with great satisfaction, and although the amount collected this year was hardly so large as that realised in 1876, they were bound to recollect the period of depression in which it was raised, and the fact that many people who had previously contributed largely were not now in a position to spare large sums. He added that the expenses of management, including advertising and salaries, were only about 3 per cent. of the whole sum collected, and this he thought a very gratifying circumstance. At the instance of the chairman, seconded by Sir R. Alcock, the laws of the constitution of the Fund were approved and passed; and on the motion of the Rev. T. J. Rowsell, seconded by the Chief Rabbi, the Council was re-elected. Bishop Claughton moved that Sunday, June 30, be fixed for Hospital Sunday of 1878, and that all metropolitan ministers of religion be invited to co-operate. Canon Fleming expressed a wish that an earlier day had been selected, as by the end of June the West-end of London was beginning to get empty, and the Fund might suffer in consequence. The Rev. J. P. Chown urged the advantage of having a settled annual Sunday fixed for the collection. Eventually the motion was adopted.

A "burial question" in America has been very summarily disposed of by a citizen of the United States. A paint manufacturer in New York, whose child died in November a few days after its birth, desired to have it buried in the Lutheran cemetery, he being a member of the Lutheran Church; but his wife being a Jewess, her family wished the body to be interred in the Jewish cemetery. The father, to settle the dispute, returned the coffin to the undertaker, and, taking the body to the paint factory, put it into an iron box, and thrust it into a furnace to be cremated. It is stated that the undertaker, dissatisfied at a proceeding which struck so directly at the root of his trade, immediately reported the circumstance to the Board of Health, and through this circumstance the facts became public.

We regret to have to record the death of Dr. W. G. Guppy, one of the surgeons sent out to the East by Lord Blantyre to aid the Turkish sick and wounded. Dr. Guppy was attacked by typhoid fever, which has been committing serious ravages at Erzeroum, and he and the other surgeons had been unremitting in their attentions to the sufferers; although ailing for some time, he would not give in until completely prostrated. Dr. Fetherstonhaugh, the chief surgeon of the ambulance, attended him with the greatest assiduity, but he died on the morning of the 17th ult. Dr. Guppy was only twenty-one, and has thus been cut off at the outset of what promised to be a distinguished career; he was buried in the small Anglo-Saxon graveyard of Erzeroum, and Turks and English alike combined to pay due honour to his memory, Ghazi Mukhtar sending a company of regular troops to escort the body to the grave.

At a meeting of the Whitehaven Board of Guardians, held last week, a resolution was read from the Governors of the Whitehaven Infirmary, stating that the fever wards had twenty

typhus fever patients, and that the Infirmary could hold no more. Dr. Henley, the Infirmary House-Surgeon, is laid up with fever, and it was resolved to communicate with the Medical Department of the Privy Council, and a committee was appointed to try and arrange with Lord Lonsdale's agents to take the Militia Barracks, which are now empty, for the further accommodation of fever patients.

A rather extraordinary case of an unauthorised post-mortem examination is reported from Wolverhampton. An adjourned inquest was held last week at Priestfields, near that town, on the body of William Hyde, a workman employed at Springvale Furnaces, who died on the 13th inst. It was elicited at a previous inquiry that a post-mortem examination had been performed by a local surgeon, the agent of an "accidental insurance company," without the permission of the coroner, or of the deceased's relations. A verdict of "Accidental death" was eventually returned by the jury, who requested the coroner to forward to the Home Secretary the following rider:—"The jury consider a most improper proceeding has taken place in the mutilation of the body of the deceased before they had had the view of it; and they consider such improper mutilation most detrimental to the interests of justice, more particularly when it is done by an agent of an insurance company, or any interested person." It transpired during the inquiry that the life of the deceased had been insured for £1000.

The Saddlers' Company have announced the following seasonable donations to medical charities:—£20 each to the Great Northern Hospital, City of London Hospital for Diseases of the Chest, Cancer Hospital, St. Mark's Hospital, Asylum for Deaf and Dumb Females, National Hospital for Paralysis and Epilepsy, Convalescent Hospital, Seaford, and the Deaf and Dumb Asylum, Margate.

An application has been made to the Hackney Guardians by a man named Lee, asking the clemency of the Board in not further prosecuting him for non-compliance with the Vaccination Acts, on the ground that he has already suffered fine and imprisonment for a similar offence; and urging that it was within the discretion of the Guardians to stay further proceedings. The Guardians having appealed to the Local Government Board on the subject, received a reply to the end that it was for the Guardians to consider in each individual case the effect likely to be produced by a continuance of proceedings. It was finally resolved, by ten votes to five, not to alter the previous decision of the Board: the prosecution will therefore be again proceeded with.

Much uneasiness has been caused at Harwich by the recent epidemic of small-pox which has occurred there. There have been between forty and fifty cases since the disease broke out, and it has now spread to the neighbouring suburb of Dovercourt. Some of the cases have proved fatal. Complaints have been made of the dilatoriness of the Town Council in neglecting to provide hospital accommodation for the district; but that body now appears to have taken up the subject in earnest.

Dr. Thomas Stevenson, Medical Officer of Health for St. Pancras, has made a report to the Vestry, in which he states that the mortality of the parish during the past month has been made up to a great extent by zymotic diseases, the deaths from these diseases being no less than 12½ per cent. of the gross mortality. In order to meet this large extension of infectious diseases, especially among children, he has put himself in communication with heads of schools, the superintendent of School Board visitors, clergymen, and others, and impressed upon them the necessity of care in receiving children into schools after absence from sickness, without inquiry if such children may be safely admitted without danger of infection. The sanitary inspectors have also visited a large number of schools, and, after obtaining the addresses of absentees, have visited their homes, and made the necessary inquiries as to their freedom from disease.

PROTECTION OF INFANT LIFE.

At the last meeting of the Metropolitan Board of Works a report was presented from the Special Purposes and Sanitary Committee, stating that they had had under their consideration the Board's letter, urging an amendment of the Act for the Better Protection of Infant Life, but the Home Secretary was of opinion that ample powers already existed for inspection under the Act. The Board had twice unsuccessfully made representations to the Government as to the inadequacy of the Act, more especially with regard to limiting its application to infants under twelve months of age, and it only remained for the Committee to consider if any further steps could be taken for giving effect to the Act as it stands. After fairly considering the point, they had come to the conclusion that by frequent and personal communication with relief and sanitary officers and with the police, by constantly watching the advertising columns of certain weekly and local journals, and by judicious inquiry in other quarters, a competent inspector would discover if violations of the Act were occurring, and if so, would bring to justice the persons offending. The Committee accordingly recommended that an inspector be appointed to carry out these duties, and the report was unanimously ordered to be adopted.

THE CONJOINT EXAMINING BOARD.

The Chairman of the Conference of the Representatives of the medical authorities engaged in the formation of a Scheme for an Examining Board for England has called a meeting of the Committee of Reference, appointed by the several authorities in accordance with the provisions of Section II. of the Scheme of May 1 last, to attend at the College of Surgeons on Friday, the 11th prox. The following gentlemen are the members of the Committee of Reference, viz.:—J. Risdon Bennett, M.D., F.R.S., President of the Royal College of Physicians, and Henry A. Pitman, M.D., representing the College of Physicians; Sir James Paget, Bart., F.R.S., and John Simon, C.B., F.R.S., Senior Vice-President of the Royal College of Surgeons, as representatives of that institution; Professor Acland, F.R.S., and Professor Rolleston, F.R.S., representing the University of Oxford; the sister University of Cambridge being represented by Professor Paget, F.R.S., and Professor Humphry, F.R.S.; the University of Durham will be represented by G. H. Philipson, M.D., and G. Y. Heath, M.B.; the University of London sends as representatives William B. Carpenter, M.D., C.B., F.R.S., and Richard Quain, M.D., F.R.S.; and the Society of Apothecaries will be represented by Edward Bradford, F.R.C.S., and George Corfe, M.D.

PATHOLOGICAL SOCIETY OF DUBLIN.

At the meeting of this Society on Saturday, December 22, the chair was taken by Dr. James Little, the senior member of Council present. Dr. E. H. Bennett exhibited microscopic specimens made from a polypus of the rectum. The tumour had been removed from a boy of ten years of age, who had presented symptoms for a period of at least eighteen months. A year ago hæmorrhage attracted attention to the case, but no disease could be proved to exist: this year a tumour projected at the anus at stool; the tumour could not be felt or seen except when brought down by action of the bowel. During removal its pedicle was found to be as thin as a crow-quill, and it gave way just when transfixed with a needle; the tumour removed was the size of a large hazel-nut On retraction into the bowel the pedicle withdrew the ligature until the knot could be with difficulty felt by a finger in the bowel. The tumour, examined by means of fresh sections cut while frozen, was found to consist of "an agglomeration

of very elongated follicles," to use Lebert's term, lined with cylindrical epithelium. The surface of the tumour between the openings of the numerous follicles was covered with a modified cylindrical epithelium. The tissue forming the nidus of the follicles was a fine myxomatous structure similar to that of the nasal polypus.

NORTHUMBERLAND AND DURHAM MEDICAL SOCIETY.

The third monthly meeting was held in the library of the Newcastle-on-Tyne Infirmary on Thursday, December 13, the President, Mr. Morgan, in the chair. Mr. H. E. Armstrong, Medical Officer of Health for Newcastle-on-Tyne, presented a report of the cases admitted to the Fever Hospital during the month of November, and stated that the health of the town was good. Mr. Spear, Medical Officer of Health for South Shields, Jarrow, and Hebburn, stated that scarlet fever was epidemic at South Shields. In several cases the disease had been propagated by children, just convalescent, being sent to school. A committee, consisting of the President, Mr. Spear, Mr. H. E. Armstrong, and Dr. B. Bramwell, was appointed to consider the matter and to report to the Society. Dr. Anderson showed three vesical calculi removed by lithotomy from two patients—the first from a boy aged four years and a half; the second from a man aged thirty-three; the third from the boy first mentioned (symptoms of stone returned in eight months, and the second operation was performed nine months after the first). All three cases had done well. Dr. Page showed two salivary calculi removed from Wharton's duct by a free incision. Dr. Page also showed a small urethral calculus which had become lodged behind a stricture; the stricture was split up by Holt's dilator, and the stone was then expelled with the urine. Dr. Arnison showed two calculi removed by lithotomy from the same patient, a boy aged three, at an interval of a year; at the first operation the bladder was carefully examined, and was found to be empty. Mr. Hopgood showed a recent specimen of placenta prævia; the gestation had advanced to the fourth month, when flooding came on; the case had done well. Mr. Morgan showed a beautiful specimen of encephaloid disease of the femur. Dr. Embleton showed several photographs of monstrosities. Dr. Byrom Bramwell showed a case of congenital microphthalmos of the left eye. Dr. Heath showed a case of hypertrophy of the tongue. Dr. Embleton read the notes of a case of empyema treated by a free incision under antiseptic precautions; the patient, a boy aged sixteen, recovered well. Dr. Murphy read the notes of two cases of chlorodyne poisoning. Dr. D. Drummond read the notes of a very interesting case of paralysis of the pharynx occurring in an infant aged fourteen months, and suggested that the paralysis was due either to plumbism or to diphtheria; the child was in the habit of sucking a leaden rattle, and there was a history of ulcerated sore throat. Dr. Byrom Bramwell continued his paper on intracranial tumours, relating three additional cases.

UNVEILING OF THE STATUE OF THE LATE DR. GRAVES, OF DUBLIN.

On Wednesday, December 19, the fine statue of the late Robert James Graves, M.D., by Mr. Albert Bruce Joy, which has been placed in one of the two halls of the King and Queen's College of Physicians, was unveiled by his Grace the Duke of Marlborough, K.G., Lord Lieutenant of Ireland, in the presence of many of the Fellows and of a large and distinguished assemblage.

The cost of the statue was defrayed by the subscriptions of a large number of members of the medical profession and others, who appreciated and admired Dr. Graves, and it has been by them presented to the College of Physicians. Mr. Joy, although resident in London, is an Irishman by birth, being the son of a distinguished Fellow of the College of Physicians. He was a pupil of Foley, and has already given proofs of genius and taste sufficient to justify the expectation that he will one day occupy a foremost position in his profession. He was amongst the audience present at the proceedings, and, after they had terminated, was presented to the Lord Lieutenant by Mr. Thomas Jones, President of the Royal Hibernian Academy.

His Grace the Lord Lieutenant having been conducted to his seat by the President and Fellows of the College, the chair was then taken by Dr. Gordon, President of the College of Physicians, who said—"My first and most pleasing duty is to thank your Grace for the honour you have conferred on the College by your visit this day, and for assisting in inaugurating a statue which is to be a lasting memorial to one of our most distinguished presidents. It is with profound regret that I have to record the absence from amongst us of two of our honorary secretaries, who worked with zeal, fidelity, and love to bring to a happy conclusion the work in which we are now engaged. Dr. Hudson, from a severe domestic affliction, is unable to be present, and my reverend friend Dr. Stokes, whose own statue was so lately inaugurated, is, I regret to say, on a bed of sickness."

Dr. Duncan, honorary treasurer of the Statue Committee, having explained the origin and progress of the movement to erect this lasting memorial to departed worth, gave a comprehensive outline of the life and labours of the late Dr. Graves, who, he said, "was a most distinguished student of Trinity College, Dublin, before he entered upon his medical career. He was eminently many-sided. The brilliancy of his undergraduate course, marked by an unprecedented number of collegiate honours, proved that he would have attained to very high distinction in any path of life. His claims to the highest posthumous honours were too numerous and too generally acknowledged to need enforcement. Various distinctions were conferred on him during life by different learned societies at home and abroad, and by some of the oldest and most celebrated universities on the Continent of Europe. Since his death, a quarter of a century ago, his reputation had lost none of its freshness or brilliancy. High testimony as to the value of his works had been borne by Professor Trousseau, Clinical Professor in the Faculty of Medicine in Paris. Sketches of his life—one written by Sir W. Wilde, and the other by Dr. Stokes—attested his enthusiastic nature, his love of truth, his thirst for knowledge, his simple but lofty eloquence, his logical accuracy, his courage in avowing and defending his opinions, whatever they were, in opposition to popular prejudices on old-established conclusions. As a lecturer he was endowed with peculiar capabilities. One of the most important benefits conferred upon modern medicine with which Dr. Graves was to be credited was the complete change he introduced into the manner in which clinical instruction was given to the students attending the hospitals. This consisted partly in distributing the care of the patients to a larger number of the advanced students than had previously been the custom, and partly in changing the scene of instruction from the lecture-room of the hospital to the bedside of the patient. By the erection of the present statue they were not rescuing a name from oblivion that would otherwise soon have passed away. The true memorials of departed greatness were those which each man made for himself; and viewed in that aspect Dr. Graves had left behind him a reputation which bade defiance to the advance of time."

The statue having been unveiled by his Grace the Lord Lieutenant,

The Provost of Trinity College said he had been asked to undertake the honourable task of presenting to the College, in the name of the subscribers, the noble work of art which had just been unveiled. In the course of his speech he alluded in felicitous terms to the fact that the School of Physic in which Graves lectured was under the joint management of the College of Physicians and of the University of Dublin.

The President said he had the utmost gratification in accepting, on the part of the College of Physicians, this most life-like representation of the illustrious individual whom it professed to idealise.

Sir Robert Kane, President of the Royal Irish Academy, and Fellow of the College of Physicians, moved—"That the thanks of the King and Queen's College of Physicians in Ireland are eminently due, and are hereby tendered, to the

subscribers who have presented to the College this beautiful and valuable gift."

Dr. A. W. Foot, Senior Physician to the Meath Hospital, and, as such, the lineal descendant of Graves in that position, in seconding the resolution mentioned the discernment with which Dr. Graves noted signs of ability in the pupils whom he taught or to whom he lectured.

The Lord Bishop of Limerick (the Right Rev. Charles Graves, D.D.), in moving that "The thanks of the subscribers be given to the Committee for their exertions," observed that he might be allowed to express, on behalf of the family to which he belonged, the satisfaction, the hearty approval, with which they regarded that statue. Those who were admitted within the circle, hallowed by friendship and affection, were reminded by it of lineaments and gestures which were in perfect harmony with the heart and mind of the man. Those who had loved him during his life could see those marble features luminated by a genial gleam of light from within; and if his premature death had caused them deep and long-continued mourning—

> "Quis desiderio sit pudor aut modus
> Tam cari capitis?"

He rejoiced that Dr. Graves' powers had been devoted to a profession in which the lessons of benevolence were put into practice in every hour of every day. On the part of the family to which he belonged, he (the Bishop of Limerick) was bound to tender to the President and Fellows of the College of Physicians the expression of their deep sense of the honour which had been done to the memory of Dr. Graves by placing his statue in that room. Its erection there after the lapse of nearly a quarter of a century attested the lasting character and still continuing growth of the reputation of which it was the memorial. The thanks of all were due to the distinguished men who formed the Committee, and by whose labours the object had been attained.

The resolution was seconded by Mr. G. H. Porter, Surgeon-in-Ordinary to the Queen, and Senior Surgeon to the Meath Hospital.

Mr. Jolliffe Tufnell, honorary secretary, briefly responded on behalf of the Committee, after which the proceedings terminated.

FROM ABROAD.

The Clinical Aspect of Cerebral Localisation.

M. Tillaux, while bringing some specimens under the notice of the Société de Chirurgie (*Union Méd.*, December 13), observed that clinical observation had not entirely confirmed the results of physiological experiments on cerebral localisation, and, as far as indications for the employment of the trephine were concerned, he owned himself entirely of the opinion of Prof. Gosselin (*Medical Times and Gazette*, April 28, page 453), that we are not authorised to resort to this instrument for primary injuries except in cases in which there is fracture with depression. He can admit but one exception to this rule—viz., when there is a fissure of the cranium opposite the centres, and motor paralysis of the opposite side. Beyond this case, the trephine is not applicable for the treatment of primary effusions of blood. Is it the same with respect to slow, delayed accidents, which appear only consecutively? M. Tillaux believes not; and it is in this direction, in his opinion, that surgeons should seek for indications for the employment of the trephine. In this view he laid specimens before the Society. The first of these was the brain of a man upon whose head a shutter had fallen, striking him upon the left side of the posterior part of the skull. The man immediately became unconscious, and on the fourth day was attacked with aphasia and with right brachial monoplegia. These accidents disappeared, and he was able to resume his employment, although there still remained very intense pain in the head. This brought him under M. Tillaux's care at the hospital, where he found great relief from the iodide of potassium. After a while a new attack of aphasia and right brachial monoplegia occurred, which terminated fatally. At the autopsy there was found a patch of meningo-encephalitis, which measured more than 0·04 centimetres, and occupied the whole of the third left frontal convolution. In face of such a lesion, the seat of which could be perfectly well determined by the occurrence of the aphasia and monoplegia, but the extent of which could not be suspected, M. Tillaux demanded what would be the effect of the trephine applied at the point indicated by Prof. Broca. The other specimen, which had been lent by M. Raynaud, was derived from a woman fifty-nine years of age, who had been the subject of complete left hemiplegia, with hemianæsthesia, immobility of the head on the side of the paralysis, and conjugate deviation of the eyes of the same side. At the autopsy there was found an encephaloid tumour the size of an egg, which occupied the most remote part of the fissure of Sylvius, having depressed the first temporal convolution, and projected upwards the parietal lobe of the left side and the third ascending frontal convolution. It is evident that this tumour would produce the phenomena of compression, which, affecting the motor centres at a distance, might give rise to serious errors as regards cerebral localisation. From these cases M. Tillaux draws the following conclusions:—1. Even when the lesion is in intimate relation with the convolution which is the centre of the abolished motion there is danger, in applying the trephine, of coming upon a large patch of meningo-encephalitis, and thus to perform an operation which is at least useless. 2. A lesion of the brain may give rise to disturbances at a distance; so that by following rules drawn from the doctrine of cerebral localisation for the application of the trephine, we are liable to attack a point very remote from the evil.

M. Lucas-Championnière observed, in reference to the second of these cases, that all writers put aside cases of cerebral tumours in relation to these localisations; but the first case proves the utility of the doctrine of localisation in a surgical point of view; for if the patient had been trephined he might have been cured. He is an advocate for the use of the trephine for the dissipation of the primary accidents in these cases. In his opinion, patients have been let die who might have been saved by the operation. There is no example on record of primary paralysis in these cases having been cured without operation; so that there is good reason to seek for indications for its performance. M. Tillaux explained that he is no adversary of indications for the use of the trephine being drawn from cerebral localisation; but he believes that more light as yet is wanted upon the subject. As to the case which he had related, trephining certainly would not have saved the patient, seeing on the one hand the extent of the lesion, and on the other that the lesion of the soft parts was situated 0·07 centimetres behind the cerebral lesion.

At a subsequent meeting of the Society (*Gaz. des Hôp.*, December 15), M. Perrin stated that he quite agreed with M. Tillaux as to the danger of hasty trephining. Cerebral localisations can be no guide for the surgeon in this operation. The cerebral disturbances that ensue may be transitory or inaccessible to treatment; and trephining in many cases would only add to the complications, some of those who recover after it recovering in spite of it. M. Lucas-Championnière has expressed himself too absolutely as to the non-recovery after fracture with primary cerebral complications, as is shown by two cases which have come under M. Perrin's own care. In one of these a soldier, whose skull was fractured by a shell, passed from a state of coma into one of aphasia, from which he recovered completely in two months. In the other case, a man had the right side of the skull fractured, with slight depression, during the siege, and immediately became unconscious. Hemiplegia of the left side soon occurred, and paralysis of the right side of the face, with dilatation of the pupil and loss of hearing on the same side, his speech being also embarrassed. These accidents became afterwards complicated with incontinence of urine, obstinate constipation, and eschars of the sacrum and paralysed limbs. Still the patient was cured, although so long a time as two years was required. M. Desprès stated that he had never as yet met with a case in which he found any indication for trephining. This abstinence from the operation was suggested to him by a case which he had seen in the service of Manec in 1859. A workman, while digging in a pit, had a heavy body fall on his head, which fractured the skull, driving into the wound fragments of bone, the scalp, and the cap he wore. For five days the patient did well, and then for a fortnight he had brachial monoplegia, and a slight degree of facial paralysis. In a short time all that had penetrated the cranium was eliminated, and the patient was cured without any other treatment than expectation.

GENERAL CORRESPONDENCE.

LENGTHENED DURATION OF PREGNANCY.

Letter from Mr. W. Duncan.

[To the Editor of the Medical Times and Gazette.]

Sir,—I shall be glad if you consider the following case worthy of a place in your journal:—At 3.30 a.m. on December 7, I delivered Mrs. S. of a strong, healthy male child, of much more than usual size and weight. A midwife had been present from the time labour commenced (at 9 p.m. the previous night), and as the head was delayed long in the pelvis (about two hours), she got frightened, contrary to the usual custom of Shetland midwives, and I was sent for. I immediately put on the forceps, and delivered in a few minutes. As I had noticed the patient for about four months previously, when engaged in carrying her supply of peats for the winter, and judged from her size at that time that a few days would bring on labour, I made inquiries, which elicited the following facts, which may be thoroughly relied upon:—

Mrs. S. last ceased to menstruate on January 15, and felt distinct fœtal movements in the beginning or middle of May, certainly within four months after the cessation of the menses, and was in daily expectation of her confinement from October 15 to 21. Her bulk was enormous; she looked more as if she were carrying triplets than a single child. She had had three previous pregnancies: her first child she carried 300 days, and the second and third about 285 days. She has thus carried her fourth child 325 clear days from the day of menstruation ceasing; and this is the longest period of gestation that I have heard of. The case that comes nearest to it in duration (so far as I have been able to discover) is recorded in Leishman's "Midwifery," page 193, where a woman carried her child 322 days; and I shall be glad to know if any of your numerous readers have noted any similar cases. The accuracy of dates in such cases is of the utmost importance.

I am, &c., William Duncan, L.R.C.S.E.

Dunrossness, Shetland, N.B., December 10.

MR. HANCOCKE WATHEN'S CASE OF EXTRA-UTERINE FŒTATION.

Letter from Mr. J. H. Wathen.

[To the Editor of the Medical Times and Gazette.]

Sir,—In reporting the case of extra-uterine fœtation, I venture to hope I was not unmindful of "doing to others as I would be done by," and as considerate for the feelings of others as was compatible with a *true* history of the case. Mr. W. Barrow Wall has, however, identified himself with the previous conduct of the case by a letter published in your columns of last week, in which letter Mr. Wall impugns, it seems to me, both my veracity and my diagnosis of the case; it behoves me, therefore, to reply, at the same time disclaiming any wish to enter on a controversy of words with Mr. Wall. Mr. Wall's charge amounts to this:—First, that I have misrepresented the opinion he expressed on his first visit to the case; and secondly, that I have put on record a case as "extra-uterine," which was a simple ordinary case of intra-uterine gestation.

My answer to the first portion of the charge is, that Mr. Wall did not consider it simply a case of colic, but that he prohibited the patient from moving out of bed, as "*the child would be born in ten minutes.*" In proof of this I have the patient's own statement.(a) She also declares that the examination hurt her very much, and in conversation with me yesterday she described Mr. Wall's preparations for the birth of the child, even to laying the scissors and ligatures on the table ready for the event—for which event he remained with the patient four hours!

To deal with the second portion of the charge—viz., that both my father and myself have incorrectly reported the case as "extra-uterine"—I would refer Mr. Wall to the *British Medical Journal* of November 10, page 665, and ask him to read the description of a case diagnosed by Dr. Matthews Duncan as "extra-uterine fœtation," and then tell me in what essential point does my case differ from Dr. Matthews Duncan's, whose powers of diagnosis Mr. Wall will hardly question.

(a) Mr. Wathen has sent to us a "verified statement" made by the patient to this effect.—Ed. *Med Times and Gaz.*

Mr. Wall says that, when he examined the woman, "the fœtal head was low down, with the anterior part of the cervix uteri over it. The os could be felt posteriorly." I have yet to learn that the cervix uteri is "rugose," which was the appearance of the investing membrane as shown through the speculum when I first saw the case.

I have no doubt that the *tactus eruditus* which left on Mr. Wall's mind "not the slightest doubt about the fœtus being in the uterus," also enabled him to detect the os uteri, but I confess *I* was not able to detect it, from the fact of the uterus being displaced by the head of the fœtus, which, as it became more enfolded by the vaginal wall, drew down the fundus, and at the same time tilted up the os uteri out of reach. The sac *was* found to be distinct from the uterus; in my description of the operation I say, "the head was found still enveloped by a membrane, and posteriorly and somewhat to the right side the uterus could be felt." It was globular, and very much like the presenting part of the child's head, and was undoubtedly the fundus anteverted.

In my report of the case I omitted to mention that during the syringing out of the sac the thrill from the rush of water could be felt, and even heard, up in the left hypochondrium; and in this same direction a thickened, hard ridge could be felt for months—evidently the sac contracting and absorbing. As a final proof that the enveloping membrane was not "the anterior part of the cervix uteri," but the vaginal wall, the cicatrix was in the vaginal wall on the last occasion when I examined the woman.

Mr. Wall sums up his view of the case being "intra-uterine" by "I attended the woman in her previous labour, which was quite natural." I utterly fail to see what connexion there can be between that labour and the one under judgment. Is not Mr. Wall aware that in most of the recorded cases of extra-uterine fœtation the women have had several previous natural confinements, the latest being Dr. Gervis's, in which the patient "had had eight children"?

I am, &c., J. Hancocke Wathen.

Fishguard, Christmas-day.

REPORTS OF SOCIETIES.

CLINICAL SOCIETY OF LONDON.

Friday, December 1.

Thomas Bryant, F.R.C.S., Vice-President, in the Chair.

A Case of Convulsion treated by Venesection.

Dr. Broadbent read notes of this case which was that of a gentleman, aged forty-one, who had had syphilis when young, and who, a year ago, had received a severe injury to the head, supposed to be fracture of the base of the skull. Since then, he at first lived abstemiously; but recently resumed his accustomed generous diet. He then had convulsions, which grew in intensity for three days, and were accompanied by capillary extravasations on the forehead and chest. On the third day, when the patient had been unconscious for four or five hours, he was seen by Dr. Broadbent. During the intervals there was then no paralysis; the eyelids were kept closed, and the pupils were equal and of moderate size. The pulse was small and weak, but long. During the convulsions the eyes were widely opened, and all the muscles of the body and limbs were affected by synchmous violent jerkings, the face became livid, the pulse imperceptible, and respiratory movements ceased; death seemed imminent when Dr. Gaven, the medical attendant, depressed the tongue and performed artificial respiration. Calomel had been already placed on the tongue, mustard applied to the calves, and chloroform administered; thirty ounces of blood were now abstracted. The convulsions at once ceased, consciousness shortly returned, and the patient in a few days left London. In commenting on the case, Dr. Broadbent thought the injury to the skull might have interfered with the circulation of the blood at the base of the brain; the patient was plethoric from his recent generous diet, and the state of the pulse was similar to that found in uræmic convulsions, in which bleeding was most useful. The pulse became large and soft as the blood flowed. Dr. Broadbent had often had to regret that an insufficient quantity of blood, or none at all, had been withdrawn never that bleeding had been practised unnecessarily or too largely.

Case of Post-partum Convulsions (Uræmic?) treated by Venesection—Death on the Seventh Day.

Mr. George Brown read notes of this case. The patient, who was in humble circumstances, was taken in labour (her sixth confinement) on December 21, 1876. Mr. Brown, being called to the case, found that the child had been born a few minutes before his arrival. A small dose of ergot was given, the placenta was removed without unusual hæmorrhage, and the patient appeared to be very comfortable, and the uterus well contracted. The patient soon afterwards fell asleep, and dozed at intervals for four hours, when she complained of feeling sick and giddy. Immediately afterwards she was seized with convulsions, the fit lasting, according to the nurse's report, about five minutes. She then lay in a semi-conscious state for half an hour, when she had another fit. Mr. Brown being summoned, found his patient in a fit. It began with twitching of the muscles of one side of the face and neck, which were so violent as to draw the head towards the chest on that side with each spasm. In about half a minute clonic spasms of the arm and leg of that side commenced, following each other with great rapidity for about a minute, and then gradually ceasing in violence and becoming less rapid. As the spasms ceased on the one side, twitching of the muscles on the opposite side of the face began, followed by similar clonic spasms of the limbs on that side also. The duration of a fit was from three to five minutes. During the fit the patient's face became quite purple. In the earlier fits she bit her tongue, but afterwards this was guarded against by placing a handkerchief between her teeth. The patient was quite unconscious in the intervals as well as during the fits. The breathing was laboured, and at times stertorous. It was found impossible to get her to swallow anything. A catheter was passed, and ten ounces of urine were drawn off; this, on being boiled, was found to contain one-third albumen. The fits succeeded each other for four hours at intervals of about ten minutes, when, as death appeared to be imminent, twenty-eight ounces of blood were taken from the left median cephalic vein. During the operation of bleeding, which occupied at least thirty minutes, the patient had two fits, but they were less violent than those which took place before venesection. After the operation the respiration became more natural and all stertor ceased; the temperature was 100°, and the pulse 150 per minute. There was no uterine hæmorrhage. Fits of a milder character occurred at intervals of about fifteen minutes for three hours, and then during four hours only four fits took place. Eight grains of calomel were then given, and two hours later an enema was administered, but it returned without producing action of the bowels. No fits subsequently occurred, but there were occasional twitchings of the limbs. After the cessation of the fits the patient was able to swallow liquids; and beef-tea, milk, and weak brandy-and-water were given; also ten grains of bromide of potassium every two hours. She remained unconscious the whole of the following day, but free from convulsions. Urine was passed involuntarily. The enema was repeated that day without result. The same night another dose of calomel (eight grains) was given. On the third day a violent fit occurred, shortly after which the bowels acted very freely. Immediately after the motion the patient became conscious, sat up in bed, and recognised her husband and other friends who were by her bedside. In two or three minutes she again became unconscious, and had another fit. The following night she again became conscious for a few minutes, and voluntarily drank a little milk. The improvement was, however, only temporary; insensiblity soon returned, the coma gradually deepened, and she died six days after the onset of the convulsions. No post-mortem examination was permitted. Mr. Brown said that, although the case terminated fatally, he had no doubt that the bleeding was the means of prolonging life, and in similar circumstances he should again adopt the same mode of treatment.

Dr. Clutton had recently seen a man, aged about fifty, reported to have had a fit, whom he found unconscious and with a full bounding pulse, and who, whilst in the fit, had been bled to the extent of sixteen ounces by another medical man. A violent convulsion immediately followed the operation. Ice was applied to the head, and an aperient given. The man had two other subsequent fits, and remained comatose for more than a day. It then came out that he had been knocked down in the street. His urine was albuminous. He was still improving, but had partial aphasia, and defective memory and vision.

Dr. Althaus was not sure the bleeding had benefited the patients whose cases had been reported; recovery often rapidly ensued without such treatment. Again, convulsions were rather due to anæmia than to increased blood-pressure. The latter was the result, and not the cause, of the fits. Spasm of the glottis was usually the cause of death when it occurred during convulsions.

Dr. Clutton, in reply to Dr. Althaus, said there was no albuminuria in his case.

Mr. Howse inquired whether there was evidence that convulsions damaged the brain-tissue. If so, treatment for fits was imperatively demanded.

Dr. Wiltshire had seen idiocy follow fits in a child; and Sir W. Jenner and Dr. Langdon Down both considered that continuous fits were injurious to the brain. If the surface-veins were full, and the pulse small and feeble, indicating an empty state of the arteries, bleeding would probably do good. He advocated more frequent recourse to venesection, to avoid congestion of the viscera. If, as he supposed, Mr. Brown's case was one of embolism, bleeding would not benefit the patient.

Dr. Myers had seen bleeding do good in cases of disturbed cerebral circulation. In Africa, he had himself suffered greatly from head symptoms after great mental strain and shock, and considered that his life was saved by his bleeding himself to the extent of ten ounces. At any rate, his relief was immediate.

Dr. Broadbent thought that convulsions produced deterioration both in the general health and the mental powers. He thought there were many cases of convulsions which were not caused by cerebral anæmia. Not only in this case, but in others (especially cases of uræmic convulsions), he had seen the fits speedily cease after venesection. But a hard pulse was not always an indication for bleeding, because such hardness disappeared when the heart had become exhausted in protracted cases. In those instances the pulse was as full between the beats as it was during the pulse-wave. The pulse in his patient was like that in uræmia, and during the venesection it became larger and softer. The superficial veins, as in that case, were often small, and their smallness sometimes interfered with the performance of venesection until convulsions again supervened, when the veins and arteries refilled.

Excision of the Ankle-Joint.

Mr. Barwell exhibited a boy, aged four years and a half, upon whom the operation had been performed on February 15. The boy left the hospital on March 27, with the wounds healed, but with the plaster of Paris bandage still applied. He had an excellent foot, the limb operated upon being as long as the other; and when he wore a boot whose sole was a little thicker on the inner than on the outer side, he walked perfectly. The case was shown chiefly to exhibit the fact that, although perfect synostosis between the tibia and astragalus should be aimed at, yet excellent results might be obtained when a false anchylosis between these bones resulted, provided that the fibrous bond were short. Mr. Barwell took occasion to point out that he was the first to describe in England Moreau's procedure, and that although Mr. Holmes ("System of Surgery"), in describing this operation, quoted Mr. Barwell's description in inverted commas, yet Mr. H. Lee called it (*Med.-Chir. Trans.*, vol. lviii., page 144) the Hancock-Holmes operation; also Mr. Barwell controverted Mr. Lee's opinion that the Moreau method was difficult, and stated that it required far less displacement of and violence to soft parts to make the tibia project at the inner wound, as Moreau recommended, than to present it at the outer wound after the method proposed by Mr. H. Lee. The case exhibited, and photographs of other cases handed round, showed the value of the results obtainable by the method he advocated.

Cases of Severe Rickety Deformity treated by Division of the Bones by Billroth's Chisel.

The first case, in which the shins were sharply curved, as shown by photograph, was operated upon in consecutive weeks, viz., on October 25 and November 1 respectively. In a fortnight union was firm, though, lest subsequent bending might take place, the limbs were left five and six weeks on plaster. The result was a very straight condition of the two legs. The other case was one of excessively bowed legs in a girl aged seventeen, who on this account could not walk at all. Mr. Barwell divided the two bones beneath the knee on April 12, and put the limbs straight in plaster of Paris on May 3; he divided the femora at the lower part of the upper fourth, and treated them in the same way. The girl had now two very sufficiently straight limbs, and walked well. Especial

attention was drawn to the fact that neither of these patients suffered pain or had febrile symptoms.

Subcutaneous Treatment of Exostosis by Fracture.

Mr. Maunder read notes of and exhibited two patients whom he had submitted to this novel method of operation for exostosis. The first case was an exostosis of the femur in a girl aged fifteen, who was admitted into the London Hospital in June, 1874. She had for many months suffered pain and discomfort at the back of the left knee, and was unable to extend the leg fully upon the thigh. When walking, she could only place the toes upon the ground. A bulging of the thigh just above the external condyle was found, and proved to be caused by a pedunculated exostosis attached to the back of the femur at its outer side, just at the junction of the epiphysis with the shaft. The tumour was pressing against the tendon of the biceps muscle and the external popliteal nerve. To relieve pain and enable her to walk, it was necessary either to remove or to dislodge the growth, which might be done either by abscission through an open wound—a formidable proceeding, with many possible concurrent and subsequent dangers,—or by subcutaneous division of the pedicle with the saw or chisel, or fracture of the pedicle by violence without any wound whatever. Supposing that by this latter method the tumour might be detached, it might become necrosed and ultimately extruded by suppuration, or might be absorbed or reunited. If suppuration occurred, it would not do so until the bone-cells of the femur, opened by the fracture, had become closed in, and thus protected from danger; if absorption occurred, there would be no further trouble; and, if reunion took place, the body of the tumour might have so changed its position as to no longer interfere with the patient's comfort. Subcutaneous fracture of the pedicle was resolved upon, and the operation was done on July 8, 1874. The skin being protected by a piece of chamois-leather, the tumour was seized with a pair of gasfitters' pliers, and, being firmly held, was suddenly jerked and its pedicle broken. Ice was applied for two or three days; and a little tenderness, swelling, and ecchymosis were the only consequences of the operation. Passive movements were afterwards kept up; but, notwithstanding these, reunion occurred. The body of the tumour, however, occupied a new position in the popliteal space, and troubled its owner no longer. The second case was one of exostosis of the tibia, also in a girl, aged fourteen, who was admitted into the London Hospital in February, 1877. She stated that, about two years before, she had slipped, and sprained her right knee. This accident was followed by pain and swelling, and she could only get about on her toes. Since then the case had been treated during one period of three months with iodine paint, but without avail. On examination, a rather large pedunculated exostosis was found attached to the inner edge of the tibia just below the internal tuberosity. This was also treated by subcutaneous fracture with the gasfitters' pliers, but with a result different from the above. The pain and inability to walk were removed; but the tumour had not reunited with the shaft of the bone, and its mobility was readily recognised. The object of the operation—relief to the patient—had been attained without any external wound: a fact upon the desirability of which it was unnecessary to dwell.

Mr. Myers wished to know what portions of the ankle-joint Mr. Barwell had excised, and how his patient had walked before the operation.

Mr. Howard Marsh thought Mr. Barwell had not sufficiently explained the conditions of the case to enable the meeting to judge exactly of the value of his operation. He himself treated many cases of disease of the joints in children upon prolonged rest, rather than upon excision. As regarded the division of bones in rickets, there were the two operations of simple division of the bone with a small saw, and that of cutting out the angle of the bend—a much more severe operation, and one which produced in effect a compound fracture. In two cases in which the lesser operation was performed, the temperature only once rose above 100°. He thought Mr. Barwell's case, now exhibited, was not bad enough to justify the operation. He thought cases of badly curved, rickety limbs became straightened under the use of splints and the administration of cod-liver oil, etc.; in children two or three years old there was almost a spontaneous tendency towards straightening.

Mr. Maunder said that, with regard to saving joints the seat of gelatinous disease, such was continually being done in the case of the well-to-do; the patients being able to afford constant surgical supervision and all such aids to recovery as country air, the seaside, good food, etc. But surgical advice, good food and physic, provided by a London hospital, did not secure all that was to be desired; and a great number of these cases progressed insidiously from bad to worse, and operation was then called for. Similar observations applied to bent legs. The poor could not attend efficiently to their children; but while simple measures, such as the application of splints which prevented walking, often sufficed to correct the deformity, severe cases with hardened bones required operation. Excision of the ankle-joint for disease was an operation not held in much favour, probably on account of the experience of Syme, who, no doubt, resorted to his operation at the ankle-joint on the ground that caries was liable to recur in tarsal bones which were left after partial amputations of the foot. This observation Mr. Maunder believed to be true in almost all instances excepting the ankle joint. In partial amputations of the foot, the small bones which were preserved were called upon to sustain the whole weight of the body, for which they were never intended; but, in excision of the ankle-joint, it would be evident that the bones of the foot were left in their natural relative position, and the arches, with their elastic property, remained, while the anatomical structure of the interior of the bones occupied its original position, that best suited to support the body. It was essential to the comfort of a patient that either a short fibrous or bony anchylosis should be secured to him. In Mr. Barwell's patient he feared the operation would be, to a certain extent, a failure; the fibrous bond being long and yielding, as though either too much bone had been cut away, or the surfaces had not been sufficiently approximated during repair. The child walked with an unsteady gait, and the foot was in a position of valgus—conditions which could only be relieved by the constant use of mechanical support.

Mr. Croft, in three cases of excision of the ankle done by himself, had not made lateral incisions, but had reflected the soft parts from before backwards. In one of his cases the much-to-be-desired result of bony anchylosis had occurred. It was probable the fibrous union in Mr. Barwell's case would, in the course of time, become firmer. The subperiosteal mode of excision had not been sufficiently practsed; in one of his cases, by separating the periosteum from the end of the fibula which he removed, he obtained a larger quantity of new bone in its place. A case of pedunculated exostosis of the tibia, in a boy eleven years of age, he had treated after the manner advocated by Mr. Maunder. The boy had, subsequently to the operation, been able to move his leg about freely.

Mr. Howse said that Mr. Marsh, in his paper in the *Medico-Chirurgical Transactions*, had rightly restricted the operation for rickety deformity to extreme cases. In the oblique variety of deformity—that in which the anterior and lateral curves were combined—splints could not be well applied, and such cases were consequently suitable for the operation. Mechanical modes of treatment often lasted for years; and this element of time was frequently a matter of the highest importance to patients, especially the poor. In four out of the five cases of doubly curved tibia operated upon by himself, a quick recovery ensued; in the fifth it was delayed, but the child now had an almost straight limb and could walk well.

Mr. W. H. Bennett said that Mr. Holmes had divided the pedicle of an exostosis with the chisel, with the result that the detached exostosis increased in size, and that a new growth of bone had occurred at the place from which it had been separated. In another case, an exostosis of the femur, being spontaneously separated in a fall, ceased to grow.

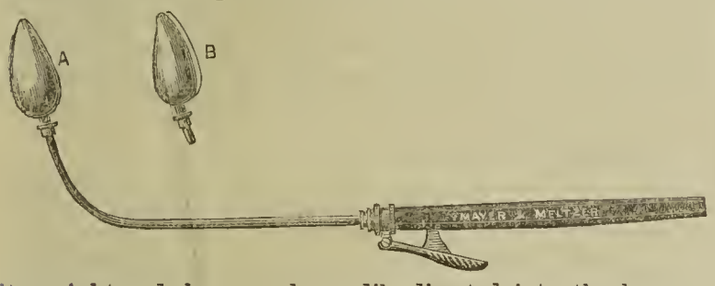
Mr. Barwell said he had always obtained bony union in excision of the ankle, except in this case. Since the operation (six weeks ago) the limb had been suspended in a plaster splint, without extension; and it was possible the union might even yet become bony. Time and rest would certainly greatly benefit diseased joints. As regarded the operation of osteotomy for rickety deformity, it should only be done in severe cases, as recommended by Mr. Marsh, who had introduced the operation. Where the bone could be straightened by being simply bent, osteotomy should, of course, not be performed.

It is said that the graduates of the London University, desirous of a reform of that institution, have unanimously agreed to organise an association, to be called the London University Reform Association.

NEW INVENTIONS AND IMPROVEMENTS.

DR. WHISTLER'S LARYNGEAL DILATOR AND KNIFE.

We have before us an instrument invented by Dr. Whistler, the value of which laryngoscopists will readily recognise. The handle and shaft, made with the usual curve for laryngeal introduction, terminates in an almond-shaped dilator. This tapers down to a point, thus resembling in shape the open glottis, and admitting easily of introduction. The dilator (any size of which may, however, be attached to the shaft) measures at its widest part antero-posteriorly eighteen millimetres; at its widest parts transversely ten millimetres (its other proportions being graduated accordingly), and from above downwards thirty-four millimetres. In the dilator anteriorly is a concealed knife with anterior egress, and this is governed from the shaft by canula mechanism. We have thus an instrument combining a dilator and a knife. The former from



its weight and shape can be readily directed into the larynx; whilst the latter is so guarded and directed that it can cut only where intended—a great advantage when we consider how little the eye can do in laryngeal operations. The class of cases in which this instrument may be employed is that wherein, with partial recovery from stenosis, there yet remains some general constriction with adhesion of the edges of the anterior parts of the cords. This is a condition which obviously impedes their function throughout, and on which medicinal agents are powerless. An instrument is thus our only aid; and the invention of Dr. Whistler fulfils perfectly the indications. It puts tissues on the stretch before cutting; produces a partly lacerated wound, so that the parts may reunite less readily, and thus admit of dilatation more easily; and it insures that the cutting shall be done in the right place. The instrument combines simplicity of construction, facility of manipulation, and surety of execution, and supplies a much-felt want. It is made by Messrs. Meyer and Meltzer.

MEDICAL NEWS.

University of Durham.—At the first examination for the degree of M.B., held on December 17, 18, 19, and 20, the following gentlemen passed:—

Lowes, Septimus, student of the University of Durham College of Medicine.

Dr. Julius Pollock presented the medals and certificates to the following successful competitors:—Senior Chemistry, Mr. Mortlock; Junior Chemistry, Mr. Heywood; Botany, Mr. Murdoch; Materia Medica, Mr. Hutton; Pharmacy, Mr. Mather.

NOTES, QUERIES, AND REPLIES.

Ye that questioneth much shall learn much.—*Bacon.*

A Fellow, Manchester.—There were eight candidates for the four vacancies in the Council of the College of Surgeons in July, 1873, viz.:—*Sir James Paget*, who polled 200 votes; Messrs. *Walton*, 136 votes; *Southam*, 113; *Marshall*, 106; Forster, 105; Savory, 97; Hird, 62; and Hussey, 29. The gentlemen whose names are printed in italics were elected. The elections always take place in July.

Abstemious, but not a Niggard.—The sumptuary laws of Edward III. limited meals on ordinary days to two courses, and on festivals to three courses. These laws were passed by the nobility and great men of the period, and show, at least, how fashion dared, in those ages, to support simplicity of diet.

Zenas.—Yes; we are glad to observe that, at length, a great many rural sanitary authorities are taking action on the important subject of your inquiry. The East Dereham Local Board have recently resolved to consider by what means an abundant supply of pure water can be obtained for the town, and also as to the establishment and construction of waterworks for the town and Local Government District of East Dereham. After nearly ten years' discussion on the subject, the Exeter Town Council have decided to purchase the waterworks of that city. This arrangement will involve an immediate outlay of £94,000 in buying up the old company, and a further sum of between £50,000 and £100,000 it is proposed to expend in procuring a fresh and better supply of water for drinking purposes from Dartmoor, or by boring into the red sandstone.

HEALTH OF THE CITY OF LONDON.

Dr. W. Sedgwick Saunders, Medical Officer of Health for the City of London, in his last fortnightly report states that there had been no case of small-pox in the City during the previous fortnight, whilst the number of deaths from the disease in the metropolis had risen to thirty-one, against twenty-five in the previous week. During the fortnight there had been thirty-five deaths and forty-four births registered in the City.

ALLEGED INSANITARY CONDITION OF A PARISH CHURCH.

The insanitary condition of the Halifax parish church having been made the subject of complaint to the Home Secretary by Mr J. H. South, who alleged that "beneath the floor of the pews is a thorough charnel-house, through which steam-pipes run, and the noxious stink which arises from beneath the floors is enough to give all attenders fever or some other undesirable disease," Dr. Holland, of the sanitary department of the Home Office, has just visited the church, and inquired into the matter. He and others could not perceive any smell, and, as the churchwardens will speedily remove all cause of complaint, Dr. Holland expressed his intention to report that there was no case.

OPIUM-SMOKING IN CHINA.

A Canton correspondent writes that a notice has been issued by the Governor, "warning the people against opium-smoking, and dwelling at some length upon the mischievous character of the drug. His Excellency also strongly advises those who are addicted to the evil habit to free themselves from it without loss of time, and cautions those who have not yet indulged in the pipes on no account to taste the drug. I presume," adds the writer, "this notice has been published in pursuance of instructions from Pekin, and as following up the Imperial edict on the subject."

SANITARY WORK, BENGAL.

The Sanitary Commissioner of Bengal, having found difficulties stand in the way of carrying out the instructions lately issued by the Home Department as to the inspection of the sanitary condition of villages within a certain radius of cantonments, the Government of India have decided that the work would be better done, in the first instance, by local committees of inspection. The experiment is to be tried at once in certain of the larger cantonments, such as Dinapur and Dum-Dum. A civil medical officer of experience, an assistant or joint magistrate, and a selected military officer—if practicable, the local officer of the quarter-master-general's department—would be, the Indian Government think, the most suitable officers for the work.

COFFEE PUBLIC-HOUSES.

It is gratifying to notice the excellent work which is being done by the "Coffee Public-House Association." The Association has opened several coffee public-houses in various parts of the metropolis, all of which have progressed satisfactorily. The good and desirable objects of the Association —to offer opportunities and inducements by coffee-houses to those who would, most probably, otherwise seek the public-house for recreation and entertainment—commend the institution to the generous support of all favourable to the temperance movement, and we hope the necessary means will be forthcoming for providing other poor districts with similar advantages, for which, we understand, the Committee are constantly receiving pressing applications.

COMMUNICATIONS have been received from—

Mr. JOHN CHATTO, London; Mr. B. R. WHEATLEY, London; Dr. J. K. SPENDER, Bath; Dr. BYROM BRAMWELL, Newcastle-on-Tyne; Mr. H. SEWILL, London; Dr. ARMSTRONG, Newcastle-on-Tyne; THE SECRETARY OF THE OBSTETRICAL SOCIETY, London; Mr. G. GASKOIN, London; THE REGISTRAR OF THE APOTHECARIES' HALL, London; Mr. W. W. REEVES, London; THE SECRETARY OF THE ROYAL INSTITUTION, London; Dr. THUDICHUM, London; Mr. H. WATHEN, Fishguard; Dr. J. W. MOORE, Dublin; Mr. T. M. STONE, London.

BOOKS AND PAMPHLETS RECEIVED—

Letts, Son, and Co., Diaries for 1878—Charles A. Cameron, M.D., On the Use of the Flesh of Animals affected with Contagious Pleuro-Pneumonia as Food for Man—Dr. J. Stilling, The Examination of the Sense of Colour of Railway Employés and Pilots—George E. Fenwick, M.D., Excision of the Knee-Joint—William Thomson, F.R.C.S. Edin., On Phthisis and the Supposed Influence of Climate—Guido Baccelli, Sulla Trasmissione dei Suoni Attraverso I Liquidi Endopleurici di Differente Natura; Un Nuovo Metodo di Cura per Taluni Aneurismi dell' Aorta—Year-Book of Pharmacy, 1877.

PERIODICALS AND NEWSPAPERS RECEIVED—

Lancet—British Medical Journal—Medical Press and Circular—Berliner Klinische Wochenschrift—Centralblatt für Chirurgie—Gazette des Hôpitaux—Gazette Médicale—Gazette Hebdomadaire—Le Progrès Médical—Bulletin de l'Académie de Médecine—Pharmaceutical Journal —Wiener Medizinische Wochenschrift—The Louisville Medical News—Boston Medical and Surgical Journal—Nature—Philadelphia Medical Times—Cincinnati Clinic—La Province Médicale—Quarterly Journal of Inebriety—Revista de Medicina y Cirugia Practicas—Transactions of the Odontological Society—Révue des Sciences Médicales—Canada Medical Record.

APPOINTMENTS FOR THE WEEK.

December 29. *Saturday* (*this day*).

Operations at St. Bartholomew's, 1½ p.m.; King's College, 1½ p.m.; Royal Free, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; St. Thomas's, 1½ p.m.

31. *Monday.*

Operations at the Metropolitan Free, 2 p.m.; St. Mark's Hospital for Diseases of the Rectum, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.
